Skin biopsy may demonstrate *Candida* in and around dermal blood vessels, but the organism can be difficult to see. Tissue culture is positive in 50% of patients, and potassium hydroxide examination of a touch prep of a tissue specimen may be useful [212, 216]. The mortality associated with *Candida* fungemia is quite high [214, 215]. Fluconazole is the empiric treatment of choice in stable patients, while amphotericin B or echinocandins are preferred in neutropenic or otherwise unstable patients [217].

Cryptococcosis

Cryptococcus neoformans infection is usually acquired via inhalation of spores found in soil or decaying wood contaminated with bird guano. Primary pulmonary infection is the most common form of cryptococcosis. Secondary dissemination most frequently results in central nervous system infection,

Fig. 22.18 Disseminated erythematous papules with central erosions and crusts due to *Candida parapsilosis*. (Image reprinted from Grossman et al. [287], Fig. 1.21, p. 14, with kind permission from Springer Nature)

followed by the skin in roughly 10–15% of immunocompromised hosts [218]. The combination of meningeal or craniobulbar signs with skin lesions in an immunocompromised patient should raise the possibility of cryptococcal infection. In most cases, this represents reactivation and dissemination of latent infection in the setting of immunosuppression [219].

Primary cutaneous cryptococcosis only rarely occurs. In cases of dissemination, skin lesions can present months before signs of systemic infection. Isolated cutaneous cryptococcosis, therefore, is considered a diagnosis of exclusion, and skin lesions should prompt a thorough workup for extracutaneous disease in all immunosuppressed patients.

Cryptococcal lesions in HIV patients are most often molluscum contagiosum-like umbilicated or crusted papules with a predilection for the head and neck. In non-HIV-related immunosuppression, cutaneous cryptococcosis, whether primary or secondary, most often presents with cellulitis, subcutaneous nodules, or ulcers [220–223]. In solid

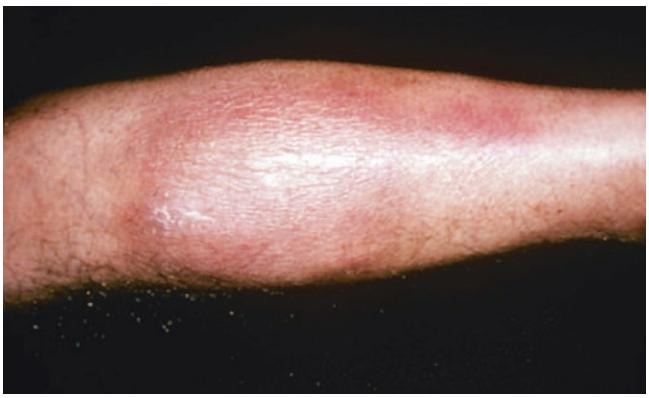

Fig. 22.19 Cryptococcal cellulitis involving the calf of a renal transplant patient. (Image reprinted from Grossman et al. [287], Fig. 1.36, p. 24, with kind permission from Springer Nature)

organ transplant recipients, cellulitis is most common [224] (Fig. 22.19). As with bacterial cellulitis, signs and symptoms include erythema, warmth, and tenderness. Patients with cutaneous cryptococcosis, however, do not respond to typical empiric antibiotics. Necrotizing cellulitis and fasciitis have also been reported in renal and cardiac transplant patients [225, 226].

Patients taking one of the calcineurin inhibitors, which inhibit *C. neoformans* growth in vitro at 37 °C, are more likely to develop cutaneous, soft tissue, bone, joint, or lung involvement than central nervous system or disseminated disease [219, 224, 227–229].

Diagnosis of cutaneous cryptococcosis can be confirmed via biopsy or culture or by visualizing the budding yeast in a Tzanck smear or India ink preparation made from vesicle fluid, ulcer exudate, or skin biopsy touch prep. Serum cryptococcal antigen is always positive in disseminated disease.

Disseminated cryptococcosis is lethal if untreated. Amphotericin B, usually in combination with flucytosine, is the treatment of choice. Lifelong maintenance therapy with fluconazole is often recommended. Reduction of immunosuppression in transplant patients, if feasible, can be lifesaving.

Coccidioidomycosis

Coccidioides immitis is a dimorphic fungus endemic to the soil of the Southwestern United States, as well as Central and South America. Primarily a respiratory pathogen, cutaneous disease can be reactive to the organism (such as erythema nodosum, erythema multiforme, and Sweet syndrome) or due to direct infection (primary inoculation or secondary dissemination) [230].

Disseminated coccidioidomycosis presents with fever, cough, and sweats; involvement of the skin, meninges, bones, and joints is common [230]. Disseminated cutaneous disease is rare even in immunosuppressed patients but may present with verrucous or crusted papules or plaques, subcutaneous abscesses, cellulitic plaques, and ulcers [231–233].

The diagnosis is confirmed through culture, histologic demonstration of the organism, or serologic testing. Treatment with amphotericin B, fluconazole, or itraconazole is recommended for immunocompromised patients in the acute phase of infection. Continuous treatment with an azole antifungal is recommended thereafter for the duration of immunosuppression.

Blastomycosis

Blastomyces dermatitidis is a dimorphic fungus endemic to the Mississippi and Ohio River valleys, the Great Lakes region, and part of Africa and India [234]. Infection usually results from inhalation and is typically asymptomatic. Skin lesions may result from dissemination, which accounts for 60% of cases involving the skin, or primary inoculation.

Primary blastomycosis presents with a solitary plaque with an atrophic, scarred, or ulcerated center and verrucous edges studded with pustules. Associated streaky lymphangitis, lymphadenitis, and red, tender nodules along the cutaneous lymphatics may also be present [218]. In immunosuppressed patients, ulceration and pustulosis may be more prominent features. Disseminated papulopustules and subcutaneous nodules may also occur [235–238].

Though most blastomycosis occurs in immunocompetent patients, severe immunosuppression, including that associated with organ transplantation, may predispose to more severe or disseminated disease and carries a mortality of 29–40% [235, 239]. The skin, bone, genitourinary system, and central nervous system are most commonly involved in cases of disseminated disease [240]. Therapy, which may be lifelong, consists of amphotericin B followed by itraconazole.

Histoplasmosis

Histoplasmosis is most commonly a self-limited primary pulmonary condition which is either asymptomatic or accompanied by flu-like symptoms. Progressive disseminated histoplasmosis can also occur, usually as a consequence of depressed cellular immunity. Symptoms include fever, respiratory symptoms, weight loss, hepatosplenomegaly, and bone marrow suppression. This presentation is most common in patients with AIDS living in endemic areas [241]. Other susceptible patients include those receiving corticosteroids or chemotherapy and those with various hematologic malignancies.

Cutaneous histoplasmosis manifests in three general ways—via primary inoculation, as a reactive erythema, or as a manifestation of disseminated disease. Primary inoculation is rare and results in a nodule or ulcer. Reactive erythema presents as erythema nodosum or erythema multiforme-type lesions. Disseminated cutaneous histoplasmosis may present with macules, papules, necrotic papules, a morbilliform eruption, pustules, nodules, ulcers, panniculitis, cellulitis, and verrucous or vegetative plaques [242].

Skin biopsy of a suspicious lesion reveals the organism within the cytoplasm of histiocytes in the dermis. Urine *Histoplasma* antigen is detected by radioimmunoassay in up to 90% of patients with disseminated disease [243]. Treatment is with amphotericin B or itraconazole. If untreated, the mortality rate of disseminated disease is 95% [241].

Sporotrichosis

Sporothrix schenckii is another dimorphic fungus which is found commonly in plant material and soil. Cutaneous inoculation is classically associated with rose thorns and sphagnum moss [244] and can occur in both immunocompetent and immunoincompetent hosts. Clinical presentations include fixed cutaneous (20%), lymphocutaneous (70%), disseminated, and extracutaneous disease [245, 246]. Disseminated and extracutaneous sporotrichosis are rare, but immunosuppression such as that due to organ transplantation, hematologic malignancy, steroid use, and HIV/AIDS increase the risk. Hematogenous spread can occur from either a primary cutaneous or pulmonary source [247].

Cutaneous sporotrichosis classically presents with a painless papule or ulcerated, draining nodule at the site of inoculation, followed by the appearance of asymptomatic erythematous nodules extending along the cutaneous lymphatics. Lesions may also become fixed verrucous or ulcerated nodules without lymphatic spread [245]. In disseminated disease, cutaneous lesions may be widely distributed ulcerated papules or plaques, crusted nodules, or necrotic ulcers [248]. Dissemination to multiple visceral organs may occur, but involvement of the bones and joints is most characteristic, occurring in 80% of cases [247, 249]. Skin lesions usually precede diagnosis of such widespread involvement.

Yeast cells may be demonstrated as cigar-shaped bodies in histologic sections but should be cultured for definitive diagnosis. Itraconazole is an accepted treatment for localized disease, whereas amphotericin B may be more appropriate in cases of dissemination or immunosuppression.

Superficial Mycoses

Dermatophytosis of the skin, hair, and nails is common in immunocompetent and immunoincompetent patients. Organisms of this group, including *Trichophyton*, *Microsporum*, and *Epidermophyton*, only rarely cause invasive infection but may do so in the severely immunosuppressed. Invasive infection usually occurs at the site of chronic superficial dermatophytosis, presenting with erythematous or violaceous papules or nodules [250–252]. Deep dermal abscesses, draining nodules, or chronic ulcers may also occur [253, 254]. Lesions are typically few but may be many [253].

Because they are rarely suspected and may mimic other cutaneous diseases, widespread, invasive, or otherwise atypical dermatophyte infections are often misdiagnosed. Annular, erythematous, scaling plaques with serpiginous borders are typical of tinea corporis (Fig. 22.20). In the immunocompromised host, a florid presentation may mimic cutaneous lupus or rosacea [255]. Pustular or bullous eruptions may mimic bacterial folliculitis or HSV/VZV, respectively [256]. Application of a topical steroid to a misdiagnosed dermatophyte infection can also produce widespread and atypical-appearing tinea with decreased erythema and scale and follicular papules or pustules [257]. Appropriate history taking and awareness should prompt a scraping for potassium hydroxide (KOH) preparation, skin biopsy, or dermatophyte culture which should, in most cases, readily demonstrate the organism in tissue.

Fig. 22.20 Coalescing annular and arciform scaly pink papules and plaques of tinea corporis on the upper legs and abdomen of a stem cell transplant patient

Superficial dermatophytosis of the skin can be treated with a topical azole antifungal or terbinafine, which may be preferred due to its greater fungicidal activity [258]. Hair and nail infections require systemic antifungals; the same is true of cutaneous dermatophytosis with follicular papules or pustules, indurated papules or plaques, nodules, abscesses, or other signs of deep, invasive, or widespread infection. Oral terbinafine is the most potent systemic drug for dermatophytosis based on in vitro testing, followed by voriconazole, itraconazole, ketoconazole, and griseofulvin. Micafungin and caspofungin also have good activity [259]. Fluconazole has a mean MIC >6 [260]. Though it has excellent in vitro activity against dermatophytes, amphotericin B is ineffective in vivo because it is not secreted in sweat or sebum, and low tissue levels are achieved in the outer layers of the skin through passive diffusion [261].

Protozoa

Trypanosoma cruzi (Chagas disease) reactivation can occur with bone marrow transplantation, solid organ transplantation, and other immunosuppressed states [262]. If the indication for transplantation was Chagas cardiomyopathy, the risk of reactivation is roughly 30% within 3 months of cardiac transplantation [263, 264]. Chagas reactivation can result from transplant-related immunosuppression in a previously infected host. The organism can also be transmitted through an infected organ. Only the donor need have a history of travel to an endemic area. Fever, myocarditis, heart failure, and painful skin lesions are typical, including tender subcutaneous nodules or painful, erythematous, indurated plaques mimicking cellulitis [264–266].

Leishmaniasis in the transplant patient occurs at a median of 18 months after transplantation. It may represent primary infection, reactivation with immunosuppression, or acquisition from an infected organ [267]. Visceral leishmaniasis is the most common form of the disease associated with organ transplantation. Primary skin lesions acquired through the bite of the *Phlebotomus* or *Lutzomyia* sandfly are classically beefy ulcers which develop at the site of inoculation (Fig. 22.21). Skin lesions due to secondary dissemination are rare; they present as erythematous or brown macules and papules and may be the presenting sign of visceral disease.

Fig. 22.21 Primary cutaneous leishmaniasis manifesting as beefy ulcerations on the dorsal hand

Fig. 22.22 A liver transplant patient with graft versus host disease developed innumerable erythematous papules and pustules with necrotic black crusts on the face, head, and neck. Skin biopsy demonstrated numerous *Acanthamoeba* trophozoites, and polymerase chain reaction testing was positive for *Acanthamoeba* species. (Image reprinted from Grossman et al. [288], Fig. 9.9, p. 198, with kind permission from Springer Nature)

Toxoplasmosis may also occur due to reactivation of past infection or de novo transition via a transplanted organ. Fever, central nervous system, and pulmonary symptoms are common, while cutaneous disease is not. When skin lesions develop, they may be disseminated erythematous papules resembling acute graft-versus-host disease [268–270].

Acanthamoeba may infect the sinuses or lungs and spread hematogenously to the skin, visceral organs, and brain, causing an almost universally fatal meningoencephalitis. Cutaneous lesions are often the presenting sign of disseminated disease. Numerous firm, purulent papulonodules develop into nonhealing, crusted ulcers (Fig. 22.22) [271, 272]. Amoebic trophozoites and cysts are readily seen on biopsy of these lesions, which is often necessary for diagnosis.

Helminths

Strongyloides stercoralis is native to parts of Asia, South America, and Africa, as well as the Southeastern United States [273]. Uniquely, the organism can complete its life cycle in one human host, persisting for years with minimal or no symptoms, sometimes far from the geographic region where it was required. During times of immunosuppression, a fulminant type of strongyloidiasis called hyperinfection syndrome may develop, wherein numerous larvae disseminate throughout the organs of the previously asymptomatic host. Defective cell-mediated immunity, as may occur in hematologic malignancy, organ transplantation, or during treatment for graft rejection or graft-versus-host disease, increases the risk [274, 275]. Organ transplantation confers an additional risk in that *Strongyloides* may be acquired from the organ itself; the concomitant immunosuppression can precipitate hyperinfection syndrome [276].

Complications of hyperinfection syndrome include persistent or recurrent Gram-negative or polymicrobial sepsis, pneumonia, or meningitis. As the larvae migrate across the intestinal wall, they bring enteric bacteria with them to sterile sites. Eosinophilia, abdominal pain, diarrhea or constipation, nausea, gastrointestinal bleeding, cough wheeze, hemoptysis, interstitial pulmonary infiltrates, and acute respiratory distress syndrome may develop. In patients requiring intubation, a dramatic cutaneous manifestation of *Strongyloides* hyperinfection may develop. Due to positive-pressure ventilation, portal venous pressure increases, shunting blood (and numerous larvae) through the periumbilical portal-systemic shunt and into the skin. Extravasation of larvae and red blood cells creates pathognomonic "thumbprint" purpura and innumerable fine petechiae on the abdomen, flanks, and thighs [277, 278]. Examination of bronchoalveolar lavage, stool, and skin biopsy specimens readily reveals the organism. Ivermectin, in addition to supportive care, is the treatment of choice.

Fig. 22.23 Crusted scabies manifesting as widespread dry scale on most of the body, accentuated in body fold areas such as the finger webs and axillae

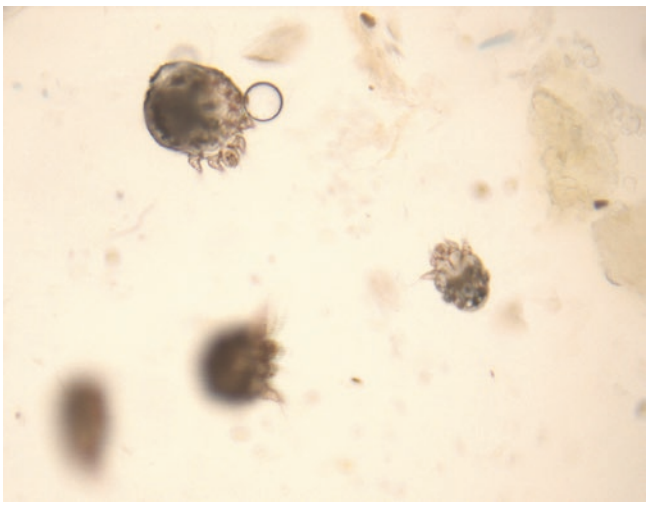

Fig. 22.24 A mineral oil preparation demonstrated numerous mites, ova, and feces

Scabies

Crusted scabies, a severe infestation with the scabies mite *Sarcoptes scabiei*, can occur in immunosuppressed patients, including those status post organ transplantation. Crusted scabies, previously called Norwegian scabies, is characterized by widespread thick, crusted, yellow-brown plaques with a predilection for the hands and feet, scalp, ears, groin, and axillae but the potential for involvement of the whole body surface (Fig. 22.23). The condition may be mistaken for severe seborrheic dermatitis or psoriasis [279]. Unlike scabies in a normal host, crusted scabies is paradoxically nonpruritic due to the absence of a normal inflammatory response. Exfoliated scale litters the environment of such patients with thousands of infectious fomites. Failure to diagnosis the condition in a hospitalized patient can therefore become a significant infection control problem.

The diagnosis can be confirmed fairly easily due to the high mite burden with either a skin scraping or biopsy demonstrating mites, eggs, or feces (Fig. 22.24). Dual therapy with oral ivermectin and topical permethrin, precipitated sulfur, or other scabicide is required [280]. Repeated treatments and scrapings to demonstrate clearance are often necessary. Bacterial superinfection of the involved skin is a frequent complication that may lead to bacteremia and mortality in some patients [281–283].

Conclusion

In transplant patients, cutaneous infections run the full gamut—they may be common or rare, present typically or atypically, be localized or widespread on the skin, and affect the skin alone or portend widespread visceral dissemination. With this myriad of presentations, the clinician must at all times be alert and aware, maintain appropriate diagnostic suspicion, and note clues suggestive of systemic disease. There should be a low threshold for biopsy and culture of unusual lesions. An understanding of these principles and disease entities hastens diagnosis and the delivery of needed therapy to this vulnerable group (Table 22.1).

Table 22.1 Clinical presentations and complications of skin and soft tissue infections in transplant recipients

Organism	Common cutaneous presentations	Atypical presentations	Complications and prognosis
Gram-positive bacteria			
Staphylococcus	Impetigo, ecthyma, folliculitis/furunculosis, cellulitis	Staph-scalded skin syndrome, botryomycosis (verrucous plaque)	Sepsis, toxic shock
Streptococcus	Similar to staph; most common cause of cellulitis/erysipelas	Necrotizing fasciitis	Sepsis, toxic shock
Clostridium	Myonecrosis (mottled, dusky, crepitus)	Hemorrhagic bullae with numerous Gram-positive rods	Sepsis; 32–79% mortality
Bacillus	Mild food poisoning	Vesicle or pustule with ulceration and rapidly spreading cellulitis	Necrotizing fasciitis, endocarditis, brain abscess; beta-lactam resistance
Corynebacterium	Skin flora; rare cutaneous infection	Cellulitis; nontender subcutaneous nodules, red papules	Skin lesions in nearly half of those with *C. jeikeium* sepsis; 34% mortality
Nocardia	Nodule, abscess, or ulcer with lymphocutaneous spread	Subcutaneous nodules, pustules, pyomyositis	Primary and disseminated skin disease are indistinguishable; must rule out sepsis and CNS/lung infection
Gram-negative bacteria			
Escherichia coli	Abscess, perirectal phlegmon, rapidly progressive cellulitis, ecthyma gangrenosum	Acral hemorrhagic bullae +/− underlying cellulitis a sign of sepsis, malakoplakia perianal or urethral draining nodules	Ecthyma gangrenosum most common in intergluteal cleft; related sepsis with 10–38% mortality
Klebsiella, Enterobacter, Serratia	Similar to *E. coli*; rapidly progressive cellulitis	Acral hemorrhagic bullae, ecthyma gangrenosum, crepitant cellulitis, necrotizing fasciitis	Acral hemorrhagic bullae are a sign of sepsis
Salmonella	Rare cutaneous infection	Subcutaneous abscess, hemorrhagic cellulitis, necrotizing fasciitis	Bacteremia in the absence of GI infection portends a poor prognosis
Legionella	Rare cutaneous infection	Refractory or relapsing necrotizing cellulitis	*Legionella* skin infection typically occurs without concurrent pneumonia
Morganella	Rare cutaneous infection	Cellulitis with hemorrhagic bullae, crepitant gangrene, ecthyma gangrenosum	Increased in hematologic malignancy, neutropenia, chemotherapy
Helicobacter	Rare cutaneous infection	Large, multifocal cellulitic plaques with adjacent large joint arthritis; superficial thrombophlebitis described	Relapsing bacteremia with recurrent multifocal cellulitis; prolonged antibiotics required
Citrobacter	Rare cutaneous infection	Cellulitis and bilateral inflammatory erysipelas of the legs, ecthyma gangrenosum and hemorrhagic bullae	Increased in organ transplantation and hematologic malignancy
Pseudomonas	Hemorrhagic bullous cellulitis, ecthyma gangrenosum (gun metal gray, necrotic plaques)	Necrotizing cellulitis with systemic toxicity and fulminant course; subcutaneous nodules	Better prognosis for isolated ecthyma gangrenosum due to inoculation and not sepsis
Stenotrophomonas	Similar to *Pseudomonas*; necrotizing cellulitis, ecthyma gangrenosum	Metastatic nodules, multifocal cellulitic plaques with eventual necrosis/ulceration	Highly resistant with high mortality rate in immunocompromised patients
Aeromonas	Rapidly progressive necrotic cellulitis	Fasciitis, myonecrosis, ecthyma gangrenosum, multiple hemorrhagic bullae	Sepsis with extensive necrotizing fasciitis and septic shock
Vibrio	Rapidly progressive edema and cellulitis with hemorrhagic bullae	Necrotic ulcers, fasciitis, gangrene	Inoculation injury in seawater or dissemination from GI tract; sepsis with hypotension, shock, >50% mortality
Bartonella	Bacillary angiomatosis with single or multiple asymptomatic red-purple papules	Flesh-colored, subcutaneous nodules	Nonspecific constitutional symptoms, dissemination to multiple organs (skin, most common clinical manifestation)
Mycobacteria			
M. tuberculosis	Acute military TB: erythematous or brown macules and papules evolving to vesiculopustules	Subcutaneous nodules, ulcerating nodules, cellulitis mimic	Generalized wasting, fever, cough with disseminated disease
Nontuberculous mycobacteria	Violaceous subcutaneous nodules with sporotrichoid spread; tenosynovitis and arthritis with lesions overlying affected joints	Widespread nodules, sinus tracts, ulcers, abscesses, cellulitis	Speciation is essential to guide management

Table 22.1 (continued)

Organism	Common cutaneous presentations	Atypical presentations	Complications and prognosis
Viruses			
Herpes simplex	Vesicles or punched-out erosions; periorificial ulcer or crust with a scalloped/polycyclic border	Ulcers of the oral mucosa, herpetic geometric glossitis, linear fissures in body folds, exophytic granulation tissue (herpes vegetans), Kaposi varicelliform eruption	Dissemination with pneumonitis, hepatitis, pancreatitis, esophagitis, retinitis, encephalitis, adrenal necrosis
Varicella zoster	Dermatomal, disseminated	Zoster sine herpete, recurrent primary varicella, chronic hyperkeratotic crusted plaques and punched-out ulcers	Pneumonitis, meningoencephalitis, hepatitis; abdominal pain with hyponatremia and SIADH
Cytomegalovirus	Rare cutaneous infection	Chronic anogenital ulcers with sharp borders; can occur elsewhere on skin, oral mucosa; rare morbilliform exanthem	Gastrointestinal ulceration, hepatitis, pneumonitis, myelosuppression
Human herpes virus 6	Exanthem subitum in infants	Erythematous morbilliform exanthem similar to acute graft-versus-host disease	Fever, pneumonitis, bone marrow suppression, encephalitis
Human papillomavirus	Verrucous papules or plaques	Extensive, numerous, exuberant, recalcitrant; may become large, confluent	Warts develop in 80% of transplant patients; can be locally destructive
Molluscum contagiosum	Small white dome-shaped umbilicated papules	Giant molluscum: verrucous, lobulated nodules; viral folliculitis mimicking tinea barbae; recalcitrant and resistant, chronic	Differentiate from disseminated cryptococcosis and histoplasmosis, which can appear molluscoid
Subcutaneous and deep mycoses			
Aspergillus	Purpuric plaques with black or purple necrotic centers; sites of inoculation or dissemination, of which it may be a presenting sign	Erythematous to violaceous plaques with pustules, subcutaneous nodules, cellulitic plaques	Most common opportunistic fungal infection s/p SCT; consider aggressive surgical management of solitary lesions; high mortality in dissemination
Fusarium	Painful red macules or papules evolving into violaceous, necrotic pustules, ulcers, or eschars; inoculation or dissemination	Acral bullae, flaccid umbilicated pustules, sporotrichoid nodules, localized abscess	Widespread cutaneous lesions more common than in aspergillosis (75–90% vs 10%); sinopulmonary, fungemia; dissemination almost uniformly fatal
Scedosporium/Pseudallescheria	Ulcerated dusky nodules, tender pustules, necrotic bullae; inoculation or dissemination	Suppurative nodules with spread along cutaneous lymphatics	More than half present with disseminated disease; around 60% die; blood cultures frequently positive; *S. prolificans* almost uniformly resistant
Mucormycosis/zygomycosis	Rhinocerebral disease most common; nasal discharge, black nasal mucosa, palatal infarction, necrotic facial lesions	Erythematous papule or plaque develops into purpuric, hemorrhagic ulcer or necrotic eschar; "bull's-eye infarct"	Rhinocerebral, pulmonary, GI, CNS, and disseminated disease; involved area may far exceed what is visible clinically; 80–100% mortality
Hyalohyphomycosis	Erythematous macules, necrotic, painful papules and nodules, vesiculopustules, cellulitis at portal of entry	Mycetoma with tumefaction and draining sinuses (*Acremonium*), onychomycosis with necrotic periungual cellulitis (*Scopulariopsis*)	*Fusarium, Paecilomyces*, *Acremonium*, *Trichoderma, Scopulariopsis*, *Trichosporon*; fungemia common and mortality high; high-level resistance
Phaeohyphomycosis	Inoculation injury with prolonged incubation period; nodule or abscess	Suppuration, sinus tract formation, ulceration; scaly/verrucous plaques; dissemination from the skin is rare	*Phialophora, Fonseca, Cladosporium, Exophiala, Alternaria, Scedosporium*; surgical debridement if possible
Candida	Local infection versus erythematous, purpuric papules with pale, necrotic, or pustular centers in disseminated disease	Subcutaneous nodules, folliculitis, and cellulitic plaques	Second most common fungal infection in SCT; skin lesions in 10% of dissemination; endophthalmitis, liver/spleen infection; high mortality
Cryptococcus	Molluscum-like umbilicated or crusted papules, cellulitis, subcutaneous nodules, ulcers	Skin lesions can present months before signs of dissemination; isolated skin lesions rare; can get necrotizing cellulitis, fasciitis	Skin lesions in 10–15% with dissemination; meningeal/ craniobulbar signs plus skin lesions
Coccidioides	Reactive erythema nodosum	Verrucous or crusted papules, plaques, abscesses, cellulitis, ulcers	Fever, cough, sweats; skin, meningeal, bone, and joint disease

(continued)

Table 22.1 (continued)

Organism	Common cutaneous presentations	Atypical presentations	Complications and prognosis
Blastomyces	Annular plaque with atrophic center and verrucous edges, pustules, and lymphatic spread	Ulceration and pustulosis, disseminated papulopustules and subcutaneous nodules	Most blasto in immunocompetent; more severe (29–40% mortality) in immunosuppressed; bone, GU, CNS
Histoplasma	Reactive erythema nodosum; macules, papules, necrotic papules, pustules in dissemination	Morbilliform eruption, ulcers, panniculitis, cellulitis, verrucous or vegetative plaques	Fever, respiratory symptoms, weight loss, hepatosplenomegaly, bone marrow suppression
Sporothrix	Fixed cutaneous (20%) or lymphocutaneous (70%); painless ulcerated papule/nodule at inoculation site	Rare extracutaneous and disseminated disease; widely distributed ulcerated papules or plaques, crusted nodules, necrotic ulcers	Bone and joints most often involved in dissemination (80%); skin lesions usually a presenting sign
Superficial mycoses			
Trichophyton *Microsporum* *Epidermophyton*	Annular pruritic scaling plaques with serpiginous borders typical of tinea corporis	Erythematous or violaceous papules, pustules, nodules, deep abscesses, draining nodules, or ulcers; can mimic folliculitis, lupus, rosacea	Rare invasive infection occurs at sites of chronic superficial dermatophytosis
Protozoa			
Trypanosoma	Tender subcutaneous nodules	Painful erythematous, indurated plaques mimicking cellulitis	Reactivation with immunosuppression or transmission via infected organ
Leishmania	Beefy ulcers at inoculation site	Rare erythematous or brown macules and papules due to dissemination; may be a presenting sign of visceral disease	Reactivation or transmission via infected organ; visceral disease most common form in transplant patients
Toxoplasma	Rare cutaneous infection	Disseminated erythematous papules resembling acute graft versus host disease	Reactivation or transmission via infected organ; fever, CNS, lungs
Acanthamoeba	Rare cutaneous infection	Numerous firm, purulent papulonodules develop into nonhealing crusted ulcers	Sinuses, lungs; spread to skin, viscera, brain; fatal meningoencephalitis
Strongyloides	Larva currens (migratory pruritic serpiginous plaques)	Hyperinfection syndrome with pathognomonic thumbprint purpura on abdomen, flanks, thighs	Reactivation or transmission via infected organ; pulmonary infiltrates, diarrhea, polymicrobial sepsis
Infestations			
Crusted scabies	Widespread thick, crusted, yellow-brown plaques with predilection for body folds	May mimic severe seborrheic dermatitis or psoriasis; can result in erythroderma, involvement of whole body surface	Bacterial superinfection can occur; highly contagious, significant infection control issue

Cutaneous Lesions that Mimic Infection in Transplant Patients

23

Ana Ciurea and Sharon Hymes

Introduction

Many cutaneous conditions may mimic infectious processes. The ability to diagnose non-infectious skin eruptions, especially in cancer patients, is oftentimes challenging. Using the morphology of the primary skin lesion as a starting point, this section will review the clinical presentation, physical examination, and diagnostic work-up of many of these conditions. This should help the clinician generate a differential diagnosis when evaluating cutaneous lesions in immunosuppressed patients.

Section 1: Pustular Lesions

Pustules are purulent collections which can be solitary or widespread. Not all the pustular processes in the skin are due to infection; pustular psoriasis is one of the non-infectious examples. They may be mistaken for bacterial, fungal, or superinfected herpetic infections.

Reactive Neutrophilic Dermatoses

Reactive neutrophilic dermatoses are a spectrum of diseases mediated by neutrophils manifested by systemic complaints in association with an underlying disease such as inflammatory bowel disorders or internal malignancies.

Differential Diagnosis: Bacterial, Fungal, and Viral Infections

Pyoderma gangrenosum is an uncommon idiopathic ulcerative skin disorder that often is associated with systemic diseases. The ulcerations are distinctive: an irregular, boggy, undermined border surrounding a purulent necrotic base (Fig. 23.1). Culture-negative pulmonary infiltrates are the most common extracutaneous site of disease [1]. PG is associated with a dysregulation of the immune system, in particular altered neutrophil chemotaxis in reaction to various precipitating causes such as inflammatory bowel diseases [2, 3]. Many conditions can be confused with the early pustular stage: folliculitis, furunculosis, carbuncles, and streptococcal gangrene. The ulcerative stage must be differentiated from cutaneous amebiasis, cryptococcosis, blastomycosis, sporotrichosis, and atypical mycobacterial infections [4–6]. PG has a tendency to recur and it usually heals with scarring.

Behcet's syndrome is a chronic relapsing, idiopathic, multisystem disease of recurrent aphthous ulcers, genital ulcers, and uveitis (Fig. 23.2). The cause is unknown; however, current research points toward an autoimmune etiology following exposure to an infectious agent which includes herpes simplex virus, *Streptococcus* and *Staphylococcus* species, and *Escherichia coli*. It has been suggested that the heat shock proteins (HSPs) found in higher concentrations in

Fig. 23.2 Behcet's disease. Oral ulcerations

Fig. 23.3 Sweet's syndrome. Erythematous, edematous plaques on the dorsal hand and fingers in a patient with acute myelogenous leukemia

skin lesions and oral aphthae can induce antibody production that cross-react with streptococcal species that are usually found in the mouth [7].

An acneiform papulopustular eruption may be seen on the face, neck, and trunk. The aphthous lesions begin as vesicles and/or pustules and tend to heal with scar formation. Tender, erythematous, recurrent nodules that resemble erythema nodosum are common on the extremities in women. Extragenital ulcerations, if present, are very specific for Behcet's disease [8]. Various treatment regimens have demonstrated benefit including systemic corticosteroids, colchicine, azathioprine, dapsone, interferon-alfa, and infliximab. The disease can be confused with herpetic gingivostomatitis and syphilis.

Acute neutrophilic febrile dermatosis (Sweet's syndrome) is a distinct entity characterized by one or more edematous red, tender, spontaneously painful plaques predominantly on the upper body, accompanied by fever, peripheral leukocytosis, and a variety of constitutional symptoms (Fig. 23.3). It is thought to be a hypersensitivity reaction of unknown cause characterized by infiltration of neutrophils in the skin. It has been associated with various carcinomas and hematopoietic malignancies especially acute myelogenous leukemia (AML) [9]. It responds dramatically to systemic corticosteroids and may resolve with treatment of the underlying disease [9, 10]. Ulcers and bullae are more common in malignancy-associated disease than in other forms. These lesions may be extensive and are generally hard to treat [11]. Sweet's syndrome must be differentiated from erysipelas, cellulitis, arthropod bites, herpetic infections, and drug eruptions.

Bowel bypass syndrome is a constellation of medical complications secondary to intestinal bypass surgery for the treatment of morbid obesity, consisting of fever, asymmetrical polyarthritis, tenosynovitis, sterile skin pustules, mucous membrane ulcerations, retinal vasculitis, and thrombophlebitis [12]. The syndrome is presumed to result from the deposition of circulating immune complexes containing bacterial antigens derived from overgrowth in the bypassed loop of the bowel [13]. Surgical excision of the blind loop or revision of the bowel bypass cures bowel bypass syndrome. The disease may resemble gonococcal sepsis, infectious panniculitis, pyoderma gangrenosum, Behcet's syndrome, and Sweet's syndrome.

Acute Generalized Exanthematous Pustulosis (AGEP)

Differential Diagnosis: Bacterial, Viral, or Fungal Infections

AGEP is a neutrophilic dermatosis characterized by acute-onset monoform, sterile, nonfollicular 1–2-mm pustules on a background of erythema secondary to drug administration, most commonly antibiotics. The lesions have a predilection for the face and intertriginous areas (Fig. 23.4). The eruption is accompanied by fever which can occur several days prior or the same day as the eruption. Widespread desquamation occurs after a few days. Neutrophilia and eosinophilia are commonly seen [14]. The precise mechanism of the disease is unknown. It is suggested that neutrophil-activating cytokines released by drug-specific T lymphocytes (IL-3, IL-8, and G-CSF) are potent triggers for blood neutrophilia and accumulation of neutrophils within the lesions [14]. It is characterized by fever which can occur several days prior to the eruption followed by the onset of classic lesions on the face or intertriginous areas. The withdrawal of the responsible drug is the mainstay of treatment in conjunction with topical corticosteroids [15].

Acneiform Hypersensitivity Drug Eruptions

Differential Diagnosis: Bacterial and Fungal Folliculitis

Acneiform eruptions are characterized by pruritic inflammatory papules or pustules localized primarily on areas with a

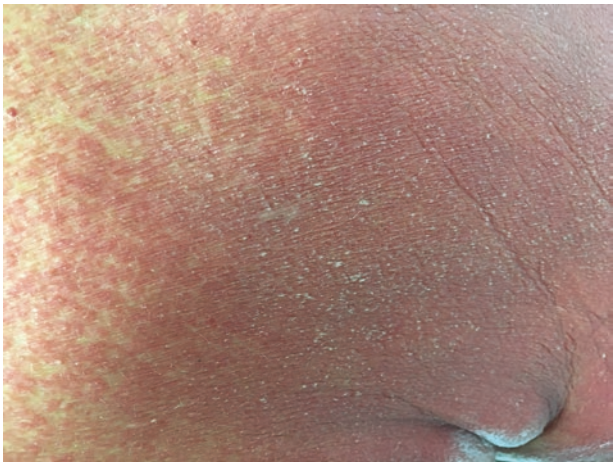

Fig. 23.4 Acute generalized exanthematous pustulosis. Affected individuals show large areas of erythroderma topped with small nonfollicular sterile pustules

Fig. 23.6 EGFR inhibitor-associated alopecia. Scalp inflammatory papules and scarring alopecia

Fig. 23.5 Acneiform drug eruption due to EGFR inhibitor erlotinib. Follicular pustules, located on the skin of the face and trunk in patient with metastatic lung cancer

large number of pilosebaceous units: face, neck, chest, and upper back, sparing the palmar or plantar surfaces (Fig. 23.5). In contrast to acne vulgaris, comedones are absent in acneiform eruptions. The eruption is common in cancer patients treated with systemic corticosteroids. Isoniazid, as well as chemotherapeutic agents including cyclosporine, azathioprine, and sirolimus, may induce acneiform drug eruptions [16, 17]. Cutaneous adverse events associated with epidermal growth factor inhibitors (EGFR) include pustular skin eruptions usually on the scalp, neck, chest, and back along with paronychia, xerosis, and alopecia (Fig. 23.6). Although the exact mechanism of the development of the rash is not completely understood, the inhibitor therapy disrupts the EGFR function by inducing terminal differentiation and apoptosis in the stratum corneum and hair follicles. Patients are often managed symptomatically or by adjusting the dose of the targeted therapy [18]. It is important to promptly identify and treat the adverse events during therapy with EGFR inhibitors to avoid drug suspension. The infectious diseases that enter the differential diagnosis of acneiform drug eruptions are folliculitis, measles, rubeola, rubella, and syphilis.

Eosinophilic Folliculitis

Differential Diagnosis: Bacterial and Fungal Folliculitis

Eosinophilic folliculitis is an uncommon recurrent eosinophilic infiltration of hair follicles manifested by pruritic papules and pustules associated with soft tissue edema seen most commonly on the head, neck, and trunk mostly in immunosuppressed patients [19, 20] (Fig. 23.7). Eosinophilic folliculitis has been classified as an AIDS-defining illness [19]. Although the exact etiology is unknown, an autoimmune reaction against sebocytes or sebum component and an abnormal T-cell immune response to a follicular antigen, such as caused by Demodex species, may be responsible for the eruption [19]. Topical corticosteroids are the mainstay of treatment for eosinophilic folliculitis. Highly active antiretroviral therapy along with isotretinoin therapy is

Fig. 23.7 Eosinophilic folliculitis. Crops of sterile papules and pustules on the face

Fig. 23.8 Transient acantholytic dermatosis or Grover's disease. This is an acquired condition that presents with pruritic vesicles and erosions on the upper trunk, most often in men

beneficial for eosinophilic folliculitis in the setting of HIV disease [21]. Clinically, it resembles bacterial folliculitis and candidiasis.

Grover's Disease

Differential Diagnosis: Bacterial and Fungal Folliculitis and Allergic Drug Eruptions

Also known as transient acantholytic dermatosis, this condition is benign, self-limited, exacerbated by heat and sweating, characterized by a sparse eruption of inflammatory papules, and fragile vesicles that erode. It is limited to the chest and upper abdomen, and it can be confused with bacterial folliculitis, herpes simplex and zoster infections, scabies, and syphilis (Fig. 23.8). Viral and bacterial pathogens have been proposed, but no causative role has been established. Potent topical corticosteroids are effective in diminishing inflammation and in controlling pruritus associated with transient acantholytic dermatosis.

Miliaria Rubra

Differential Diagnosis: Bacterial and Fungal Folliculitis

Miliaria rubra is a common anhidrotic disorder in which an obstruction of the sweat duct occurs in the deeper level of the epidermis characterized by minute erythematous macules with a punctate vesicle usually centrally located. The lesions can be seen to be extrafollicular, in contrast to the pustules of folliculitis (Fig. 23.9). It is the only type of miliaria in which the symptom of pruritus is experienced [22]. It occurs primarily at sites of occlusion such as the back of febrile,

Fig. 23.9 Miliaria rubra. Multiple erythematous pinpoint macules and papules, especially prominent on the occluded surface of the back

ill patients. Resident bacteria, such as *Staphylococcus epidermidis and Staphylococcus aureus*, may play a role in the pathogenesis of miliaria [23].

Neutrophilic Eccrine Hidradenitis

Differential Diagnosis: Cellulitis

Also known as toxic erythema of chemotherapy, neutrophilic eccrine hidradenitis is a skin condition observed in the setting of AML treated with cytarabine and has been reported in persons with various neoplastic and non-neoplastic conditions and otherwise healthy individuals [24]. It is characterized by solitary or multiple, red and purpuric, macules,

Fig. 23.10 Neutrophilic eccrine hidradenitis. Facial erythematous, indurated plaques

papules, nodules, or plaques most frequently located on the trunk or extremities (Fig. 23.10). The plaques are often tender. Neutrophilic eccrine hidradenitis can simulate orbital and facial cellulitis [24, 25]. Anthracyclines, antimetabolites, taxanes, vinca alkaloids, mitotic inhibitors, and granulocyte colony-stimulating factors may induce this disorder [26].

Section 2: Papulosquamous Lesions

Dermatitis

Dermatitis also known as eczema reflects an inflammatory skin reaction due to exposure to irritants, drugs, and other unknown triggers. It often presents as scaly erythematous plaques and patches, not uncommonly secondarily infected. 90% will be culture positive for *Staphylococcus aureus* [27].

Differential Diagnosis: Superficial Fungal Infection and Cellulitis

Stasis dermatitis presents as erythema and light-brown pigmentation on the lower extremities, especially above malleolus, associated with eczematous dermatitis (Fig. 23.11). It is a cutaneous marker for venous insufficiency and often mistaken for cellulitis. When chronic venous insufficiency is present, patients may present with marked woody induration in a stocking distribution associated with dyspigmentation, termed "lipodermatosclerosis."

Pityriasis alba is a form of dermatitis frequently atopic in origin, characterized by slightly scaly hypopigmented patches on the cheeks, upper arms, and trunk in children (Fig. 23.12). Potassium hydroxide examination of the fine white scale can rule out superficial cutaneous dermatophyte infection.

Fig. 23.11 Stasis dermatitis. Post-inflammatory hyperpigmentation over the medial malleolus on the background of varicose veins

Drug eruptions mimic various dermatoses and the morphology includes exanthem (morbilliform), papulosquamous, urticaria, vasculitis, and erythema nodosum. It should be suspected in any patient taking medication who developed a symmetric cutaneous eruption (Fig. 23.13). Chemotherapeutic agents such as busulfan and gentifinib are common causes for intertriginous drug eruption which can be confused with dermatophyte or yeast infection [28, 29].

Acute radiation dermatitis commonly occurs following local radiation therapy for various malignancies, with more than 90% of the patients experiencing erythema and more than 30% experiencing moist desquamation [30] (Fig. 23.14). Intense inflammatory reaction may result in a breakdown of the skin's barrier function and accompanying bacterial colonization, with organisms like *Staphylococcus aureus* [31, 32].

Psoriasis

Differential Diagnosis: Superficial Fungal Infection

Psoriasis is a complex multisystem inflammatory disorder of unknown etiology showing wide variation in severity and

Fig. 23.12 Pityriasis alba. Circumscribed scaly hypopigmented lesions on the face

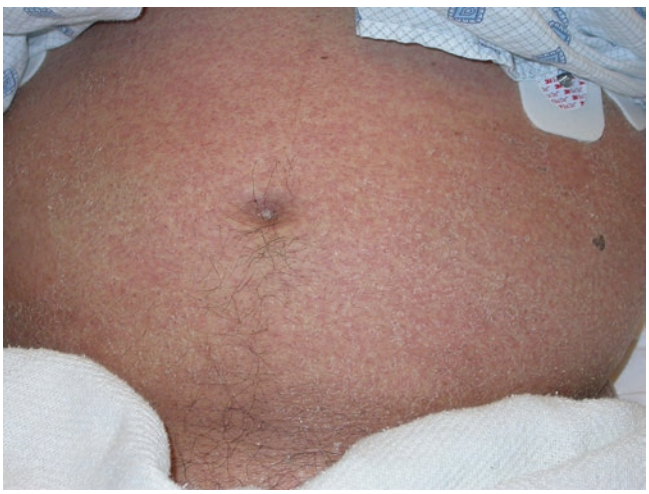

Fig. 23.13 Drug eruption. Morbilliform macules and papules on the abdomen resulting from cefepime

distribution of skin lesions. The most common skin manifestations are erythematous macules, papules, and plaques with thick silvery scale that follow an irregular chronic course marked by remissions and exacerbations of unpredictable onset and duration (Fig. 23.15). Although no region is exempt from involvement, psoriasis has a predilection for the scalp, elbows, and knees [33]. Psoriasis plaques can be mistaken for cutaneous tinea corporis or secondary syphilis.

Pityriasis Rubra Pilaris

Differential Diagnosis: Superficial Fungal Infection

Pityriasis rubra pilaris, a rare scaly, erythematous skin condition of unknown etiology with a preference for the follic-

Fig. 23.14 Acute radiation dermatitis. Extensive erythema and crusting with geographic borders defined by the radiation field

ular apparatus, is considered a disturbance of keratinization with predilection for the ears, trunk, neck, and extremities. Clinical features include discrete follicular-based reddish papules on the hands dorsum and diffuse palmar exfoliation (Fig. 23.16). Confluent scaly, salmon-colored plaques may appear on the trunk within islands of normal skin. A skin biopsy is mandatory to distinguish this from psoriasis and fungal infection and a search for occult malignancy should be considered if the presentation is atypical or in older patients.

Pityriasis Rosea

Differential Diagnosis: Superficial Fungal Infection and Syphilis

This is an acute self-limited, clinically distinctive exanthematous eruption of unknown etiology more commonly seen in adolescents and young adults. A mild prodrome manifested by malaise, fatigue, headache, and sore throat precedes the skin eruption with a few days. The earliest change is the "herald patch," a solitary, oval, or annular plaque on the trunk, arms, and thighs, followed by eruptive erythematous, flat plaques measuring 0.5–1.5 cm in diameter (Fig. 23.17). The clinical features and course of pityriasis rosea strongly suggest a viral etiology; however, no single virus has been proven to cause the disease. The widespread lesions of secondary syphilis and tinea versicolor may resemble pityriasis rosea [34]. Tinea corporis can be confused with the herald patch seen earlier during the course of the disease.

Fig. 23.15 Psoriasis vulgaris. Typical plaques of psoriasis with thick, white scaly overlying erythema

Fig. 23.16 Pityriasis rubra pilaris. Symmetric, diffuse, scaly erythema

Cutaneous T-Cell Lymphoma

Differential Diagnosis: Superficial Fungal Infection

Cutaneous T-cell lymphoma, a class of non-Hodgkin lymphoma, is characterized by infiltration of the skin by clonal malignant T-cells and has many clinical variants, but the classic subtype is characterized by sharply demarcated plaques, uniform in color, ranging from an erythematous to a violaceous hue (Fig. 23.18). The clinical features, histomorphology, and cytomorphology of the lesions are diagnostic clues, and demonstration of a dominant T-cell clone in skin biopsy specimens constitutes an additional diagnostic test to distinguish CTCL from inflammatory dermatoses.

The early stage is typically nonspecific and is often misdiagnosed as eczema, psoriasis and superficial fungal infection.

Fig. 23.17 Pityriasis rosea. Truncal involvement with larger plaques and predominantly round patches with peripheral scale

Fig. 23.18 Cutaneous T-cell lymphoma. Hyperpigmented scaly patches with minimal scaling

Section 3: Purpuric and Petechial Lesions

Purpura is the multifocal extravasation of blood into the skin or mucous membranes manifested by distinctive red macules a few millimeters in size. Petechiae are superficial, pin-

Fig. 23.19 Leukocytoclastic vasculitis. Multiple purpuric papules in a patient with drug-induced hypersensitivity vasculitis

head-sized hemorrhagic macules, bright red at first, seen in the dependent areas. Petechiae most often imply a disorder of platelets.

Leukocytoclastic Vasculitis

Differential Diagnosis: Bacterial and Fungal Infection

Leukocytoclastic vasculitis (LCV) represents a hypersensitivity reaction secondary to immune complex deposition, other autoantibodies, inflammatory mediators, and local factors that involve the endothelial cells. Palpable purpura is the clinical prototype of LCV in which the vascular insult is at the level of arterioles and postcapillary venules. Lesions appear in crops, ranging from 1 to 2 mm in size, and have a predilection for dependent parts. Palpable purpura is generally asymptomatic, but in severe cases (with erosions, bullae, and hemorrhagic vesicles) patients may experience pruritus, edema, and burning [35] (Fig. 23.19). It can be mistaken for systemic bacterial infections including candidiasis and meningococcemia. Skin biopsy reveals the presence of vascular and perivascular infiltration of polymorphonuclear leukocytes with formation of nuclear dust (leukocytoclasis), extravasation of erythrocytes, and fibrinoid necrosis of the vessel walls.

Superficial Thrombophlebitis

Differential Diagnosis: Cellulitis

An inflammatory reaction in which clotting appears on the wall of an inflamed vein in patients with idiopathic venous stasis, prolonged bed rest, local injury to endothelium by trauma, and superficial thrombophlebitis presents with erythema, edema, and tenderness in the affected limb (Fig. 23.20). This needs to be distinguished from cellulitis which is a nonnecrotizing inflammation of the skin and subcutaneous tissues.

Fig. 23.20 Superficial thrombophlebitis. Erythema and edema along the leg vein

Calciphylaxis

Differential Diagnosis: Cellulitis, Ecthyma Gangrenosum, and Bacterial and Deep Fungal Infections

This is a highly morbid syndrome characterized by painful ischemic tissue necrosis primarily on fingers, legs, and thighs surrounded by livedo reticularis in patients with chronic renal insufficiency and hyperparathyroidism [36]. Lesions of calciphylaxis typically develop suddenly and progress rapidly. The clinical manifestations of calciphylaxis are similar to those of a significant number of other disorders, including among others cellulitis, necrotizing fasciitis, ecthyma gangrenosum, vibrio vulnificus infection, cholesterol embolization, warfarin necrosis, cryoglobulinemia, and vasculitis [37, 38] (Fig. 23.21).

Fig. 23.21 Calciphylaxis. Deep skin necrosis and non-healing ulcer

Fig. 23.22 Petechiae. Pinpoint, monoform red macules on the lower legs

Petechiae

Differential Diagnosis: Rickettsial, Bacterial, and Fungal Infection

Petechiae are small purpuric lesions up to 2 mm in size often occurring in crops due to extravasation of red blood cells into the skin. The purpura is not palpable, in contrast to palpable and sometimes tender purpura observed in patients with vasculitis. It tends to form in areas of increased venous pressure, such as the legs (Fig. 23.22). The etiology is multifactorial and includes among others thrombocytopenia, defective platelet function, increased intravascular venous pressure, vitamin C deficiency, and localized trauma or pressure. Purpura is often seen at intravenous injection sites in cancer patients. It must be distinguished from the eruption of Rocky Mountain spotted fever (RMSF), a tick-borne disease caused by the organism *Rickettsia rickettsii.* The hallmark of RMSF is a petechial eruption beginning on the palms of the hands and soles of the feet [39].

Disseminated Intravascular Coagulation

Differential Diagnosis: Bacterial and Fungal Sepsis

Disseminated intravascular coagulation may produce a clinical picture varying from a severe and rapidly fatal disorder (purpura fulminans) to a relatively minor disorder. Varying combinations of bleeding, thromboembolism, and hemolytic anemia are superimposed on the clinical picture caused by primary disorders which include, among others, extensive tissue damage, severe infections, and malignant diseases. The normal inhibitory mechanisms of clotting are overcome so that there is intravenous coagulation, followed by consumption and depletion of platelets and plasma clotting factors. In the most severe cases onset is sudden with fever and a very extensive, symmetrical purpura of the extremities but also on the ears, nose, and lips (Fig. 23.23). Lesser changes include petechiae, purpuric papules, hemorrhagic bullae, and acral cyanosis. Treatment includes that appropriate for the underlying condition, treatment of shock, and replacement therapy as indicated.

Section 4: Lesions of the Adipose Tissue

Differential Diagnosis: Bacterial, Deep Fungal, and Mycobacterial Infections and Cellulitis

Panniculitis is an inflammation occurring within the adipose tissue. It can occur in the septae, lobules, or both. It is often associated with a variety of systemic diseases and clinical syndromes and it often presents as red-to-violaceous nodules and plaques that have a predilection for lower extremities.

Nodular Vasculitis

Nodular vasculitis also called erythema induratum is a vasculitis of the muscular arteries of the deep dermis and fat that result in secondary lobular panniculitis. It occurs in middle-aged women who develop painful, reddish-blue, variably tender nodules and plaques over the lower extremities, especially the calves (Fig. 23.24). A severe small-vessel vasculitis is seen on histologic examination. Nodular panniculitis may be idiopathic but is most commonly due to infections such as tuberculosis and occasionally histoplasmosis,

Fig. 23.23 Disseminated intravascular coagulation. Extensive skin necrosis with hemorrhagic bullae

Fig. 23.24 Nodular vasculitis. Tender blue-reddish nodules on the lower legs

HIV, and hepatitis C [40–42]. Painful, indurated red plaques located on the extremities resembling erythema induratum have been reported in patients with chronic myelogenic leukemia undergoing treatment with imatinib [43] and dasatinib [44]. The differential diagnosis of nodular vasculitis includes erythema nodosum, granulomatous vasculitis, and miscellaneous forms of panniculitis.

Fig. 23.25 Pancreatic panniculitis. Faint erythematous tender plaques on the lower extremities

Cold Panniculitis

Cold panniculitis is an acute, nodular eruption usually limited to areas exposed to the cold. Cold panniculitis results from a cold injury to the adipose tissue. It is more common in women. The eruptive phase usually begins 48 h (range, 6–72 h) after a cold injury to exposed or poorly protected areas. The lesions should be distinguished from cellulitis and deep fungal or mycobacterial infections.

Pancreatic Panniculitis

Pancreatic panniculitis, acute pancreatitis, and pancreatic tumors may cause fat necrosis of the pancreas and of the subcutaneous tissue. The clinical picture consists of raised, erythematous nodules, 1–3 cm in size, located on the upper and lower extremities (Fig. 23.25). The pathogenic mechanisms underlying the various features of pancreatic panniculitis are unclear.

The histopathology of pancreatic panniculitis is pathognomonic, characterized by ghost adipocytes that are necrotic,

Fig. 23.26 Erythema nodosum. Tender red oval nodules on the extensor aspect of the legs

Fig. 23.27 Lipodermatosclerosis. Chronic inflammation and fibrosis of the skin surrounding the entire lower legs

anucleate and contain basophilic material within the cytoplasm indicating dystrophic calcification from the saponification of fat [45]. The exact mechanism is unknown, but it is believed that lipase plays a strong pathogenic role for subcutaneous fat necrosis. The Schmid's triad of panniculitis, polyarthritis, and eosinophilia portends very poor prognosis in a patient with pancreatic carcinoma.

Septal Panniculitis (Erythema Nodosum)

Septal panniculitis (erythema nodosum) is the most common form of inflammatory panniculitis manifested by erythematous, tender nodules on anterior shins, thighs, and lateral aspects of the lower legs and occasionally on the face, accompanied by fever, chills, arthralgias, and leukocytosis (Fig. 23.26). It results from an immunologic reaction triggered by drugs; benign and malignant systemic illness; bacterial, fungal, and viral infections; pregnancy; and medications including oral contraceptives. Circulating immune complexes have not been found in idiopathic and uncomplicated cases but demonstrated in patients with inflammatory bowel disease [46]. It resolves without scarring in 4–6 weeks.

Sclerosing Panniculitis (Lipodermatosclerosis)

Sclerosing panniculitis (lipodermatosclerosis) is a disease process that clinically appears as painful indurated erythematous hyperpigmented plaques and nodules on the lower extremities in middle-aged women. The underlying fibrosis and lobular atrophy give the impression of an inverted champagne bottle with a hard, wood-like appearance which becomes circumferential in well-developed lesions (Fig. 23.27). Occasionally there is overlying ulceration or crusting. Lipodermatosclerosis (LDS) is believed to be associated with chronic venous insufficiency. Abnormal fibrinolysis, an excessive proteolytic activity by matrix metalloproteinase, and the upregulation of an inflammatory response by interleukin-8 are thought to be the causes for this condition [47, 48].

Traumatic Panniculitis

Traumatic panniculitis represents a localized reaction of the subcutaneous tissue following minor trauma. It is most frequently seen in obese women. The lesions consist of indurated, inflamed nodules that undergo necrosis. When localized to the breast, they may clinically simulate a carcinoma or infectious mastitis. Traumatic panniculitis is usually a self-limiting disorder and requires only symptomatic treatment.

Section 5: Vesiculobullous Lesions

A vesicle is a fluid-filled blister less than 0.5 cm in its greatest dimension, while bullae is greater than 0.5 cm. Vesiculobullous lesions may be solitary, grouped, or annular and either localized or widespread in distribution. The etiology of these lesions varies, and valuable clues may be found in the patient's history, clinical presentation, and skin biopsy. From an infectious disease specialist's viewpoint, blistering lesions are often caused by herpetic eruptions or infectious pathogens which produce skin necrosis. However, a variety of non-infectious vesiculobullous lesions may occur in the transplant setting and are reviewed in this section.

Fig. 23.28 Allergic contact dermatitis. Characterized by well-defined plaques of vesiculopapules overlying erythema and edema. Oozing and secondary infection are common

Fig. 23.29 Mechanical blister. Flat bullae on the toe dorsum secondary to trauma

Acute Dermatitis

Differential Diagnosis: Viral Infections and Impetigo

The vesiculobullous eruption associated with acute dermatitis is caused by inter- and intracellular edema in the epidermis, also called spongiosis. The patient may be aware of a preceding irritant or allergen applied to the skin, including surgical preparations, topical antibiotics, or tape. Allergic contact dermatitis may be linear or geometric, corresponding to the application of the precipitating agent (Fig. 23.28). As the blisters rupture, a superficial crust forms, which may be mistaken for impetigo. It is not unusual for the dermatitis to become secondarily infected, especially in the immunosuppressed transplant patient. On occasion, non-infectious vesicular lesions may appear distant to the site of the original dermatitis, a phenomenon known as autosensitization dermatitis. This should be distinguished from a disseminated herpetic process.

Diabetic Blisters

Differential Diagnosis: Viral Infection and Cellulitis

Also known as bullosis diabeticorum [49], this condition is characterized by the spontaneous appearance of intraepidermal or subepidermal, clear, tense bullae on the non-erythematous skin of diabetic patients. These blisters are most often found on the lower extremities and are minimally symptomatic. The pathogenesis may be related to diabetic angiopathy or trauma, and this condition should be distinguished from infectious cellulitis.

Mechanical Blisters

Differential Diagnosis: Cellulitis and Ecthyma

These painful blisters occur in areas of high friction or pressure, which causes epidermal necrosis. The surrounding erythematous rim may mimic cellulitis. Mechanical blisters are also precipitated by burns, extravasations of toxic substances, or vesicants. Hemorrhagic bullae may occur at sites of injections in patients with thrombocytopenia or capillary fragility (Fig. 23.29).

Coma Blister

Differential Diagnosis: Cellulitis and Ecthyma

Skin blisters at sites of pressure and associated with underlying sweat gland necrosis were reported in comatose patients with carbon monoxide intoxication as early as 1812 [50]. Also called barbiturate or neurologic blisters, these lesions are at times associated with surrounding erythema that may look like cellulitis. While barbiturates are the most frequently reported causative agent [51, 52], similar findings have been reported with other medications including tricyclic antidepressants [53] and benzodiazepines [54]. Coma blisters have been associated with central nervous system disorders [55], hypoglycemia [56], and diabetic ketoacidosis [57]. The etiology is multifactorial, but in some cases, a direct toxic drug effect has been implicated, perhaps via drug excretion through the eccrine glands. The bullae may appear as early as 1 h after acute intoxication and usually resolve in 2–4 weeks. They may be clear or hemorrhagic and should be distinguished from ecthyma or cellulitis.

Miliaria Crystallina

Differential Diagnosis: Herpes Infection

Miliaria crystallina, also known as sudamina, occurs in the setting of profuse sweating and epidermal occlusion. It is characterized by 1–2-mm asymptomatic vesicles on a non-inflammatory base, which are easily "wiped away" with pressure. As opposed to grouped herpetic vesicles on a more erythematous base, miliaria crystallina appears on occluded skin, with no underlying erythema (Fig. 23.30).

Edema and Lymphedema Blisters

Differential Diagnosis: Cellulitis

Large dependent bullae may develop in the setting of peripheral edema, anasarca, and lymphedema, especially if the onset of swelling is acute. Although these bullae are usually found on normal-appearing skin, underlying stasis changes may make it difficult to distinguish from bullous cellulitis. Initially, the blisters are tense and clear but may become hemorrhagic or superinfected. Treatment is directed at minimizing the underlying edema.

Bullous Drug Eruptions

Differential Diagnosis: Viral Infections, Ecthyma, and Cellulitis

Bullous drug reactions may be localized or widespread. When localized and recurrent at the same site after drug re-challenge, they are referred to as fixed drug eruptions. Fixed drug eruptions initially appear within 2 weeks of the inciting drug exposure but within 30 min–24 h after re-challenge. The eruption is characterized by erythema, sometimes the formation of bullae, and often characteristic residual "slate-grey" pigmentation as the lesion resolves. Findings suggest that fixed drug eruptions are a form of classic delayed-type hypersensitivity mediated by CD8+ cells [58], although mast cells may play a role [59]. When located on the genitalia the blisters may look like acute herpes simplex infection and, on other sites, cellulitis. Widespread bullous drug reactions have varying etiologies and pathologic features. Certain medications may produce immune-mediated blistering, characterized by the deposition of IgA at the dermal-epidermal junction. This is of special interest to infectious disease specialists as it has been reported with antibiotics like trimethoprim-sulfamethoxazole, penicillin, metronidazole, and rifampicin [60].

Bullous Graft Versus Host Disease

Differential Diagnosis: Viral Infection and Cellulitis

Allogeneic hematopoietic stem cell transplantation is widely used for the treatment of hematologic malignancies, bone marrow failure syndromes, and immunodeficiency. The skin is commonly affected in patients who develop graft-versus-host disease (GVHD). Grade 4 acute GVHD of the skin is characterized by a generalized exfoliative dermatitis, ulcerative dermatitis, and bullae [61] that may be mistaken for disseminated viral infection (Fig. 23.31). In these cases, the damage at the epidermal-dermal junction is severe enough to allow the dermis to separate from the epidermis. Bullae may also appear in the setting of scleroderma-like GVHD changes [62, 63].

Fig. 23.30 Miliaria crystallina. Clear, thin-walled vesicles occurring in crops on otherwise normal-appearing skin

Fig. 23.31 Bullous graft-versus-host disease. Tense bulla and vesicles on the ear in patient with diffuse erythema of the head and neck

Although the pathogenesis is unknown, these cases show significant fibrosis and dermal edema [64, 65].

Porphyria Cutanea Tarda (PCT) and Pseudoporphyria Cutanea Tarda

Differential Diagnosis: Viral and Bacterial Infections

Porphyria cutanea tarda (PCT) is a group of familial and acquired disorders characterized by deficiency in the activity of uroporphyrinogen decarboxylase, an enzyme key in heme synthesis. In the transplant setting, this may be precipitated by exposure to environmental agent such as excess iron [66], coexisting conditions that affect the liver, and infection agents including hepatitis C [67] and HIV [68]. Patients exhibit skin fragility and blistering, especially in sun-exposed areas, as well as hypertrichosis, scleroderma-like changes, milia (small white cysts), and dystrophic calcification (Fig. 23.32). Pseudoporphyria mimics the findings of PCT without demonstrable porphyrin abnormalities. It has been reported in the setting of chronic renal failure and dialysis [69], as well with medications like beta-lactam antibiotics [70], ciprofloxacin [71], voriconazole [72], and tetracycline [73].

Autoimmune Bullous Diseases

Differential Diagnosis: Viral Infection, Cellulitis, and Scabies

This broad category of diseases is characterized as immune-mediated blistering of the skin. Bullous pemphigoid presents with tense skin blisters, urticarial (hive-like) lesions, and variable mucosal involvement. It is characterized by autoantibodies located in the hemidesmosomal complex of the basement membrane zone. It may occur de novo, with other autoimmune diseases, or occasionally with malignancies. Some antibiotics implicated in pathogenesis include amoxicillin [74], cephalexin [75], and ciprofloxacin [76]. The clinical presentation of tense blisters associated with urticaria may be mistaken for cellulitis.

Pemphigus presents on the skin and mucous membranes with intraepidermal flaccid bullae. It is divided into three forms: vulgaris; foliaceus; and paraneoplastic. Patients with pemphigus vulgaris develop painful mucosal erosions and skin lesions, which may resemble a herpetic process. Patients with pemphigus foliaceus develop extensive crusted erosions, easily confused with cutaneous infection (Fig. 23.33). Paraneoplastic pemphigus is associated with underlying neoplasms, and characterized by severe stomatitis, often mistaken for herpetic stomatitis. The lesions on the skin are polymorphous and may resemble lichen planus or erythema multiforme. (These patients may also develop lung involvement characterized by bronchiolitis obliterans [77]). Antibiotics are implicated in the pathogenesis of pemphigus vulgaris, including ampicillin, penicillin, cefadroxil, and rifampicin [60, 78]. In these cases, the eruption usually starts a few weeks after starting the medication. The diagnosis of pemphigus is made by performing a skin biopsy, which demonstrates an intraepidermal vesicle with acantholysis (separation between epidermal cells). Direct immunofluorescence of peri-lesional skin demonstrates IgG and/or C3 binding to the intercellular cement or keratinocyte cell surface [79]. Dermatitis herpetiformis, a cutaneous manifestation of

Fig. 23.32 Porphyria cutanea tarda. Vesicles and bullae on light-exposed cutaneous surfaces, especially the dorsal aspects of the hands

Fig. 23.33 Pemphigus vulgaris. Painful scalp erosions with underlying erythema

Fig. 23.34 Dermatitis herpetiformis. Grouped, symmetric, and pruritic papules on the elbow

gluten-sensitive enteropathy, is characterized by pruritic, tiny vesicles easily reminiscent of scabies or herpes infections. These are most commonly found on the elbows, back buttocks, and knees (Fig. 23.34). The biopsy shows neutrophils in the dermal papillae and granular deposits of IgA. The eruption may be worsened by ingestion or application of iodide [80].

Bullous Insect Bite Reaction

Differential Diagnosis: Ecthyma, Viral Infection, and Cellulitis

Insect bite reactions may produce varying degrees of erythema and are less commonly vesicles, bullae, and necrosis. Exaggerated bite reactions have been reported in the setting of chronic lymphocytic leukemia as well as other hematoproliferative disorders and human immunodeficiency virus infections [81, 82]. Many patients have no recollection of the bite.

Section 6: Erythematous Lesions

Injury, infection, vascular reactivity, and inflammation may cause erythema of the skin. Most of the conditions discussed in this section produce blanchable erythema, that is, resolution of the erythema with pressure. So-called reactive erythema is a cutaneous response to an underlying systemic process, which may be infectious, malignant, or drug related. The primary lesions are red plaques that may be annular, transient, or fixed.

Fig. 23.35 Urticaria. Transient, well-circumscribed erythematous dermal plaques on the trunk

Fig. 23.36 Tinea corporis. An expanding, erythematous annular plaque

Urticaria

Differential Diagnosis: Cellulitis and Superficial Fungal Infections

Urticaria, commonly referred to as hives or wheals, are well-demarcated, smooth, dermal plaques that may become confluent and demonstrate a variable degree of pruritus. When associated with significant edema and warmth, they are mistaken for cellulitis (Fig. 23.35) and when annular in configuration, for tinea corporis (Fig. 23.36). Because they result from transient dermal edema, they tend to change in size and shape and are rarely present in the same spot for more than 48 h. When persistent, a biopsy may demonstrate urticarial vasculitis, characterized by small vessel destruction.

Angioedema presents with deep and painful swelling, without urticaria. Transplant patients may be at increased risk

of angiotensin-converting enzyme (ACE)-associated angioedema because of the effects of immunosuppressants on the activity of circulating dipeptidyl peptidase IV (DPPIV) [83].

Erythema Multiforme (EM)/Stevens-Johnson Syndrome (SJS), and Toxic Epidermal Necrolysis (TEN)

Differential Diagnosis: Disseminated Viral, Bacterial, or Fungal Infections

At the onset, erythema multiforme presents as erythematous macules and plaques on the extensor surfaces of the limbs and on the palms and soles. Other infectious etiologies for palm and sole lesions including rickettsia, spirochetes, or viruses should be considered. The classic target or iris lesion is characterized by a dusky center, red border, and surrounding pallor (Fig. 23.37). If enough epidermal apoptosis is present, the center may appear bullous, hemorrhagic, or necrotic, suggestive of ecthyma or embolic infection. SJS may be complicated by significant mucous membrane involvement of the lips, buccal mucosa palate, conjunctivae, urethra, and vagina. TEN is a life-threatening condition characterized by detachment of the epidermis from the dermis (Fig. 23.38). The differential diagnosis includes staphylococcal scalded skin syndrome (SSSS). However, SSSS causes a more superficial subcorneal skin split that can readily be distinguished by skin biopsy.

EM, SJS, and TEN are associated with many different etiologies. Infectious agents are important precipitating factors in children and young adults [84], whereas drug reactions and malignancy are more important in adults [85, 86]. Herpes simplex, mycoplasma pneumonia, Coxasackie B-5, influenza type A, and echo viruses have all been implicated in pathogenesis [87].

Gyrate Erythema

Differential Diagnosis: Superficial Fungal, Bacterial, or Rickettsial Infections

A gyrate erythema is characterized by polycyclic erythematous plaques. In the case of erythema annulare centrifugum, the lesions slowly expand, disappear over weeks, and are replaced by new annular lesions (Fig. 23.39). Some cases are associated with dermatophyte infections, but the lesions themselves do not contain fungus. This condition is rarely associated with internal malignancy, and the clinical presentation may mimic secondary syphilis, dermatophytosis, Hansen's disease or erythema migrans, and the gyrate erythema associated with Lyme disease.

Necrolytic migratory erythema, associated with glucagon-secreting tumors of the pancreas, is a gyrate erythema that

Fig. 23.38 Toxic epidermal necrolysis. Extensive erosions and sloughing of skin resembling wrinkled, wet tissue paper

Fig. 23.37 Erythema multiforme. Round lesions in which concentric rings with color variation are present

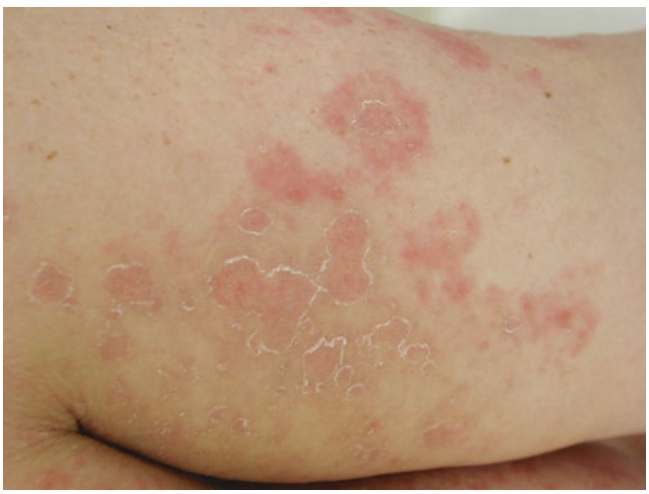

Fig. 23.39 Gyrate erythema. Slowly expanding annular lesions and palpable scaly erythematous borders

Fig. 23.40 Granuloma annulare. Annular, dusky-red, nonscaly plaques on the trunk

Fig. 23.41 Squamous cell carcinoma. Large, sun-induced, keratotic, non-ulcerated nodule on the arm

occurs in periorificial, flexural, and acral areas. The eruption may resemble chronic mucocutaneous candidiasis, severe seborrheic dermatitis, or acrodermatitis enteropathica associated with zinc deficiency. It has also been associated with hepatitis C [88].

Granuloma Annulare

Differential Diagnosis: Superficial Fungal Infection

This granulomatous process presents with annular and serpiginous plaques with no significant scale (Fig. 23.40). In some studies, GA has been associated with diabetes mellitus [89], but many cases are idiopathic. The lesions may be confused with a superficial fungal infection.

Section 7: Ulcerative Lesions and Skin Tumors

Differential Diagnosis: Bacterial, Fungal, Mycobacterial, or Parasitic Infections

Organ transplantation markedly increases the risk of developing non-melanoma skin cancers, the most common of which are squamous cell carcinoma followed by basal cell carcinoma [90] (Fig. 23.41). Compared to the biologic behavior in non-immunosuppressed individuals, the squamous cell carcinomas tend to be more aggressive, with a higher risk of invasion of surrounding structures as well as metastasis [91, 92]. Kaposi's sarcoma and Merkel cell carcinomas occur with increased frequency [90]. In organ transplant patients with chronic ulcerations, it may be prudent to biopsy for bacterial, fungal, and acid-fast culture as well as for histopathology.

Section 8: Hair and Scalp Lesions

Transplant patients may present with inflammatory lesions of the scalp and alopecia as a result of bacterial and fungal infections. This section will review some of the non-infectious etiologies of hair and scalp lesions.

Tumors

Differential Diagnosis: Bacterial and Deep Fungal Infections

The incidence of squamous cell and basal cell carcinomas of the skin increase with the duration of immunosuppressive therapy in transplant recipients and affect at least 50% of Caucasian transplant patients [93]. Approximately 80% of tumors develop on the head [94] with associated ulceration, crusting, and erosions. Early on, these crusted lesions may be mistaken for bacterial or fungal infections, delaying the diagnosis. Some of these tumors resemble warts and, in fact, human papillomaviruses may be cocarcinogenic [95]. Patients post-organ transplantation may also be at a higher risk for melanoma [96], Kaposi's sarcoma [97], and Merkel cell carcinoma [98].

Plaques and Pustules

Differential Diagnosis: Bacterial and Fungal Infections

While erythematous plaques and pustules on the scalp may be caused by dermatophyte and bacterial infections, this is also a common presentation of scalp psoriasis. The characteristic well-demarcated, scaly plaques may be studded with

Fig. 23.42 Dissecting cellulitis of the scalp. Painful cutaneous nodules and patchy alopecia

sterile pustules; the latter may be precipitated by systemic corticosteroid withdrawal or taper. Dissecting cellulitis of the scalp, also called perifolliculitis capitis abscedens et suffodiens, produces boggy and fluctuant scalp nodules with interconnecting sinus tracts and sterile, purulent discharge (Fig. 23.42). This disorder often responds better to retinoids than antibiotics [99]. Other common causes of sterile pustules and inflammation on the scalp include acne keloidalis or inflamed cysts.

Introduction

Gram-positive bacterial (GPB) infections are an important cause of serious illness in patients undergoing transplantation [1]. In recipients of hematopoietic stem cell transplantation (HSCT), GPB are by far the most common bacterial pathogens isolated. A relative decline in infections due to Gram-negative bacteria (GNB) has been attributed to a variety of factors: (1) frequently used antimicrobial prophylaxis with an emphasis on prevention of systemic infections resulting from these microorgansisms; (2) a rise in drug-resistance among disease-casuing GPB due to extensive exposure to healthcare environment and frequent use of broad-spectrum antibiotics that are often given as preventive or empiric therapy; (3) the necessity for maintenance of vascular access results in retention of intravascular devices for extended duration; (4) orointestinal mucositis associated with conventional preparatory regimens in patients undergoing allogeneic stem cell transplantation; (5) the presence of severe pre-engraftment neutropenia that may result in protracted courses of recovery in certain high-risk transplant groups, such as adults following conventional cord blood stem cell transplantation; (6) the emergence and widespread distribution of community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) colonization and subsequent risk for invasive disease; (7) acute and chronic graft-versus-host disease (GVHD) involving the skin and orointestinal tract; and (8) hyposplenism noted in patients with chronic GVHD, which promotes the likelihood for serious, invasive pneumococcal disease and infections due to other encapsulated microorganisms [2–4].

Infection prevalance varies among patients undergoing solid organ transplantation (SOT), in most part the risk is a reflection upon the transplanted organ allograft and surgical procedure(s) involved. Deceased donor allograft-derived and organ perfusion fluid (PF)-associated GPB infections are a potential source for such infections. The risk of invasive bacterial infections reflects a proclivity for GPB in this group, and mostly related to surgical procedures that are often long and difficult. Prolonged tissue hypoperfusion, posttransplant allograft ischemia, and retransplantation procedures further increases the risk for bacterial infections. Furthermore, surgical drain(s) that are left in place for a long duration; external biliary tract drains like percutaneous transhepatic biliary catheter; percutaneous nephrostomy catheter, chest tube, and thoracic drains to name a few, promote risk for hospital-acquired bacterial infections; among such infections, GPB are common pathogens encountered. Postsurgical wound infections including wound dehiscence or other early complications following transplant surgery such as the development of primary or secondary hematoma or persistent seroma in the deep surgical bed may provide a nidus for bacterial infection; GPB are also prominent in such post -surgical complications. It is important to note that colonization with MRSA and vancomycin-resistant enterococci (VRE) poses a substantial burden due to a more noticeable risk for subsequent invasive bacterial disease and the risk for potential allograft compromise [5, 6].

Presence of extended-use intravascular access devices that are crucial in patients undergoing transplantation for supportive care that includes and not limited to fluid, electrolyte and mineral supplimentation, hyperalimentation, renal replacement therapy, plasma exchanges, blood and blood product transfusions, and administration of antibiotics among other medications needed to be given parenterally. These intravascular acess devices serve as a direct conduit between skin and blood vessels thereby promoting the risk

for bloodstream infections (BSIs). Skin commensals such as coagulase-negative staphylococci (CoNS) and *Corynebacterium jeikeium* are a well-recognized cause of catheter-related bloodstream infection (CR-BSI). Similar to HSCT recipients, patients undergoing SOT are also susceptible to serious invasive disease due to CA-MRSA. Allograft rejection and need for intensified drug-induced immune suppression further promote the risk for invasive disease due to conventional and opportunistic bacterial pathogens. In this regard, *Staphylococcus aureus*, viridans streptococci, and *Enterococcus* spp. are important pathogens [7–10].

Genetic susceptibility for GPB infections may be further accentuated in patients undergoing allograft transplantation. Minor genetic alternations such as single-nucleotide polymorphisms (SNPs) in the essential components of innate immune signaling pathways may become unmasked following trnspantation procedure and are thought to increase hosts' susceptibility for infections. Toll-like receptor 2 (TLR2) is an immune sensor for the components of GPB cell wall. Genetic alterations in the TLR2 gene may render this important pattern recognition receptor with impaired function, thereby enhanced susceptibility for GPB infections in such individuals. In a cohort of 694 liver transplant recipients, it was interesting to note that patients with TLR2 R753Q SNP (an amino acid substitution of arginine for glutamine at position 753) had similar frequency of GPB infections compared with those individuals without this TLR2 SNP. However, the presence of TLR2 R753Q SNP was identified in patients with higher rates of infection recurrence (28% vs. 12%, $P = 0.07$) and initial infection presentation with septic shock was significatly higher in subjects with this TLR2 mutation (11% vs. 1%, $P = 0.04$) versus those without. Important to note that presence of TLR2 R753Q SNP did not result in higher infection-related deaths among liver transplant recipients in this report [11].

Further studies are underway to assess clinical relevance for this and other genetic minor aberrations that may unmask minor immune dysfunction against commonly encountered pathogens, especially in individuals following allograft transplantation.

Staphylococcus Species

Staphylococci are the predominant GPB with the ability to cause serious illness in patients undergoing transplantation [12, 13]. Staphylococci can be divided into two main classes based on their ability to coagulate rabbit plasma. *Staphylococcus aureus* being coagulase positive and all other *Staphylococcus* species are referred to as coagulase-negative staphylococci (CoNS). Infections due to *S. aureus* may present as simple cellulitis or bacteremia versus a disseminated disease that features involvement of various organ systems. Patients with disseminated *S. aureus* infection usually present as life-threatening illness with sepsis or severe sepsis and even in non-transplant immunocompetent patients such infections may progress, in short order, to cause multiorgan dysfunction, disseminated intravascular coagulation, hemodynamic collapse and death. Probablity of severe illness is emphasized in transplant recipients with compromised immune defenses and compounded by dysregulation of hosts' immune-inflammatory response. The potential to cause pneumonia, endovascular and prosthetic device infections is an important ability of *S. aureus* and to a lesser extent by species belonging to the CoNS group. In general, infections due to CoNS are less severe, which is a reflection of low inherent virulence of these bacteria to cause disease in humans [14, 15].

Staphylococcus aureus

Epidemiology and Pathogenesis

S. aureus is a common commensal that can be isolated from 10% to 40% of individuals residing in various communities [16]. *S. aureus* has been well-established as a leading cause of both community-onset and nosocomial infections. Prior to the year 2000, a vast majority of MRSA infections were related directly, or indirectly, to the exposure to healthcare environment. *S. aureus* infections acquired in the community, almost exclusively were methicillin-susceptible strains of *S. aureus* (MSSA) [17]. The emergence and global spread of CA-MRSA have resulted in an increased prevalence of these pathogens among the general population and those undergoing transplantation procedures. MRSA colonization has been regarded as an important risk factor among HSCT recipients, and a precursor for subsequent invasive staphylococcal disease [18]. The risk for such infections now extends beyond healthcare exposure and must be entertained when assessing the possibility of illness due to staphylococci in the transplant population [19].

Most invasive *S. aureus* diseases in transplant recipients occur when mechanical defenses are breached, for example, due to break in the skin barrier resulting from catheter placement or bypassing upper airway defenses following insertion of an endotracheal tube [20]. The main risk factors include severe neutropenia, GVHD, allograft rejection, solid allograft retransplantation, treatment with systemic corticosteroids, and complicated allograft transplant surgery. *Staphylococcus aureus* infections are also encountered in a high frequency among patients requiring prolonged intensive care unit stay, mechanical assisted ventilatory support, renal replacement therapy, and those with severe pre-engraftment neutropenia. Diabetic patients with persistent hyperglycemia-induced neutrophil and macrophage dysfunction are also at risk for potentially severe staphylococcal disease [21, 22].

HSCT Recipients

A recent study from Europe in 15,181 neutropenic HSCT patients assessed 2,388 episodes of BSI. The annual incidence of BSI in this population was 16%; 62% had undergone allogeneic and 38% autologous stem cell graft transplants [23]. The authors noted an increase in enterococcal BSI from 2% in 2002 to 3% in 2014 ($P < 0.001$). Whereas the incidence of bacteremia due to CoNS declined from 8% to 5% ($P < 0.001$), in autologous stem cell recipients, this decline was even more pronounced, from 8% to 2% between 2002 and 2011, respectively ($P = 0.02$). No significant change in the trend for MRSA or vancomycin-resistant *Enterococcus* (VRE) bacteremia was evident during the study years. The case fatality rate among 2,388 bacteremia episodes was 3% and remained unchanged over the course of the study [23].

Myeloablative preparative conditioning regimen promotes the risk for bacterial infections. In a recent study of 460 patients, the risk of BSI was assessed during the first year after transplantation between 2008 and 2013. Thirty-four percent of patients who received myeloablative conditioning developed BSI, whereas, in patents, in whom nonmyeloablative stem cell transplantations were performed, BSIs were 17%. Sixty-eight percent of bacteremia episodes were due to GPB [24].

At a comprehensive cancer center in New York, the frequency of late HSCT *S. aureus* bacteremia was reported as 6 episodes per 100,000 patient-days. The median time of onset after transplantation was 137 days, and ranged between 55 and 581 days. Majority of these infections (84%), as expected, were acquired in the community [25]. Risk factors included ongoing acute GVHD, acute or chronic GVHD involving the skin ($P = 0.002$), use of systemic corticosteroids, liver dysfunction, and prolonged transplantation-related hospitalization ($P = 0.02$). *S. aureus* bacteremia in HSCT recipients at this large stem cell transplant center for the most part, occurred in patients with GVHD and/or those receiving systemic corticosteroids [25].

Solid Organ Transplant Recipients

Solid organ transplantation is a high-risk setting for MRSA and VRE colonization, and the carrier state is associated with a heightened risk for subsequent invasive bacterial disease. In a recent meta-analysis of 23 studies, including 17 with reference to liver transplants, the prevalence estimates for MRSA and VRE colonization prior to transplantation surgery were 8.5% and 12%, respectively. After transplantation, the prevalence estimates for MRSA were 9% and 16% for VRE. MRSA colonization significantly increased the risk for invasive bacterial disease both before and after transplantation (risk ratio [RR] 5.5 and RR 10.5, respectively). Similarly, VRE colonization was also associated with a significantly higher risk for subsequent invasive disease (RR 6.6 during pre-transplant and RR 7.9 after transplantation) [6]. In a small study of patients undergoing small bowel and multivisceral transplantation at the University of Nebraska, nearly one-third (36%) of *S. aureus* isolates associated with systemic infection were strains exhibiting resistance to several classes of antimicrobials [26].

Bacterial contamination of solid allograft perfusion fluid has been regarded as a potential source for organ graft contamination, which may result in early postsurgical allograft infection that carries a greater risk for systemic dissemination and sepsis during this period of high immune vulnerability. Microbiological data of 290 PF infections from a single center showed 35% PF had positive cultures for microorganisms, and of these, half (50%) were *Staphylococcus* species. However, it was important to note that invasive bacterial disease seldom resulted following PF contamination graft transplantation compared with patients in whom allografts were transported in PF with no evidence of contamination [27].

Donor-derived infection is an important concern in harvesting organs from donors with a recent history of, or ongoing high-grade *S. aureus* bacteremia, with or without evidence of endovascular infection. Transmission of such infections are well-established by sophisticated epidemiologic analysis and provides a pause for concern in assessing risk of exposure to potentially life-threatening *S. aureus* disease [28]. It is important to note that despite appropriate systemic antibiotics given after such allograft transplantation, patients remain at risk for these infections during or after the antibiotic prophylaxis has ended [29].

In living donor liver transplantation, the prominent risk factors for early bacterial infections were a high serum creatinine level (odds ratio [OR] 1.5), a long anhepatic arterial perfusion phase (OR 1), a reoperation (OR 6.4), young age (OR 1), and recipient who had no history of hepatocellular carcinoma (OR 2) [30].

In patients with cystic fibrosis (CF) undergoing lung transplantation, higher risk of infection is seen in a disease caused by mutations involving endosomal cystic fibrosis transmembrane conductance regulator (*Cftr*), pulmonary *S. aureus* colonization that occurs early in the course of illness and often, prior to colonization with pathogens such as *Pseudomonas aeruginosa.* These patients continue to remain susceptible to *S. aureus* infections as a result of intracellular survival of *S. aureus* in macrophages. In animal experiments, *S. aureus* after being internalized by *Cftr*-deficient macrophages are not killed due to a defect in the fusion of endosomal phagosomes with lysosomes [31]. This defect may persist in CF patients following pulmonary allograft transplant surgery.

A 5-year retrospective study from the University of Pittsburgh evaluated *S. aureus* infections within the first 90 days after lung transplantation [32]. In 596 patients following lung transplantation, 18% developed *S. aureus* infection, of these 38% were MRSA. The study observed an incremental increase in MRSA prevalence over the duration of the study.

Isolation of MRSA from the nares ($P < 0.0001$) or from respiratory tract samples ($P = 0.02$) at the time of transplantation was noted to significantly increase the risk for invasive MRSA disease within 3 months after transplantation [32].

Clinical experience at the University of Pittsburgh endorsed that *S. aureus* screening and decolonization for patients undergoing heart and heart-lung transplantation was fiscally beneficial, and averted 6.7 *S. aureus* infections (4.3 MRSA and 2.4 MSSA) leading to a cost saving of $240,602. The authors found that 89 patients were needed to be screened to prevent one *S. aureus* infection in this at risk organ transplant group [33].

The cross talk between bacterial communities and innate immune cells potentially determines the functional integrity of the transplanted lung allograft. In lung transplant recipients, long-term graft survival depends upon the balance between inflammation and tissue remodeling. Host-microbe interactions after lung transplant determines the immunologic tone of the airways and, consequently, may possibly, impact survival of the pulmonary allograft. In a French and Swiss study, the characteristics of the pulmonary microbiota aligned with distinct innate cell gene expression profiles provided evidence that bacterial dysbiosis could lead to proinflammatory or remodeling profiles in macrophages, whereas a congruous microbial community maintained homeostasis. Such an impact was associated with equitable distribution of bacterial communities with proinflammatory properties such as *Staphylococcus* spp. and *Pseudomonas* spp. versus bacteria like *Prevotella* and *Streptococcus* spp. with low immune-inflammation potential [34]. Further research is underway to assess the impact of host lung and respiratory tract microbiota and its impact on allograft survival.

Clinical Manifestations

S. aureus infections commonly involve the skin and skin structures, and clinical presentations include cellulitis and abscesses; systemic infections and end-organ disease are seen in both immunocompetent and immunocompromised patients [35, 36]. *S. aureus* is a leading cause of catheter-related bacteremia, prosthetic joint infections, and infections following a surgical procedure [15]. Suppurative complications such as infective endocarditis, pneumonia with concurrent bacteremia, osteomyelitis, spinal diskitis, native and prosthetic joint infections, and septic pulmonary emboli from subcutaneous abscesses may occur due to secondary bacterial seeding in patients with high-grade, persistent *S. aureus* bacteremia [37].

Bacteremia is a serious complication in patients undergoing HSCT. A recent 6-year single-center experience in patients with bacteremia following stem cell allograft transplantation, the 2-year overall survival was 46% compared with 60% survival noted among patients without BSI (HR 1.5; $P = 0.07$). *P. aeruginosa* and *E. coli* bacteremia were associated with highest mortality rates of 50% and 33%, respectively [38].

Late *S. aureus* BSIs occurred in HSCT recipients, and 40% involved a focal site of infection. Persistent bacteremia for more than 3 days despite removal of endovascular access was noted in more than 50% of cases. The median survival rate after *S. aureus* bacteremia was 135 days and ranged between 1 and 1,765 days [25].

In a kidney transplant unit in London, England, between 2012 and 2013, graft pyelonephritis was noted as a prominent cause of bacteremia (69%). Methicillin-sensitive *Staphylococcus aureus* was the most common pathogen isolated (26%), followed by, and expectedly, *Escherichia coli* (25%) [39].

Necrotizing pneumonia due to *S. aureus* in transplant patients usually occurs in critically ill patients with respiratory failure requiring prolonged assisted mechanical ventilation; as in general population, superimposed bacterial pneumonia may complicate the course during or after a viral upper respiratory tract infections due to influenza and other respiratory tract viruses [40].

The rise of CA-MRSA has been especially concerning given that CA-MRSA isolates can cause devastating disease including necrotizing fasciitis and necrotizing pneumonia even in otherwise healthy individuals; the potential for such complictions become more pronounced in the immunosuppressed patients undergoing transplantation [41, 42]. It is not uncommon to find *S. aureus* in patients with pyomyositis, septic arthritis, and septic bursitis, which may have occurred due to contiguous infection or from hematogenous bacterial seeding [43, 44].

Nosocomial pneumonia after lung and heart-lung transplantation was assessed between 2008 and 2010 at a surgical unit in France [45]. The authors reported their prospective evaluation of 79 lung or heart-lung transplant recipients, 35 (44%) of whom developed 64 episodes of nosocomial pneumonia. Pneumonia recurrence was seen in 40% of the cases; severities of illness and lung injury were the two main contributors for infection recurrence. *Staphylococcus aureus* accounted for 20% of these episodes, whereas *Enterobacteriaceae* (30%) and *Pseudomonas aeruginosa* (25%) were also common. It was interesting to note that ICU mortality did not greatly differ in patients with nosocomial pneumonia (14%), those with pneumonia recurrence (10%), and patients without pneumonia (11%; $P = 0.9$). It was however, unexpected that diagnosis of pneumonia had no impact on ICU mortality, especially in this high risk transplant group [45].

In 596 patients following lung transplantation at the University of Pittsburgh, *S. aureus* pneumonia (48%) was the most common presentation in 109 lung transplant recipients with *S. aureus* infection. Tracheobronchitis (26%), bacteremia (12%), intrathoracic infections (7%), and skin/soft tissue

infections (7%) were also noted. Risk factors included mechanical ventilation for >5 days and isolation of *S. aureus* from recipients' sterility surveillance cultures. Patients with these infections had prolonged hospitalization and intensive care unit stays ($P < 0.0001$). Further, in patients with *S. aureus* infections that occurred after undergoing lung transplantation; acute and chronic allograft rejection at 1 and 3 years ($P = 0.04$ and $P = 0.002$, respectively) and mortality at 1 and 3 years ($P = 0.05$ and $P = 0.009$, respectively) were significantly higher than in other patients in this series without *S. aureus* infection. Mortality rates of 7% on day 30 and 12% by day 90 after *S. aureus* infection was a sobering reminder regarding the severity of this infection in the vulnerable population [32].

In a large study from the Cleveland Clinic in Ohio 2,959 patients with *S. aureus* bacteremia were evaluated; 70 had undergone solid organ transplantation including 26 lung, 19 liver, 18 kidney, and 7 patients following heart allograft transplantation. The overall rate of *S. aureus* BSI was 22.9 per 1000 transplant patients. Early-onset bacteremia within 90 days after the transplant procedure was common in liver allograft recipients (79%) vs. 17% in patients having undergone renal allograft transplants. As expected, the duration of bacteremia was longer in SOT patients vs. non-solid organ transplant population (mean 3.8 days vs. 1.6 days; $P < 0.01$), and SOT recipients had significantly higher frequency of MRSA infection (86% vs. 52% in non-SOT population; $P < 0.0001$). The all-cause 30-day and 1-year mortality rates were 6% and 28% in patients following SOT, respectively. Pneumonia as a source of bacteremia was associated with a higher 30-day mortality (18% vs. 2% nonpulmonary source; $P = 0.04$). It was interesting to note that SOT status was independently associated with a lower risk of 30-day mortality (risk ratio [RR]: 0.37; $P = 0.02$) and may represent high vigilance and prompt institution of empiric antimicrobial therapy in this group [46].

At the University of Nebraska, the first *S. aureus* infection in a liver allograft recipient developed at a median of 29 days after undergoing transplantation. Just over half of these infections occurred during the first month after the liver transplant surgery [47]. As expected, 88% were hospital-acquired infections, 41% were polymicrobial, and nearly half (47%) were due to MRSA. Liver transplant patients with *S. aureus* infection were intubated more frequently (odds ratio [OR] 26.9; $P = 0.0006$), had an indwelling intravascular catheter (OR 11.6; $P = 0.02$), and underwent recent surgery (OR 26.9; $P = 0.0006$). Multivariate analysis revealed a 26.9 times higher risk of developing *S. aureus* infection in patients in whom surgery was performed within 2 weeks prior to infection diagnosis ($P = 0.0006$). Recent surgical procedure was the only significant independent risk factor for *S. aureus* infections after liver transplantation in this analysis [47].

Staphylococcus aureus infections in small bowel and multivisceral transplantation were assessed retrospectively in 22 cases at the University of Nebraska. The median age was 2 years; 43% of the first infection episodes were bacteremia, followed by pneumonia (30%), and surgical site infections (26%). As expected, the time to surgical site infections (41.0; range, 0–89 days) was significantly shorter than that to lung infections (266; range, 130–378 days; $P = 0.01$). When compared with other small bowel and visceral transplant recipients without *S. aureus* infection, the 22 cases studied had higher likelihood of CMV seromismatch (OR 3.0; $P = 0.08$); it was interesting to note that patients with CMV seromismatch had higher probability for developing *S. aureus* infection (OR, 2.9; $P = 0.085$). Patients in this transplant population with *S. aureus* infection were 2.2 times more likely to die ($P = 0.04$) and had a significantly shorter survival (28.5 months) compared with patients without *S. aureus* infection (45.8 months; $P = 0.04$) [26].

Diagnosis

These bacteria are hardy, grow well in enriched laboratory media, and are relatively easy to identify. The presence of *S. aureus* in specimens from sterile body sites in most instances represents microbiologic evidence of an infection. *S. aureus* contamination of blood cultures has been suggested [48]; in authors' view, this phenomenon occurs rarely and must not be entertained, especially in transplant population.

S. aureus has propensity to colonize various body sites, such as the oral and nasal cavities, upper respiratory tract, skin, and lower intestinal and genitourinary tracts. Therefore, isolation of *S. aureus* from endotracheal aspirate or urine sample obtained from an indwelling urinary catheter and even bronchial wash samples must be assessed in context of clinical presentation, pathogen-disease compatibility, and importantly, hosts' susceptibility along with pretest probability for such infections. However, these factors assist mainly in decision-making for individuals with intact immune function and may not necessarily enable determination regarding bacterial colonization versus locally invasive disease in severely immunosuppressed patients undergoing allograft transplantation.

Serologic or antigen assays have not proven to be clinically helpful in the diagnosis of *S. aureus* infection. The new diagnostic assessment including PCR for prompt determination of MRSA represents encouraging development [49]. A detailed review of the advancements in infection diagnosis is presented in the "Diagnoses and Prevention" section.

Treatment

Therapy for systemic *S. aureus* disease constitutes a comprehensive approach toward the patient, which involves (1) lowering the level of immune suppression; (2) identifying and addressing the source and/or primary focus of infection such

as (2a) removal of the infected or potentially infected foreign device, when feasible; (2b) surgical drainage of infected collections and debridement of necrotic tissue; and (3) selection of appropriate empiric antibiotic while awaiting culture and drug susceptibility results [50]. The importance of drainage of deep tissue infected collections and surgical removal of devitalized tissue cannot be overemphasized, as in many patients with localized infection, removal of the nidus and primary focus of infection alone may be curative and often supplemented with an abbreviated course of systemic antibiotic therapy [51]. In concert, if an infected foreign material, such as an indwelling intravascular catheter or an infected prosthetic joint, remains in place, then therapeutic success of antibiotic therapy alone tends to be suboptimal [52, 53].

Antibiotic treatment of *S. aureus* infection is complicated by emergence and speard of bacterial starins with extensive antimicrobial drug resistance. When the organism is sensitive, β-lactam antibiotics are the drugs of choice for *S. aureus* infections including nafcillin and oxacillin [54, 55]. Vancomycin is considered by most as optimal treatment for invasive MRSA infections, although increasing frequency of vancomycin treatment failures, especially in oncology and transplant population, have questioned this approach [56]. Treatment of MRSA bacteremia with vancomycin given as a single agent has been associated with a high rate of treatment failure evident as lack of clinical response and complete recovery, or early infection relapse, which may be observed in 15%–20% of the episodes; although overt vancomycin resistance by in vitro drug testing still remains an elusive phenomenon [57]. Failure to vancomycin therapy has motivated a search for alternative treatment options including newer drugs such as linezolid, tedizolid, tigecycline, ceftaroline, and daptomycin, to name a few.

Each of these agents, similar to vancomycin, has significant limitations. Proven treatment efficacy and superiority to vancomycin as a first-line agent for the treatment of systemic MRSA infections such as bacteremia, pneumonia, complicated intra-abdominal infections, and bone and joint infections need further clinical validation. It is imperative to take into account the potential for adverse events and systemic toxicity associated with vancomycin and these newer antibiotics including the following consideration: a) hosts' variables which may at times, influence drug clearance in patients undergoing transplantation; b) drug-drug interactions, with particular emphasis on pharmacokinetics and pharmacodynamics of drugs commonly use to treat allograft rejection GVHD; c) inherent or postexposure development of drug resistance, or selection of less drug susceptible bacterial strains, especially in at risk transplant population, in whom extensive prior exposure to the healthcare environment and the need for periodically given systemic broadspectrum antibiotics for recurrent or suspected infections are routinely priscribed both prior to, and following the transplantation procedure [58–69].

Selection of effective empiric antibiotic therapy for the treatment of glycopeptide-nonsusceptible staphylococci is difficult, as true resistance is rare and isolates exhibiting heterogeneous resistance or vancomycin tolerance may not become evident even after the drug susceptibility profiles are known. In patients undergoing SOT, use of vancomycin has been associated with low therapeutic efficacy and high rates of drug-induced renal impairment, which in part is a reflection of the cumulative nephrotoxicity resulting from standard practice antirejection drug regimens including calcineurin inhibitors given for prolong duration after the allograft transplant surgery.

A study from Spain during 2008 and 2010 enrolled 43 patients mostly after liver and kidney transplantation who received daptomycin for the treatment of GPB infections including CoNS catheter-related bacteremia (23.2%), *S. aureus* skin and skin structure infections (11.5%), and intra-abdominal abscess due to *Enterococcus faecium* (20.9%). The daily daptomycin dose was 6 mg/kg in 74% of the patients. On day 7 of daptomycin treatment, median estimated area under the curve was 1251 μg/mL/h. No changes were observed in tacrolimus serum levels. Daptomycin was not discontinued in any of these patients due to adverse events. Eighty-six percent clinical success with daptomycin therapy was noted in this small group of transplant recipients [63].

The potential role of antibiotics in modulating virulence among *S. aureus* is an intriguing phenomenon and needs further exploration, especially for the treatment of difficult-to-treat infections. The effects of antibacterial agents on pathogens' expression of virulence and on hosts' immune response are currently being explored. A recent review of the literature evaluated relevant articles that explored the effects of antibiotics on staphylococcal toxin production and the impact of these ancillary mechanisms on hosts' immune function. Most in vitro data pointed to a reduced level of expression of bacterial virulence following treatment with ribosomally active antibiotics such as linezolid and clindamycin, whereas cell wall-active antibiotics like beta-lactams were associated with amplified bacterial exotoxin production/release. In vivo studies confirmed the suppressive effect mediated by clindamycin and linezolid on the expression of bacterial virulence, supporting their utilization as a valuable management strategy to improve patient outcomes in cases of toxin-mediated staphylococcal disease [70].

The duration of therapy for *S. aureus* infection is highly individualized. A minimum of 2 weeks is recommended for patients with uncomplicated catheter-related bacteremia [71]. A longer course of antibiotic treatment is generally given ranging from 4 to 8 weeks in patients with complicated infections such as infective endocarditis, necrotizing pneumonia, empyema, septic arthritis, allograft pyelonephritis,

intra-abdominal deep tissue abscesses such as liver and splenic abscesses, and osteomyelitis. The antibiotics are usually given intravenous for more serious infections, whereas in select low-risk cases a transition to oral drugs that exhibit dependable enteral bioavailability may be considered as an option. Regardless of treatment duration, *S. aureus* systemic infection-related complications may arise during the course of therapy or long after the antibiotic therapy has ended. New suppurative foci may arise months after a successful resolution of acute *S. aureus* illness. Patients with serious *S. aureus* disease require a close and continued follow-up for the possibility of infection recurrence that may present as a suppurative focus, and may occur remote from the original site of infection; days to months after completing an appropriate course of concordant antibiotic therapy.

Coagulase-Negative Staphylococci

Epidemiology

Coagulase-negative staphylococci (CoNS) are part of the normal hosts' microflora; up to 90% of humans are colonized with these low-virulence environmental organisms [57]. Skin, orointestinal, and genitourinary mucosa are prominent sites of bacterial colonization. Unlike general population, patients undergoing transplantation are vulnerable to invasive disease due to CoNS. This is in most part attributed to breach in protective barriers resulting from (1) indwelling intravascular catheters; (2) surgical wounds; (3) various surgical drainage catheters including percutaneous nephrostomy tubes, external biliary tract catheters, and thoracic cavity drains, among others; (4) implantable left ventricular assist device in patients with advanced heart failure awaiting transplantation; (5) the presence of severe mucositis involving the orointestinal tract resulting from allogeneic HSCT preparatory conditioning regimens or in patients with post-HSCT GVHD; and (6) recently recognized periodontal disease as a risk factor for CoNS bacteremia in patients with pre-engraftment neutropenia following hematopoietic stem cell graft transplantation [23, 72, 73].

When species studies are performed, *S. epidermidis* is generally the leading cause of invasive CoNS infections in the immunosuppressed population [74]. *Staphylococcus lugdunensis* is an emerging member of the CoNS group, which has increasingly been recognized as a cause of severe endovascular infection. Such infections are clinically indistinguishable from that caused by *Staphylococcus aureus*. The potential for endocarditis due to this novel bacterial pathogen in transplant population needs further investigation. *Staphylococcus lugdunensis* has been associated with a variety of infections, especially osteoarticular infections, foreign body-associated infections, and bacteremia. Several putative virulence factors have been identified including adhesion factors, biofilm production, and proteolytic factors appears to proffer opportunistic potential of these newly recognized pathogens, which is in contrast to more insidious, less virulent species of bacteria grouped among CoNS [75]. In a recent retrospective analysis between 2011 and 2014, in only 45 of 2263 CoNS clinical isolates, *S. lugdunensis* was confirmed; skin and skin structure infections being the most common clinical presentation. It was interesting to note that patients with neutropenia did not appear to have a higher frequency of *S. lugdunensis* infections compared with patients with normal peripheral blood neutrophil count [76].

HSCT Recipients

Microbial contamination of hematopoietic stem cell graft derived from peripheral blood or bone marrow is uncommon, albeit, when this does occur, it may potentially lead to devastating systemic graft-acquired infection, especially in patients during pre-engraftment neutropenia. A microbiological evaluation of 291 peripheral blood and 39 bone marrow stem cell samples was conducted at a center in Poland between January 2012 and June 2013; bacterial contamination was demonstrated in nearly 3% of stem cell products. CoNS and *Micrococcus* species were the most frequent organisms detected in their air microbial contamination control environment. The risk for bacterial contamination increased with each step of cell processing, suggesting that least possible manipulation of the stem cells would improve microbial sterility of the transplant material. The authors also endorsed air contamination control environment as essential in the preparation of hematopoietic stem cells in order to reduce the risk for potential bacterial contamination [77].

SOT Recipients

Bacterial contamination of solid organ allograft preservation solution is not uncommon; in some studies, up to 44% of graft preservation fluid may exhibit bacterial and fungal contamination, or both; and as expected, CoNS is the most prevalent (64%) bacteria isolated in this setting [78]. It is important to recognize that only a small number of (~5%) infections after liver transplantation procedure were related to the organisms isolated in the preservation solution [78].

Disease Pathogenesis

The major CoNS diseases in transplant patients include bacteremia associated with an indwelling intravascular device and surgical site infections. The pathogenesis of device-related CoNS infection is thought to stem from bacterial capability to form biofilm on the foreign implanted material [79]. A recent study from Brazil showed that all CoNS strains isolated from patients with bacteremia were biofilm forming phenotypes and exhibited a high prevalence of atlE, indicting

an enhanced potential for autolysin/adhesin [80]. The investigators also showed that these blood-borne CoNS had an increased frequency of staphylococcal enterotoxin (SE) A gene and potential for exotoxin production. These heat-stable enterotoxins are a leading cause of gastroenteritis. In addition, SEs are powerful superantigens that stimulate nonspecific T-cell proliferation and indiscriminate lymphocyte activation bypassing the normal, highly regulated antigen presentation process; the resultant unrestraint systemic inflammatory response and hosts' organ damage is often lethal [81]. However, most reports of severe septicemia in transplant patients associated with SE-producing staphylococcus are attributed to *S. aureus* [82].

Clinical Manifestations/Diagnosis

Fever without an apparent focus of infection is the most common clinical presentation in transplant patients with catheter-related CoNS infection including those with a positive blood culture [83]. In the transplant patients, clinical evidence of catheter infection including insertion site inflammation, which is expected to present as pain, erythema, induration, and purulent drainage or an abscess formation along the catheter insertion site, subcutaneous reservoir pocket, or catheter tunnel is frequently absent. Diagnosis requires a high level of suspicion as patients may appear relatively asymptomatic withor without a nonspecific low-grade, persisent febrile illness [84]. Native valve infective endocarditis and hematogenous osteoarticular seeding has been noted in patients with CoNS catheter-related bacteremia, although these complications are far less frequent than those observed with *S. aureus* or GNB indwelling intravascular device infections with or without concurrent bacteremia.

In patients with prosthetic valves, especially those with persistent, recurrent, or relapsing CoNS bacteremia, secondary seeding of the prosthetic heart valves should be taken into consideration [85]. In patients with prosthetic valves, CoNS endocarditis similar to such infections caused by *S. aureus* may present with valve dysfunction and intracardiac abscesses, or both. In such cases, CoNS species evaluation becomes important, with an emphasis for *S. lugdunesis* as a potential pathogen.

Clinical presentation for infections involving nonvascular or non-articular prosthetic devices may also be clinically subtle and often vary based on the type of device used, organ system involved, and the degree of hosts' inflammatory immune response. Patients with CoNS cerebrospinal fluid shunt infection are sicker and have clinical features of bacterial meningitis; subtle clinical presentation such as low-grade fever, alteration in mental status, and shunt malfunction should also alert the treating physician for possible shunt infection; and CoNS are not uncommon pathogens for such device-related infections [86, 87]. The presence of pleocytosis in CSF has limited diagnostic value, as white cell counts in CSF may be either marginally increased or within the normal limits among patients with CoNS shunt infections. Patients with CoNS infection of prosthetic joints may not have significant clinical symptoms and rang from nominal joint discomfort rather than overt joint dysfunction, which is frequently seen in patients with *S. aureus* prosthetic joint septic arthritis. Such infections are less often accompanied with prominent, localized inflammatory response including joint effusion and adjacent tissue inflammation and swelling [88].

Diagnosis

The diagnosis of CoNS infection relies on isolation of the organism from appropriately obtained clinical sample. As expected, false-positive cultures due to bacterial colonization and contamination of the sterile-site samples such as blood cultures are not uncommon and leads to difficulty in interpretation and ascertaining true versus pseudobacteremia [89]. Reliability of blood cultures in reports of CoNS catheter-related bloodstream infections provides an outline for how to approach and determine clinical relevance of CoNS isolated in blood culture specimens [90]. In quantitative cultures, catheter-drawn blood samples exhibit (fourfold) higher number of bacterial colony-forming units compared with blood drawn from a peripheral site and hence regarded as an important diagnostic predictor for infected intrevascular catheter as the source of bacteremia [83]. Similarly, blood drawn through an infected catheter tend to become positive early (~2 h), a reflection on high bacterial inoculum size compared with blood culture samples drawn from a peripheral blood vessel [83, 91]. Isolation of these bacteria from a single blood culture sample or low-grade CoNS growth in quantitative blood cultures often reflects a poor preparation of the blood culture site resulting in inadvertent sample contamination. The diagnosis of CoNS infection from sources other than the blood needs to be considered based on the clinical setting with an understanding that these bacteria are the most common cause of culture contamination, while inversely, also a well-recognized cause of prosthetic joints and other implantable device infections.

Treatment

Removal of the infected device is regarded as the definite therapeutic intervention that is imperative for successful resolution of such infections and importantly, for reduce risk of early and late infection recurrence. The presence of bacteria-induced biofilm on the foreign surfaces and necrotic tissues such as chronically infected bones provides a niche for the bacteria to evade hosts' immune clearance, and commonly used antibiotic classes such as beta-lactams and glycopeptide have limited penetration and significantly

reduced antimicrobial activity against non-planktonic bacterial isolates frequently found in the biofilms [92].

Most CoNS isolates from healthcare-associated infections are resistant to β-lactam antibiotics [93]. Almost all clinical CoNS isolates are susceptible to vancomycin, although in vitro drug MICs have been increasing in the recent decades, and now a substantial number of clinical isolates exhibit vancomycin MICs between 1 and 2 μg/ml [94]. As true Vancomycin resistance still remains highly unlikely; most vancomycin clinical failures may result due to heteroresistance, vancomycin tolerance, or yet unknown other potential mechanism(s) at play [95].

Rifampin is active against the non-planktonic CoNS in the biofilms; for serious CoNS infections involving prosthetic heart valves and prosthetic joints that cannot be removed, salvage therapy with the addition of rifampin has been used, although prospective data for assessing efficacy for such intervention is not clear [96, 97]. CoNS are usually susceptible to new antimicrobials such as daptomycin, linezolid, and tedizolid, including recent addition of long-acting lipoglycopeptides like oritavancin and dalbavancin. Daptomycin has the lowest MICs against clinically important bacterial species grouped under CoNS [98].

With the exceptions of prosthetic valve endocarditis, CNS shunt and reservoir, ventricular assist device, and prosthetic joint infections, most CoNS infections respond readily to appropriate antimicrobial therapy. It is prudent and imperative that an infected device, when feasiable, must be removed; this recommendation is for mitigation of patient morbidity and cost of care incurred due to infection recurrence and relapse [99, 100]. Guidelines suggest that 7 days of appropriate concordant antibiotic therapy should be adequate for most uncomplicated CoNS catheter-related bacteremia in nonimmunocompromised patients. Longer treatment duration is suggested for patients with severe immune suppression and those with profound neutropenia; relapse rates of invasive CoNS infections are generally lower than those noted with systemic *S. aureus* disease [90].

Streptococci

The streptococci are a heterogeneous group of Gram-positive disease-causing bacteria with a wide-ranging nomenclature that continues to change [101]. Here we use the clinical microbiology laboratory approach toward these pathogens and consider them as follows: viridans group streptococcus (VGS), β-hemolytic streptococcus, and *Streptococcus pneumoniae*. Streptococci not outlined in these groups rarely cause invasive disease in the immunosuppressed patients undergoing transplantation procedure.

Viridans Group Streptococci

Epidemiology

Viridans group streptococci (VGS) are a diverse group of bacteria. They are often isolated from human orointestinal, upper respiratory, and female genital tracts [102]. Viridans, derived from *viridis*, refers to green color appearance in laboratory blood-enriched culture media due to the breakdown of hemoglobin also known as α-hemolysis. Among α-hemolytic streptococci, the most important pathogen is *Streptococcus pneumoniae*; for most non-*S. pneumoniae* α-hemolytic streptococci, further species determination is performed on request at most microbiology laboratories. The major VGS responsible for invasive disease in patients undergoing transplantation and patients with severe neutropenia belong to the *mitis* group and include *Streptococcus mitis*, *Streptococcus gordonii*, *Streptococcus oralis*, *Streptococcus sanguis*, and *Streptococcus parasanguis* [103–105]. Infections due to *Streptococcus anginosus* group are also seen, albeit less frequently and include *Streptococcus anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius*.

VGS are considered to have low intrinsic virulence, and in patients with intact immune function, they are mainly associated with endocarditis [106]. Similar to CoNS, VGS are far more likely to cause disease in neutropenic patients with cancer undergoing HSCT. In a recent study among children with cancer undergoing HSCT, diagnosis of leukemia and bacteremia due to *S. mitis* was common. It is important to note that 15% of these infection episodes were associated with Viridans Group Streptococcal Shock Syndrome, resulting in most patients (75%) requiring treatment in ICU, and half of the patients needing ICU care died with multiorgan failure [107].

VGS bacteremia occurs almost exclusively in patients receiving aggressive cytoreduction therapy for conditions such as acute leukemia and patients undergoing allogeneic HSCT preparatory conditioning regimen [108].

Treatment-induced mucosal dysruption of the orointestinal tract has been regarded as a major risk factor for systemic translocation of these low-virulence commensal bacteria, allowing them to gain access into the blood circulation [109]. It is also important to recognize that VGS breakthrough bacteremia are attributed to the widely priscribed antimicrobials for infection prophylaxis with drugs that are known to have limited activity against these organisms such as trimethoprim-sulfamethoxazole and fluorinated quinolones [110].

Clinical Presentation/Diagnosis

Most patients with invasive VGS disease present with fever in the setting of mucositis and profound neutropenia [111]. Approximately 25% of patients may present with a fulminant

septic shock syndrome characterized by hypotension, skin rash, and adult respiratory distress syndrome; *S. mitis* is the VGS species most commonly isolated from such patients [103, 111, 112]. This dramatic clinical presentation may represent a combination of hosts' susceptibility due to the underlying severe neutropenia additionally, bacterial exotoxin, which act as superantigen resulting in unrestraint activation of immune-inflammatory pathways resulting is rapidly progressive illness with a substantial risk for multiorgan failure and death [113].

Unlike general population, VGS bacteremia seldom leads to endocarditis in patients with neutropenia and those undergoing a stem cell transplantation procedure. The *risk* of endocarditis in patients following solid organ allograft transplantation who develop high-grade VGS bacteremia is not dissimilar to that observed in general population [114].

Group milleri streptococci (GMS) may cause chronic intra-abdominal and intrathoracic abscesses. Infections due to GMS were reported in 45 SOT recipients between 2001 and 2004. Patients following liver transplantation were prominently respresented (n = 34) in this cohort, followed by four kidney and pancreas; two small bowel; three combined liver and kidney; and combined kidney plus small bowel and a kidney allograft transplants, in one patient each. Most GMS infection episodes (42 cases) were intra-abdominal infections, pleural empyema in two, and one patient with soft tissue infection. It was interesting that unlike neutropenic cancer patients and those undergoing HSCT, only one patient had evidence of bacteremia. It was also of note that 61% of these infections were polymicrobial; recurrent cholangitis (38%) associated with anastomotic and nonanastomotic biliary strictures was the most common intra-abdominal infection, which required a need for repeated stenting or surgical intervention and prolonged antibiotic therapy. In one patient pancreatic allograft failed because of hemorrhagic erosion from bacterial abscess. There were no deaths attributed to MGS infections in the SOT recipients in this report [115].

Intrathoracic GMS infections after thoracic surgery, are an uncommon complication (4%). Most intrathoracic GMS infections present as empyema, infected pleural effusion, whereas bacterial mediastinitis is a rare complication. As seen in patients undergoing intra-abdominal allograft transplantation, GMS intrathoracic infections are frequently polymicrobial (64%), and infection recurrence (27%) may occur in nearly one-thrid of the cases [116].

Diagnosis

The diagnosis of VGS disease relies on isolating the organism from a sterile body site. The presence of VGS in blood cultures obtained adhering to the standard aseptic blood culture techniques may be regarded as a true pathogen. Isolation of VGS from the skin or mucosal sites, as expected, has limited clinical significance, as these organisms are part of the normal cutaneous and mucosal microbiota in humans. It is also important to take note of the possibility of blood cultures contaminated with VGS; however, their presence in blood samples must be considered clinically relevant, especially in high-risk patients such as those with antineoplastic chemotherapy-induced neutropenia and chemotherapy- or radiation-associated mucositis and patients with severe neutropenia and mucositis following condition preparatory regimens for allogenic stem cell transplantation [117]. Serologic or antigen tests have no diagnostic value for invasive VGS disease, even in the high-risk patients undergoing allograft transplantation.

Treatment

Therapy of VGS disease is limited by the high level of β-lactam antimicrobial resistance [118, 119]. The clinical samples isolated from patients with neutropenia, less than half (~40%) of the VGS isolates, exhibit in vitro susceptibility to penicillin [120]. However, for β-lactam-susceptible organisms, these drugs are considered first line of therapy. Vancomycin susceptibility among clinical VGS isolates is close to 100%. In cancer patients with mostly acute leukemia and those undergoing HSCT, nearly 30% of isolates were reported as penicillin resistant, whereas all isolates exhibited in vitro susceptibility to vancomycin [107].

An increasing level of resistance is observed for fluoroquinolone, especially in patients routinely given this class of antibiotics for prophylaxis; empiric therapy with fluoroquinolone to treat systemic or invasive VGS infections is therefore, not recommended [121, 122]. VGS bacteremia is generally treated for 10–14 days; patients with endovascular site of infection including endocarditis should receive treatment for 4 weeks. Patients with septic arthritis and osteomyelitis may be given intravenous antibiotics for 3–4 weeks followed by an oral agent for suppressive therapy for another 4–8 weeks or even longer duration, which depends on the hosts' risk factors, including cumulative immune suppression, severity of infection; and in cases where deferment of excision of necrotic or ischemic debridable tissue leaves the focus of infection unattended. The role of intravenous immunoglobulin and plasmapheresis has been explored for patients with exotoxin-mediated toxic shock syndrome and currently not considered as standard of care for severe VGS infections [113].

GMS were susceptible to penicillin G, carbapenems, and clindamycin, whereas cephalosporins and quinolones showed intermediate activity or resistance in some cases, and it is important to note that GMS bacteria in general tend to be resistant to aminoglycosides [115].

β-Hemolytic Streptococci

The β-hemolytic streptococci reflect upon their ability to cause full red blood cell lysis in the blood-enriched culture media. Group A β-hemolytic streptococci (GAS) or *Streptococcus pyogenes* is a common pathogen followed by group B β-hemolytic streptococci (GBS) or *Streptococcus agalactiae* and groups C and G β-hemolytic streptococci (GCS and GGS, respectively) also known as *Streptococcus dysgalactiae* subspecies *equisimilis* [123–125].

Epidemiology

β-Hemolytic streptococci are ubiquitous in the human and animal population; colonization of the skin and mucous membrane is a common event. They are also an important cause for locally invasive disease such as pharyngitis, lower urinary tract infection, and superficial skin and skin structure infections. Severe systemic disease may occur in the general population and those with immune dysregulation after undergoing allograft transplantation [126]. The oropharynx and skin are the main sites of GAS, GCS, and GGS colonization [127, 128], whereas GBS commonly colonize the perineal area [128–130]. In the general population, majority of β-hemolytic streptococcal infections are acquired and presented from the community [83]. Immunosuppressed patients, especially those undergoing antineoplastic chemotherapy and recipients of HSCT, have a much higher risk for invasive β-hemolytic streptococcal disease compared to the general population [131, 132]. Cancer patients with lymphedema due to cancer infiltration or surgical lymph node dissection or those with radiation-induced tissue scarring impeding lymphatic circulation are especially at risk for such infections [133]. GBS are the most common of the invasive β-hemolytic streptococci isolated from patients with cancer and those undergoing stem cell transplantation [134, 135]. The development of invasive GAS, although less common than GBS, may result in a devastating disease that carries high fatality rates in excess of 50% [125].

Clinical Manifestations

Most β-hemolytic streptococcal infections in immunosuppressed cancer and stem cell transplant patients present with cellulitis and subcutaneous abscesses. In patients undergoing solid organ transplantation procedure, surgical wound infection, deep surgical bed infection, secondary infections of postoperative seromas, and deep tissue hematomas may also be prominent clinical manifestations of β-hemolytic streptococci. It is important to note that number of these infections may accompany other pathogens; appreciation for polymicrobial aspect of such infections is the central tenet in planning and executing a comprehensive treatment approach for deep tissue, and body cavity infections following transplant surgery [136].

Disease may range from relatively uncomplicated cellulitis and superficial wound infection to necrotizing fasciitis with or without exotoxin-induced toxic shock syndrome. The latter two complications are almost exclusively associated with GAS infection. Cellulitis due to β-hemolytic streptococci tends to develop rapidly, spread quickly, and may be accompanied by systemic manifestations such as fatigue, severe prostration, chills, rigors, with high-grade fever [137]. Erysipelas is a form of superficial cellulitis, in which the disease is restricted to the dermis. These lesions are elevated and well-demarcated from the healthy surrounding tissues [138]. Recurrence of erysipelas is a concern and often seen in patients with impaired lymphatic circulation. Infections due to GAS, GCS, and GGS are the leading bacterial causes of pharyngitis in children; most infections are readily treatable, although peritonsillar abscess and cervical lymphadenitis may rarely occur [128].

Invasive, systemic β-hemolytic streptococcal disease causes serious morbidity in patients with a suppressed immune response. Adults with β-hemolytic streptococcal bacteremia, especially patients with advancing age, the risk of death from such infections is high [125]. β-hemolytic streptococcal skin lesions that are greater than 5 cm in diameter, presence of pain that is out of proportion to findings on physical examination, disproporte severity in pain to gentle touch, and signs of systemic toxicity, skin discoloration, and/or presence of bullae on the overlying skin should raise concern for deep tissue involvement; possibility of necrotizing fasciitis, pyomyositis, and compartment syndrome should be entertained in such patients [139]. β-hemolytic streptococci disease via exotoxin production, especially by GAS, leads to extensive destruction of hosts' tissue and usually spreads at an exceedingly fast pace. Streptococcal toxic shock syndrome has also been described in cancer patients with mortality rates exceeding 50% [135]. Patients with diabetes are susceptible to hematogenous bacterial seeding to the bones resulting in remote site acute osteomyelitis [140].

A higher incidence of GAS necrotizing fasciitis was recently observed in Montréal, Canada. The authors reported that varicella and the presence of *speC* gene in GAS strains were associated with necrotizing fasciitis. In patients undergoing transplantation, bacterial genetic factors and potential synergistic or additive effect of concurrent viral infections like varicella on risk of GAS-related necrotizing fasciitis is not known [141].

Diagnosis

β-Hemolytic streptococci are readily isolated from cultures that are appropriately obtained. Rapid antigen tests are reliable for the diagnoses of GAS pharyngitis in patients when such infections are suspected [142]. Recovery of β-hemolytic streptococci from sterile-site samples such as blood, joints,

deep tissue, and body cavity abscesses indicates a true infection. In contrast, isolation of β-hemolytic streptococcus species from mucous membranes and skin frequently reflects bacterial colonization.

An exception to the preceding stipulation is the isolation of GAS in mucosal site culture samples to assist in the diagnosis of toxic shock syndrome [143]. Serologic tests are not useful in patients with acute β-hemolytic streptococcal infections. Acute and convalescent serum for antibodies to streptolysin O or DNase can determine a recent infection due to GAS, although such serological tests are now seldom used in clinical practice [144].

Treatment

Penicillin and other β-lactam antibiotics are considered drugs of choice for the treatment of infections due to β-hemolytic streptococci [145]. For patients who cannot receive β-lactams, treatment with vancomycin is recommended. Carbapenems may also be an option in patients with non-life-threatening penicillin allergy [146]. Macrolide and lincosamide should not be used for serious infections as drug resistance is unpredictable and highly variable; these agents should only be used when susceptibility results are available, especially for outpatient transition of therapy [147]. Similarly, resistance to tetracyclines and trimethoprim-sulfamethoxazole warrants the use of these agents empirically to treat β-hemolytic streptococcal disease [148, 149]. Clinical experience with newer gram-positive drugs like daptomycin; the oxazolidinones, such as linezolid and tedizolid; tigecycline; and long-acting lipoglycopeptides such as dalbavancin and oritavancin is encouraging with good in vitro susceptibility data for β-hemolytic streptococcal clinical isolates [150, 151]. In cases of serious soft tissue infection, especially toxic shock syndrome, addition of clindamycin is strongly recommended to attenuate bacterial exotoxin production by slowly dying bacteria after exposure to beta-lactam antibiotics [152]. Uncomplicated bacteremia can be treated with a 10-day course of antibiotics, whereas fiat for complicated β-hemolytic streptococcal disease has traditionally been longer duration of antibiotic therapy. Surgical debridement of devitalized tissue and drainage of large purulent deep tissue collections is, as with any other bacterial or fungal infection, remains important for containment and resolution of infection [139].

Streptococcus pneumoniae

Epidemiology

S. pneumoniae is genetically similar to other bacteria in this category, although it is a prominent pathogen associated with a wide spectrum of invasive disease in immunocompromised patients and those in the general population.

Nasopharynx colonization due to pneumococci occurs more frequently in children (20–40%) compared with healthy adults (10–20%) [153]. *S. pneumoniae* is the leading cause of bacterial pneumonia that commences while patients are in the community [154]. Bacterial meningitis is also an important complication of *S. pneumoniae* in patients with community-onset meningitis [155]. Patients with chronic obstructive pulmonary disease, chronic kidney disease, and deficiencies in humoral immunity such as those following anti-CD20 and other B-cell targeted therapies and patients with chronic lymphocytic leukemia, B cell lymphoma, and plasma cell neoplasms like multiple myeloma; and those with hereditory hypogammaglobulinemia are especially susceptible to pneumococcal invasive disease. Similarly, patients with hyposplenism including those with sickle cell diseases and patients after splenectomy are at risk for, often severe disseminated infection due to *S. pneumoniae* [156]. Patients with chronic graft-versus-host disease following allogenic stem cell transplantation are vulnerable to infections due to encapsulated bacteria; *S. pneumoniae* is prominent in this regard [157].

It has also been suggested that prolonged exposure to systemic corticosteroids increases the risk for pneumococcal infection as is the extremes of age [158–160]. A high prevalence of *S. pneumoniae* in children less than 5 years of age is well recognized; young children with B-cell cancer or those undergoing anti-B-cell-targeted therapy for allogenic hematopoietic or solid organ transplantation are particularly susceptible to serious infection [156].

Clinical Presentation

S. pneumoniae is a major respiratory tract pathogen. Infections in adults involve lower respiratory tracts, and bacterial pneumonia is a common disease presentation; bronchitis and paranasal sinus infections may also occur [161], whereas in children, otitis media is not an uncommon presentation.

Community-onset pneumonia in the immunocompromised transplant recipients is a serious infection. Patients commonly present with chills, fever, and fatigue; cough is generally accompanied by purulent sputum and shortness of breath [162]. Patients with inflammation of the parietal pleural with or without bacterial empyema may present with pleuritic chest pain. Bacterial lung abscess due to *S. pneumoniae* is not an uncommon complication of invasive pulmonary pneumococcal disease and often associated with cavitary lung lesions [163].

In recent animal experiments, pneumococcal infection was shown to cause nonspecific ischemic cardiac alterations, myocardial necroptosis, and apoptosis in both acutely ill and convalescent nonhuman primates [164]. *S. pneumoniae* was detected in the myocardium of all animals with acute severe pneumonia. Furthermore, evidence of cardiac scar formation

was observed only in convalescent animals [164]. This study suggested a potential role of invasive pulmonary pneumococcal disease in the humans, with the possibility of subclinical bacterial invasion of the myocardium, resulting in cardiac injury from necroptosis and apoptosis, followed by cardiac scarring and remodeling after antibiotic therapy [164]. Clinical importance and cardiac impact in humans with invasive pneumococcal disease need further evaluation.

Patients with bacterial meningitis may often have concurrent bacteremia, whereas pneumonia may not be present. Fever and neck stiffness along with persistent and often severe headache are common clinical features of bacterial meningitis. In patients with advanced pneumococcal meningeal disease, altered sensorium, obtundation, and coma may be the initial presentation.

Other disease manifestations include septic arthritis, usually involving the native large joints. Pneumococcal septic arthritis involving the symphysis pubis is often misdiagnosed as osteitis pubis, a sterile inflammatory condition seen in women following urinary incontinence surgery and sports such as soccer and also in patients with pelvic malignancies. *Staphylococcus aureu*s was the major cause among athletes and *Pseudomonas aeruginosa* among intravenous drug users. Septic arthritis in patients with pelvic malignancies are usually polymicrobial infections involving the fecal flora. Antibiotics are recommended for 6 weeks, and surgical debridement is required in nearly half of the patients [165].

Osteomyelitis of spinal and paraspinal tissues caused by *Streptococcus pneumoniae* is an uncommon complication as reported by the group in Houston, Texas. These infections mostly occurred in the absence of recent surgical procedure or presence of a foreign device. The lumbar spine was the frequent site of infection. Such infections complicated by spinal epidural abscess or the presence of a phlegmon were accompanied by neurologic deficits and carried a higher risk for death. Antimicrobial therapy for 6 weeks was effective [166, 167].

In a report from Japan, 6% of patients with invasive pneumococcal disease had evidence of pneumococcal vertebral osteomyelitis. Most infections were acquired in the community and had no recent history of a surgical procedure or trauma. In their experience, the lumbar spine was involved in nearly two-thirds of patients, and the remaining patients had cervical spine involvement. Bacteremia in this group was nearly universal; none of the patients had a primary site of pneumococcal disease. Good response to intravenous beta-lactam therapy in this group was encouraging [168].

HSCT

In HSCT recipients, pneumococcal infections present as late-onset bacteremia. These late-onset BSIs were associated with worse outcomes including septic shock, ICU stays, and high risk for deaths [157, 169]. Early-onset bloodstream infections in patients undergoing HSCT are frequently associated with severe neutropenia, mucositis, and indwelling intravascular catheter infections. Whereas, late-onset BSIs are commonly seen in severely immunosuppressed allogeneic HSCT recipients with GVHD and those undergoing systemic corticosteroid therapy. Since majority of *S. pneumoniae* bacteremia occur during late transplantation period, effective preventive strategies such as immunization with newer, immunogenic conjugated pneumococcal vaccines and drug prophylaxis with agents that have activity against majority of *S. pneumoniae* isolates in the community are considered standard of care. Infection prevention is highly desirable as pneumococcal bacteremia in this population carries unacceptably high case fatality rates.

In patients after undergoing allogeneic HSCT, diagnosis of pneumonia and chronic GVHD was associated with high mortality and a significantly lower probability of survival; this was evident in patients even after a single episode of pneumonia [170]. Pneumococcus is an important bacterial pathogen in allogeneic stem cell transplant recipients and mostly noted as late bacterial pneumonia with or without bloodstream infection. Pneumonia during the first 100 days after allograft stem cell transplantation are significantly more invasive fungal lung disease among individuals with acute GVHD; in such patients acute respiratory failure, and presence of septic shock predicted high risk of death [170].

Memory B-cell defects in allogeneic HSCT recipients increases susceptibility for encapsulated bacterial infections, as effective containment and remedy for these organisms require intact opsonization to promote phagocytosis. In a recent study, circulating IgM memory B cells (CD19+, CD27+, IgM+); and switched memory B cells (CD19+, CD27+, IgM(−), which are indicators of normal B cell activation and development were evaluated in 37 allogeneic HSCT recipients and compared with 35 healthy controls [171]. Among other parameters assessed were T-lymphocyte subpopulations, serum immunoglobulin levels including IgG subclasses, and antibodies to pneumococcal polysaccharides. A significant deficiency in both switched memory and IgM memory B cells was evident in the stem cell transplant cohort compared with the individuals in the healthy control group [171]. This observation was noted throughout the period following transplantation procedure and possibly reflect a switch to impaired B-cell isotype(s) in germinal centers within lymph nodes and other secondary lymphoid tissue. As expected, presence of GVHD was associated with lower IgM memory B-cell counts and lower serum levels of IgG2, IgG4, IgA, and antipneumococcal antibodies. Allogeneic HSCT recipients are susceptible to pneumococcal disease, which in most part is a reflection on the underlying defects in memory B-cell function aggravated in the presence of chronic GVHD [171]. Furthermore, hyposplenism is a frequent feature in HSCT recipients with chronic

GVHD, which further enhances the risk for systemic infections due to encapsulated bacteria.

In a transplant unit in Canada, the probability for pneumococcal disease among HSCT recipients was 30-fold higher than the general population (regression ratio = 30.2; $P < 0.00001$). Serotypes 23F and 6B were most prevalent [172]. All infection-associated serotypes were included in pneumococcal polysaccharide vaccine, whereas only 69% were represented in the conjugate vaccines. It was also important to note that the level of resistance to trimethoprim-sulfamethoxazole was high among the *S. pneumoniae* isolated from the transplant population during this study [172].

At M.D. Anderson Cancer Center between 1989 and 2005, 47 of 7,888 HSCT recipients developed 54 episodes of *S. pneumoniae* infections, accounting for 7 infection episodes per 1000 stem cell transplants [157]. The incidence was significantly higher in the allogeneic vs. autologous stem cell graft recipients, nine vs. five infection episodes per 1000 HSCTs, respectively. Thirty-six percent had graft-versus-host disease, and as expected, 16 of 17 patients had chronic GVHD. The total of 54 episodes of *S. pneumoniae* infection occurred median 433 days after transplntation; 11% of these patients had infection recurrence [157]. All 50 late posttransplant episodes were community-acquired infections and seen 473 ± 671 days after transplantation. Bacteremic pneumonia was the most common presentation (61%), followed by pneumonia without bacteremia (19%) and uncomplicated bacteremia alone (15%) [157]. Regression analysis showed that treatment with corticosteroids significantly increased the risk for bacteremic pneumonia (OR, 11.7; $P \leq 0.025$). In bacterial isolates from 29 episodes, 93% of patients received concordant antimicrobial therapy. It was unexpected that only one of the six patients (13%) who died of *S. pneumoniae* infection had chronic GVHD. The probability of death was higher in patients receiving care in the ICU at the time of infection diagnosis (OR, 15.5; $P \leq 0.007$) and those with each unit increase in APACHE II score (OR, 1.9; $P \leq 0.008$). Vaccine-breakthrough *S. pneumoniae* infection occurred in 5 patients after a median of 546 days following immunization; most such patients (80%) had pneumonia and concurrent bacteremia [157]. It is noteworthy that there were no cases of extrapulmonary focus of pneumococcal disease in HSCT recipients presented in this report.

Nontropical pyomyositis is an uncommon infection, such severe bacterial infections occur mostly in patients with suppressed immune response. *S. aureus* is the prominent pathogen associated with this disease. Pyomyositis due to *S. pneumoniae* is rare [173]. A recent report of hematogenous pneumococcal pyomyositis in an allogeneic stem cell graft recipient involved erector spinae muscles that presented 34 months after the transplantation procedure. Patient had a favorable response to 4 weeks of intravenous benzyl penicillin therapy [173].

SOT

As in HSCT, patients undergoing solid organ transplantation are at a greater risk for IPD compared with general population. Invasive pneumococcal disease is mostly seen in the late posttransplant period, and infections commonly start in the community. A prospective, population-based surveillance from Toronto, Canada, assessed systemic pneumococcal infections in SOT recipients between 1995 and 2004 [174]. The incidence was 146 infections from sterile body sites per 100,000 persons per year compared with 11.5 per 100,000 persons per year in the general population (RR, 12.8; $P < 0.00001$). When they also included the isolates from the respiratory tract, the incidence rate in transplant patients rose to 419 per 100,000 persons per year. Serotypes 23F and 22F were most common; 85% of these infection-associated serotypes were included in the 23-valent pneumococcal vaccine [174]. The antimicrobial resistance in SOT population was similar to that observed in the pneumococcal isolates for the general population and was especially high for penicillin and TMP/SMX.

A large database of 4,458 pediatric heart transplant recipients between 1993 and 2014 showed that the risk of bacterial infection was highest in the first month after transplantation; 25% of patients developed bacteremia. It was not unexpected to notice that community-acquired *S. pneumoniae* (6%) and *Haemophilus influenzae* (3%) were prominent during the late transplant period, whereas within a month following transplant procedure, CoNS (16.97%), *Enterobacter* spp. (12%), and *Pseudomonas* spp. (12%) were the prominent bacterial pathogens [175]. A large proportion of the infections were caused by multidrug-resistant organisms. Patients at risk for bacterial infection following heart transplantation included young age and ventilator or extracorporeal membrane oxygenation during transplantation. Thirty-four percent died due to bacterial infections, and prior cardiac surgery and multiple sites of infection were independent predictors of death [175].

In the Netherlands, a prospective nationwide study between 2006 and the end of 2014 assessed the risk and frequency of community-acquired bacterial meningitis among 16-year-old or older solid organ transplant recipients [176]. Six SOT recipients had bacterial meningitis; interestingly all six had undergone renal allograft transplantation. The annual incidence of bacterial meningitis was sevenfold higher for renal transplant recipients as compared with the general population: 9.5 vs. 1.3 per 100,000 patients per year [176]. It is important to note that in majority of the patients (83%), classic presentation of bacterial meningitis such as fever, neck stiffness, and changes in mental status were not present. Further complicating early diagnosis and prompt institution of appropriate antibiotic therapy for this life-threatening disease in this susceptible population. Seizures were present in 33% of patients. *Streptococcus pneumoniae* and *Listeria*

monocytogenes were identified in two patients each, whereas, *Escherichia coli* and *Pseudomonas aeruginosa* were seen in one patient each. Another valuable observation in this report was the high incidence (67%) of unfavorable functional outcomes that probably were a reflection on the hosts' immunocompromised status and, importantly, atypical clinical presentation of bacterial meningitis in patients undergoing solid allograft transplantation [176].

A retrospective review from London, England, assessed long-term outcome in patients who underwent orthotopic cadaveric donor heart and lung transplantation between July 1986 and July 2006 [177]. The mean posttransplant follow-up was 5.4 ± 5.5 years. Bacterial meningitis was diagnosed in 39 adults after receiving 15 heart transplants, 12 lung including 4 bilateral lung transplants, and 12 heart-lung transplants. *Neisseria meningitidis* (54%) and *Streptococcus pneumoniae* (41%) were prominent pathogens followed by *Haemophilus influenzae* (5%). Hospital mortality rate was 10%, and none of these patients developed long-term complications after bacterial meningitis [177].

In a study from South Korea, 14 of 42 episodes of respiratory infections were noted after 1 month following lung transplantation [178]. Six were bacterial, four were viral, and two episodes were fungal infections. Among bacterial infections, two were due to MDR *Acinetobacter baumannii* and one each due to MDR *P. aeruginosa*, ESBL (+) *K. pneumoniae*, MRSA, and *Streptococcus pneumoniae*. Infection-related death occurred in 6 of the 14 episodes (43%) [178].

In a report from Barcelona, Spain, 138 episodes of spontaneous bacterial peritonitis (SBP) in 19 liver transplant recipients and 119 in nontransplant patients showed *Escherichia coli* (35.7%) and *Streptococcus pneumoniae* (21.4%) as the prominent pathogens [179]. It was interesting to note that pathogens associated with SBP were significantly more frequently identified in patients following transplantation (74%), whereas only 39% of nontransplant population with SBP had a positive culture ($P = 0.004$). As expected, renal failure (58% vs. 25%; $P = 0.004$) and hepatic encephalopathy (42% vs. 22%; $P = 0.08$) were more often seen in liver transplant recipients vs. the nontransplant group, respectively [179]. Similarly, deaths during the SBP episodes (53% vs. 13%; $P < 0.001$) and 6 months after the infection diagnosis (71% vs. 35%; $P = 0.005$) were significantly higher in the transplant population. The risk of death associated with the SBP was sixfold higher in patients with a high (>18) Model for End-Stage Liver Disease (MELD) score and fourfold higher in patients who had undergone liver transplantation. Mortality 6 months after SBP was fourfold higher in patients with hepatocellular carcinoma [179].

Orthotopic liver transplantation from a potential donors with active bacterial meningitis has been regarded as a contraindication for allograft procurement from such a donor. Due to a global shortage of liver allografts, in Birmingham, England, orthotopic liver transplants were performed from 33 donors with acute bacterial meningitis, 14 *Neisseria meningitidis*, 4 *Streptococcus pneumoniae*, 2 *Streptococcus* spp., and a single patient with *Haemophilus influenzae*. In 12 donors, a pathogen was not identified [180]. Of 34 recipients, 27 underwent elective and 7 had emergency transplantat surgery including 21 whole liver, 10 reduced-liver, and 3 split-liver allograft transplants. Adequate antimicrobial therapy before organ procurement and after transplant was administrated. The mean duration of follow-up after transplantation was 37 months (ranged from 1 day to 106 months). Overall patient (79% and 77%) and graft survival was; 72% and 65% at 1 and 60 months, respectively [180]. Patients who underwent elective liver transplant had significantly better survival compared with those who underwent emergency transplantation ($P < 0.05$). There was no difference in recipient and graft survival between the 34 patients who had received allograft from a donor with acute bacterial meningitis compared with recipient-matched groups. The authors observed no infectious complications in the recipient due to bacteria associated with meningitis after transplantation. Further data is needed before routine acceptance of liver allografts from donors with active bacterial meningitis becomes an acceptable practice, although study such as this, underscores that lifesaving procedure such as liver transplantation may be safly performed provided both donors and recipients are given adequate antimicrobial therapy. Furthermore, the optimum duration of antibiotic therapy in such recipients is not certain.

Diagnosis

Isolation of *S. pneumoniae* in blood, joint fluid, bronchial wash or lavage samples, and cerebrospinal fluid is regarded as diagnostic. Isolation of *S. pneumoniae* in sputum samples is a challenge, as diagnostic yield is significantly reduced in patients exposed to antibiotic(s) [181]. It has been estimated that only one-fourth of the patients with pneumococcal pneumonia will have a positive blood culture [182]. As with staphylococcal and other streptococcal infections, serologic studies have limited clinical use in assisting with the diagnosis of an acute infection episode. Detection of C-polysaccharide (BINAX-NOW) in the urine of adults with pneumococcal pneumonia is isolated in 75–85% of the patients; this test has high specificity and reliable negative predictive value [183]. Polymorphonuclear-predominant pleocytosis, low glucose, and high protein in the cerebrospinal fluid are the hallmarks of bacterial meningitis that are as expected to be present in most patients with pneumococcal meningitis. Gram-stain, bacterial antigen assays and culture of cerebrospinal fluid obtained promptly prior to extensive antibiotic exposure are essential for establishing the correct diagnosis [182].

Treatment

S. pneumoniae penicillin susceptibility and laboratory breakpoints have been reevaluated as to include the site of infection and the route by which the antibiotics may be administered [184]. For all pneumococcal infections other than the central nervous system, organisms demonstrating in vitro penicillin susceptibility of ≤2 μg/ml, reflecting approximately 95% of clinical pneumococcal cases in the United States, have good probability for attaining a clinical response to high-dose penicillin given intravenously [184]. For treatment of pneumococcal meningitis, penicillin MIC of <0.06 μg/ml is considered susceptible, and others with MIC ≥ 0.12 μg /ml are regarded as resistant bacterial strains; nearly 75% of pneumococci isolated in patients with meningitis in the United States fall in the susceptible category [184]. Pneumococcal isolates are universally susceptible to vancomycin. Respiratory fluorinated quinolones such as levofloxacin and moxifloxacin retain susceptibility for most pneumococcal isolates, although due to limited clinical experience and unpredictable response, authors recommend not to use these agents alone to treat patients with *S. pneumoniae* CNS infections [185, 186]. In *S. pneumoniae* isolated from respiratory specimens in the United States, resistance to macrolides, clindamycin, trimethoprim-sulfamethoxazole, and tetracyclines ranged from 20% to 40% [187]. In the authors' opinion, these drugs should not be used for the treatment of invasive pneumococcal disease in the transplant population.

Linezolid is an effective and safe treatment option for patients with *S. pneumoniae* infections [188]. Linezolid was shown to be effective and well tolerated in severely immunocompromised children with an underlying malignancy including those at young age [189]. The increased susceptibility to bacterial respiratory tract infection following a viral infection was associated with a substantial increase in local and systemic IFN-γ concentrations. Linezolid was shown to reduce IFN-γ and TNF-α production in stimulated peripheral blood mononuclear cells. In mice, linezolid recently showed protection from post influenza pneumococcal infection, and this reversal of immune hyporesponsiveness was attributed to the drug's ability to mitigate exaggerated postviral IFN-γ and TNF-α immune responses [190]. This ancillary immune modulatory effect of linezolid, especially in patients that are susceptibile for postviral superimposed bacterial pneumonia, is intriguing and needs further evaluation.

Daptomycin should not be used to treat lung infections, especially bronchogenic pneumonia because of limited drug diffusion in the alveolar space and inactivation of daptomycin by pulmonary surfactant [191].

Mortality for invasive pneumococcal disease remains around 15% within the first week of hospitalization, and most infections respond to a relatively short course of antibiotic therapy; extended therapy for over 2 weeks is recommended for patients with meningitis, empyema, bone and joint infections, and deep tissue abscesses that are not evacuated and patients with complicated bacteremia with an endovascular focus of infection [182].

S. pneumoniae is the only Gram-positive bacteria for which there are licensed vaccines available globally. The role of pneumococcal vaccine in transplant population is discussed in Chap. 63.

Enterococcus

Epidemiology

Enterococci, not dissimilar to CoNS and VGS, cause a disproportionately higher number of infections in the immunosuppressed cancer and transplant patients compared with the general population [192]. Most enterococcal infections are associated with prolonged exposure to healthcare environment. Enterococci are prominent bacteria in human intestinal microbiome. *E. faecalis* and *E. faecium* are two most frequently isolated species from infections in humans [193]. Patients with cancer and those undergoing transplantation have especially high rates of intestinal colonization and subsequent risk for invasive disease due to vancomycin-resistant enterococci (VRE). The factors promoting selection and persistence for VRE colonization in certain high-risk individuals with cancer and those undergoing transplantation procedure remain unclear, although prior exposure to m antibiotics has been proposed. It was interesting that a recent report indicated transplant unit reconstruction had interrupted endemic transmission of VRE, which resumed with novel enterococcal strains upon reopening of the unit. It was hypothesized that endemic VRE transmission in this transplant unit probably reflected VRE contamination of shared equipment and environmental surfaces [194]. This provides further insight into the possible reason that VRE has been an unabating challenge at certain transplant units, whereas less of a problem in patients undergoing a similar transplantation procedures at other institutions. This hypothesis was further emphasized in a recent study from Buffalo, New York, that active surveillance and contact precautions for VRE colonization were not effective in preventing VRE bacteremia in patients undergoing stem cell transplantation at their institution [195], whereas, a group from Salt Lake City, Utah reported in 2016 that VRE transmission from room surfaces appeared to be an infrequent event, thereby concluding that adherence to VRE surveillance, disinfection strategies, and contact isolation protocols are needed to be adhered to and may reduce VRE colonization rates in patients with hematologic malignancies and those undergoing HSCT [196].

HSCT

A single-center experience among patients admitted for induction chemotherapy or those undergoing HSCT from 2006 to 2014 showed that the incidence of VRE bacteremia was 6.5% of admissions or 2.7 VRE bacteremia per 1000 bloodstream infection at-risk days [192]. Mortality and length of stay were significantly higher in patients in whom VRE bacteremia were to occur. Patients with prior VRE colonization had eightfold higher probability for VRE bacteremia; similarly, patients with renal insufficiency (twofold), aminoglycoside use (~fivefold), and antibiotics with anaerobic activity (~threefold) had significantly higher risk for VRE bacteremia. The authors also reported using a predictive model, which identified severe neutropenia and prior beta-lactam antibiotic use were among prominent risk factors for VRE bloodstream invasion and infection [192].

A recent report from Salt Lake City, Utah, showed that VRE bacteremia after stem cell engraftment and resolution of neutropenia in HSCT recipients was associated with a much higher mortality compared with VRE bacteremia during the neutropenic pre-engraftment period [197]. Pre-engraftment bacteremia from any organism resulted in an increase length of hospitalization and higher cost of care. Mortality was similar for pre-engraftment VRE bacteremia and bacteremia due to other organisms in this neutropenic phase following stem cell transplantation. The authors pointed out that a high VRE bacteremia mortality rate observed during the post-engraftment period was largely associated with severe graft-versus-host disease and relapsed leukemia [197]. It was also interesting to note that frequently VRE strains switched phenotypes when isolated from patients before and after the transplantation procedure [197].

A contrasting review of patients undergoing HSCT at the Mayo Clinic in Rochester, Minnesota concluded that VRE colonization was a surrogate marker and not an independent predictor of mortality in HSCT recipients [198]. They observed high morbidity in their transplant patients with VRE bacteremia, although this had no significant impact on posttransplant survival. The data was generated between 2004 and 2014 by conducting twice-weekly perirectal swab PCR screening for vanA and vanB. In 73 of 203 patients, VRE colonization was noted prior to HSCT and in 11% VRE colonization occurred within the first 100 days after transplantation [198]. There was no significant difference in overall survival based on pretransplant VRE colonization status. However, patients that developed VRE colonization within the first 100 days after HSCT had a significantly worse survival. During the first 30 days following transplant, 91% had screened positive for VRE colonization prior to developing bacteremia. On multivariable analysis, advanced age (≥60 years), high HSCT comorbidity score, and prior VRE colonization were independent risk factors for VRE bacteremia. It was notable that only one patient had died with VRE bacteremia during the first 100 days after HSCT [198].

The findings from a center in Cleveland, Ohio, were in concert with the report from the Mayo Clinic; they found that between 1997 and 2011, the incidence of VRE-B had increased in 800 adult allogeneic HSCT recipients. Seventy-six patients developed VRE-vanB bacteremia after a median of 46 days following transplantation. Multivariable analysis showed that the risk for VRE-vanB bacteremia was higher in patients with high HSCT comorbidity score, with diagnosis of acute lymphoblastic leukemia, and recipients of unrelated donor and umbilical cord blood stem cell allograft transplantation. A fourfold higher probability of death in patients with VRE-vanB bacteremia was a significant finding on multivariate analysis; however, only 6% of 67 deaths within 5 weeks after transplantation were attributed to VRE infection [199], drawing attention to the clinical relevance of VRE bacteremia in high-risk transplant patients as a potential surrogate marker for poor prognosis during the early posttransplant period.

The preceding observation was also noted in a review of 247 adult patients in whom 28% had VRE colonization after allogeneic HSCT between 2008 and 2009 [200]. This report from Memorial Sloan Kettering Cancer Center in New York reported VRE bacteremia (54%) as the leading cause of bloodstream infection within 30 days after HSCT at their institution. Only 57% of patients with VRE bacteremia had VRE colonization during pretransplant screening [200]. Attributable mortality to VRE infection was low (9%), reflecting VRE bacteremia as a surrogate marker for altered host intestinal tract microbiota and perhapse an indicator for a subgroup of high-risk individuals undergoing allogeneic stem cell graft transplantation.

In patients undergoing autologous stem cell transplantation, despite having a high rate of VRE colonization, the risk for invasive bacterial disease is low. High rates of VRE colonization in this group may potentially serve as a reservoir for transmission to other higher-risk patients in a transplant unit or center [201].

In patients following allogeneic stem cell graft transplantation, donor-derived T cells recognize host tissues as foreign and orchestrating an assault on the recipient tissues, clinically known as GVHD. The intestinal tract is the most common site of GVHD, and in recent years, an interest in the composition of gut microbiota and its relationship with the development of GVHD was explored. The loss of intestinal bacterial diversity is common in patients undergoing HSCT due to prophylactic, preemptive, and empiric use of broad-spectrum antibiotics. This loss in intestinal biodiversity and overgrowth of opportunistic pathogens belonging to the phylum *Proteobacteria* and genus *Enterococcus* in patients following HSCT have been linked to enhance the risk for treatment-related mortality including GVHD, systemic

infections, and organ failure [202]. In animal experiments, interventions to mitigate alternations in selective intestinal bacterial overgrowth with the use of prebiotic and probiotic strategies have shown favorable results on the risk and severity of GVHD [202]. Further clinical studies are needed to explore these and other interventions that may restore healthy intestinal microbiota, especially in patients undergoing allogeneic stem cell to promote.

In patients undergoing HSCT, 2% chlorhexidine bathing was effective in regards to VRE colonization and infection [203], whereas no similar benefits were noted in protection against MDR-GNB, especially for infections due to *P. aeruginosa.*

A review of 822 autologous and allogeneic HCST recipients at Northwestern Memorial Hospital between 2004 and 2008 noted a 10% incidence in *Clostridium difficile*-associated diarrhea (CDAD) [204]. A significant association became apparent between CDAD and VRE colonization among other prominent risk factors for CDAD such as febrile neutropenia; exposure to ciprofloxacin, vancomycin, and aztreonam; prolonged duration of antibiotic therapy, and allogeneic stem cell transplantation [204].

Experiments have shown the protective significance of the normal microbiota; VRE colonization serves as a surrogate, representing alteration in the intestinal microbiome, especially following the influential perturbation during and after prolonged, broad-spectrum antibiotic therapy. Exogenously administered VRE was shown to efficiently and nearly completely displace the normal microbiota of the small and large intestines in mice after antibiotic therapy [205]. Furthermore, investigators from a comprehensive cancer center in New York showed that VRE colonization preceded bacteremia and sepsis in patients undergoing allogeneic HSCT [205].

SOT

Enterococcus species are recognized for nearly three decades as a potential pathogen in patients undergoing liver and other abdominal visceral transplants. Early on at the Mayo Clinic in Rochester, Minnesota, 405 consecutive liver transplantations were conducted between 1985 and 1993, a selective bowel decontamination prophylaxis regimen was routinely given [206]. In 52 patients (13%), 70 episodes of bacteremia were seen; most infections were due to *Enterococcus faecalis* (n = 50), and 18 isolates of *Enterococcus faecium*; vancomycin resistance in clinical enterococcal isolates was not an issue during the study years. It was important to note that nearly half (49%) of these infections were polymicrobial and one-third (34%) of the patients had complications involving the biliary tract. Not dissimilar to the observation in allogeneic HSCT recipients, most deaths (73%; 11 of 15) were not associated with enterococcal bacteremia. Significant risk factors in this group for enterococcal bacteremia included Roux-en-Y choledochojejunostomy (P = 0.005), a cytomegalovirus-seropositive donor (P = 0.013), prolonged transplantation time (P = 0.02), and strictures in the biliary tract (P = 0.016). On univariate analysis, diagnosis of primary sclerosing cholangitis (P = 0.009) and symptomatic cytomegalovirus infection (P = 0.008) was significantly present in patients in whom bacteremia due to *Enterococcus* spp. was observed [206]. Further underpinning the significance of isolation of these low-virulence pathogens in blood culture samples among patients undergoing liver transplantation, as a potential surrogate for identifying a highly susceptible subgroup of patients who have undergone abdominal visceral allograft transplantation surgery.

Selective bowel decontamination prophylactic regimens were suggested for mitigation of intestinal colonization due to MDR microorganisms. The Mayo Clinic reported isolation of VRE in early 1995 from surveillance cultures obtained from patients undergoing liver and kidney transplantation. By the end of 1997, 52 patients had VRE colonization, importantly with a single vanB clone [207]. VRE infection was observed in six patients (11%) [207].

In a longitudinal study from Pittsburgh, Pennsylvania, between 1990 and 1999, 165 patients underwent liver transplantation. Fifty-one (31%) patients developed posttransplant infection due to one or more MDR bacteria. A substantial number of bacteria (69%) were MDR pathogens. A high level of drug resistance was noted in *S. aureus* (91%) and enterococcal isolates (50%) [208]. During the decade-long study, a significant trend emerged for infections due to MDR bacteria mainly due to GPB infections like MRSA (P = 0.0001) and VRE (P = 0.04). In contrast, no significant increase was reported among MDR-GNB infections during the course of this study [208].

Patients undergoing solid organ transplantation are at an increased risk for colonization due to MRSA and VRE, an observation similar to patients undergoing allogeneic stem cell transplantation. As pointed out in a number of studies, bacterial colonization is an important precursor for invasive disease, especially those undergoing abdominal visceral allograft transplantation. A meta-analysis involving 23 published studies assessed the burden of MRSA and VRE colonization in patients undergoing solid organ transplantation; 17 of these studies were in liver transplant population [6]. The pooled prevalence estimates before transplantation were 8.5% for MRSA and 11.9% for VRE. However, MRSA colonization estimate was lower (4.0%) in studies involving 200 or more patients. The prevalence estimates for bacterial colonization after the transplantation procedure were 9.4% and 16.2% for MRSA and VRE, respectively. The risk for MRSA infection was significantly higher in patients with MRSA colonization before transplantation (RR 5.5) and also for patients in whom colonization occurred after the

transplantation procedure (RR 10.56). In concert with the risk for subsequent MRSA infection, VRE colonization before (RR 6.6) and after transplantation (RR 7.9) were associated with significantly higher risk of invasive VRE disease [6].

Most early posttransplant VRE infections are a result of complications arising from transplant surgery, a need for extended stay in transplant or surgical critical unit and prolonged exposure to broad-spectrum antibiotics. Bacteremia, intra-abdominal infections, urinary tract infections, and surgical site infections are common clinical presentation. VRE endovascular infections including endocarditis in the SOT population is rarely seen [114, 209]. Complications involving the biliary tract, such as strictures and biliary leaks, and importantly the interventions to ameliorate these compilations are important risk factors for VRE infection in patients undergoing liver transplantation [209, 210].

In kidney transplant recipients, VRE infections are prominent in patients with HCV infection, those undergoing multivisceral transplantation such as kidney and pancreas allograft surgery, patients requiring renal replacement therapy after transplantation surgery; nephrostomy tube placement, and patients taken back to the operation room for re-exploration surgery [211].

Left ventricular assist devices (LVAD) are used as a bridge to cardiac transplantation in patients with severe life-threatening heart failure awaiting transplant surgery. Pretransplant infection of LVAD increases the risk for post-transplant infections including infections due to VRE. Patients with LVAD infections commonly present as primary bacteremia, pocket and tunnel infection, endovascular infections including LVAD endocarditis, and infections involving the mediastinum. In a report from Rush University Medical Center in Chicago, IL 46 LVAD-related infections were diagnosed in half of patients who underwent LVAD implantation as a bridge to transplantation. Twenty-nine episodes of LVAD-related bacteremia included five patients with LVAD endocarditis; presence of diabetes appeared to increase the risk for bacteremia. VRE infection was diagnosed in six patients with LVAD-related infection who had undergone transplantation surgery; four of these six patients died. It was interesting to note that VRE infections were not seen in patients without pretransplant LVAD-related infection [212].

Diagnosis

Culture is the mainstay of diagnosis, with serologic or antigen tests having no value. The isolation of enterococci from non-sterile specimens such as urine, sputum, or external wound drainage usually represents colonization or subclinical infection rather than infection that requires treatment. Prescribing antibiotics in this situation generally fails to eradicate the organism while promoting the risk for development of antimicrobial resistance and exposing the patient to adverse events and toxicicty plus potentil for drug-drug interactions [213]. Even when isolated from sterile sites such as the abdominal cavity, enterococci are usually present along with one or more other organisms [136], and treatment of more virulent pathogens has been shown to cure such infections even in the absence of targeted anti-enterococcal therapy [214]. This concept is illustrated by the highly effective nature of cephalosporins in treating intra-abdominal infections despite having limited activity against enterococci [215].

Treatment

Treatment of enterococcal infection is complicated; bacterial species and drug resistance profile are the main influence in selection of drug(s) for a specific type of infection. Most clinical *E. faecalis* isolates show in vitro susceptibility to common beta-lactam drugs such as penicillin, ampicillin, amoxicillin, and piperacillin and to carbapenems like imipenem. Nafcillin is not effective against *E. faecalis*. It is important to remember that *E. faecalis* isolates are intrinsically resistant to cephalosporins [216]. In contrast, *E. faecium* isolates exhibit a high level of penicillin resistance, which in most cases exceeds 50% [216]. Macrolides, TMP-SMX, and fluoroquinolones are generally not effective against enterococci [217]. Vancomycin is regarded as the drug of choice for treating enterococci infections in patients with serious hypersensitivity to beta-lactams and those with beta-lactam-resistant isolates. However, with the emergence and spread of vancomycin nonsusceptible strains, the choice(s) of optimum effective therapy remains uncertain [213]. Enterococci may exhibit tolerance to β-lactam antibiotics, meaning that bacterial growth is inhibited in vitro following exposure at low drug concentrations, however bacterial killing induced by autolytic cellular pathways is not achievable following exposure to, even high antibiotic levels that could be given at physiologic doses [218]. Beta-lactam tolerance is an important mechanism underlying treatment failure and/or infection recurrence in severely immunosuppressed patients with neutropenia and those with endovascular infections [213]. A bactericidal effect may be achieved against some isolates by the addition of an aminoglycoside [218]. The bacterial killing after the addition of aminoglycosides only occurs in isolates that show in vitro susceptibility to these drugs, and as expected, no synergistic benefit should be expected among bacterial strains that are tolerant to beta-lactam drugs and also resistant to aminoglycosides [218].

Linezolid, tedizolid, daptomycin, and seldom-used quinupristin/dalfopristin are the drugs active against VRE. Quinupristin/dalfopristin lacks efficacy against *E. faecalis*. Enterococcal bloodstream infection and with rare hematogenous seeding of the meninges resulting in bacterial meningitis that may occasionally occur in severely immunocompromised patients including those undergoing HSCT;

linezolid monotherapy was reported to be effective, although clinical experience is limited [219]. Furthermore, linezolid resistance has emerged as a daunting concern, especially in patients undergoing HSCT. In a study in Essen, Germany, conducted between 2014 and 2015, 20 patients had linezolid-resistant VRE, and 18 of these patients underwent HSCT [220]. Twenty-five percent of patients developed bloodstream infection. Ten patients had bacterial colonization at the time of hospitalization. Eighty percent of patients with hospital-onset linezolid-resistant VRE had prior therapy with linezolid [220]. The authors report no clear evidence of patient-to-patient or environment-to-patient transmission within the transplant unit. It was interesting to note that a single genotype in six patients was noted, and all such patients were referred for the same hospital.

A report from the University of Illinois in Chicago conducted between 2000 and 2008 assessed 48 hospitalized patients being treated with linezolid and reported reduced susceptibility to VRE in these clinical isolates [221]. A significantly high risk for such infections was seen in patients undergoing allogeneic stem cell or solid organ allograft transplantation (OR: 2.6), treatment with immunosuppressive agents (OR: 2.4), both systemic corticosteroids (OR: 2.4) and noncorticosteroid immunosuppressive drugs (OR: 2.3), and exposed to linezolid with 1 year prior to infection diagnosis (OR: 34.5). Multivariable analysis showed that the risk of reduced susceptibility to linezolid among clinical VRE isolates was 32-fold greater in individuals who had received linezolid within 1 year of infection diagnosis. It is important to note that in this report most patients with VRE infections due to reduced linezolid susceptibility had not been treated with linezolid in the year prior and reduced linezolid susceptibility did not impact patient outcomes, which included clinical or microbiological cure, length of hospitalization, and all-cause mortality [221]. Further studies are needed to understand the clinical relevance and potential for treatment failure in patients with the emerging reduced linezolid susceptibility VRE infections and how best to manage such infections.

The in vitro susceptibility data for daptomycin and tigecycline are encouraging. Emergence of daptomycin resistance among clinical VRE isolates, especially in patients undergoing HSCT is of grave concern [222]. Reports of clinical failures with these agents in the setting of high in vitro drug MICs have underscored the potential threat [223]. However, in a recent report among adults with VRE bacteremia following HSCT and those with hematologic malignancies, the duration of bacteremia and microbiological failure rates did not differ by daptomycin MICs [224]. Multivariable analysis indicated an interesting trend that all-cause 30-day mortality was low in patients with VRE bacteremia due to bacterial strains that had high daptomycin MICs (3–4 micrograms/L) [224]. This trend, however, did not reach a level of statistical significance [224]. If this were to be a valid and significant finding, such an observation would put "disease-causing fitness" of such bacterial strains into question and, as mentioned earlier in various reports, and place emphsis on the surrogate nature of enterococcal infections, especially in high-risk patients following allogenic stem cell or solid organ allograft transplantation.

Summary

Gram-positive bacteria (GPB) are an important cause of serious systemic disease in the immunocompromised patients, especially patients after undergoing allograft transplantation. A rise in infections due to GPB in the last two decades has been attributed to a variety of reasons that prominently include antimicrobial prophylaxis with a focus on the prevention of Gram-negative bacterial infections and common use of indwelling intravascular access devices. In solid organ transplant recipients, postsurgical wound and deep tissue infections resulting from tissue ischemia, prolonged and complicated surgical procedures, allograft rejection, and severity of iatrogenic drug-induced immune suppression are important contributing factors. Severe orointestinal mucositis, prolonged pre-engraftment neutropenia, and graft-versus-host disease involving the skin and orointestinal tract are important consideration to promote risk among patients undergoing hematopoietic stem graft transplants. Community-acquired methicillin-resistant *Staphylococcus aureus* is now frequently encountered. Similarly, drug resistance among various pathogenic *Staphylococcus*, *Streptococcus*, and *Enterococcus* species has a substantial impact on selection of empiric antibiotic therapy in this population with suspected bacterial infection. Early diagnosis, prompt institution of appropriate therapy, assessment for outcome prognosticators, and recognizing the potential for early and late infection- and treatment-related complications forms the bases for providing optimum management of GPB infections in the transplant population.

Enterobacteriaceae in Transplantation

25

Kathryn Whitaker, Valerie Cluzet, and Emily A. Blumberg

Introduction

Enterobacteriaceae, Gram-negative, facultative anaerobes that ferment sugars, are common causes of infection and colonization in solid organ transplant (SOT) recipients and have become increasingly important pathogens in hematopoietic stem cell recipients (HSCT). The group comprises diverse organisms including *Escherichia coli*, *Klebsiella* spp., *Enterobacter* spp., *Serratia* spp., *Citrobacter* spp., *Proteus* spp., *Salmonella* spp., *Shigella* spp., and *Yersinia* spp., among others (Table 25.1). Of particular concern is the rise of multidrug-resistant organisms within the *Enterobacteriaceae* family, resulting in difficult-to-treat infections in an already immunosuppressed population of patients. Additionally, due to their immunosuppressed state, solid organ transplant recipients and hematopoietic stem cell recipients can have true infections with typically nonpathogenic bacteria in the *Enterobacteriaceae* family. This chapter will review the epidemiology and risk factors for these infections as well as specific syndromes commonly found in transplant recipients.

Table 25.1 Organisms in the *Enterobacteriaceae* family

Organism
Escherichia coli
Klebsiella spp.
Enterobacter spp.
Serratia marcescens
Citrobacter spp.
Morganella morganii
Proteus spp.
Providencia spp.
Edwardsiella spp.
Salmonella spp.
Shigella spp.
Yersinia spp.

Epidemiology and Risk Factors

Solid organ transplant recipients are at particular risk for infection with *Enterobacteriaceae* and other bacteria, given end-organ failure, surgical intervention, and immunosuppression. In fact, solid organ transplantation is an independent risk factor for acquiring infection with *Klebsiella pneumoniae* [1]. These infections are most commonly seen in the first 30 days following transplantation but can also occur later in the post-transplant period. They can be donor derived, nosocomial, or community acquired. The development of antimicrobial resistance in *Enterobacteriaceae* is a growing problem worldwide [2, 3]. This increase has been noted in the transplant population as well. Moreover, it appears that SOT recipients may be at greater risk than the general population for the development of infections with resistant organisms.

Infections with *Enterobacteriaceae* can occur at multiple sites, including the urinary tract, bloodstream, respiratory tract, intra-abdominal region, and wounds. The most common sites of infection differ depending on the type of transplant. Kidney and kidney-pancreas transplant recipients are at highest risk for urinary tract infections (UTIs) [4–8]. The most common infection after lung or heart transplant is pneumonia [9–11]. Intra-abdominal and wound infections are the predominant bacterial infections seen in liver and small bowel transplant recipients [12, 13]. Liver and kidney transplant recipients are also at high risk of developing bloodstream infections [7, 12–14].

Hematopoietic stem cell transplant recipients (HSCT) are also at increased risk for infections with *Enterobacteriaceae*, with different patterns of infection related to the timing of the infection [15]. Early infections during the pre-engraftment phase are secondary to loss of host defenses, including neutropenia and mucosal surface breakdown, thus increasing the risk of Gram-negative rod (GNR) bacteremia. Prior to the 1980s and 1990s, GNRs were the most common organisms associated with BSI in patients undergoing HSCT; however, with antibacterial prophylaxis and the increased use of central venous catheters, Gram-negative infections including those due to *Enterobacteriaceae* have become less frequent. This decline has been counteracted by the increase in antimicrobial resistance. Early post-engraftment bacterial infections with GNR are most commonly related to enteric GVHD allowing for translocation, as well as the immunosuppression associated with the treatment of GVHD.

Enterobacteriaceae can cause a variety of infections in the HSCT population. Bloodstream infections are the most commonly documented bacterial infection in the adult HSCT population, and pneumonia is the second most frequent, followed by gastrointestinal infections [16, 17]. *Enterobacteriaceae* contribute between 25% and 30% of BSIs in this population [17]. In a study of pediatric HSCT patients, *Enterobacteriaceae* were the most common cause of bacterial infections in matched related and unrelated donors, most frequently in association with enteritis and UTI [18].

Urinary Tract Infections

The urinary tract is the most common site of infection in kidney and kidney-pancreas transplant patients with a reported frequency of 4–86% but is also a source of infection in other SOT recipients [4–8, 19]. The highest risk is in the 30 days following the transplantation procedure, likely related to urinary tract instrumentation, with the exception of kidney transplant recipients whose major at-risk period extends at least to the first 6 months following transplant [7]. Patients with kidney and liver transplants are more likely to develop upper tract infections than other SOT recipients [7]. Additionally, kidney transplant recipients are also more likely to develop bacteremia related to UTI [6]. Risk factors for the development of UTI include female gender, age, diabetes, length of hospitalization, and presence of urinary catheters; additional factors specific to kidney transplant patients include deceased donor organ and posttransplant dialysis [7, 8, 19]. Studies have not shown increased mortality due to bacterial UTI [7].

Similar to normal hosts, *Enterobacteriaceae* are the most common organisms causing UTIs in transplant recipients. *Escherichia coli* is the most commonly identified organism, followed by *Klebsiella* species; *Enterobacter* species are also commonly seen [7, 19]. Resistance to trimethoprim-sulfamethoxazole is seen in most of these organisms, probably related to the use of this agent for *Pneumocystis jirovecii* infection prophylaxis [20]. Fluoroquinolone resistance is seen in over one-third of infections, and greater than one-quarter are extended-spectrum beta-lactamase (ESBL)-producing organisms [21–23]. Recent reports also noted the increasing presence of carbapenemase-producing *Enterobacteriaceae* UTIs [24, 25].

Special Consideration: Kidney Transplant

Although bacterial UTI is not associated with increased mortality [14], it is potentially important in kidney transplant patients as infections may lead to graft dysfunction and potentially rejection [26, 27]. Studies evaluating this association have noted contradictory results. A few studies found that episodes of pyelonephritis are associated with an increased risk of graft failure or death at 5 years [28, 29]. Additionally, investigators using data from the United States Renal Data System (USRDS) demonstrated that late infections (occurring after 6 months following transplantation) are associated with similarly poor outcomes [30]. However, other investigators found no association between graft pyelonephritis and graft dysfunction [31, 32]. Because measures of renal function vary with methodology, some of the differences may be explained by the assessment measures [33]; preexisting medical comorbidities likely play a role as well. Risk factors for UTI following kidney transplant include factors unrelated to transplant such as female sex and diabetes mellitus and those related to immunosuppression, especially the use of antimetabolites and cell-depleting agents, and instrumentation including prolonged use of urinary stents and other foreign devices [19].

Intra-abdominal Infections

Intra-abdominal infections are usually related to technical problems with surgery, resulting in lacerations, perforations, or anastomotic leaks. These are most commonly seen after liver, pancreas, and small bowel transplants. *Enterobacteriaceae* are a major component of gut flora and, therefore, are predominant pathogens in these infections.

Special Consideration: Liver Transplant

Intra-abdominal infections due to *Enterobacteriaceae* are especially common following liver transplant, with inci-

dence rates ranging from 53% to 79%, with most occurring in the first 2 months after transplantation [12, 13, 34]. Infections with *Enterobacteriaceae* can involve the liver, biliary tract, or peritoneal cavity. Most of these infections are related to surgical complications or biliary tract complications [35]. Patients who develop graft ischemia secondary to hepatic artery thrombosis and those experiencing biliary tract complications are at increased risk of developing hepatic abscesses, which are most frequently caused by *Enterobacteriaceae* [36]. Risk factors for intra-abdominal infections after liver transplantation include prolonged surgical time, high intraoperative transfusion requirement, reoperation or re-transplantation, prolonged hospitalization, acute rejection, CMV infection, and elevated preoperative creatinine and bilirubin levels [12, 34, 35].

The choice of biliary anastomosis can also predispose the liver transplant patient to intra-abdominal infections. Choledochocholedochostomy is the preferred method of anastomosis, as compared to the Roux-en-Y choledochojejunostomy, which is used in patients who have anatomic abnormalities of the extrahepatic biliary system such as primary sclerosing cholangitis, patients undergoing re-transplantation, and those with a history of prior bile duct surgeries [37–40]. The choledochocholedochostomy preserves the sphincter of Oddi, whereas the Roux-en-Y anatomy facilitates reflux of enteric organisms into the biliary system, thereby increasing the risk of infections with these organisms. In live donor liver transplantation, lower graft-to-recipient weight ratio has also been noted to be a risk factor for surgical site infection in liver transplantation [41].

Respiratory Tract Infections

Lower respiratory tract infections (LRTI) are the leading cause of morbidity and mortality after transplant and the most common infection following lung and heart transplants [42–45]. They also occur frequently following liver transplant, perhaps related to the presence of right-sided pleural effusions and atelectasis, and are frequently seen in stem cell recipients with graft versus host disease [34, 46–48]. As many as 55–75% of the LRTIs identified in SOT recipients are hospital acquired or health-care associated, usually related to aspiration [44, 47, 49]. Bacterial pneumonia occurs most commonly in the first 3 months after transplantation [47], with GNRs among the more common organisms identified. One study found that infections with *Enterobacteriaceae* such as *E. coli*, *Klebsiella* spp., *Enterobacter* spp., and *Serratia* spp. were equally common as those with non-fermentative organisms, such as *Pseudomonas aeruginosa* [47]. Transplant recipients are at higher risk of acquiring infections with resistant organisms [49]. Mortality from bacterial LRTI is high, especially when the infection occurs in the immediate posttransplant period and in patients with nosocomial infection and recurrent pneumonia, those requiring prolonged mechanical ventilation, and those admitted with sepsis related to pneumonia [42, 46, 48, 50–52]. *Enterobacteriaceae* are common causes of nosocomial pneumonia and contribute significantly to this mortality risk.

Special Consideration: Lung Transplant

Historically, the incidence of pneumonia following lung transplantation ranged from 22% to 39% [44, 52, 53]. A more recent prospective multicenter cohort demonstrated 72 episodes per 100 lung transplant years; 82.7% were due to bacteria and the median onset of bacterial pneumonia occurred at 31 days after transplantation [54]. Studies specifying the microbiologic causes of pneumonia in lung transplant recipients identify *Enterobacteriaceae* as common etiologic agents [54, 55]. Deusch et al. reported that *Klebsiella pneumoniae* was the most commonly identified pathogen, with *Escherichia coli* and *Enterobacter cloacae* also making up a significant proportion of very early post-lung transplant LRTIs [53]. In a lung transplant subset of the RESITRA cohort, a large Spanish registry focused on transplant-related infections, and *Enterobacteriaceae* were also commonly seen as causes of pneumonia, although they were less frequently noted than the non-fermentative GNRs [54].

Wound/Surgical Site Infections

In SOT recipients, wound infections after transplant occur with the same frequency as with other surgeries, with incidences of 5–51% [56–67]. Gram-negative wound infections, including members of the *Enterobacteriaceae* family, are more commonly seen in wound infections after transplants involving organs below the diaphragm, specifically small bowel [59, 60], kidney, pancreas or simultaneous kidney-pancreas [5, 61, 63, 64], and liver [13, 34, 35, 66] transplants. Recently, surgical site infections are increasingly due to multidrug-resistant organisms, including ESBL- and *K. pneumoniae* carbapenemase (KPC)-producing organisms [35]. Of additional concern are reports of necrotizing skin infections due to *Klebsiella* spp. in liver transplant patients [67]. Risk factors for surgical site infections in transplant recipients mirror those seen in non-transplant patients and include increased BMI, reoperation, diabetes mellitus, and increased operative time [62, 65, 68–73]. Transplant-specific

factors include prior transplantation, surgical approach such as choledocho- or hepaticojejunostomy, choice of immunosuppression, especially the use of mTOR inhibitors, graft rejection, prolonged ischemic time, increased packed red blood cell transfusion requirement, dialysis, and delayed graft function [64, 65, 68–74].

Bloodstream Infections

Bloodstream infections in SOT recipients are common. Mortality is higher with Gram-negative infections compared with Gram-positive BSI [75–79]. Over 75% of these infections are nosocomial. *Enterobacteriaceae* are among the most common etiologic agents. Al-Hasan and colleagues conducted a retrospective study of GNR BSI in 3367 diverse SOT recipients (kidney, liver, kidney-pancreas, pancreas, heart, and lung transplant recipients) followed for 12 years and found a declining incidence; nevertheless, GNR BSI occurred at a 20-fold higher rate than that in the general population [78]. The highest incidence is in the early posttransplant period during the first 30 days, with a sharp decline thereafter. Importantly, however, the incidence of GNR BSI 12 months after transplant is still notably higher than the general population, especially in kidney transplant recipients. In contrast to earlier studies [76, 77, 79], Al-Hasan et al. found a lower 28-day mortality in their cohort of patients (4.9% vs. 25–59%), which may be related to advances in medical care [78]. However, SOT recipients who developed GNR BSI in the first year after the transplantation procedure continue to have higher 1-year mortality than those who do not [78].

Similar to the general population, the most common GNR organism seen in BSI in SOT patients is *Escherichia coli*, followed by *Klebsiella pneumoniae*; other important *Enterobacteriaceae* seen commonly in BSI are *Enterobacter cloacae* and *Citrobacter freundii*. *Escherichia coli*, along with *Pseudomonas aeruginosa*, account for most of the infections in the early posttransplant period, while *Escherichia coli* and *Klebsiella pneumoniae* are seen more commonly 12 months or later after transplantation [78]. The rates of resistance to antimicrobials, including ampicillin for *Escherichia coli*, fluoroquinolones, and trimethoprim-sulfamethoxazole, and ESBL-producing strains are increasing in GNR BSI; this is an important consideration for empiric selection of antimicrobial therapy [78, 80].

The urinary tract is the most common source of GNR BSI, followed by the gastrointestinal (GI) tract, respiratory tract, intravenous catheters, and skin and soft tissue [78]. Females are more likely than males to have a urinary source of GNR BSI [78]. A urinary source is more common in kidney transplant patients, whereas liver transplant patients are more likely to have a GI source and lung transplant recipients a respiratory tract source [76, 78].

Bacteremia is also common in HSCT recipients, with an incidence between 21% and 43% and an attributable mortality of 3.3–22.6%; overall mortality is substantially higher in HSCT recipients than in the general population [81–83]. Most BSIs are noted during the pre-engraftment period represented by severe neutropenia, compared to the post-engraftment period [81, 83]. However, the occurrence of grade 2 or greater GVHD in the post-engraftment period has been associated with an increased risk of bacteremia, as well [81, 82]. Additional risk factors for bloodstream infection include reduced intensity allogeneic stem cell transplantation [83, 84]. Bloodstream infections have been reported frequently in both allogeneic and autologous stem cell recipients. The timing of infection may vary however, and in at least one study, later infections such as those occurring at least 180 days after transplant were more common in allogeneic stem cell graft recipients [85].

Depending on the study, *Enterobacteriaceae* make up a majority of the GNRs isolated in HSCT recipients, with a median incidence of 30%. Within the *Enterobacteriaceae* group, *E. coli* is the most common isolated organism, approximately 25%, although with great variability in studies [16, 81, 82]. As described with other sites and solid organ transplant recipients, antimicrobial resistance has been increasingly described and may reflect the near-universal use of fluoroquinolone prophylaxis during periods of neutropenia [16, 82, 85].

Multidrug-Resistant *Enterobacteriaceae*

Multidrug-resistant *Enterobacteriaceae* (MDRE) are a growing problem worldwide. Solid organ and hematopoietic stem cell transplantation are independent risk factors for acquiring infection with MDRE [86–89]. Other risk factors include antibiotic exposure, surgery, hospitalization, mechanical ventilation, renal replacement therapy, and the presence of indwelling devices, all of which are common in SOT recipients [89, 90]. MDRE, specifically those that have plasmid-encoded genes that produce extended-spectrum beta-lactamases, AmpC beta-lactamases, and carbapenemases, are a particularly important problem given their rapidly rising rates and limited treatment options. Extended-spectrum beta-lactamase- and AmpC beta-lactamase-producing organisms confer resistance to penicillins and cephalosporins and are often only susceptible to carbapenems. Carbapenemase-producing organisms produce an even larger problem, as they are more globally resistant with even fewer treatment options. Not unexpectedly, infection with drug-resistant

Enterobacteriaceae is associated with increased cost of care, treatment failure, and risk for death [90–93].

Solid organ transplantation is an independent risk factor specifically for infection with ESBL-producing *Enterobacteriaceae* and carbapenem-resistant *Klebsiella pneumoniae* [87, 90]. Infections with ESBL-producing strains of *Enterobacteriaceae* are extremely common in SOT recipients, with rates of up to 53% identified in some studies [4, 66, 89]. Outbreaks within institutions, particularly on transplant wards and in intensive care units, are often reported [94–99], the majority of which involve liver and kidney transplant recipients. Patel and Bergamasco found that 35–41% of the cases in carbapenem-resistant *Klebsiella pneumoniae* outbreaks occurred in SOT patients and all transplant patients who were colonized with KPC later developed infection [90, 94]. Even more worrisome is a report of pelvic abscess in a renal transplant recipient which grew New Delhi metallo-b-lactamase-1-producing *Klebsiella oxytoca* [100]. Infection with carbapenemase-producing organisms confers a high mortality rate in the transplant population as well as the general population, and 30-day and 1-year mortality rates in posttransplant cohorts have been reported between 30% and 79% [90, 94, 101–104].

Similar to that seen in SOT recipients, there has been a rise in resistant GNR infections in HSCT recipients [81, 82], from 3% to 11% in one study [105]. Mechanisms of resistance vary; there have been report of ESBL producers and Amp C beta lactamases in addition to diverse mechanisms of carbapenem resistance and fluoroquinolone resistance. ESBL-producing *Enterobacteriaceae* are frequent, with prevalence ranging from 13% to 48% [16]. Some studies have shown that MDR Gram-negative bacterial bloodstream infections are more common in allogeneic HSCT compared to those who underwent autologous stem cell transplantation. This is likely due to underlying malignancies that require allogeneic HSCT compared to autologous HSCT. Patients undergoing allogeneic stem cell transplants frequently have more prolonged periods of neutropenia and have had more courses of treatment with broad-spectrum antibiotics [85]. In one study comparing allogeneic HSCT to autologous HSCT, GN bacterial infections caused by MDR pathogens represented 78% of infections in allogeneic graft recipients compared to 20% in autologous HSCT. Of those in the allogeneic HSCT group, 72.5% were ESBL-positive, and 5.5% were AmpC-positive [106]. Another potential risk factor for resistance may be the use of prophylactic antimicrobials, and the use of fluoroquinolones, per guidelines, in high-risk neutropenic populations has been associated with increased resistance to fluoroquinolones [82, 107]. In one study, in an institution using fluoroquinolone prophylaxis for neutropenic patients, all isolated GNR bacteria were resistant to fluoroquinolones, and 92.8% were multidrug-resistant organisms [82]. The rate of fluoroquinolone resistance in *E. coli* has increased, irrespective of the use of fluoroquinolones for prophylaxis [16]. As with SOT recipients, infection with resistant *Enterobacteriaceae* has been associated with increased mortality; in some cases, mortality in HSCT has exceeded that seen in SOT [108]. Of special concern has been pneumonia due to carbapenemase-producing *Klebsiella pneumonia* in HSCT recipients, which has a reported attributable mortality rate between 38% and 67% [16].

Mechanisms of Resistance

Mechanisms of resistance are diverse and can be encoded on plasmids or chromosomes. Resistance may be intrinsic or inducible. All types of resistance have been encountered in transplant recipients [80, 93–100, 109]. Almost all species of *Enterobacteriaceae* can produce ESBL. They are plasmid-encoded genes and are therefore easily transmissible among organisms. The types of ESBL include TEM, SHV, and CTX-M, which is currently the most commonly seen [110]. Plasmid-encoded AmpC beta-lactamases have been identified in *Escherichia coli*, *Klebsiella pneumoniae*, and *Proteus mirabilis*. Certain *Enterobacteriaceae*, including *Enterobacter*, *Citrobacter*, and *Serratia* species, have chromosomally encoded AmpC beta-lactamases, which confer resistance to third-generation cephalosporins and may be inducible, an important consideration when choosing antimicrobials. Several distinct carbapenemases have been described, including chromosomal- and plasmid-encoded types. The most common carbapenemases seen in the United States are various types of KPC. Worldwide, other types are geographically distributed, such as metallo-beta-lactamases including VIM in Southern Europe and Asia and NDM-1 in the United Kingdom, India, and Pakistan and oxacillinase-48-type carbapenemases in Mediterranean countries, Europe, and India [111]. However, these types are not geographically isolated and global spread is increasing. Fluoroquinolone resistance generally results from chromosomal mutations leading to target enzyme modifications or efflux pumps. However, there is also a plasmid-encoded qnr gene that is associated with fluoroquinolone resistance in *Escherichia coli* and *Klebsiella pneumoniae*. Table 25.2 outlines diagnostic and treatment considerations for MDRE.

Donor-Derived Infections

Donor-derived *Enterobacteriaceae* infections have been reported most frequently involving abdominal organs and donors with abdominal trauma [112, 113]. With the rising rates of colonization and infection with multidrug-resistant *Enterobacteriaceae* in hospitalized patients as well as increasing rates of community-acquired MDRE,

Table 25.2 Multidrug-resistant *Enterobacteriaceae*

Organism	Diagnosis	Treatment
Extended-spectrum beta-lactamase producers	Double-disk diffusion assay Microbroth dilution Refer to new CLSI breakpoints	Carbapenems
Carbapenemase producers	Disk diffusion assay: screen using ertapenem or meropenem Microbroth dilution: screen using imipenem, meropenem, or ertapenem Automated susceptibility testing: screen using ertapenem	Ceftazidime avibactam Colistin or polymyxin B (IV)[a] Aminoglycoside[a] Tigecycline[b] Fosfomycin (only available in oral formulation in the United States, for uncomplicated UTI)

[a]May be given in combination with either carbapenem or tigecycline
[b]Second-line therapy. Avoid for urinary tract infections and bloodstream infections

donor-derived infections with MDRE are also being more frequently reported.

Donor-derived infection with MDRE is particularly concerning because of the high mortality rate associated with these infections as well as the risks related to treatment. There have been several case reports detailing donor-derived infections with MDRE [114–117]. These include transmission of MDR *E. coli* to two kidney transplant recipients from one donor, with resultant graft loss due to infection in one recipient [114]. There have also been case reports of donor-derived carbapenem-resistant *K. pneumoniae* infections [115–117]. Transmission of resistant pathogens has been variable and may not be related to the presence of infection versus colonization in the donor [115]. In one report, the recipient of one of the lungs became infected and died, whereas the two kidney recipients, the liver recipient and the other lung recipient, did not develop infection [118]. In a second case report, the recipient of simultaneous kidney-liver transplant developed infection with KPC, whereas the other kidney, heart, and vein graft recipients did not develop signs of infection [119]. Cases in which single recipients are involved primarily involve donors in whom the infection is localized to a single organ without evidence of bloodstream infection at the time of procurement [119].

It is unclear whether organs from donors infected with MDRE should be used; currently, there is no standard approach to the use of these organs. In some cases, prompt initiation of effective antimicrobials may improve outcomes, although the impact of antimicrobial prophylaxis may be variable, even among recipients of the same donor [115]. Because of variable outcomes in recipients of these organs, recipients of organs from donors known to have Gram-negative bacterial infections, especially those with resistant *Enterobacteriaceae*, should be warned about the potential risk of transmission [120]. Additionally, it is important to tailor antimicrobial prophylaxis to include the resistant pathogen to minimize the risk of poor recipient outcome.

Notably, delays in communication between the reference laboratories that receive bacterial cultures at the time of organ procurement and the clinicians caring for the recipient have resulted in delayed initiation of appropriate therapy and increased risk of transmission [121]. This delay in communication of culture information is highlighted in the report of transmission of MDR *E. coli* described above. The Organ Procurement and Transplantation Network mandates reporting of potential donor-transmissible infections when initially suspected, in part to mitigate risks of donor-derived infection to other recipients of organs from the same donor [122].

Infection Diagnosis

Diagnosis of infection with *Enterobacteriaceae* first involves assessment of the source of the culture and the method of collection. Cultures from sterile sites indicate true infection, whereas cultures from wounds, the respiratory tract, or intravenous lines need to be interpreted in the context of the clinical scenario in order to distinguish infection from colonization. In patients who are mechanically ventilated, distal sputum samples obtained through bronchoscopy and bronchoalveolar lavage are more specific than standard tracheal aspirates and have been shown to have high diagnostic yield in solid organ and stem cell transplant patients [123–126]. In one randomized study, patients who underwent invasive procedures to gather sputum samples had improved outcomes over those whose samples were procured via tracheal aspirate [127]. It is also important to distinguish asymptomatic bacteriuria from true urinary tract infection, even in the setting of kidney transplantation (see below) [128].

Both broth dilution and disk diffusion methods are recommended by the Clinical and Laboratory Standards Institute (CLSI) for susceptibility testing in *Enterobacteriaceae* [129]. CLSI updated MIC and diffusion cephalosporin and aztreonam breakpoints for *Enterobacteriaceae* in 2014 to reflect the increasing problem of resistance via multiple

Table 25.3a Laboratory breakpoints for *Enterobacteriaceae*[a]. MIC breakpoints (μg/ml)

Agent	Susceptible	Intermediate	Resistant

mechanisms and treatment failure with traditional antibiotics, despite "susceptible" MICs. The revised breakpoints eliminated the need to perform ESBL screening and confirmatory tests. Screening for carbapenemase-producing organisms can be done using ertapenem or meropenem for disk diffusion susceptibility testing; using imipenem, meropenem, or ertapenem for microbroth dilution; or using ertapenem in automated susceptibility testing. All require special interpretive criteria. Production of KPC can be detected using the modified Hodge test. Laboratories should be familiar with these new guidelines and breakpoints in order to correctly identify multidrug-resistant *Enterobacteriaceae*. If the laboratory is not experienced with the evaluation of unusual susceptibility patterns, referral to a reference laboratory may be warranted (Tables 25.3a and 25.3b).

Treatment

Prompt recognition of infection with *Enterobacteriaceae*, particularly multidrug-resistant organisms, and initiation of appropriate antimicrobials are essential. Removal of known foci of infection such as indwelling catheters or drainage of abscesses is strongly recommended, when possible. Initial empiric therapy should be guided by the hospital or region's known *Enterobacteriaceae* resistance patterns, and definitive antimicrobial therapy should be chosen based on susceptibility testing.

Carbapenems are the mainstay of treatment for infections with ESBL-producing *Enterobacteriaceae* [110, 130]. Cephalosporins and penicillins should be avoided in AmpC-producing organisms as they can induce hyper-production of beta-lactamase; in these cases, a non-beta-lactam antibiotic should be chosen [110, 130]. Agents that are active against carbapenemase-producing *Enterobacteriaceae* include ceftazidime avibactam, polymyxins like colistin and polymyxin B, the aminoglycosides, fosfomycin for urinary tract infections, and tigecycline [108, 110, 130]. Use of tigecycline is no longer routinely recommended as there is a trend toward increased mortality when this antibiotic is used due to low drug concentrations in the blood and urinary tract [131]. There are no good data on optimum therapy or combination therapy for these infections. In vitro studies show synergy when using colistin with carbapenems [132–134], but, thus far, there have been no definitive studies showing significant difference in clinical outcomes when "synergistic" combinations are used [135–137].

Special Consideration: Asymptomatic Bacteriuria

Due to the severity of the potential outcomes of graft pyelonephritis, as well as the higher level of immunosuppression in the first few months following transplant, some experts recommend treatment of asymptomatic bacteriuria during the early posttransplant period [138]. In the general population, treatment of asymptomatic bacteriuria is not recommended, and at least one prospective trial has failed to confirm any benefit from treating asymptomatic bacteriuria in renal transplant recipients [128, 139]. Consequently, there is no consensus on whether to treat asymptomatic bacteriuria, at least in the early posttransplant period, and the benefits from routine screening are unknown.

Special Consideration: Febrile Neutropenia

Neutropenic patients represent a specific group at risk for infection, most commonly seen in the pre-engraftment period following HSCT. Because *Enterobacteriaceae* are common pathogens in neutropenic patients, high-risk groups should be admitted and started on empiric IV antibiotics with cefepime, a carbapenem, or piperacillin-tazobactam, depending on local resistance patterns [140]. Low-risk populations, as defined by the Multinational Association for Supportive Care in Cancer (MASCC) score, may be managed with empiric enteral antibiotics. Modification of the empiric regimen should be made if organisms are isolated and susceptibilities are available; otherwise empiric treatment is recommended until engraftment and recovery of peripheral blood granulocyte count [140].

Prevention

Prophylaxis

Given the diversity of timing and sources of infections with *Enterobacteriaceae* in SOT recipients, there is limited data regarding prevention of infections with these organisms during the extended posttransplant period. Most reports have focused on early infections. Historically, several studies have shown that prophylaxis with co-trimoxazole given mainly for prophylaxis against *Pneumocystis jirovecii* infection has reduced the incidence of UTI and bacteremia after solid organ transplantation [141, 142]; however, in a study by Vidal et al. [7], co-trimoxazole prophylaxis did not demonstrate a protective effect. Interestingly, the use of co-trimoxazole has not contributed to increased colonization with MDRE organisms, although the rates of co-trimoxazole resistance are expectedly high [7, 20, 141, 142]. Selective bowel decontamination prior to liver transplant has been evaluated in several randomized controlled trials, which have produced conflicting results, although the regimens and time courses varied from study to study [143–146]. A systematic analysis by Safdar et al. [146] showed that selective bowel decontamination reduces infections with Gram-negative organisms. None of the studies were adequately powered to detect a difference in mortality, however, and Gram-positive infections have been noted with this approach [143]. The emergence of antimicrobial resistance was not explored. Based on the limited impact on survival and the risk for resistance, this strategy is not routinely recommended [146].

In HSCT recipients, antibiotic prophylaxis with fluoroquinolones has demonstrated reduction in the incidence of Gram-negative sepsis during neutropenia, albeit no mortality benefit has been consistently demonstrated [147]. Moreover, fluoroquinolone resistance has been noted in patients receiving this prophylaxis [82, 107]. Current recommendations still include antibacterial prophylaxis for high-risk neutropenic patients with anticipated prolonged neutropenia (ANC <100 cells/mm^3) for a minimum of 7 days [140, 147]. Antimicrobial prophylaxis is not currently recommended for low-risk neutropenia patients with a short duration of anticipated neutropenia, especially those undergoing uncomplicated autologous stem cell transplantation.

In SOT and HSCT recipients, colonization with CRE has been associated with subsequent infections with CRE [108, 148, 149]. There are no data available to recommend either alteration of antimicrobial prophylaxis or exclusion from transplantation. As noted previously, the use of CRE-infected or CRE-colonized donors is not specifically contraindicated; adjustment in prophylactic regimens to cover resistant pathogens should be considered [108, 115]. Regardless, greater emphasis on infection control measures is recommended for patients known to have prior infection or colonization with CRE, especially to prevent spread of resistant organisms on transplant units [108, 130].

Infection Control

Cross-transmission of ESBL-producing and carbapenem-resistant *Enterobacteriaceae* is common, as evidenced by the previously mentioned outbreaks. Therefore, it is crucial that institutions introduce strict infection control policies in order to prevent the nosocomial spread of highly resistant organisms. In HSCT recipients, current recommendations include screening for MDR bacteria, especially in institutions with known high prevalence, and instituting contact precautions to prevent cross-patient transfer of such organisms [150]. There are no specific recommendations with respect to screening SOT recipients, although many centers with increased prevalence of CRE are screening candidates and recipients in transplant units. The Centers for Disease Control and Prevention has developed a tool kit for facilities and clinicians outlining procedures to prevent spread of resistant *Enterobacteriaceae*, and current guidelines designed for solid organ transplant recipients recommend adherence to this tool kit [130, 151]. Procedures include cohorting patients and staff with known MDRE colonization or infection, use of contact precautions including gown and gloves, strict enforcement of hand hygiene, minimization of invasive device use, promotion of antimicrobial stewardship in order to curb the development of resistance, and implementation of surveillance and screening protocols [151].

Infectious Diarrhea with *Enterobacteriaceae*

Epidemiology

Diarrhea is common among SOT recipients and most frequently attributed to the direct effects of immunosuppression. However, these recipients are also at increased risk for infections with pathogens that cause gastroenteritis. Transplant patients tend to be symptomatic for longer and have less abdominal pain, which may make it difficult to assess for secondary complications [152]. Transplant recipients are at risk for acquisition of community-acquired infectious diarrhea with viral and bacterial organisms, including those in the *Enterobacteriaceae* family such as *Escherichia coli*, *Salmonella* spp., *Shigella* spp., and *Yersinia* spp. as well as extraintestinal manifestations of these infections [153, 154]. Arslan et al. reported that the rate of infectious diarrhea in SOT recipients caused by *Enterobacteriaceae* was similar to the general population [154]. *Salmonella* was the most common

bacterial etiologic agent, causing 42% of infectious diarrhea cases that were attributed to bacteria other than *Clostridium difficile*. Additional causes included *Campylobacter* (not in the *Enterobacteriaceae* family) (27%), *Shigella* (15%), pathogenic *E. coli* (35), and *Yersinia* (<1%). Although the incidence of *Salmonella* as a cause of infectious diarrhea did not seem to differ from the general population, the incidence of extraintestinal infections with non-typhoidal *Salmonella* species was much greater in renal transplant recipients, approximately 20 times higher than in the non-transplant population [155].

Diagnosis

Determination of the etiology of diarrhea in a solid organ transplant patient is complicated due to the diversity of pathogens in this population as well as the immunosuppressive medications that often have diarrhea as a side effect. A thorough history, including timing, volume, and presence of bloody diarrhea and/or fever, exposure history, and full physical exam should be completed. Stool samples should be sent for routine culture and, based on clinical presentations such as the presence of bloody diarrhea, fever, and exposure history, may include special culture for Shiga toxin-producing *E. coli*, *Campylobacter* spp., and *Yersinia* spp., as well as multiplex PCR for enteric pathogens and Shiga toxin (Table 25.4a) [153]. In addition, stool should be tested for non-*Enterobacteriaceae* bacterial pathogens including *Clostridium difficile*; parasitic infections such as *Giardia*, *Cryptosporidium*, *Isospora*, and *Cyclospora*; microsporidiosis; and both community-acquired and opportunistic viruses.

Treatment

Given the multiple potential causes of diarrhea in SOT recipients, empiric treatment recommendations vary with individual circumstances. Empiric treatment is generally withheld until an etiologic agent is identified. However, if shigellosis or *Campylobacter* spp. infection is suspected in a patient with bloody diarrhea, fever, and appropriate exposure history, it is advisable to provide empiric treatment. In the immunocompetent host, most gastrointestinal infections caused by *Enterobacteriaceae* are self-limited illnesses and do not require treatment with antibacterials; however, transplant recipients with more severe infection should receive treatment [153, 156]. Anti-motility agents should be avoided in patients with bloody diarrhea due to the risk of prolonging infection. Table 25.4b outlines diagnostic and treatment considerations in patients with diarrhea due to *Enterobacteriaceae*.

Emerging Pathogens

Due to their immunosuppressed state, SOT recipients are at risk for infections with organisms that do not usually cause infection in immunocompetent individuals. There

Table 25.4a *Enterobacteriaceae* causing infectious diarrhea: organisms and clinical presentation

Organism	Common subtypes	Symptoms/signs	Seasonality	Exposures	Complications
Salmonella	Non-typhoidal: *S. enteritidis*, *S. typhimurium* Typhoidal: *S. typhi*, *S. paratyphi*	Nausea, vomiting, nonbloody diarrhea, abdominal cramping Typhoid fever: Fever, rose spots, hepatosplenomegaly	None	Raw eggs, poultry, pork, beef; reptiles	Extra-intestinal disease (bone and joint, bacteremia, meningitis, myocarditis Reactive arthritis
Shigella	*S. sonnei* (most common), *S. dysenteriae*, *S. flexneri*, *S. boydii*	Diarrhea with blood or mucous, crampy abdominal pain, fever	Summer/fall	Sick contacts, contaminated food (salads, dairy products, raw vegetables, seafood, raw meat)	HUS Reactive arthritis, seizures, perforation
E. coli	Enterotoxigenic (ETEC) Enteroadherent (EAEC), Enteropathogenic (EPEC), Enterohemorrhagic (EHEC), Enteroinvasive (EIEC)	Varies Nonbloody diarrhea: ETC, EAEC Bloody diarrhea: EIEC, EHEC, and EPEC Fever: EIEC, EHEC	None	ETEC, traveler's diarrhea, waterborne, soft cheeses, raw vegetables; EAEC, children with chronic diarrhea in developing countries; EPEC, infants and nurseries; EIEC, person-to-person, fecal-oral; EHEC, undercooked meat, raw milk, unpasteurized juices, raw vegetables, waterborne	Hemorrhagic colitis (EHEC), HUS (*E. coli* 0157:H7)
Yersinia	*Y. Enterocolitica*	Watery or bloody diarrhea, fever	Winter	Pork (chitterlings), beef, poultry, lamb, seafood, waterborne	Pseudoappendicitis, perforation, intussusception, peritonitis, toxic megacolon, cholangitis, bacteremia, reactive arthritis

Table 25.4b Diagnosis and treatment of infectious diarrhea caused by *Enterobacteriaceae*

Organism	Diagnostic considerations	Treatment	Treatment considerations
Salmonella	Routine stool culture	Empiric: Fluoroquinolone or third-generation cephalosporin for 5–7 days	Duration of treatment for extraintestinal, dependent on site of infection Typhoid vaccine should be administered to travelers
Shigella	Routine stool culture	Fluoroquinolone or TMP-SMX for 3–7 days	Avoid anti-motility agents
E. coli	Request special medium to isolate E O157:H7	Fluoroquinolone for moderate to severe traveler's diarrhea (ETEC), EPEC, or EIEC	NO antibiotics if E O157:H7 confirmed, unless septic
Yersinia	Request special medium	Doxycycline, TMP-SMX, aminoglycosides, fluoroquinolones	

are several members of the *Enterobacteriaceae* family that are commensal or environmental organisms that have been shown to cause infection in patients undergoing transplantation. Notably, infections with *Hafnia alvei*, a commensal organism in soil, water, and the GI tract of mammals, reptiles, birds, and fish, have been reported in kidney, liver, and lung transplant patients [157–161]. *Pantoea agglomerans* formerly *Enterobacter agglomerans*, an organism found in the environment, usually on plants, fruits, and vegetables, has been described as a cause of pneumonia in a heart-lung transplant patient [162]. Finally, *Kluyvera*, another member of the *Enterobacteriaceae* family that inhabits the human gastrointestinal and respiratory tracts, has been found to be one of the etiologic agents of a polymicrobial liver abscess in a transplanted liver as well as of pyelonephritis in a transplanted kidney [163].

Summary

Enterobacteriaceae are important etiologic agents of bacterial infections in transplant recipients. They are prominent pathogens in both the early and late posttransplant periods and can cause infection at any site. Antimicrobial resistance among *Enterobacteriaceae* is increasing, and this is reflected in the transplant population as well. Given that transplantation is an independent risk factor for infection with resistant *Enterobacteriaceae*, providers should have a high level of suspicion and choose empiric therapy accordingly in order to improve outcomes.

Pseudomonas, *Stenotrophomonas*, *Acinetobacter*, and Other Nonfermentative Gram-Negative Bacteria and Medically Important Anaerobic Bacteria in Transplant Recipients

Kenneth V. I. Rolston and Amar Safdar

Introduction

Aerobic gram-negative bacilli currently account for 15–20% of monomicrobial bacterial infections in neutropenic patients, including patients with hematologic malignancies and those undergoing stem cell allograft transplantation [1, 2]. Furthermore, 80% of polymicrobial infections have a gram-negative component [3]. Since polymicrobial infections now account for 25–30% of documented bacterial infections, a trend that has been increasing in recent years, gram-negative bacilli are isolated from nearly 50% of bacterial infections in this patient population. This occurs despite the use of antimicrobial prophylaxis directed primarily against gram-negative bacilli in high-risk patient groups. The majority of gram-negative pathogens are residents of the human gastrointestinal or skin microflora, although some are acquired from environmental or other sources. In general, monomicrobial gram-negative and polymicrobial infections are associated with greater morbidity and mortality than infections due to gram-positive bacteria. Consequently, the prompt administration of empiric broad-spectrum, parenteral, antimicrobial therapy is considered the standard of care for febrile neutropenic patients, who are at increased risk for developing such infections [4]. Unfortunately, neutropenic episodes occur often, and the frequent use of antimicrobial agents for prophylaxis and therapy often leads to the emergence and/or selection of resistant microorganisms [5–7]. Some organisms acquire several mechanisms of drug resistance that render them nonsusceptible to a number of antimicrobials belonging to different classes of antibiotic. Multidrug resistant (MDR) bacteria are defined as exhibiting resistance to three or more classes of antimicrobial agents that are expected to be active against a particular pathogen. MDR gram-negative pathogens such as *Pseudomonas aeruginosa*, *Stenotrophomonas maltophilia*, and *Acinetobacter* species pose a significant problem, especially since the research and clinical development of novel antimicrobial agents remains relatively scarce as outlined by several recent monographs and publications from Infectious Diseases Society of America (IDSA) [8, 9].

Current Spectrum of Gram-Negative Infections

Most cancer and transplant centers have documented a decline in the proportion of bacterial infections caused by aerobic gram-negative bacilli over the past three decades, with a corresponding increase in gram-positive and polymicrobial infections [1, 2, 10]. Of late, some centers are reporting a shift back toward a predominance of gram-negative infections with an alarming increase in the frequency of MDR organisms [11, 12]. Unfortunately, most epidemiologic studies have focused primarily on monomicrobial bacteremia and have failed to provide data on polymicrobial infections and on sites of infections other than the bloodstream such as the respiratory tract, urinary tract, skin/skin structure, hepatobiliary, and intestinal tract infections [1, 13]. Since bacteremia account for only 15–25% of infections in such patients, these data underscore an incomplete picture regarding the epidemiology of gram-negative infections including those caused by NFGNB, and perhaps substantially underestimating their true frequency [2], whereas bacteremic infections including catheter-related bacteremia are caused predominantly by skin-dwelling gram-positive organisms in up to 75–80% in some

reports. Gram-negative bacteria predominate at most other sites of infection. Additionally, 80% of polymicrobial infections have a gram-negative component, and 30–35% are caused by multiple gram-negative bacterial species [3, 14].

Consequently, when all sites of infections and polymicrobial infections are taken into account, a substantially different epidemiologic picture emerges, with a greater proportion of infections being caused by gram-negative organisms. The most common sites of bacterial infection in HSCT recipients are depicted in Fig. 26.1. These include urinary tract infections, bacteremia, and respiratory tract infections. Other less common but important sites include the hepatobiliary and intestinal tracts such as cholangitis; neutropenic enterocolitis; perirectal infections; and infections involving pleura, peritoneum, synovium, and meninges.

A number of studies from various parts of the globe have consistently shown that *Escherichia coli*, *P. aeruginosa*, and *Klebsiella* species are the most common gram-negative pathogens isolated from patients undergoing stem cell graft transplantation and solid organ allograft, especially kidney, intestinal, liver, and lung transplantation both in adults and in children [1, 13, 15, 16]. Local and institutional differences do occur. It is therefore important to conduct periodic epidemiologic surveillance studies in order to determine the most current spectrum of infections and antimicrobial drug susceptibility profile of clinically prominent bacteria, particularly at institutions that care for a large number of immunosuppressed transplant population (Fig. 26.2). The rest of this chapter will focus on specific infections caused by NFGNB.

Nonfermentative Gram-Negative Bacilli

Despite the overall decline in the frequency of gram-negative infections in cancer patients, there has been an increase in the proportion of such infections caused by NFGNB [17, 18]. Collectively, NFGNB caused 36–38% of documented gram-negative infections in this setting, a proportion that has steadily increased over the past three decades—Table 26.1 [19–22].

P. aeruginosa is the most frequently isolated and the most important pathogen in this group. Non-*aeruginosa Pseudomonas* species such as *Pseudomonas putida and Pseudomonas fluorescens* are much less common and considered less serious compared with infections due to *P. aeruginosa* [17, 18, 23]. The frequency of infections caused by *S. maltophilia* has risen dramatically over the past two decades and may be related to the widespread use of the carbapenems and broad-spectrum beta-lactams as monotherapy in febrile neutropenic patients [24]. *S. maltophilia* is now the second most common NFGNB isolated from patients being treated in our intensive care unit (unpublished data from the MDACC antimicrobial stewardship program and infection control service). These isolates are often multidrug resistant and appear to be causing infections in patients without classic predisposing factors [25]. *Acinetobacter* species are still relatively uncommon, particularly if only bacteremic infections are considered and poses a serious challenge, as most hospital-onset infections are resistant to a number of broad-spectrum antibacterial drugs. Other NFGNB including *Achromobacter* spp. and *Alcaligenes* spp. are distinctly uncommon but do cause serious infections. These pathogens will be discussed in greater detail below.

Pseudomonas aeruginosa

P. aeruginosa has emerged as a common cause of bacterial infections in neutropenic patients in the 1900s, and before the availability of antipseudomonal agents such as carbenicillin, infections due to *P. aeruginosa* were associated with mortality rates in excess of 90%. Since then, the development of potent antipseudomonal agents such as aminoglycosides,

[a]Abscess formation is uncommon in patients with severe and prolonged neutropenia

penicillins, cephalosporins, and carbapenems along with advances in critical and supportive care have resulted in markedly reduced mortality to less than 20%. Substantial regional and institutional variation in the frequency of pseudomonal infections has been documented [15]. Some institutions have reported a decline in the frequency of infections caused by *P. aeruginosa* possibly related to the use of fluoroquinolone prophylaxis in the high-risk patient population. However, at most major cancer and stem cell transplant treatment centers, *P. aeruginosa* remains among the three most common gram-negative pathogens and causes between 15% and 20% of all gram-negative invasive bacterial disease [1, 2, 10, 11]. Additionally it is the most common gram-negative organism isolated among immunosuppressed patients with polymicrobial bacterial infections [3, 14]. Drug susceptibility and resistance patterns also differ from institution to institution. Consequently, knowledge of local epidemiology and susceptibility and resistance patterns is critical, particularly since the administration of empiric therapy in high-risk patients with fever or suspected sepsis is the standard of care. A recent review of *P. aeruginosa* infection episodes in cancer patients identified several risk factors [26]. Most patients (54%) had an underlying hematologic malignancy; usually a variant of acute leukemia. *P. aeruginosa* bacteremia was 27 times more common in patients with acute leukemia than in patients with solid tumors. During the 2 weeks prior to documentation of *P. aeruginosa* bacteremia, 89% of patients received some form of antineoplastic therapy, prominently myelosuppressive chemotherapy, and 43% underwent an invasive procedure or placement of a medical device such as urinary or intravascular catheter or an ommaya reservoir. Additionally, during the 7 days preceding the onset of *P. aeruginosa* bacteremia, 36% of patients had received antibiotics for presumed or documented infections. The practice of administering intensive chemotherapy in the outpatient setting, and of outpatient-early discharge following hospitalization for the transplantation procedure, has had an impact on *P. aeruginosa* infections. In the study cited above, 50% of patients with *P. aeruginosa* bacteremia were not hospitalized. However, 9% had been discharged during the preceding 3 days, and 25% had been discharged during the preceding week.

The spectrum of clinical disease caused by *P. aeruginosa* is wide (Table 26.2). Pneumonia, primary and catheter-related bacteremia, and urinary tract infections are common. Other serious, often life-threatening infections include neutropenic enterocolitis, perirectal infections, and meningitis. When central venous catheters, or other foreign medical devices are infected, removal of the device, in addition to antipseudomonal therapy, is almost always necessary [27]. Colonization of the respiratory tract often precedes infection. Some experts recommend the use of aerosolized antimicrobial agents, especially the aminoglycosides in addition to systemic agents, in patients with pseudomonal pneumonia, although definitive evidence of the usefulness of this approach is lacking [28]. True abscess formation is uncommon in patients with neutropenia, and surgical incision and drainage are often beneficial in patients with perirectal infections [29]. Complicated urinary tract infections are difficult to cure, especially if foreign bodies such as stents or anatomical diversions are present. Recurrent episodes of infection are common, and long-term suppressive therapy may occasionally be necessary.

P. aeruginosa has the potential for developing resistance to antimicrobial agents by multiple cellular mechanisms of resistance [30, 31]. A recent study demonstrated that the risk factors associated with multidrug-resistant *P. aeruginosa* infections were the use of a carbapenem as monotherapy for >7 days, a history of *P. aeruginosa* during the preceding year, and a history of chronic obstructive pulmonary disease [32]. Data from M.D. Anderson Cancer Center Infection Control and Antimicrobial Stewardship Programs demonstrated that the frequency of multidrug-resistant pseudomonal infections at this institution was 0.16 per 1000 patient

days from 2009 to mid-2011. Consequently, the Antimicrobial Stewardship team started monitoring carbapenem usage since July 2011. Patients receiving carbapenems, except ertapenem, were identified and the primary team caring for the patient were asked to (a) justify further usage of the agent usually based on microbiologic criteria, (b) discontinue the agent, or (c) seek the advice of the consulting Infectious Diseases team for possible alternative treatment options. Compliance with these options was about 70% and resulted in a substantial reduction in carbapenem usage; furthermore, a decline in the frequency of MDR infections to 0.10 per 1000 patient days was encouraging [33].

Table 26.3 Frequency of moderate- to high-grade bacteremia[a] caused by NFGNB in cancer patients at M.D. Anderson Cancer Center

Organisms	Moderate- to high-grade bacteremia No. (%) of isolates

Stenotrophomonas maltophilia

S. maltophilia colonization and infection rates in patients with cancer and HSCT have progressively increased over the past two to three decades. Surveillance studies conducted at the University of Texas M.D. Anderson Cancer Center have documented an increase in the proportion of *S. maltophilia* from 2% of all gram-negative bacilli isolated in 1986 to 7% in 2012. During this period, *S. maltophilia* increased from being the ninth most common gram-negative bacteria isolated to the fifth most common. Patients with prolonged neutropenia, those exposed to broad-spectrum antibiotics, especially the carbapenems, and those requiring mechanical ventilation have a higher risk for such infections [34–36]. The shift from TMP/SMX, which has potent activity against *S. maltophilia* to the fluoroquinolones and are far less active against *S. maltophilia,* as the standard agent for antibacterial prophylaxis in high-risk patients may also have contributed to the rise in infections caused by *S. maltophilia* (K. Rolston – unpublished data). *S. maltophilia* infections are also being documented more often in patients without traditional risk factors [25]. Some of these infections appear to be community onset, as they are being encountered in patients not previously exposed to the healthcare environment. The most common clinical manifestations of *S. maltophilia* infections in HSCT recipients include bacteremia, which is often related to an indwelling intravascular device, pneumonia, tracheitis, or airway anastomosis site infection in lung transplant recipients, skin and skin structure infections, and complicated urinary tract infections that is often noted in patients with obstructive uropathy or presence of indwelling foreign medical devices such as percutaneous nephrostomy tubes, among others [34, 37, 38]. Rapidly progressive hemorrhagic pneumonia is not an uncommon clinical presentation, particularly in patients who have failed to engraft allogenic stem cell infusion and remain severely neutropenic [39, 40]. This condition is often fatal despite prompt therapy and appropriate supportive care. Furthermore, at the author's (K. Rolston) institution, *S. maltophilia* bacteremia has been associated with a significant increase in moderate- to high-grade bacteremia, defined as greater than 100 CFU/ml in quantitative blood culture measurements, and may reflect a heightened severity for these infections (Table 26.3).

Recovery of *S. maltophilia* on microbiological cultures does not always indicate the presence of infection. Skin and intestinal colonization are not uncommon, especially in patients with extensive exposure to healthcare environment. Intestinal colonization may occur after fluroquinolone prophylaxis. In a recent study, *S. maltophilia* intestinal colonization was demonstrated in 10% of hospitalized neutropenic patients [41]. *S. maltophilia* colonization of the respiratory tract occurs frequently in patients with (a) prolonged stay in an intensive care unit, (b) presence of a tracheostomy, (c) prolonged exposure to broad-spectrum antibiotics, and (d) those with cystic fibrosis being considered for lung transplantation. Colonization often precedes infection.

For decades, trimethoprim/sulfamethoxazole (TMP-SMX) has been the agent with the most potent and reliable activity against *S. maltophilia*, but resistance appears to be increasing [42]. Several beta-lactams including ceftazidime, cefepime, ticarcillin-clavulanate, and piperacillin-tazobactam, have been reported to have variable activity, ranging from 35% to 70% against clinical *S. maltophilia* isolates [43]. The organisms are uniformly resistant to the carbapenems and the aminoglycosides also have poor activity against them. The fluoroquinolones have variable activity, with newer agents such as moxifloxacin being more active than ciprofloxacin and levofloxacin [17, 44]. Minocycline and the novel glycycline, like tigecycline, are also active against many *S. maltophilia* isolates [45]. TMP/SMX still represents the agent of choice for the treatment of infections caused by *S. maltophilia*. Some experts recommend high doses of TMP/SMX similar to doses used for pneumonia caused by *Pnemonocysits jiroveci*. Combination regimens based on the susceptibility of individual isolates are often employed.

Acinetobacter baumannii Complex

Acinetobacter baumannii is being increasingly recognized worldwide as a significant cause of morbidity and mortality in hospitalized patients, especially those with hematologic malignancies and neutropenia [46–48]. Many centers are reporting high rates of *Acinetobacter* spp. isolation. In one Brazilian cancer center, *A. baumannii* represented 9.3% of bloodstream infections over a 2-year period [49]. This rate slightly surpassed that of *P. aeruginosa* isolated in clinical specimens. Similarly, at the National Taiwan University hospital, the *A. baumannii* isolation rate was 6%, being higher than those of *P. aeruginosa* and *Enterobacter* spp. [47]. At the National Cancer Institute in Cairo, Egypt, *Acinetobacter* spp. comprised 6.9% of over 770 isolates from patients with hematologic malignancies and/or solid tumors [50]. *Acinetobacter* is also seen in the pediatric population. In one report, 92 bloodstream infections were caused by *Acinetobacter* spp. over a 5-year period, including nearly 50% of cases in children [51].

The clinical manifestations of *Acinetobacter* spp. infection are similar to those seen with other gram-negative bacillary infections, with pneumonia, bacteremia, urinary tract infections, and wound infections being predominant [52–54]. Although having an underlying malignancy is an important risk factor for the development of *Acinetobacter* spp. infection, it is not clear whether patients with cancer have a higher attributable mortality due to these infections compared with non-immunosuppressed oncology population despite the fact that a number of such infections may be due to multidrug-resistant isolates [46, 55].

The rising levels of antimicrobial resistance that have been documented among other gram-negative bacilli are also being seen in clinical *Acinetobacter* isolates [56]. In a large European study of antimicrobial susceptibility of bacterial isolates collected between 2004 and 2007, approximately 16% of the *A. baumannii* isolates were noted to be MDR organisms [57]. Due to the development of MDR gram-negative isolates, older drugs such as colistin and other polymyxin compounds, which have been long disfavored mainly due to systemic drug toxicity, are making a comeback [58]. In an attempt to reduce toxicity and maintain, or even enhance efficacy, strategies such as aerosolized/inhaled colistin administration are being evaluated and, to some extent, have been shown to be successful [59, 60]. Unfortunately, resistance to colistin among *A. baumannii* isolates has also been reported. In a recent study looking at colistin resistance among *A. baumannii* isolates collected from across the globe, 23% were found to be colistin heteroresistant [61]. In another recent study, the in vitro activity of tigecycline, minocycline, and a colistin/tigecycline combination against *A. baumannii* including colistin-resistant strains was evaluated [62]. Tigecycline showed better activity than minocycline even against pandrug-resistant bacterial strains. As with other antimicrobial agents, resistance to tigecycline is emerging [63].

Other NFGNB

Approximately 4–7% of all gram-negative infections in HSCT recipients are caused by other less common, albeit clinically important NFBNB such as *Achromobacter* species, *Alcaligenes* species, *Burkholderia* species, *Chryseobacterium* species, and non*aeruginosa Pseudomonas* species like *P. fluorescens* and *P. putida*. *Achromobacter* sp. and *Alcaligenes* species are ubiquitous organisms and most infections can be traced to sources such as contaminated dialysis fluid, chlorhexidine solution, deionized water, mechanical ventilators, and incubators [64]. Patients with cancer, those undergoing HSCT or solid organ transplantation, and those with HIV/AIDs or other immune compromised states are at increased risk. These infections are often life threatening. The most common clinical manifestation is primary uncomplicated bacteremia, although infected indwelling catheters and other foreign medical devices, pneumonia, and meningitis have also been reported. Although uncommon, the clinical importance of these organisms has increased in recent years, as they may occur in outbreak clusters and due to infecting organisms may not be susceptible to commonly used antibiotics.

These organisms are uniformly resistant to the fluoroquinolones, and the impact of near-universal use of fluorinated quinolone prophylaxis in HSCT and high-risk solid organ allograft recipients, the frequency of such infections, needs to be formally studied. Most isolates are susceptible to TMP-SMX, and the frequency of these infections appears to have increased, albeit slowly, since TMP-SMX was abandoned in favor of the quinolones for routine antibacterial prophylaxis [65]. Most isolates are also susceptible to the carbapenems. Of concern is the detection of IMP-type metallo-B-lactamases from these organisms in the past decade, conferring carbapenem resistance [66]. Some combination regimens have been shown to be synergistic in vitro and may be preferred for therapy in neutropenic patients with severe sepsis and multiorgan dysfunction [67].

Burkholderia cepacia complex (BCC) are opportunistic pathogens that occasionally cause outbreaks in patients with cancer including HSCT recipients [68, 69]. These outbreaks can generally be traced to contaminated intravenous solutions, disinfectants such as chlorhexidine and povidone–iodine solutions, ultrasound gel, mouthwashes, and aerosols [70]. Infection of central venous catheters is common. The organisms are often susceptible to TMP-SMX, the carbapenems, fluroquinolones, and extended-spectrum cephalosporins including cefepime, ceftazidime and semisynthetic penicillin such as piperacillin, piperacillin-tazobactam. These infections are especially of concern among patients with advanced cystic fibrosis and those undergoing lung transplantation with severe long-standing structural lung disease. Presence of biofilm plays an important role in prolonged BCC colonization of the respiratory tract in such induvuduls and poses a serious risk of potentially life-

threatening infection of the pulmonary allograft following transplantation. Aerosolized aminoglycoside have played an important role in ameliorating this complication and recurrent infections due to *B. cepacia* complex. Early recognition of outbreaks and strict implementation of infection control measures, once an outbreak has been identified, is an essential component of management.

Chrysobacterium species such as *Chrysobacterium meningosepticum* and *Chrysobacterium indologenes* are rare pathogens; however, life-threatening infections such as bacteremia, pneumonia, and meningitis, especially in immunocompromised individuals, may occasionally be seen [71–74]. Previously considered *Flavobacterium* species, some C*hrysobacterium* species, have now been regrouped as *Elizabethkingia* gen. nov., which was based on 16s r RNA gene sequencing analysis with the names as *Elizabethkingia meningoseptica* and *Elizabethkingia minuscola* [75]. They are waterborne, saprophytic microorganisms, ubiquitous in nature including plants, water, soil, and the hospital environment. Primary and catheter-related bacteremia, pneumonia, meningitis, and skin and skin structure infections have been reported [76]. *E. meningoseptica* displays a strong biofilm-forming phenotype, which may play a role in its pathogenicity [77]. Carbapenem resistance has been described and appears to be mediated by metallo-B-lactamase Bla B [78]. The organisms are susceptible to TMP-SMX, fluoroquinolones, rifampin, minocycline, tigecycline, vancomycin, and piperacillin-tazobactam [79–81]. The overall mortality is approximately 25%, and combination drug therapy may be the prudent option in most cases [82].

P. fluorescens and *P. putida* are members of the fluorescent-pseudomonad group. Unlike *P. aeruginosa*, these organisms have low levels of inherent virulence. They do colonize the skin in some individuals and can cause pseudo-bacteremia and procedure-related infections [83]. The association between *P. fluorescens* and contaminated blood products has been well established [84–86]. They are also present in commercial bottled water, which can be a source of infection in neutropenic HSCT recipients [87–89]. Catheter-related bacteremia and pneumonia are the most common clinical manifestations [23]. Carbapenems have the most reliable activity against these organisms. The activity of other beta-lactams and fluoroquinolones is variable [17]. The overall mortality associated with these organisms is low. Many patients respond to the removal of the offending catheter alone, and most respond to appropriate antimicrobial therapy.

Anaerobic Gram-Negative Bacterial Infections

Stem cell and solid organ transplantation is a lifesaving medical intervention in patients with aggressive hematologic malignancies and end-stage solid organ dysfunction and organ failure [90–94]. Iatrogenic drug-induced immune suppression is needed for the maintenance of a functioning solid organ allograft; to harness and sustain the delicate balance between potentially devastating graft-versus-host disease and the much desired, allogenic stem cell-assisted graft-versus -leukemia/lymphoma or antitumor effect; the resultant immune suppression contributes significantly toward hosts' susceptibility for opportunistic infections [94–99]. In patients undergoing solid organ transplantation, surgical site and deep tissue infections are mostly seen during the early (≤1 month) post-transplantation period [90]. Most bacterial infections in such patients, despite having severe immune defects, are due to conventional aerobic bacteria. Anaerobic gram-positive or gram-negative bacteria, on the other hand, are a seldom cause for systemic disease. In this section, a brief review of anaerobic infections is provided.

In prior reports, the four prominent anaerobic bacterial genera isolated from HSCT recipients included *Propionibacterium* spp. [100], *Bacteroides* spp. [101], *Clostridium* spp. [102], and *Prevotella* spp. [96]. Whereas, in patients undergoing solid organ transplantation, *Bacteroides* spp. [97], *Clostridium* spp. [92], and *Prevotella* spp. [92] are dominant anaerobic bacterial genera isolated.

Stem Cell Transplantation

In a retrospective 4-year review of BSIs following HSCT, 17% of infections were due to anaerobic bacteria [103]. In this report, *Fusobacterium nucleatum* (n = 17) followed by *Leptotrichia buccalis* (n = 4) were prominent, whereas *Clostridium septicum* (n = 1) and *Clostridium tertium* (n = 1) were rarely isolated [103]. Presence of severe mucositis was associated with a greater than fourfold higher probability of infection due to anaerobes [102–104]. Interventions that reduce severity and duration of early post-transplant mucositis are important factors for risk mitigation for such infections [103]. This was supported by higher frequency of invasive bacterial infections due to commensal anaerobic bacteria noted during mid and late 1990s, a period during which high-dose methotrexate was routinely used for pre-HSCT conditioning and its well-established risk for debilitating mucositis. Furthermore, others have observed an association between the risk of post-transplant bacteremia and high-dose preparatory conditioning regimens given prior to transplantation [105].

A novel anaerobe, *Leptotrichia hongkongensis,* was isolated in five of eight patients with multiple myeloma undergoing autologous stem cell infusion after high-dose chemotherapy. This commensal bacterium that primarily resides in the orointestinal and female genital tracts is difficult to isolate in routine laboratory anaerobic cultures. Molecular diagnostic assays are needed for identification and confirmation of this fastidious pathogen [105, 106]. *Leptotrichia* infections are rare in the general population;

risk for these uncommon pathogens increases in patients with suppressed immune response and along with other risk factors stated earlier for invasive anaerobic bacterial disease [107, 108]. It is important to emphasize that on Gram staining, *Leptotrichia* may be misidentified as a gram-positive rod and disregarded as probable *Bacillus* spp. contamination [109]. Along with other difficult-to-culture pathogens, 16S rRNA analysis has become the gold standard in the diagnosis of *Leptotrichia* spp. infection [110, 111].

Patients with impaired cell-mediated immune response are at an increased risk for *Legionella* spp. infection. In recipients of allogeneic stem cell or solid organ transplantation, legionella infection frequently presents as serious systemic illness involving lungs as well as life-threatening extra-pulmonary disease. In transplant patients with *Legionella pneumophila* infection, secondary infection(s) may involve an anaerobic bacteria such as *Prevotella* spp. [112]. As with other immunosuppressed patients, those undergoing transplantation, who develop lung abscess or empyema, a heightened awareness for polymicrobial infection with mixed aerobic and/or anaerobic bacteria will assist in appropriate empiric selection of antibiotics. The authors are of the opinion that early surgical therapeutic drainage of lung abscesses and empyema will also provide a desirable specimen for microbiological diagnosis. When anaerobes are suspected, use of advanced molecular diagnostic assays such as 16SrRNA analysis will improve the diagnostic yield compared with conventional anaerobic laboratory culture methods.

Acute GVHD is a serious complication after allogeneic stem cell transplantation. The composition of the intestinal microflora of patients, especially prevalence of anaerobic microbiota, was investigated as a potential predictor for the risk of acute GVHD [113]. A favorable impact for GVHD risk in nonprimates and nonhuman primates was demonstrated by creating a germ-free or decontaminated intestinal microenvironment [114–116]. Results of these experiments encouraged clinical evaluation for such interventions in patients undergoing allogeneic HSCT. In 194 patients undergoing identical sibling bone marrow stem cell transplantation, influence of intestinal bacterial decontamination and strict isolation protocol on the risk of moderate to severe acute GVHD was assessed [113]. Acute GVHD was noted in 23% of patients after a median of 33 days following transplantation; sustained suppression of intestinal anaerobic bacteria microflora favorably influenced the cumulative incidence of acute GVHD in this study ($P < 0.006$) [113]. Further large scale clinical assesssment is needed for validation of this hypothesis.

Intestinal anaerobic microflora from the domain Archaea are methanogens or methane producers that have evolved to adapt to extremes of environment conditions. The predominant methanogen in the human intestinal tract is a gram-negative anaerobe, *Methanobrevibacter smithii* [117]. These bacteria are nonsusceptible to most antibiotics, although they retain susceptibility to metronidazole [118]. Metronidazole prophylaxis has been associated with reduced frequency of moderate to severe acute GVHD [119, 120]. The underlying hypothesis is based on reduced immunostimulation caused by bacterial products, especially by methanogens. Eleven of 13 patients undergoing HSCT treated with metronidazole showed reduced methane gas in feces [121]. In all 11 patients with post-metronidazole treatment-negative fecal methane detection observed at 2 and 5 weeks after transplantation, risk for acute GVHD was significantly modified [121]. The authors caution regarding drug-induced suppression of anaerobic microbiota in the lower intestinal tract, especially in the immunosuppressed patients undergoing allogeneic stem cell transplantation. The extended alteration in homeostasis of patients' intestinal microflora may compromise the physiologic protection proffered by the gram-negative anaerobes in the large intestine, thereby creating a niche for colonization and subsequent disease due to microoragnisms such as MDR GNB, vancomycin-resistant enterococci and exotoxin-producing *Clostridium difficile*, to name a few.

Solid Organ Transplantation

In the past three decades, overall survival and quality of life after solid organ allograft transplantation have greatly improved. Advances in surgical techniques, sophistication in prevention and treatment of allograft rejection, progress in infection prophylaxis and management, and additionally improved comprehensive supportive care have all contributed favorably toward this trend. Infections are either due to microorganisms that are endogenous to the host microbiota or acquired from the environment of patients [122]. The overall frequency of infection varies among various solid allograft recipients: 33–68% after liver transplantation; 21–30% after heart; 35% following pancreas; 47% in kidney; and 54% in patients undergoing lung transplantation [90]. Enteric pathogens such as *Enterococcus* spp. and gram-negative aerobic and anaerobic bacteria are prominent bacterial pathogens in patients after liver transplantation. In many transplant centers, selective bowel decontamination sparing the gut anaerobic flora has been used to reduce the risk for early post-transplant infections due to aerobic gram-negative bacteria; this is an important consideration in patients who are considered at increased risk for such infections [123, 124]. However, the data supporting selective bowel decontamination as a routine practice remain controversial. Furthermore, concern for selection and colonization with drug-resistant pathogens like MDR *Pseudomonas*, extended-spectrum beta-lactamase-producing *Enterobacteriaceae*, vancomycin-resistant enterococci, yeast overgrowth, and expansion of microaerophilic gram-positive bacteria like *Lactobacillus* spp. are a hypothetical, albeit, serious concern [125, 126]. It is appealing that selective bowel decontamination has shown reduced risk for GNB infections during the early post-transplant period in patients undergoing solid organ allograft transplant surgery [100, 101, 127–130].

In 103 patients following orthotopic liver transplantation, half of 115 bacterial infections observed in 68% of patients were noted within 2 weeks following transplant surgery [131]. Among 190 organisms recovered from 115 infection sites, gram-negative bacteria as expected were common (65%), with *E. coli* being the most prominent aerobic gram-negative pathogen. *Enterococcus* spp. were prevalent in 38% of gram-positive organisms. Eight percent anaerobes other than *C. difficile* included 4% *Bacteroides fragilis*. It is important to recognize that polymicrobial infections were observed in 37% of the episodes [131]. Intra-abdominal infections were common (69%), followed by surgical wounds (42%) and lung infections (36%) [131].

Pulmonary infections are considerably prominent in patients undergoing heart and heart–lung transplantation [132, 133]. In 12 heart–lung allograft recipients, 29 infection episodes accounted for 2.4% of infections per patient [133]. Among 18 of 29 bacterial infections, only one episode was due to *Bacteroides melaninogenicus* and presented as polymicrobial infection with aerobic bacteria. In the recipients of heart–lung allografts, anaerobic bacterial infections are often related to transtracheal and transthoracic aspiration; however, these infections are rarely observed [133].

The incidence of urinary tract infections after allograft renal transplantation ranges from 28% to as high as 90% in high-risk subgroups. Bacterial contamination of cadaveric renal grafts may be as high as 25%, although its association with post-transplant graft pyelonephritis is not convincing. In an earlier study, UTIs in renal transplant population due to anaerobic bacteria were 8%, which included *B. fragilis* and *B. melaninogenicus*; aerobic bacteria accounted for 24% of infections [134]. It appeared that most of these anaerobic infections were seen in patients following cadaveric renal grafts and associated with infections in the early post-transplant period; in contrast, post-transplant UTIs due to anaerobic bacteria were not noted following living donor renal graft transplantation. Since the introduction of routine prophylaxis with trimethoprim–sulfamethoxazole (TMP-SMX) in patients receiving comprehensive antirejection regimens after kidney transplantation, the overall frequency of bacterial UTIs with or without concurrent bacteremia have declined significantly [135–137].

Newer Agents

The emergence of resistant gram-negative bacilli including NFGNB as well as the *Enterobacteriaceae* created substantial therapeutic problems as outlined in several monographs and publications [8, 9]. These problems were made worse by the fact that new drug developments had come to a virtual standstill. In response to this, a global initiative termed "the 10 by 20 initiative" was launched with the goal of developing 10 agents with activity against resistant microorganisms by the year 2020 [138]. This initiative has encouraged the development of several novel agents, some of which have been approved by the FDA while others are in advanced stages of development (Table 26.4). Many of these agents have provided newer options for the treatment of resistant gram-negative infections and, to some extent, have replaced or supplanted older and more toxic agents such as the polymyxins [139]. Unfortunately, there already are reports of resistance to some of these newer agents**,** which have raised caution and as with all other antimicrobial agents, in vitro susceptibility should be performed when an infection-causing GNB is isolated in cultures [140–142]. It is important to recognize the advantage the new combination drugs offer against bacteria; they have acquired capability to produce serine carbapenemase including KCP, extended-spectrum beta-lactamase, and MDR *Pseudomonas*; these drugs, however, lack activity against metallo-beta-lactamase-producing organisms, including bacteria that are mostly seen as sporadic, nonoutbreak infections in the US hospitals [142]. Additional agents that are in early stages of development are in the pipeline and continue to provide hope for the future.

Table 26.4 Newer agents for the treatment of gram-negative bacterial infections[a]

Beta-lactam/beta-lactamase inhibitor combinations
Ceftazidime/avibactam[b]
Ceftolozane/tazobactam[c]
Meropenem/vaborbactam[c]
Imipenem-cilastatin/relebactam
Aztreonam/avibactam
Other agents
Cefiderocol (a novel siderophore cephalosporin)
Plazomicin (aminoglycoside derivative)
Eravacycline (a synthetic tetracycline derivative)

[a]Several other agents are in earlier phases of development (Phases 1 and 2)
[b]Ceftazidime/avibactam has been approved by the US Food and Drug Administration (FDA) and the European Medicines Agency
[c]Ceftolozane/tazobactam and meropenem/vaborbactam have been approved by the US FDA

Summary

An increasing proportion of bacterial infections in patients following stem cell and high-risk organ allograft recipients are due to NFGNB, which is despite the overall decline in the frequency of microbiologically proven invasive gram-negative bacterial disease in the immunosuppressed population. The spectrum and clinical manifestations of these infections are similar to those caused by *Enterobacteriaceae*. A common theme among many NFGNB is the development of resistance to multiple antimicrobial agents. Strategies to combat these infections include (a) judicious use of currently available antimicrobial agents with assistance and adherence to the antimicrobial stewardship protocols; (b) encourage and promote development of novel antimicrobial drug classes with nonre-

dundant target of antibacterial activity, (c) revival of older antimicrobial agents with combination of novel classes of antibacterial hydrolyzing enzyme inhibitors, (d) development of novel antimicrobial agents, and (e) strict adherence to infection prevention guidelines and infection control policies designed to limit the spread of such infections, when they do occur. Nevertheless, infections caused by NFGNB, especially in the highly diverse and complicated transplant population, will continue to challenge clinicians in the foreseeable future.

Nocardiosis and Actinomycosis

27

Heather E. Clauss and Bennett Lorber

Nocardiosis

Microbiology

Nocardia are informally known as "aerobic nocardioform actinomycetes," along with *Corynebacterium*, *Gordonia*, *Rhodococcus*, *Tsukamurella*, *Actinomadura*, and *Mycobacterium* [1]. There are more than 50 known species of *Nocardia*, less than half of which are human pathogens. Newer molecular methods of identification have expanded the spectrum of *Nocardia* species known. The most important causes of *Nocardia* infection in transplantation are *Nocardia asteroides* sensu stricto, *N. nova*, *N. farcinica*, and *N. brasiliensis* [2]. *Nocardia asteroides* sensu stricto are distinct from "*N. asteroides* complex," which is an older designation.

Typical findings on Gram stain include gram-positive, beaded, branching rods with acute pyogenic inflammatory reaction. Sulfur granules may be found in nocardial lesions, similar to those seen in actinomycosis.

There are several known virulence factors that play a role in the pathogenesis of nocardiosis. One of the most important factors is *Nocardia*'s cell wall and its components, including peptidoglycan and mycolic acid polymers. Another factor in virulent *Nocardia* strains is the innate resistance to neutrophil-mediated killing. *Nocardia* have resistance to the oxidative burst within the phagosomes of neutrophils and macrophages. There is a well-documented association between nocardiosis and chronic granulomatous disease (CGD) for this reason [3]. Also, pathogenic *Nocardia* species secrete superoxide dismutase (SOD) into growth media, while nonpathogenic species do not [4]. This contributes to the protection of *Nocardia* species within the host. Finally, the ability of some *Nocardia* species to exhibit tropism for the cerebral tissue is evident and may vary between strains.

The response of the host to *Nocardia* species is determined by the portal of entry of the organism, the tissue tropism, growth rates in vivo, and the ability to survive the phagocytic attack. The key host defenses against developing nocardiosis are T cell mediated. There is little effective humoral response.

Epidemiology

Nocardia are ubiquitous in the environment, living in soil, water, and vegetable matter. Infection occurs most commonly via inhalation, with hematogenous dissemination to other tissues including the brain. Also, direct inoculation of the skin can occur via penetrating injuries. *Nocardia* infections have increased in the last 20 years, due to both increased detection and identification by molecular methods and the expanding use of immunosuppressive agents [1]. The use of immunosuppressive medications is the hallmark of organ transplantation, and these procedures have increased in recent years. *Nocardia* are considered opportunistic pathogens, causing infection in patients with impaired cell-mediated immune response, including patients with organ transplantation, lymphoreticular neoplasia, HIV/AIDS (CD4 counts <100 cells/mm^3), diabetes mellitus, alcoholism, and patients treated with chronic corticosteroid therapy. More than 60% of *Nocardia* cases occur in these settings [5]. *Nocardia* cases in transplant recipients typically occur within the first year following transplantation, although cases in the first month, prior to the period of heaviest immunosuppression, following transplant are rare. However, if aggressive immunosuppression is used, this diagnosis should be considered even in the first month posttransplant. However, in a published 30-year experience of 19 cases of *Nocardia* in 4600 adult solid organ transplants, 2 occurred after 1 month, 4 after more than 3 months, and 13 after over 1 year [6].

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_27

The incidence of *Nocardia* infection varies somewhat by the organ transplanted. In a review of over 5000 transplant recipients, lung transplant recipients had the greatest incidence of *Nocardia* (3.5%), followed by heart (2.5%), intestine (1.3%), kidney (0.2%), and liver (0.1%) recipients [7]. The overall rate of *Nocardia* in this group, from 1995 to 2005, was 0.6%. These numbers were similar to a 30-year experience in Spain of 4600 adult solid organ transplants where lung transplant recipients had a slightly higher incidence (1.78%) than heart recipients, renal recipients, and liver recipients (0.65%, 0.26%, and 0.18%, respectively) [6]. Lung transplant recipients may have a higher rate of this infection due to the fact that the respiratory tract is the natural access route and also the higher immunosuppression given to lung transplant recipients. In the first paper mentioned, the species of *Nocardia* causing infections in transplant recipients were as follows: *N. nova* in 49%, *N. farcinica* in 28%, *N. asteroides* in 23%, and *N. brasiliensis* in 3% [7].

Risk Factors

Several risk factors for *Nocardia* infection in organ transplant recipients were determined via a matched case control study. These include receipt of high-dose steroids, a high median calcineurin inhibitor level in the preceding 30 days (15 mcg/mL for tacrolimus and >300 ng/mL for cyclosporine), and cytomegalovirus (CMV) disease in the preceding 6 months [7]. In another paper, CMV coinfection was present in 53% of *Nocardia* cases, 47% of cases were dialysis patients, and 26% of cases had diabetes mellitus [6]. Newer immunosuppressive therapies may also be risk factors for *Nocardia* infections. First, alemtuzumab, a humanized monoclonal antibody against CD52 found on B and T lymphocytes, monocytes, and natural killer cells, is being used commonly as induction immunosuppression prior to solid organ transplantation as well as treatment for rejection. It causes lymphopenia and is most commonly associated with CMV infection but also is associated with *Nocardia* infections [8]. Rituximab is a monoclonal antibody directed against the CD20 antigen found on B cells and has been used to treat or prevent antibody-mediated rejection. This agent has been described as a risk factor for cerebral nocardiosis in a non-transplant recipient [9]. Additionally, hypogammaglobulinemia in the setting of transplant immunosuppression has been implicated as a risk factor for the development of *Nocardia* infections [10]. These are intriguing findings, given that there is thought to be little humoral response to *Nocardia* infection. Perhaps, antibody-dependent cellular cytotoxicity plays more of a role in the defense against nocardiosis. Finally, there have been reports of *Nocardia* infections in patients with rheumatologic diseases treated with tumor necrosis factor (TNF) blockers [11].

Clinical Syndromes

Clinical syndromes caused by *Nocardia* species include pulmonary masses, nodules, infiltrates and cavities, brain abscesses, systemic disease, and nodular lymphangitis. Primary infection occurs via inhalation or direct inoculation of skin and soft tissues. Then, bloodstream dissemination can cause metastatic infection throughout the body, most commonly to the central nervous system (CNS). Sites of metastasis can include virtually any other anatomic site.

The most important site of primary infection is the lung. Pulmonary nocardiosis is the predominant clinical manifestation, seen in over 40% of nocardiosis cases in organ transplant recipients [7]. The *N. asteroides* complex are the main species causing pulmonary nocardiosis. Common clinical symptoms include a subacute course (from days to weeks) of fever, cough, purulent sputum production, malaise, anorexia, dyspnea on exertion, and sometimes pleuritic chest pain. Oxygenation is usually preserved at rest until disease has advanced. This is commonly a suppurative infection but may be granulomatous. Chest radiograph findings can include focal or multifocal disease, nodules, or consolidations that can progress to cavities [12]. Additionally, there can be necrotizing lung abscess and cavitary disease with contiguous extension to the surface and deep structures, including effusion and empyema. The "halo sign," typically associated with pulmonary aspergillosis, has been described [1]. On bronchoscopy, endobronchial masses can be visualized in some cases. In one Spanish study, predisposing conditions for 31 pulmonary nocardiosis patients were transplantation (29%), HIV infection (19%), and treatment with steroids (64.5%) [13]. In this study, the median time to diagnosis was 42 days, and the mortality rate for pulmonary nocardiosis was 41% and 64% for disseminated nocardiosis. Progressive fibrosis may develop if pulmonary nocardiosis is incorrectly or inadequately treated. This infection should be considered in the differential diagnosis of indolent pulmonary disease in organ transplant recipients. Evidence pointing to a diagnosis of pulmonary nocardiosis may be spread of infection to contiguous structures within the chest.

Disseminated infection involving two or more body sites can occur in nocardiosis. There is local and hematogenous spread, but *Nocardia* species are isolated from blood cultures only rarely. When *Nocardia* species are isolated from patients, it is typically in association with central venous catheters, not disseminated disease. *Nocardia* species can erode into blood vessels and disseminate to the retina, skin, subcutaneous tissues, kidneys, joints, bones, and heart. Most commonly, *Nocardia* species spread to the CNS.

Nocardia species have a particular tropism for the brain and spinal cord. In all cases of pulmonary and disseminated nocardiosis, an MRI of the brain should be performed to evaluate for CNS infection. The differential diagnosis of

pulmonary-CNS syndromes in organ transplant recipients includes *Nocardia*, *Cryptococcus*, *Aspergillus*, *Rhodococcus*, and posttransplant lymphoproliferative disease (PTLD).

CNS involvement is seen in 44% of cases of disseminated nocardiosis. A third of *Nocardia* cases in the literature involved the CNS without evidence of other infections [5]. CNS lesions can be seen throughout the brain, and there may be meningitis with or without involvement of other portions of the brain and spinal cord. Clinical presentation is usually subacute to chronic (months to years), as with the pulmonary infection. Location of the abscess or granulomas determines the clinical manifestations seen in patients with CNS nocardiosis. Chronic behavioral and psychiatric disturbances can be seen. Tissue diagnosis of a brain mass may not be necessary in the setting of pulmonary nocardiosis [12]. However, one should consider brain biopsy for definitive diagnosis in an organ transplant recipient with an isolated CNS lesion, as the differential diagnosis is broad and includes many bacterial, mycobacterial, fungal pathogens, PTLD, and other malignancies and rarely *Acanthamoeba* or toxoplasmosis.

Nocardia species can also cause cutaneous, subcutaneous, and lymphocutaneous (sporotrichoid) disease following direct, traumatic inoculation of the organism into the skin. *N. brasiliensis* is the most common case of these conditions. These can occur after animal or insect bites, puncture wounds, and contaminated abrasions [1]. These may appear to be *staphylococcal* abscesses, which are much more common. The diagnosis of *Nocardia* may be confused or missed. In transplant patients, self-limited infections may be treated initially as *staphylococcal* abscesses, but if these do not improve, less common infections such as cutaneous nocardiosis should be considered. Mycetomas can form, which can be suppurative or necrotic and may form sinus tracts. *Nocardia* can spread through the lymphatics causing sporotrichoid nocardiosis in immunocompromised hosts. Inoculation injuries can also occasionally affect the cornea [1].

Nocardiosis in Cancer Patients and Hematopoietic Stem Cell Recipients

In a study at MD Anderson Cancer Center conducted between 1988 and 2001, 42 cancer patients were diagnosed with nocardiosis, in the first large series of patients of this type [14]. Twenty-seven (64%) patients had hematologic malignancies, and in 13 patients, nocardiosis complicated bone marrow transplantation (BMT). Patients had received steroids in 25 (58%) episodes of nocardiosis and had received chemotherapy within 30 days before the onset of nocardiosis in 10 (23%) episodes. Pulmonary nocardiosis was diagnosed in 30 of 43 cases (70%), while only 1 (2%) patient developed CNS nocardial infection. The mortality rate in this study was 60%.

In bone marrow transplant patients at one institution, the rate of nocardiosis was 1/554 (0.2%) among autologous BMT recipients and 5/302 (1.7%) in allogeneic BMT recipients from 1980 to 1994 [15]. All but one of the six cases had graft-versus-host disease. Four of the cases had extensive exposure to soil or dust prior to their nocardial infection. Also, nocardial infection in this BMT population was associated with a high rate of invasive fungal infection. In a retrospective study of 27 patients with nocardiosis at 3 centers, the median time to the diagnosis of nocardiosis after bone marrow transplantation was 210 days, and all of the infections occurred in allogeneic marrow recipients [16]. In this paper, 96% of the isolates were *N. asteroides* complex. The survival rate from *Nocardia* infection was 84%. Forty percent of these patients had taken trimethoprim-sulfamethoxazole (TMP-SMX) regularly prior to developing nocardiosis. Interestingly, 3/6 patients in the first paper mentioned developed nocardiosis despite taking TMP-SMX for *Pneumocystis jiroveci* prophylaxis. TMP-SMX may not be protective against nocardial infections in immunosuppressed patients the same way it is protective against *Listeria monocytogenes* and other gastrointestinal and genitourinary infections.

Diagnosis

The mainstay of diagnosing nocardiosis is to inform the laboratory this diagnosis is being considered. The diagnosis can be missed by routine laboratory methods. The organism must be isolated from a clinical specimen, noting that *Nocardia* species are not common lab contaminants or oral flora. However, some patients with chronic lung disease can have transient nocardial carriage which must be interpreted with caution. Often this diagnosis requires an invasive procedure such as a lung biopsy, skin biopsy, or brain biopsy. All biopsies should be evaluated by Gram stain, modified acid-fast staining, culture, and pathology. Gram staining can reveal fine gram-positive, beaded, branching rods surrounded by white blood cells. Acid-fast staining by modified Kinyoun stain can be weakly positive. Blood cultures for *Nocardia* species require prolonged incubation (up to 14 days), and selective media such as Thayer-Martin agar or Buffered Charcoal Yeast Extract (BCYE) agar should be used. The organism will grow in 3–5 days. Molecular methods may be needed to accurately identify species of *Nocardia*. It is important to accurately identify the species causing infection in order to predict antimicrobial susceptibility. Techniques that have been developed include ribotyping, polymerase chain reaction (PCR), restriction fragment length polymorphism (RFLP) analyses, and DNA sequencing [2]. There is genetic variation within the *Nocardia* heat shock protein 65 (hsp65) gene and the 16S rRNA gene region that can be used in these analyses [1].

Treatment

The mainstay of treatment of nocardiosis is antibiotic therapy. The Transplant Infectious Disease Guidelines published in 2009 recommend antimicrobial susceptibility testing for all nocardial isolates against amikacin, amoxicillin-clavulanate, ceftriaxone, ciprofloxacin, clarithromycin, imipenem, linezolid, minocycline, TMP-SMX, and tobramycin [17]. TMP-SMX is the preferred treatment for most forms of nocardiosis, given its high tissue concentrations in the lungs, brain, skin, and bone [18]. The recommended dosage is 15 mg/kg of TMP divided into 3–4 doses/day. Higher doses are used for patients with high disease burden in the central nervous system. Side effects include nausea and vomiting (especially with oral therapy) and rash but can include more serious issues such as myelosuppression, hyperkalemia, and erythema multiforme. Of note, some species of *Nocardia* are sulfonamide resistant, such as *N. farcinica* and *N. nova*.

In immunosuppressed patients and patients with CNS involvement or disseminated disease, the combination of imipenem/cilastatin and amikacin is recommended empirically until sensitivities are known [17]. There may be synergism between these agents. The toxicities of imipenem include rash and seizures, while the toxicities of amikacin include renal failure and ototoxicity. Of note, there may be enhanced nephrotoxicity in patients taking aminoglycosides in conjunction with calcineurin inhibitors. Meropenem may be a better choice for those patients with CNS disease, as there is good blood-brain barrier penetration and fewer seizures with this agent. Also, meropenem may have better activity against *N. brasiliensis*, but it may be less active against *N. asteroides* complex organisms than imipenem [17]. Ertapenem has significantly less activity in vitro than imipenem and meropenem [19].

Another option for treating CNS nocardiosis includes third-generation cephalosporins such as ceftriaxone and cefotaxime [17]. There are case reports of their success, usually in combination with other agents [20]. There are minimal side effects to these medications. Minocycline has been used as an alternative to TMP-SMX for *Nocardia* treatment, at doses of 200 mg twice daily orally or intravenously [21]. However, several strains of *Nocardia* are resistant, so susceptibility testing should be used to determine if this antibiotic would be successful. Toxicities include photosensitivity, dizziness, nausea, and ulceration of the esophagus. A 2003 report describes six cases of nocardiosis, including CNS infection, successfully treated with linezolid [22]. The dosage is 600 mg twice daily, either intravenously or orally. Side effects include nausea and rash, as well as more severe adverse effects such as thrombocytopenia, aplastic anemia, peripheral neuropathy, and lactic acidosis.

Surgical drainage should be considered in patients with cerebral disease and maybe other large soft tissue abscesses. In patients with CNS abscess, drainage should be considered when the patient's condition deteriorates, if the abscesses are accessible and relatively large, if the lesions progress despite 2 weeks of therapy, or if there is no reduction in abscess size within a month of therapy [23]. Surgical therapy should be performed in conjunction with pharmacologic treatment.

Common recommendations for treatment of nocardiosis include 3–4 weeks of intravenous therapy, followed by several months of oral therapy, especially in particularly ill patients [1]. In patients with CNS infection, a minimum of 9–12 months would be appropriate [17]. Pulmonary and soft tissue infection can be treated within 6–12 months depending on the response to therapy [17]. If graft rejection and increased immunosuppression are required, therapy may need to be extended to 12 months or longer. Patients with cerebral *Nocardia* infection should have repeat CT or MRI of the brain to follow the response to therapy.

Prevention/Prophylaxis

Primary prophylaxis against *Nocardia* infections is not indicated due to the low overall incidence of nocardiosis; however, some centers initiate secondary prophylaxis for this infection. One study suggests that when solid organ transplant recipients take TMP-SMX daily to prevent *Pneumocystis jiroveci* pneumonia, it reduces the rate of nocardiosis [24]. This observation has also been made in the HIV-infected population. However, as discussed above, in two studies of nocardiosis in bone marrow transplant recipients, 40–50% of patients who developed nocardiosis were taking TMP-SMX prophylaxis [15, 16]. Also, in a study of *Nocardia* infection in solid organ transplant recipients, 69% (24/35) of the patients developed their infection while on TMP-SMX [7]. On univariate analysis in this paper, TMP-SMX was not shown to be protective against the development of nocardiosis. This may be because organ transplant recipients tend to take a regimen of TMP-SMX two to three times per week or because of the strength of posttransplant immunosuppression combined with the coexistence of opportunistic infections in this population. Many breakthrough infections in patients taking TMP-SMX cast doubt on its prevention of nocardiosis in the transplant population.

Cure Rates/Prognosis

Clinical improvement of nocardiosis should be expected within 3–5 days from the initiation of appropriate therapy, at least within 10 days [25]. Reasons for failure of initial antimicrobial therapy include inadequate penetration of drug to the site of infection, primary drug resistance, or a focus of infection requiring surgical drainage. In organ transplant

recipients, reasons could also include a coexisting opportunistic infection or overwhelming nocardial sepsis. Nearly 100% of cutaneous nocardiosis is treated successfully while pulmonary nocardiosis slightly less so (90%). In one study, 31/35 cases (89%) of both pulmonary and disseminated nocardiosis, including CNS infection, were cured [7]. Of note, most transplant patients are cured despite immunosuppression being continued.

Infection Control

Inhalation of *Nocardia* species from environmental sources is the main route of transmission, followed by direct inoculation via penetrating cutaneous injury. There have been reports of outbreaks of nocardiosis around construction sites; however, most infections are sporadic in nature [5]. Also, reports of nosocomial outbreaks of *Nocardia* infection have been published, but did not include strain testing with molecular methods to document the relationship between infections [3]. Person-to-person transmission and common source environmental transmission have been shown by pulsed-field gel electrophoresis in healthcare facilities [26]. However, there is no data to support respiratory isolation of patients with nocardiosis while they are in a hospital, and there is no effective measure to prevent inhalation. It is controversial if TMP-SMX reduces the incidence of *Nocardia* infections in high-risk transplant recipients.

Actinomycosis

Microbiology

Actinomycetes are gram-positive branching rods which are anaerobic or microaerophilic. On Gram stain, these are indistinguishable from *Nocardia*; however, *Nocardia* will weakly stain with an acid-fast Kinyoun stain, while actinomycetes will not. The most common species causing human disease is *Actinomyces israelii*. Less common species that cause actinomycosis include *A. naeslundii*, *A. odontolyticus*, *A. viscosus*, and *A. meyeri*. Most evidence supports that most actinomycotic infections are polymicrobial in nature [27]. Commonly isolated in combination with actinomycetes are *Eikenella corrodens*, *Fusobacterium*, *Bacteroides*, *Capnocytophaga*, *Staphylococci*, *Streptococci*, and *Enterobacteriaceae*. These organisms may inhibit host defenses or reduce oxygen tension allowing actinomycetes to thrive.

The virulence factors for actinomycetes and their ability to grow contiguously, ignoring tissue planes, have not been well defined in vitro or in animal models. Also it is unclear which arm of host defenses is necessary to prevent and control these infections.

Epidemiology/Risk Factors

Actinomycetes are part of the endogenous flora of the mucous membranes of humans [28]. These organisms can be cultured from the gastrointestinal tract as well as the female genital tract. Oral cavity colonization is nearly 100% by 2 years of age [29]. There has never been documented person-to-person transmission of actinomycetes, and this organism has never been cultured from the environment [30]. The incidence of actinomycosis was 1 in 100,000 persons in Europe in the 1960s [28]. The highest incidence is from ages 10–60. Cases outside of that age range are less frequent. Males are more frequently infected than females at a 3:1 ratio [27]. Possible reasons for this imbalance have been hypothesized, including poorer dental hygiene among men as well as increased oral trauma in this population. These hypotheses remain unproven. Risk factors for actinomycosis in the general population may be lack of access to dental care and bisphosphonate use (cervicofacial actinomycosis), as well as long-term use of intrauterine devices (IUDs) (abdominal actinomycosis) [27].

Disruption of the mucosal barrier is an important step in the pathogenesis of actinomycosis. Dental procedures, trauma, oral surgery, and radiation of the head and neck are associated with the development of oral and cervicofacial actinomycosis [31]. Pulmonary actinomycosis occurs due to aspiration. Abdominal actinomycosis is associated with foreign bodies in the gastrointestinal/genital tracts as well as gastrointestinal surgery for diverticulitis or appendicitis.

It is unclear whether immunosuppression is a risk factor for actinomycosis. There are cases reported to be associated with HIV [32] and infliximab [33] use for Crohn's disease. Also there have been reported cases with steroid use [34] and cancer chemotherapy [35]. Case reports of actinomycosis in solid organ transplant recipients are slightly more frequent, but far from common. There have been documented cases in renal transplant recipients including a patient with an abdominal mass 4 years posttransplantation who was found to have abdominal actinomycosis [36] and a patient with actinomycosis of the posterior glottis involving both vocal processes [37]. Additionally, a patient was found to have pulmonary actinomycosis 6 months following a cadaveric liver transplant [38]. Finally, one lung and one heart-lung recipient each developed thoracopulmonary actinomycosis following transplant [39]. However, it is uncertain the role of organ transplantation and its associated immunosuppression played in these cases.

Clinical Syndromes

Actinomycetes cause several types of infections including oral-cervicofacial disease, thoracopulmonary disease, abdominal disease, pelvic disease, CNS disease, musculoskeletal disease, and, rarely, disseminated disease. Oral-cervicofacial

actinomycosis is the most common variety, accounting for 55% of cases [40]. The typical presentation is a soft-tissue swelling, mass, or abscess that is mistaken for malignancy. The angle of the jaw is the most common location for cervicofacial actinomycosis, but these masses can present anywhere in the head and neck and are often painless. Often these masses will temporarily respond to short courses of antibiotics, then relapse. Associated lymphadenopathy is rare. Extension to any contiguous structure may occur, without regard for tissue planes. Dental infections can also occur and are typically periapical. Spread to the skin from a dental focus with sinus tract formation is the hallmark of this infection. Infected osteoradionecrosis, a complication of radiation therapy, and bisphosphonate-associated osteonecrosis have both been associated with cervicofacial actinomycosis. These conditions may alter host defenses, which, if followed by dental procedures disrupting the mucosa, can lead to infection with actinomycetes. Actinomycosis is also an uncommon cause of otitis media, which, if untreated, can spread to the CNS.

Thoracopulmonary actinomycosis is less common, in about 15% of cases, and can present with chest pain, fever, and weight loss. Cough and hemoptysis may be present as well. This infection can involve the chest wall, the pleural space, or the lung parenchyma itself. On radiography, there can be a consolidation or a mass lesion, and cavitary disease and/or hilar lymphadenopathy can develop as well. Lung disease that crosses lobes or fissures or invades the mediastinum or the bones and muscles of the chest well or a sinus tract should make one consider the diagnosis of pulmonary actinomycosis. The usual source of this infection is aspiration of oral organisms. Again this infection can be mistaken for malignancy. Mediastinal actinomycosis is very uncommon.

Approximately 20% of cases of actinomycosis involve the abdomen [40]. The inciting conditions are not always obvious, but they involve a breach in the gastrointestinal mucosa. Months to years usually pass from the inciting event to the diagnosis of abdominal actinomycosis [41]. These events include, but are not limited to, appendicitis (most commonly), peptic ulcer disease, diverticulitis, bowel surgery, foreign body perforation, or ascension from IUD-associated pelvic disease. Any organ, region, or space can be involved due to the flow of peritoneal fluid and direct extension of primary disease [41]. These infections can be mistaken for malignancy and present often as a mass or abscess fixed to the underlying tissue. As in oral-cervicofacial disease and pulmonary disease, sinus tracts to the body wall can form. Liver infection can present as single or multiple abscesses. Renal disease can present as perinephric abscess or pyelonephritis. The diagnosis of abdominal actinomycosis is rarely considered until pathologic specimens are obtained and evaluated.

Pelvic actinomycosis is most commonly associated with ascending infection from a uterus containing an IUD. It may also occur after perforated appendicitis. The likelihood of infection from an IUD increases with time. Pelvic actinomycosis rarely occurs when an IUD has been in place for less than a year. Often, this infection is seen in the setting of the "forgotten" IUD. This infection can also occur as a consequence of other pelvic foreign bodies such as pessaries and contraceptive devices. Pelvic actinomycosis can present in an indolent fashion, with fever, weight loss, abdominal pain, and vaginal bleeding or discharge. The first stage is an endometritis, which can be followed by a tuboovarian abscess. The diagnosis is often delayed, sometimes until there is a "frozen pelvis" which can mimic malignancy or endometriosis. Seven percent of women who use an IUD can have actinomycetes on their Papanicolaou-stained cervical specimens [42]. This finding alone, in the absence of symptoms, has a low predictive value for pelvic disease and does not warrant the removal of the IUD. However, if pain, abnormal bleeding, or discharge are present and cannot be attributed to another condition, the removal of the IUD may be necessary, along with a 14-day course of a penicillin or a tetracycline for treatment of possible early pelvic actinomycosis [28].

CNS actinomycosis is rare and may be from a hematogenous source or from the direct extension of oral-cervicofacial disease. Brain abscess is the most common presentation [28]. Clinical features include headache and focal neurologic findings. Fever can also be present. On radiography, there can be single or multiple lesions, which are most often ring enhancing and irregular. Diagnosis can be made by biopsy or examination of the cerebrospinal fluid, having low to normal glucose, elevated protein, pleocytosis (lymphocyte predominant), and a negative culture.

Musculoskeletal actinomycosis is also rare and may result from the spread of soft tissue infection, trauma, or hematogenous spread of infection. It also may be associated with osteoradionecrosis and bisphosphonate use. The most frequent bones involved in this infection are the mandible and maxilla [43]. However, contiguous spread from oral-cervicofacial, thoracopulmonary, or abdominal actinomycosis can cause osteomyelitis of many bones. Cutaneous sinus tracts may develop. As discussed above, the presentation is often indolent and can be confused with other infections as well as malignancy.

Actinomycetes are capable of hematogenous dissemination resulting in multisystem involvement of infection [28]. Disease in any of the areas described can result in widespread infection. The liver and the lungs are the most common organs involved, again mimicking malignancy.

Diagnosis

The diagnosis of actinomycosis is not often considered until pathologic specimens have been obtained and evaluated. This is particularly true when actinomycosis causes mass lesions or nodules that mimic malignancy. Since medical therapy is typically sufficient for cure, the key is to maintain an index of

suspicion for this infection, prior to invasive debulking procedures. Fine needle aspiration or biopsy may give enough sample to make the diagnosis. The diagnosis is most commonly made by microscopic identification of sulfur granules, which are in vivo matrices of bacteria and host material [41]. These can be missed, however, when only small samples are available, making a surgical diagnosis necessary at times. Microbiological identification is less common, but when actinomycetes are isolated in culture of a sterile site, the diagnosis is confirmed. These organisms are normal flora of the oral cavity and the female genital tract, so isolation of the bacteria alone, without sulfur granules or clinical symptoms, is of little significance.

In order to grow actinomycetes in culture, strict anaerobic processing must be used. The microbiology lab should be notified that this diagnosis is being considered. These organisms will grow in 5–7 days, but it may take longer to confirm the diagnosis. Specialized media are not required. Gram staining may be more sensitive than culture, especially if the patient received antibiotics prior to the specimen being obtained [28]. Amplification and sequencing of 16S rRNA genes is beginning to be used in the diagnosis of actinomycosis.

Treatment

The mainstay of treatment of actinomycosis is penicillin; it is necessary to use high doses of this antibiotic for a prolonged period of time. Commonly recommended therapy is 18–24 million units of intravenous penicillin for 2–6 weeks followed by oral penicillin or amoxicillin for 6–12 months, depending on the severity of disease. Treatment should continue until radiologic resolution of disease to minimize relapse of infection. For penicillin-allergic patients, tetracycline is the antibiotic of choice. Possible alternative therapies include erythromycin, doxycycline, minocycline, or clindamycin [28]. Agents that should be avoided are metronidazole, aminoglycosides, oxacillin, dicloxacillin, and cephalexin.

Other bacteria isolated along with actinomycetes may require therapy as well. If these do not grow in culture, it is important for the clinician to consider the site of actinomycosis when selecting an empiric regimen. In many cases, medical therapy alone is sufficient for cure. Surgical therapy often can be avoided or a less extensive procedure can be performed. The same principles apply when treating organ transplant recipients with actinomycosis of any area.

Prevention/Prophylaxis

Actinomycosis is rarely reported in organ transplant recipients. Therefore, no specific prophylaxis is recommended or required for these, or any, patients. However, this diagnosis must be considered when evaluating organ transplant recipients with cutaneous draining sinus tracts, nodules, or mass lesions of uncertain etiology.

Cure Rates/Prognosis

Nearly all infections with actinomycetes can be cured with medical therapy. Refractory disease has been described in patients with HIV as well as normal hosts. If medical therapy does fail, surgical resection of the infection, especially in critical areas of the body, will often be curative in combination with antibiotic therapy. However, surgery can often be avoided, at least initially. Prognosis is good, but if extensive surgery is necessary, there can be sequelae, depending on the location of the infection and the extent of the procedure.

Infection Control

There have been no reported cases of person-to-person transmission of actinomycosis. Therefore, no particular infection control measures need to be taken in hospitalized patients or outpatients. There is minimal to no risk to organ transplant recipients who have a household contact with a person with actinomycosis.

Listeriosis

28

Heather E. Clauss and Bennett Lorber

Introduction

The bacterium *Listeria monocytogenes* infrequently causes illness in the general population. In some groups, however, including pregnant women, newborns, elderly persons, and those with impaired cell-mediated immunity, including many transplant recipients, it is an important cause of invasive disease, particularly bacteremia, meningoencephalitis, and brain abscess [1–3]. Additionally, listeriae may cause other clinical syndromes, including in utero infection typically resulting in miscarriage or stillbirth, as well as focal infections of heart valves, joints, liver, and peritoneum. Growing interest in this organism has resulted from foodborne outbreaks, concerns about food safety, and the recognition that foodborne infection can result in self-limited febrile gastroenteritis in healthy persons [4].

Listeria monocytogenes is a short, non-branching, gram-positive rod that is facultatively anaerobic and nonsporulating and grows readily on blood agar where it produces incomplete beta-hemolysis [5]. The bacterium exhibits characteristic tumbling motility at room temperature and, unlike most bacteria, grows well at refrigerator temperatures (4 °C–10 °C). In clinical specimens, the organisms may be gram-variable and may look like diphtheroids, cocci, or diplococci leading to misdiagnosis. The isolation of a "diphtheroid" from blood or CSF always should alert one to the possibility that the organism is really *L. monocytogenes.*

Pathogenesis

Human-to-human transmission of *L. monocytogenes* has not been reported aside from vertical transmission between mother and child and sporadic cross contamination in neonatal nurseries [6]. Most commonly, listeriae are transmitted via the ingestion of contaminated food with subsequent mucosal invasion and systemic infection. In mammals, $\geq 10^9$ organisms are required for infection [7]. Alkalinization of the stomach with antacids, H_2 blockers, proton pump inhibitors, or achlorhydria associated with advanced age may promote infection [8]. The incubation period for invasive disease (bacteremia, meningitis) is not well established, but evidence from cases related to specific ingestions points to a range from 11 to 70 days (mean 31 days) [9].

Once inside an enterocyte or macrophage, *L. monocytogenes*, a facultative intracellular parasite, uses its major virulence factor, listeriolysin O, to escape from the phagosome [10]. Through other novel mechanisms, it then can move from cell to cell without entering the extracellular space, thus avoiding contact with complement, antibodies, and neutrophils [11]. There is no increased frequency of listeriosis in those with deficiencies in neutrophil numbers or function, splenectomy, complement deficiency, or immunoglobulin disorders, the latter not surprising given that *L. monocytogenes* can be passed from cell to cell without being exposed to antibody.

Listeriae have a particular predilection for the central nervous system (CNS). Experimental data indicate that *L. monocytogenes* can use several different mechanisms to invade the CNS: (1) transportation of bacteria to the CNS within circulating leukocytes in a phagocyte-facilitated (Trojan horse) mechanism, (2) via direct invasion of endothelial cells of the blood-brain barrier by blood-borne bacteria, or (3) via a neural route whereby bacteria are inoculated into oral tissues when abrasive food is chewed, followed by tissue macrophage phagocytosis of the bacteria making possible the invasion of cranial nerves [12]. In the latter case, bacteria move in a retrograde direction through the nerve

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_28

axons, eventually reaching the CNS where they continue to spread intercellularly to the parenchyma.

Another important virulence factor for *L. monocytogenes* is the ability to scavenge iron. In vitro, iron enhances organism growth [13]. In animal models of listeria infection, iron overload is associated with enhanced susceptibility to infection and iron supplementation with enhanced lethality, whereas prolonged survival results from iron depletion [14]. Iron overload states are risk factors for listerial infection, and clinical correlates include outbreaks of listerial infection in patients receiving hemodialysis who have transfusion-induced iron overload and patients with hemochromatosis [9].

Epidemiology

Listeria monocytogenes is readily isolated from soil and vegetation and has been found to be present in the feces of many mammals [15]. The organism has been isolated from the stool of ~5% of healthy adults [16]. In three healthy, asymptomatic adults followed up for 1 year, *L. monocytogenes* was present transiently in 3.5% of stool specimens [17]. Many foods are contaminated with *L. monocytogenes*; recovery rates of 15–70% have been found from raw vegetables, unpasteurized milk, fish, poultry, and meats [18]. Ingestion of listeriae must be a common occurrence. Nonperinatal listeriosis is almost always the result of foodborne infection. Listeriosis is a relatively rare foodborne illness (~1% of US cases) but is associated with a case fatality rate of 16–20% (second only to *Vibrio vulnificus* at 35–39%) and causes 19–28% of all foodborne disease-related deaths [19, 20]. Mortality risk factors in nonperinatal cases include nonhematological cancers, steroid medication, and renal disease.

Numerous foodborne outbreaks have occurred with vehicles including unpasteurized soft cheeses, hot dogs, and deli-style ready-to-eat sliced poultry products. In October 2002, *L. monocytogenes* was found in sliced deli-style turkey meat, the ingestion of which produced illness in 54 patients in 9 states, resulting in the largest recall of meat ever in the United States (more than 30 million pounds of food products) [21]. In 2011, cantaloupes contaminated by *L. monocytogenes* were responsible for the deadliest foodborne outbreak in US history with 28 states reporting cases [22]. The epidemic affected 146 persons, 30 of whom died (21% mortality).

The highest infection rates of invasive listeriosis are seen in adults >60 years of age and in infants <1 month old [23]. The rate of infection declines sharply between the ages of 1 and 11 months. Pregnant women account for approximately 30% of all cases of listerial bacteremia and 60% of cases in the 10- to 40-year age group. It is noteworthy that although pregnancy is a clear risk factor for bacteremia, for unknown reasons, listerial meningitis is exceedingly rare during pregnancy unless a second risk factor, such as corticosteroid therapy, is present. Seventy percent of nonperinatal infections occur in patients with impairments in cell-mediated immunity. Seemingly normal persons may develop invasive disease, particularly those older than age 60.

The major risk factor for listeriosis is impaired cell-mediated immunity whether due to a specific disease or due to immunosuppressive therapy. Specific risk factors for developing listeriosis include corticosteroid treatment, organ transplantation, malignancy, AIDS, pregnancy, liver failure, diabetes, and age >60 [24]. In a review of almost 2000 cases of listeriosis reported in France from 2001 to 2008, when compared with healthy persons under the age of 65, those with chronic lymphocytic leukemia had a >1000-fold increased risk of acquiring listeriosis, and those with hepatic cancer; myeloproliferative disorder; myeloma; acute leukemia; giant cell arteritis; dialysis; esophageal, stomach, pancreas, lung, and brain cancer; cirrhosis; organ transplantation; and pregnancy had a 100- to 1000-fold increased risk of listeriosis [25]. Reports continue to be published of *L. monocytogenes* meningitis presenting as an opportunistic infection in AIDS [26] and as a complication of solid organ transplantation [27]. One new risk factor for listerial infection is the use of antitumor necrosis factor alpha (TNF-α) agents. Case reports describe listerial meningitis complicating infliximab treatment for Crohn's disease [28] as well as etanercept treatment for Still's disease [29]. An interesting basic science correlate of these clinical events is the observation that, in a murine model, TNF was found to play a crucial role in the intracerebral control of *L. monocytogenes* infection [30].

Major Clinical Syndromes

The species name derives from the fact that an extract of the *L. monocytogenes* cell membrane has potent monocytosis-producing activity in rabbits [31], but monocytosis is a very rare feature of human infection.

Infection in Pregnancy and the Neonatal Period

Pregnant women are prone to develop listerial bacteremia with an estimated 17-fold increase in risk [32]; clinical illness most often occurs in the third trimester. Listeriae proliferate in the placenta in areas that appear to be unreachable by usual defense mechanisms [33], and cell-to-cell spread facilitates maternal-fetal transmission [34]. For unexplained reasons, CNS infection, a commonly recognized form of listeriosis in other groups, is extremely rare during pregnancy in the absence of other risk factors [9, 16, 35]. Bacteremia is manifested clinically as an acute febrile illness, often

accompanied by myalgias, arthralgias, headache, and backache. Twenty-two percent of human perinatal infections result in stillbirth or neonatal death; spontaneous abortion is common. Untreated bacteremia is generally self-limited, although if there is a complicating amnionitis, fever in the mother may persist until the fetus is spontaneously or therapeutically aborted. Among women who have listeriosis during pregnancy, two thirds of surviving infants develop clinical neonatal listeriosis. Early diagnosis and antimicrobial treatment of the infected woman can result in the birth of a healthy infant [9, 32].

Similar to disease due to Group B streptococcus, neonatal infections manifest as early-onset sepsis with disseminated infection, typically in premature infants, or late-onset meningitis, typically in term infants who were healthy at birth.

Bacteremia

Bacteremia without an evident focus is the most common manifestation of listeriosis after the neonatal period [2, 24]. Clinical manifestations are similar to those seen in bacteremia with other causes and typically include fever and myalgias; a prodromal illness with diarrhea and nausea may occur [9].

Central Nervous System Infection

The organisms that cause bacterial meningitis most frequently (*Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae*) rarely cause parenchymal brain infections such as cerebritis and brain abscess. In contrast, *L. monocytogenes* has tropism for the brain itself, particularly the brain stem, as well as for the meninges [2, 3, 36]. Many patients with meningitis have altered consciousness, seizures, or movement disorders, or all of these, and truly have a meningoencephalitis.

Meningitis

In an active meningitis surveillance study [37], *L. monocytogenes* accounted for 20% of cases in neonates and 20% in those older than 60 years. Worldwide, *L. monocytogenes* is one of the three major causes of neonatal meningitis, is second only to pneumococcus as a cause of bacterial meningitis in adults older than 50 years, and is the most common cause of bacterial meningitis in patients with lymphomas [38], organ transplant recipients, or those receiving corticosteroid immunosuppression for any reason [9].

Clinically, meningitis caused by *L. monocytogenes* is usually similar to that due to more common causes [39, 40]; features particular to listerial meningitis are summarized in Table 28.1. Despite the name "monocytogenes," the CSF pleocytosis is more often neutrophilic than monocytic.

Table 28.1 Features particular to listerial meningitis as compared to more common bacterial etiologies[a]

Feature	Frequency (%)
Presentation can be subacute >24[b]	~60
Absence of stiff neck is more common	25
Movement disorders (ataxia, tremors, myoclonus) are more common	15–20
Seizures are more common	10–25
Fluctuating mental status is more common	~75
Focal neurologic findings are more common	35–40
Positive blood culture is more common	50–75
Cerebrospinal fluid (CSF):	
Positive Gram stain is less common	30–40
Normal CSF glucose is more common	>60
Mononuclear cell predominance is more common	~30

[a]Adapted from [9, 39, 41]
[b]May be several days or more and mimic tuberculous meningitis in ~10–30%

The first prospective study of meningitis due to *L. monocytogenes* recently was reported from the Netherlands [41]. In this nationwide cohort study of 30 adults, notable clinical features of listerial meningitis included headache in 88%, nausea in 83%, and fever in 90%; but only 75% of patients had a stiff neck at the time of presentation. A focal neurologic deficit was present in 37% (many patients with meningitis have simultaneous infection of the brain parenchyma and truly have a meningoencephalitis). Only 43% had the classic meningitis triad of fever, neck stiffness, and change in mental status. At the time of presentation, 19 out of 30 patients had symptoms persisting for greater than 24 h, and 8 had symptoms for ≥4 days. Remarkable CSF findings included a median white blood cell count of 620 (range 24–16,003) and protein of 2.52 g/L. Spinal fluid Gram stain revealed a gram-positive rod in only 28% of patients, while blood cultures were positive for *L. monocytogenes* in 46% of patients. These data illustrate how difficult it can be to make a definitive diagnosis of listerial meningitis at initial presentation.

Mortality from listerial meningitis has variously been reported at 15% in a CDC active surveillance study [37], 27% in the Massachusetts General Hospital review [39], and 17% in the prospective study from the Netherlands [41]. In the last report, all deaths occurred within 3 days of being admitted to the hospital. Mortality is low (zero to 13%) for adults without serious underlying disease or immunosuppressive treatment [36].

Brain Stem Encephalitis (Rhombencephalitis)

An unusual form of listerial encephalitis involves the brain stem [42]. In contrast to other listerial CNS infections, this illness usually occurs in healthy adults. The typical clinical picture is one of a biphasic illness with a prodrome of fever, headache, nausea, and vomiting lasting about 4 days followed by the abrupt onset of asymmetric cranial nerve

deficits, cerebellar signs, and hemiparesis or hemisensory deficits, or both. About 40% of patients develop respiratory failure. Nuchal rigidity is present in about one half, and CSF findings are only mildly abnormal with a positive CSF culture in about one-third. Almost two-thirds of patients are bacteremic. Magnetic resonance imaging is superior to computed tomography for demonstrating brain stem encephalitis [43]. Mortality is high, and serious sequelae are common in survivors.

Brain Abscess

Macroscopic brain abscesses account for about 10% of CNS listerial infections. Bacteremia is almost always present, and concomitant meningitis with isolation of *L. monocytogenes* from the CSF is found in 25–40%; both these features are rare in other forms of bacterial brain abscess [44]. Most cases occur in known risk groups for listerial infection [45]. Subcortical abscesses located in the thalamus, pons, and medulla are common; these sites are exceedingly rare when abscesses are caused by other bacteria. Mortality is high, and survivors usually have serious sequelae.

Febrile Gastroenteritis

Many patients with invasive listeriosis have a history of antecedent gastrointestinal illness, often accompanied by fever. Isolated cases of gastrointestinal illness due to *L. monocytogenes* are rare, but at least seven outbreaks of foodborne gastroenteritis due to *L. monocytogenes* have been documented [4]. Illness typically occurs 24 h (range 6 h to 10 days) after ingestion of a large inoculum of bacteria and usually lasts 1–3 days (range 1–7 days); attack rates have been quite high (52–100%). Common symptoms include fever, watery diarrhea, nausea, headache, and pains in joints and muscles. Vehicles of infection have included chocolate milk, cold corn and tuna salad, cold smoked trout, and delicatessen meat. *Listeria monocytogenes* should be considered to be a possible etiology in outbreaks of febrile gastroenteritis when routine cultures fail to yield a pathogen.

Listeriosis in Cancer Patients

Louria, in 1967 [46], was the first to point out the strong association between opportunistic listerial infection and malignancies, particularly Hodgkin's disease being treated with corticosteroids. He described 18 cases of invasive listerial infection, 16 of which had underlying hematologic malignancies. Twelve of the 18 cases were receiving corticosteroids at the time of diagnosis.

Listeria monocytogenes infection occurred in 94 patients during 1955–1997 at the Memorial Sloan Kettering Cancer Center; the incidence was 0.5 (1955–1966), 0.96 (1970–1979), and 0.14 (1985–1997) cases per 1000 new admissions [38]. Eighty-five of 94 (90%) patients had listerial bacteremia, and 34/94 (36%) had evidence of intracranial infection. Listeriosis in these patients with cancer occurred most often in individuals receiving antineoplastic therapy for advanced or relapsed malignancy (77%) and systemic corticosteroids (68%). In another study, combined treatment with fludarabine and prednisone in patients with chronic lymphocytic leukemia decreased their CD4+ T lymphocyte counts and increased their incidence of listeriosis; fludarabine alone was not associated with listeriosis [47].

In a comprehensive review [39] of 33 years of experience at the Massachusetts General Hospital with CNS listeriosis outside of the neonatal period and pregnancy, including a case series of 41 patients and 776 episodes from the literature, the most common predisposing factor for developing listerial meningitis was malignancy (both solid tumor and hematologic), occurring in 24% of patients.

At another institution, from 1990 to 2001, 34 cancer patients with listeriosis were reviewed, and 20 (59%) had an underlying hematologic malignancy [48]. In 11 patients, listeriosis complicated bone marrow transplantation. Twenty-six patients received prior corticosteroids. Here again, bacteremia was the most common presentation of listeriosis (74%), followed by meningoencephalitis (21%). The rate of response to antimicrobial therapy was 79%, and no relapses were identified. Listeriosis contributed to death in 9 (75%) of the 12 patients who died. In the Memorial Sloan-Kettering study [38], 37 (39%) of the 94 patients died of listeriosis; more than one-third of deaths occurred within the first 48 h after *L. monocytogenes* cultures were obtained.

In a recent study of all listeriosis cases in France over an 8-year period, having chronic lymphocytic leukemia, myeloproliferative disorders, liver cancer, myeloma, acute leukemia, or cancers of the esophagus, pancreas, and lung was associated with a 100- to 1000-fold risk of listeriosis, when compared with persons less than 65 years of age with no underlying conditions [25]. Mortality from listeriosis in those with hematological malignancies was increased by more than fivefold compared with those without underlying disease.

In the elderly, listerial meningitis may serve as a marker for cancer. In a recent Danish study [49], adult survivors of meningitis had an increase in cancer-related deaths during the 5-year period after the diagnosis of meningitis. Another interesting relationship exists between listeriosis and cancer. Listerial endocarditis, not bacteremia per se, in an otherwise healthy person, may be an indicator of underlying gastrointestinal tract pathology, including colon cancer [50].

Listeriosis in Transplant Recipients

A little more than 30 years ago, Nieman and Lorber, in a case series and review of listeriosis in the preceding decade [36], pointed out an emerging association between transplantation and the risk of listeriosis. The last three decades have strengthened this association with numerous reports and reviews of invasive *L. monocytogenes* infection in both solid organ and bone marrow transplants. A recent nationwide review of listeriosis in France during an 8-year period showed that, when compared with healthy persons under age 65, the risk of acquiring infection in patients with solid organ transplants was increased 164-fold; all were receiving immunosuppressive therapy [25].

Two other observations illustrate well the strong link between transplantation and listeriosis risk. Firstly, of the six species of *Listeria*, *L. monocytogenes* is almost exclusively responsible for human disease. But, as shown in well-documented instances of bacteremia due to *L. grayi* in a heart transplant recipient [51] and a stem cell recipient [52], along with bacteremia due to *L. ivanovii* in a renal transplant recipient [53], transplanted individuals are at particular risk for listeriosis, even when due to species other than *L. monocytogenes.* Secondly, recurrent listerial infection is exceedingly rare, but again, reports of recurrent *L. monocytogenes* meningitis in heart transplant recipients [54] and of recurrent bacteremia in a liver transplant recipient [55] show the high risk of listeriosis in transplanted persons.

Both solid organ and bone marrow transplant recipients are considered to be at increased risk for listeriosis due to immunosuppressive therapy-related defects in cellular immune function. In a matched case-control study of risk factors for listeriosis in solid organ transplant recipients [56], independent risk factors for infection included diabetes, cytomegalovirus infection or disease in the preceding 6 months, and high-dose corticosteroid therapy in the preceding 6 months; trimethoprim-sulfamethoxazole prophylaxis was protective. In this study, CMV disease or infection carried the highest risk; the immunomodulatory effects of CMV infection and associated infection risk due to a variety of agents are increasingly recognized. The median time to diagnosis for listeriosis after transplantation was 202 days (range, 16–5189 days); 50% of cases occurred more than 6 months following transplantation. The 30-day mortality rate was 27%.

The impact of antecedent or concurrent CMV infection on listeriosis risk has also been noted in the setting of allogeneic blood and marrow transplantation. Six systemic *L. monocytogenes* infections were seen on the bone marrow transplantation service at one cancer center during a 13-year period; four of the six were being treated for acute CMV viremia [57]. Bacteremia is more common than CNS infection, and most listerial infections are seen more than 60 days after bone marrow transplantation. Hemophagocytosis syndrome has been reported as an unusual complication of listerial infection in a bone marrow transplant recipient [58].

An early series of listeriosis complicating renal transplantation was reported by Stamm and colleagues in 1982 [59]. They described an outbreak involving six cases in a 10-week period and reviewed 102 cases. Meningitis was the presenting illness in 50% of patients, parenchymal brain infection in 10%, combined meningeal and parenchymal CNS infection in 9%, and primary bacteremia in 30%. Mortality rate was 26%. In a large review of 820 cases of CNS listeriosis at a single institution, hematologic cancers and renal transplantation were the two most common predisposing factors [32].

A 2007 review of *L. monocytogenes* infection following orthotopic liver transplantation described a case of meningitis and reviewed 14 cases from the English language literature [27]. Time from transplantation to infection ranged from 7 days to 32 months; ten patients presented with bacteremia and five with CNS infection. Diagnosis in the index patient in this report was delayed because the severe headache that developed on day 5 posttransplant was initially thought to represent tacrolimus encephalopathy.

Listerial infection following lung transplantation has been reported rarely. In one case [60], a 59-year-old man developed a pleural effusion 8 days after bilateral lung transplantation. Pleural fluid contained 3900 white blood cells/mm^3 (85% neutrophils) and had a pH of 7.29; cultures of blood and pleural fluid grew *L. monocytogenes.* Pleuropulmonary listeriosis is rare. Most cases have been associated with hematological malignancies and presented with isolated pleural effusion or empyema.

Another unusual manifestation of listerial infection is myocarditis which has been reported in two heart transplant recipients who presented with heart failure that was initially attributed to graft rejection [61].

Although transplant recipients are at markedly increased risk for listeriosis when compared with the general population, the overall risk remains small and has been reported to be 0.12% [56] in solid organ recipients and 0.47% in allogeneic marrow recipients [57].

All transplant recipients should be given information on foodborne illnesses including listeriosis and should be instructed in the importance of handwashing along with food safety and handling (see Prevention section).

Diagnosis

The key to making a diagnosis of listerial infection and initiating early, appropriate treatment is to know when it should be considered. CNS listeriosis should be a major

consideration as part of the differential diagnosis in the following clinical settings:

1. Meningitis or parenchymal brain infection in:
   - Patients with organ or bone marrow transplantation, corticosteroid immunosuppression, hematologic malignancy, or AIDS or those receiving anti-TNF agents.
   - Patients with a subacute presentation of meningitis.
   - Neonates and adults >50 years of age.
   - Those in whom CSF shows gram-positive rods or is reported to have "diphtheroids" on Gram stain or culture.
2. Simultaneous infection of the meninges and brain parenchyma.
3. Subcortical brain abscess.
4. Spinal symptoms in the setting of acute bacterial meningitis of uncertain etiology.
5. Fever during pregnancy, particularly in the third trimester.
6. Blood, CSF, or other normally sterile specimen reported to have "diphtheroids" on Gram stain or culture.
7. Foodborne outbreak of febrile gastroenteritis when routine cultures fail to identify a pathogen.

Diagnosis requires isolation of *L. monocytogenes* from a normally sterile site such as blood or CSF and identification through standard microbiologic techniques. Antibodies to listeriolysin O have proved useful during investigation of outbreaks of febrile gastroenteritis [62] but have not proved useful in invasive disease [63]. *Listeria monocytogenes* DNA in CSF and tissue can be detected specifically by polymerase chain reaction (PCR) assays [64]. Real-time PCR of CSF for the *hly* gene, which encodes listeriolysin O, has been useful in diagnosing CNS listeriosis, including cases in which the routine bacterial cultures were negative [65], but this test is not yet commercially available. MRI is superior to CT for demonstrating parenchymal brain involvement, especially in the brainstem [42, 43].

Treatment

Many antimicrobials show in vitro activity against listerial isolates, but only a few agents have been proved clinically efficacious. Ampicillin has been the most widely used agent in the treatment of *L. monocytogenes* infections and generally is considered the preferred agent [2, 40]. Synergy has been demonstrated both in vitro and in animal models when an aminoglycoside is added to ampicillin or penicillin, and many authorities recommend the addition of an aminoglycoside to ampicillin for at least the first week in treatment of CNS infection [9].

In the absence of a positive CSF Gram stain, initial therapy for bacterial meningitis in adults older than age 50 should include an anti-listerial agent (either ampicillin or trimethoprim-sulfamethoxazole) [2]. Due to the high affinity of *L. monocytogenes* for the CNS, meningitis doses of the chosen antibiotic should be used for all bacteremic patients, even in the absence of CNS findings, until the CSF is examined. An exception is bacteremia in pregnancy without another risk factor, since, in this group, CNS infection is almost never present. Relapses are reported in those with meningitis treated for less than 2 weeks; therefore, treatment for 3 weeks is recommended for all cases of listerial meningitis. Bacteremic patients with normal CSF may be treated for 2 weeks. Patients with brain abscess, cerebritis, or rhombencephalitis should be treated for at least 6 weeks and followed up with repeated brain imaging studies. In cases of listerial brain abscess, surgical intervention may not be necessary; numerous case reports describe successful treatment with antimicrobial therapy alone.

In those with penicillin hypersensitivity, trimethoprim-sulfamethoxazole is the treatment of choice and appears to be bactericidal and as effective as the combination of ampicillin and gentamicin. Cephalosporins have limited activity against listeriae. Many reports document treatment failures with cephalosporins, and patients have developed listerial meningitis while receiving cephalosporins for other reasons. Chloramphenicol has also been shown to have an unacceptable failure rate and should not be used. Erythromycin and tetracycline have been reported to be effective but are unreliable therapeutic options and should be avoided. Vancomycin has been used successfully in penicillin-allergic patients, but listerial meningitis has developed in patients being treated with vancomycin. Both imipenem and meropenem have also been used with success to treat cases of listeriosis, but caution is advised because both drugs lower the seizure threshold, imipenem was less effective than ampicillin in a mouse model [66], and meropenem clinical failure has been documented [67].

In an animal model of listerial meningitis, the addition of rifampin to ampicillin was no better than ampicillin alone. While some newer quinolones and linezolid show good in vitro activity, clinical experience is mixed [68–70] and, to date, too limited to support recommending these antimicrobials.

Although adjunctive corticosteroids have become the standard of care in the initial management of bacterial meningitis, their value in listerial infection remains unknown. Listeriae use iron as a virulence factor; therefore, in patients with iron deficiency, it seems prudent to withhold iron replacement until treatment of infection is completed.

Prevention

Food industry regulations were instituted in the United States over 20 years ago to minimize the risk of foodborne listeriosis and cut foodborne infection rates by more than one-half; rates have been relatively stable for several years [71, 72]. In contrast, rates of listerial infection appear to be rising in Europe [73].

Transplant recipients, cancer patients with hematological malignancies, and/or those on corticosteroids should be advised to avoid certain foods. Detailed recommendations from the CDC concerning food handling and avoidance for those at risk for listeriosis can be found on the CDC website at (http://www.cdc.gov/listeria/prevention.html#melonsafety). Major recommendations are summarized in Table 28.2.

Except from infected mother to fetus, human-to-human transmission of listeriosis does not occur; therefore, patients do not need to be isolated.

Listerial infections are effectively prevented by trimethoprim-sulfamethoxazole given as *Pneumocystis* prophylaxis to those on long-term corticosteroids [74].

Table 28.2 Recommendations for preventing foodborne listeriosis

General recommendations:
Washing and handling food
Rinse raw produce thoroughly under running tap water before eating, cutting, or cooking. Even if the produce will be peeled, it should still be washed first
Scrub firm produce, such as melons and cucumbers, with a clean produce brush
Dry the produce with a clean cloth or paper towel
Keep your kitchen and environment cleaner and safer
Wash hands, knives, countertops, and cutting boards after handling and preparing uncooked foods
Be aware that *Listeria monocytogenes* can grow in foods in the refrigerator. The refrigerator should be 40 °F or lower and the freezer 0 °F or lower.
Clean up all spills in your refrigerator right away—especially juices from hot dogs and lunchmeat packages, raw meat, and raw poultry
Cook meat and poultry thoroughly
Thoroughly cook raw food from animal sources, such as beef, pork, or poultry, to a safe internal temperature
Use precooked or ready-to-eat food as soon as you can. Do not store the product in the refrigerator beyond the use-by date
Use leftovers within 3–4 days
Choose safer foods
Do not drink raw (unpasteurized) milk, and do not eat foods that have unpasteurized milk in them
Recommendations for persons at higher risk, such as pregnant women, persons with weakened immune systems, and older adults in addition to the recommendations listed above, include:
Meats
Do not eat hot dogs, luncheon meats, cold cuts, other deli meats (e.g., bologna), or fermented or dry sausages unless they are heated to an internal temperature of 165 °F or until steaming hot just before serving
Avoid getting fluid from hot dog and lunchmeat packages on other foods, utensils, and food preparation surfaces, and wash hands after handling hot dogs, luncheon meats, and deli meats
Do not eat refrigerated pâté or meat spreads from a deli or meat counter or from the refrigerated section of a store. Foods that do not need refrigeration, like canned or shelf-stable pâté and meat spreads, are safe to eat. Refrigerate after opening
Cheeses
Do not eat soft cheese such as feta, queso blanco, queso fresco, brie, Camembert, blue-veined, or panela (queso panela) unless it is labeled as made with pasteurized milk. Make sure the label says, "*made with pasteurized milk*."
Seafood
Do not eat refrigerated smoked seafood, unless it is contained in a cooked dish, such as a casserole, or unless it is a canned or shelf-stable product
Canned and shelf-stable tuna, salmon, and other fish products are safe to eat
Melons
Wash hands with warm water and soap for at least 20 s *before* and *after* handling any whole melon
Scrub the surface of melons with a clean produce brush under running water, and dry them with a clean cloth or paper towel before cutting. Be sure that your scrub brush is sanitized after each use
Promptly consume cut melon or refrigerate promptly. Keep your cut melon refrigerated for no more than 7 days
Discard cut melons left at room temperature for more than 4 h

Cynthia Portal-Celhay and Jennifer A. Philips

Mycobacterium Tuberculosis Pathogenesis and Host Response

Basic Biology of Mycobacterium Tuberculosis

Robert Koch identified *Mycobacterium tuberculosis* (Mtb) as the causative agent of tuberculosis (TB) nearly 130 years ago, and it is estimated to infect one third of the world's population. It is a rod-shaped bacterium with a very high lipid and mycolic acid content in its cell wall. This makes it stain poorly with Gram stain, but it retains certain dyes such as Ziehl-Neelsen after acid treatment, resulting in characteristic "acid-fast" staining. Other unique features are its exceptionally slow growth, dividing approximately every 20 h, and its ability to establish latent infection. While few people infected with Mtb develop acute disease upon infection, most individuals, even those with a seemingly normal immune system, are unable to eradicate infection.

People are initially infected via an aerosol route. In contrast to infections with non-tuberculous mycobacteria (NTM), there is no known environmental reservoir, so infection only occurs after contact with a person with active disease. It is thought that the infectious dose is quite low, perhaps on the order of several bacilli, and the initial infection generally is not clinically recognized. The initial site of infection in the lungs, referred to as a Ghon complex, is most often in the upper part of the lower lobe or the lower part of the upper lobe. Inhaled bacteria are deposited in the distal alveoli where they encounter and are taken up by alveolar macrophages. Additional phagocytic cells recruited to the infected lung, including neutrophils, monocyte-derived macrophages, and dendritic cells (DCs), ingest bacteria and play an important role in the outcome of the infection [1].

The initial interaction between bacteria and cells of the innate immune system occurs through pattern recognition receptors such as Toll-like receptors, complement receptors, mannose receptors, and C-type lectin receptors, such as Dectin-1 and the macrophage-inducible C-type lectin, Mincle [2–4]. Unlike pathogens that avoid uptake into host cells, Mtb appears to take advantage of multiple possible receptors to enter phagocytic cells. Bacteria are taken up into the macrophage phagosome, a compartment that ordinarily becomes acidified and fuses with lysosomes forming a phagolysosome. However, the phagosome containing mycobacteria does not fully acidify or acquire features of mature phagolysosomes [5, 6]. Mycobacteria have long been thought to persist and grow within this specialized cellular compartment that resembles an early endosome, which allows the bacteria to acquire nutrients, such as iron via recycling endosomes, while avoiding the acidic, degradative environment of the lysosome [7]. More recent work has shown that the bacteria also gain access to the host cell cytoplasm [8, 9], which activates host cytosolic sensors and alternative pathways for phagosome maturation [10–12].

In contrast to their usual role in protecting the host, macrophages appear to be an important determinant of bacterial spread and dissemination. For example, studies performed using a zebrafish model and *Mycobacterium marinum*, a close genetic relative of Mtb, revealed that uninfected macrophages are actively recruited to the area surrounding an infected cell [13]. Following replication of mycobacteria in the initial macrophage, bacteria released into the extracellular space are rapidly ingested by the recruited, surrounding macrophages, allowing further expansion and dissemination of the pathogen population [14].

Based upon work in mice, DCs, myeloid cells that are specialized for antigen presentation, transport Mtb from the lungs to the local draining lymph nodes to present antigen to naive T cells. T helper (Th)1 cells that are activated in the

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_29

draining lymph node then travel back to the lung, where they can subsequently activate infected macrophages. T cell activation is delayed compared to other infections, which may be important in allowing the bacteria to establish their initial niche [15]. T-cells activate infected macrophages by secreting cytokines such as interferon-gamma (IFN-γ) and tumor necrosis factor-alpha (TNF-α), which promote the ability of macrophages to restrict mycobacterial growth. IFN-γ promotes production of reactive nitrogen intermediates [16], enhances phagosome maturation in a manner dependent upon the immunity related GTPases [17, 18], and promotes autophagy, a host cellular mechanism recently appreciated to clear certain intracellular pathogens including Mtb [10, 12, 19, 20]. Nonetheless, the host is ultimately ineffective at eradicating infection. One reason for this may be is that although there is a robust immune response to Mtb antigens, there may be limited availability or recognition of antigen within the infected tissue [21–23]. In addition, although cytokines can improve the antimycobacterial capacity of macrophages, Mtb impairs the responsiveness of the infected macrophage [24, 25].

In addition to activating a Th1 response, Th17 cells, which are characterized by the secretion of IL-17, IL-21, and IL-22, are also induced in the draining lymph node and return to the lung where they exert effector function. The balance of Th1 and Th17 responses appears to be important in the outcome of Mtb infection [26]. One way in which Th17 cells and IL-17 influence immunity and immunopathology in TB is the recruitment of neutrophils, a cell type whose role in TB infection is increasingly appreciated. Neutrophils are recruited early during initial infection, are a dominant infected cell population, and promote granuloma formation [27]. In addition, infected apoptotic bodies are transferred from neutrophils to DCs, which promotes T cell priming in the draining lymph node, although Mtb appears to impair this process by inhibiting apoptosis and promoting cellular necrosis [28–31]. Although neutrophils appear to have a role in host protection early during infection, mouse models and recent human data suggest they are also associated with immunopathology and poor outcome in Mtb infection. Neutrophilia may indicate a failed Th1 immune response, as IFN-γ inhibits pathogenic neutrophil accumulation and impairs neutrophil survival in a mouse model [32]. In humans, an analysis of gene transcriptional responses in Mtb-infected patients found that patients with active tuberculosis exhibit a signature reflecting a neutrophil-driven type I IFN-α,β and IFN-γ signaling that was reversed with drug treatment [33].

The histological response to Mtb infection is characterized by granuloma formation. Granulomas contain an organized aggregate of macrophages [34], which exhibit a variety of phenotypes, including epithelioid macrophages, foamy macrophages, and multinucleated giant cells formed by the fusion of multiple macrophages, along with other cell types such as lymphocytes, neutrophils, and dendritic cells. Classically, granulomas have been thought to "wall off" infection, implying they are primarily of benefit to the host. However, more recent data suggest that granulomas may also benefit the pathogen, and several mycobacterial components promote granuloma formation. Granulomas may benefit the bacilli by serving as a site for macrophage recruitment and concomitant bacterial expansion [14]. In addition, during the early stages of granuloma formation, a fraction of infected macrophages may depart from the nascent granuloma and initiate infection at distant sites. Granulomas are also probably important for immune control of TB, since they are a site for interactions between antigen-presenting cells and effector T cells. Therefore, granulomas may more accurately be thought of as a site of the stalemate between bacteria and host, providing benefit to both.

Latent TB infection (LTBI) is characterized by absent or very limited bacterial replication and no clinical symptoms. The only evidence of infection is an immune response to Mtb antigens. A striking feature of tuberculosis is that this situation can persist for decades. However, while the host immune response is inadequate to eradicate bacteria, it is important in preventing active disease. Approximately 5% of people will become sick in the first 2 years after initial infection, and an additional 5% will reactivate infection sometime during their lifetime. In apparently normal hosts, reactivation most commonly occurs in the lungs, resulting in characteristic cavitary disease. However, since the bacteria are able to disseminate during infection, they can also reactivate in distant tissues. Unlike the détente of latent infection where the bacterial burden is low and tissue injury is minimal, during active disease, the granuloma becomes necrotic, resulting in the tissue damage that is necessary to promote transmission. Thus, while Mtb appears to be minimally inflammatory during latent infection, it must generate a robust immune response to successfully transmit. Thus, it must be exquisitely adept at manipulating the host immune response in two seemingly distinct manners [35].

Host Determinants of Disease

The host immune response is critical in susceptibility to tuberculosis infection. Animal models have shown that both CD4+ and CD8+ T-cells are required for protection against disease [36, 37], an observation borne out clinically in patients who lack adequate T cell function. Individuals with reduced CD4+ T cells, such as those infected with HIV, have markedly increased susceptibility to tuberculosis [38, 39]. Similarly, chemotherapy that impairs T cell function, such as fludarabine, results in enhanced susceptibility to Mtb [40]. T cells are essential for the maintenance of organized

granulomas and the control of infection. Thus, the highest frequency of disseminated disease is found in those HIV-infected patients with the lowest CD4+ T cell counts. At least part of the importance of T cells is to activate infected macrophages, making them more potently bactericidal. Hence, cytokines that mediate the interaction between T cells and macrophages have also been shown to be critically important in host immunity. For example, mice lacking IFN-γ die rapidly of Mtb infection [41]. Likewise, children with mutations in genes involved in IFN-γ-mediated immunity, including interferon gamma receptor 1 (IFNGR1), interferon gamma receptor 2 (IFNGR2), signal transducer and activator of transcription 1 (STAT1), interleukin 12B (IL12B), interleukin 12 receptor, beta 1 (IL12RB1), NF-κB essential modulator (NEMO), cytochrome b-245, beta polypeptide (CYBB), interferon regulatory factor 8 (IRF8), and ubiquitin-like protein ISG15, suffer from susceptibility to weakly virulent mycobacteria such as *Mycobacterium bovis*-bacillus Calmette-Guerin (BCG), a vaccine strain, as well as to *Salmonella* and Mtb [42–45]. In addition, neutralizing anti-IFN-γ-autoantibodies have been found in Asian patients with an adult onset immunodeficiency syndrome that makes them highly susceptible to mycobacterial infection [46]. Vitamin D is important in the ability of macrophages to respond to IFN-γ [47], and clinical studies have linked serum 25-hydroxyvitamin D levels with susceptibility to tuberculosis [48–51]. Detailed studies of human macrophages have illuminated the mechanism by which vitamin D improves clearance of intracellular bacteria, a pathway that appears to operate both in response to Toll-like receptor signaling [52] and IFN-γ signaling, suggesting vitamin D is important in both the innate and acquired response to Mtb.

In addition to IFN-γ, tumor necrosis factor-alpha (TNF-α) is essential for control of Mtb. Mice lacking TNF-α are highly susceptible to Mtb [53]. TNF-α activates macrophages and modulates apoptosis of infected cells [54, 55]. At the same time, excess TNF-α contributes to the immunopathology of TB [56, 57], and Mtb has developed specific mechanisms to modulate macrophage production of TNF-α [58]. Patients who receive TNF-α inhibitors for rheumatoid arthritis or Crohn's disease are at increased risk of reactivation of latent tuberculosis, often presenting with disseminated disease [59]. Use of infliximab, an anti-TNF-α antibody, has illustrated the importance of TNF-α in humans, as well as pointing to the importance of a particular set of CD8+ T-cells. Patients treated with infliximab have a significantly higher risk of reactivating Mtb than those treated with etanercept, a soluble TNF receptor that functions as a decoy receptor to block TNF signaling [60, 61]. This may be explained by the fact that infliximab binds much better than etanercept does to transmembrane TNF, which is found on a specific population of CD8+ T-cells that exhibit antimicrobial activity against Mtb. Infliximab binding to these cells makes them susceptible to complement-mediated lysis [62], and they are depleted in patients treated with infliximab. This is consistent with additional literature pointing to the role of CD8+ T cells in host defense against Mtb. To conclude, animal models and human studies all support the fact that T cells, IFN-γ, and TNF-α play central roles in host defense against Mtb. When these are impaired—by disease states, genetic mutations, or therapeutic intervention—the risk of developing active tuberculosis rises substantially. There are certain to be other critical determinants, for example, the inflammasome and IL-1β, which are actively under investigation, but their contribution in human infection has yet to be fully elucidated [63].

Bacterial Determinants of Disease

Determinants of Mtb virulence include secreted proteins and biologically active lipids. These components interact with the host to modulate intracellular bacterial trafficking, host cellular signaling, host cell death pathways, and granuloma formation. Mycobacteria have an unusual lipid-rich cell envelope containing distinctive long-chain fatty acids such as mycolic acids. These lipids play an important role in bacterial pathogenesis and have been an active focus for research on interactions with the host. For example, a complex lipid (phthiocerol dimycoserate) is required for bacterial growth in the lungs of mice [64, 65]. An abundant cell wall lipoglycan, mannose-capped lipoarabinomannan (ManLAM), is implicated in affecting intracellular bacterial trafficking. ManLAM has been extensively investigated as a potential virulence factor because LAM is mannosylated in pathogenic mycobacteria, whereas in the cell wall of environmental mycobacteria, LAM is capped by arabinose or inositol phosphate [66]. Trehalose dimycolate (TDM), a glycolipid historically known as cord factor, has profound immunomodulatory roles. It induces inflammatory cell recruitment and granuloma formation, and its receptor, Mincle, was recently identified [3, 4, 67]. TDM and other mycobacterial glycolipids can promote the formation of multinucleated giant cells found in granulomas, and ManLAM can mediate the aggregation of mononuclear cells [68]. Thus, the unique and complex cell envelope of Mtb is central to the biology of the organism.

In addition to being a source of bioactive molecules, the cell envelope also represents a hurdle for bacteria to secrete virulence factors, and recent work has shed light on a specialized protein secretion system that enables mycobacteria to transport virulence factors across their complex and impermeable cell envelope [69]. This secretion apparatus came to light based upon a direct genomic comparison between the avirulent vaccine strain, BCG, and Mtb [70, 71]. Although there is considerable sequence identity between these strains,

several genomic regions are deleted in BCG. Among these is a region that encodes a type VII secretion apparatus (TSSS), called ESAT-6 system 1 (Esx-1), and several associated secreted proteins, including EsxA and EsxB. EsxA and EsxB also known as early secreted antigen target-6 (ESAT-6) and 10-kDa culture filtrate protein (CFP-10), respectively, are highly secreted, prominent antigens recognized by CD4+ and CD8+ T cells [72]. The absence of this region in BCG largely accounts for why the vaccine strain is attenuated [73–75], so it has been the focus of intense study. Esx-1 plays a central although incompletely understood role in Mtb pathogenesis that includes effects on intracellular trafficking and innate and adaptive immune responses. The Mtb genome encodes five separate TSSSs, but less is known about the others. The Esx-5 locus is required for transport of many proteins from two gene families found uniquely in mycobacteria termed PE and PPE proteins named for their conserved proline and glutamic acid (PE) and proline-proline-glutamic acid (PPE) motifs [76]. Remarkably, approximately 10% of the coding capacity of Mtb is dedicated to these gene families, which remain poorly understood. Thus, the secreted effectors of the TSSSs are likely to be critical in the pathogenesis of Mtb infection, but currently there is limited insight into their mechanism of action.

In addition, a growing number of proteins have been implicated in modulating the cell biology of macrophages. For example, the secreted bacterial proteins phosphotyrosine protein phosphatase (PtpA), dihydrolipoamide dehydrogenase (LpdC), secreted acid phosphatase (SapM), zinc-dependent metalloprotease (Zmp1), and nucleoside diphosphate kinase (NdkA) are implicated in arresting phagosome maturation, creating the early endosome-like niche of Mtb [77–79]. Mtb appears to impair apoptosis of infected cells, and bacterial mutants defective in this activity are attenuated [29]. Molecules such as the abundantly secreted 19-kDa lipoprotein antigen blunts IFN-γ signaling in macrophages [80], and a secreted bacterial adenylate cyclase modulates macrophage production of TNF-α [58]. It is not surprising that a bacterium that has evolved to make its home in human macrophages has a complex set of tools to remodel its residence. Currently, we are developing a better understanding of the tool set and how the individual components work together to orchestrate the complex life cycle of the bacteria under active investigation.

Tuberculosis in the Transplant Population

Epidemiology

Transplant patients are highly susceptible to Mtb infection. Most posttransplant TB cases occur due to reactivation of latent infection, but acquisition from donor tissue and primary infection are also seen, although they are relatively rare. Donor transmission was the proposed source in 4% of cases based upon a review of the literature from 1967 to 1997 [81] and has been described even in countries with a low overall TB incidence because of global immigration [82]. The overall incidence of posttransplant tuberculosis varies by geographic region based upon the local prevalence of Mtb (http://www.who.int/tb/publications/global_report/2010/en/index.html) and has been reported to be 20–74-fold higher in solid organ transplant (SOT) patients than the general population. Across different studies from developed countries, the frequency of TB in SOT patients ranged from 0.25% to 6.4% [81, 83–85], while in countries where tuberculosis is highly endemic, such as India and Pakistan, it has been reported to be as high as 15% [86, 87]. In bone marrow transplant (BMT) patients, the prevalence of active tuberculosis has been reported to be in the range of 0.23–0.79%. As for SOTs, regions of high TB endemicity, such as Taiwan and Hong Kong, report much higher rates (1.4–5.5%) [88–92]. A review of the literature between 1967 and 1997 indicated that active tuberculosis infection was diagnosed in 0.35–1.2% of kidney, 1–1.4% of heart, 0.9–2.3% of liver, and 2–6.5% of lung transplant recipients [81]. The type of graft influences risk, but which type is at highest risk may depend upon the local population; a large cohort of patients from 16 centers in Spain were followed prospectively, and the highest frequency was found in lung transplant recipients [84]. In contrast, the largest series of SOTs from a single US center comes from Columbia University College of Physicians and Surgeons in New York City, where renal transplant patients had the highest risk of tuberculosis [93]. In that study, Hispanic patients were overrepresented among kidney transplants as compared with those receiving other SOTs, suggesting the higher rate among renal transplant patients may, at least in part, reflect a higher rate of prior TB exposure in that population. In endemic areas such as Taiwan, it was recently reported that kidney transplant recipients were also found to have a higher risk of TB infection compared to other SOTs such as liver and heart [94].

Risk Factors

Since most posttransplant tuberculosis is due to reactivation of latent infection, the risk depends upon the likelihood of pre-transplant infection. Risk factors for Mtb infection and for progression to active tuberculosis infection in the general population are provided below.

Individuals at higher risk for latent tuberculosis infection are as follow:

(a) Close contacts of persons with known or suspected active tuberculosis, infections including residents and employees of congregate settings where residents are at

increased risk for active tuberculosis such as correctional and long-term care facilities, homeless shelters, and healthcare workers who serve patients at higher risk for active tuberculosis infection.

(b) Foreign-born persons from regions with high rates of active tuberculosis infection including Africa, Asia, Eastern Europe, Latin America, and Russia; individuals from low tuberculosis-endemic regions become at increased risk for tuberculosis infection if they visit high tuberculosis-endemic regions frequently and for an extended duration.

(c) Local populations considered at risk for latent tuberculosis infection possibly include medically underserved, low-income population or those with a history of chronic alcohol abuse and/or illicit recreation drug use.

Risk factors for progression of latent tuberculosis infection to active tuberculosis are outlined below:

(a) Persons with primary tuberculosis exposure and latent infection of less than 24-month duration.

(b) Patients with active tuberculosis that was not treated or received inadequate antituberculosis therapy, especially in individuals with evidence of pulmonary fibrosis.

(c) Patients with underlying medical conditions such as silicosis, chronic renal disease, diabetes mellitus, leukemia, lymphoma, head and neck or lung cancer. Patients who have undergone gastrectomy or jejunoileal bypass surgery are also at an increased risk for developing active tuberculosis infection.

(d) Individuals with history of cigarette smoking and alcohol and drug abuse and those with severe emaciation (<90% of ideal body weight) are considered at risk.

A subgroup of patients not only have higher risk for active tuberculosis infection, but such an infection, when it occurs, carries poor prognosis including tuberculous meningitis, disseminated multiorgan involvement, and death. In this group, infants and children aged <5 years, persons with HIV/AIDS, those receiving TNF inhibitors, high-dose systemic corticosteroids, and solid organ transplant recipients on antirejection regimens are prominent.

In transplant patients, the risk has been shown to be related to similar factors, such as history of exposure to Mtb based upon positive TST results or radiographic evidence of previously untreated Mtb, as well as clinical conditions present in this population, including chronic renal insufficiency or hemodialysis, diabetes mellitus, chronic liver disease, and other co-existing opportunistic infections. In a study in Spain, the recipient's age was a risk factor, likely reflecting the decrease in TB in the general population in recent years, such that older people are more likely to be latently infected [84]. Although positive TST results are a significant risk factor, it is important to note that only 20–25% of cases of posttransplant tuberculosis occur in patients with positive TSTs before transplant, reflecting the poor sensitivity of this test in patients with underlying end-organ failure [95].

A consistent finding has been that immunosuppressive regimens that contain (muromonab-CD3) OKT3 or antithymocyte globulin (ATG) enhance the risk of tuberculosis. OKT3 is an antibody that blocks T cell function by binding the surface molecule, CD3, on T cells. ATG is either pooled rabbit or horse antibodies against human T cells and results in T cell depletion. It is not surprising that these agents enhance the risk of tuberculosis given the importance of T cells in preventing reactivation of latent infection. In addition, intensification of immunosuppression to treat graft rejection is also a predisposing factor. In BMT patients, risk factors include graft-versus-host disease and total body irradiation [88].

Timing of Diagnosis

More than two-thirds of posttransplant tuberculosis in SOT patients are diagnosed in the first year posttransplant, with a median time to diagnosis of ~ 6–9 months (range 0.5–144 months) [81, 83, 84, 96]. The fact that the majority of patients develop tuberculosis in the first year posttransplant is consistent with the idea that most disease is due to reactivation of latent infection. Late cases presumably reflect a mix of both late reactivation and new infection and therefore may be more common in settings with a high local prevalence of tuberculosis where reinfection is more likely to occur [97]. Although rare, nosocomial transmission posttransplant has also been reported. In one instance, active tuberculosis occurred in ten renal transplant patients over an 11-month period. The median incubation period was only 7.5 weeks and 5 of the patients died a median of 8 weeks after diagnosis [98], pointing to the high susceptibility of transplant patients to primary infection.

Risk factors for diagnosis in the first year of transplant include non-renal transplant, history of early allograft rejection, immunosuppressive therapy with OKT3 or anti-T cell antibodies, and clinical and/or radiographic evidence of prior tuberculosis [81, 83]. Other immunosuppressive reagents also influence the time to diagnosis. In an Egyptian study, the introduction of cyclosporine A (CsA) in 1987 resulted in a shorter time to TB diagnosis than in previous patients who had received azathioprine and steroids (64 months versus 130 months) [99]. In a series of renal transplant patients in Turkey, the use of tacrolimus and/or mycophenolate mofetil was associated with earlier development of TB posttransplant than regimens with azathioprine, CsA, and prednisolone [100].

In bone marrow transplant patients, tuberculosis occurs with a mean time to presentation of ~9 months [88–90]. Few

patients are diagnosed during the period of neutropenia, and most cases (75%) occur after day 100. This pattern may reflect that fact that bacteria reactivate during the early phase of the BMT due to immunosuppressive therapy and total body irradiation, but given the slow growth of Mtb and the lack of a robust immune response, disease rarely manifests until later during periods of immune reconstitution [88].

Clinical Manifestations

Regardless of transplant type, the organ most frequently with tuberculosis is the lung, but approximately one third to one half of patients present with extrapulmonary or disseminated disease, compared with ~15% in immunocompetent individuals [101, 102]. Extrapulmonary and disseminated disease can involve nearly any organ with atypical and varied clinical presentations. Thus, tuberculosis should be considered in all patients with fever of unknown origin. The frequency of disseminated disease does not differ significantly based upon the type of SOT, but is more likely to occur if patients receive OKT3.

Fever is nearly a universal finding in patients with disseminated disease (>90%), and also occurs with localized infection in ~60% of patients [81]. Night sweats and weight loss are often present. Hepatic involvement has been reported in ~50% of liver transplant patients, and it has been reported at a similar rate in renal, heart, and lung transplant patients in whom liver tissue samples were studied by biopsy or at autopsy [81]. Gastrointestinal disease outside of the liver can have a wide variety of forms including gastrointestinal bleeding, peritonitis, and abscess formation. It often presents with abdominal pain and gastrointestinal bleeding that can be exsanguinating. It is often unsuspected until laparotomy or colonoscopy and most often involves the ileocecal area. Colonic disease can present as a perforated abscess or mimic a tumor. Isolated pancreatic tuberculosis has also been reported. Septic arthritis, cutaneous abscesses, and pyomyositis can occur, most commonly in the context of disseminated disease. Vertebral osteomyelitis is relatively rare, and more often occurs as localized infection and early symptoms may be atypical [103]. Central nervous system disease can present as either meningitis, which is most often associated with disseminated disease, or as focal abscesses, which can be the only site of infection or as part of disseminated illness. The most common symptoms of TB meningitis include fever, headache, vomiting, and altered consciousness. Involvement of the basilar meninges and cistern can cause cranial nerve dysfunction [104]. Renal and genitourinary disease occurs both in renal transplant patients as well as other SOT recipients. Lymphadenitis most often occurs as part of disseminated infection but can be localized. In summary, tuberculosis can involve almost any tissue, and other less commonly reported sites of infection include the pericardium, spleen, larynx, tonsil, and ocular choroid. Co-infections occur in up to 20% of patients; cytomegalovirus infection, *Nocardia* infection, community-acquired pneumonia, urinary tract infection, and invasive mold infections may modify the nonspecific symptomatology and further delay tuberculosis diagnosis [95].

Although acquisition from donors is relatively rare, it does occur and can present with various manifestations [81]. In one example, an American-born woman underwent a double lung transplant. Routine BAL on postoperative day 1 grew Mtb in culture, as did bronchial washing from postoperative day 10. The donor had no known Mtb risk factors except recent immigration from Guatemala. Retrospectively, a faint opacity was seen in the donor's chest radiograph prior to transplant, which corresponded with a left upper lobe micronodular infiltrate on the recipients CT scan. Genotypic analysis of the isolate suggested it was related to strains in Guatemala, not to those in California where the transplant was performed [105]. In another case, the donor had active pulmonary tuberculosis, and the sole site of Mtb in the recipient was an abscess in the hepatic allograft [106]. Graft-related infections need not involve the transplanted graft as in the cases above. For example, in one case, separate grafts from a single donor resulted in genitourinary infection in the renal transplant recipient, but osteomyelitis in a liver transplant patient. Interestingly, a third patient who received a renal graft from the same donor was asymptomatic and was treated for LTBI [107].

Radiographic Findings

Although posttransplant tuberculosis often involves the lungs, there is no characteristic radiographic pattern seen, which makes diagnosis difficult. In fact, as few as 4% of patients present with cavitary disease. Instead, focal infiltrates, a miliary pattern, nodules, and pleural effusions are more common. Diffuse interstitial infiltrates can also be seen [81]. The findings can be subtle, such as bronchial narrowing caused by an endobronchial granulomatous mass [108].

Diagnosis

It is important to diagnose LTBI in donor and recipient pretransplant in order to consider pre- or posttransplant chemoprophylaxis. The decision to treat LTBI requires weighing the risk of reactivation with the possible drug toxicities and drug-drug interactions [109]. Careful screening of donors has become increasingly important as the donor pool has become more ethnically diverse, and a recent international working group formulated consensus recommendations for screening of donors [110–112].

Unfortunately, there is no gold standard to detect LTBI. Clinical history is useful in assessing the risk of latent TB infection, and questions about country of origin, travel, exposure to patients with active tuberculosis, and social and medical risk factors should be evaluated. In addition, CXR may reveal old granulomatous disease or apical scaring as evidence of prior TB. Evidence of latent TB infection can be obtained by tuberculin skin testing (TST) or IFN-γ release assays (IGRAs) [113]. When conventional TST is used, ≥5 mm of induration at 48–72 h should be considered positive in transplant patients [114]. Repeating the test 7–10 days after an initial negative TST may reveal that the first test was falsely negative, as the first administration of PPD can boost the response in individuals with remote TB exposure. There are two FDA-approved IGRAs available in the United States: QuantiFERON-TB Gold In-tube test (QFT-GIT, Cellestis Ltd) and T-SPOT.TB test (T-Spot, Oxford Immunotec Ltd). Guidelines on their use is available from the CDC [115], and the American Academy of Pediatrics has published guidance for their use in children [116]. Like TST, IGRAs detect an immunological response to Mtb antigens. TSTs detect a delayed type hypersensitivity response to purified protein derivative (PPD) in vivo. PPD is a crude mix of Mtb antigens that can also elicit responses due to prior vaccination with BCG or exposure to non-tuberculous mycobacteria. In contrast, IGRAs detect IFN-γ release in vitro from T cells in response to TB antigens, EsxA and EsxB, which are absent from BCG and most environmental mycobacteria. *M. kansasii*, *M. szulgai*, and *M. marinum* are exceptions as they encode homologs of Mtb EsxA and EsxB, so sensitization to these organisms might cause false-positive results in IGRAs. Importantly, unlike TST, positive test results using IGRAs are not confounded by prior BCG vaccination. Thus, IGRAs offer higher specificity than TSTs, particularly in BCG vaccinated populations, although they do not provide a major increase in sensitivity.

Unfortunately, TST performs poorly in transplant populations, both prior to transplant, due to anergy related to end organ disease or long-term corticosteroid treatment, and after transplant due to immunosuppressive agents. The data on IGRAs in immunocompromised patients is more limited than TSTs, but IGRAs appear to perform similarly to or slightly better than TST in SOT patients prior to transplant [117–122]. Only two studies have looked at hematopoietic stem cell transplant patients prior to transplant, and there was a poor correlation between the TST and GTF-GIT, regardless of BCG vaccination history [123, 124]. Thus, although testing for LTBI should be performed prior to transplant, a negative TST or IGRA prior to or after transplant does not rule out prior infection with Mtb [125]. In fact, only 20–25% of cases of active tuberculosis after transplantation occur in patients with positive TST reactions before transplant [95].

Data on the ability of IGRAs to predict subsequent active tuberculosis are limited, particularly in immunocompromised individuals. However, they appear to perform similarly to TST in studied populations, and IGRA can detect some TST-negative subjects who go on to active disease [126]. Routine testing with both TST and IGRAs is not generally recommended, but it might be useful in high-risk transplant patients, when indeterminate results are obtained with one test or when active tuberculosis is suspected [115]. If both TST and IGRA are performed, a positive result in either should be taken as evidence of infection. Since TST and IGRAs detect an immune response to Mtb, they cannot distinguish latent from active infection. Thus, in the case of a positive result, active infection must be ruled out. If clinical or radiographic data suggest TB, sputum smears and cultures or, if necessary, bronchoalveolar aspirate or lavage should be performed. Additional imaging and biopsy may be necessary depending upon the clinical history. TST and IGRAs cannot rule out active infection, as only 75–90% of patients with active tuberculosis are TST positive and the sensitivity drops in patients with underlying immunosuppression [127]. In the case of disseminated disease, approximately 50% of patients have negative TSTs. Therefore, these tests can neither "rule in" nor "rule out" active infection.

Diagnosis of tuberculosis in the posttransplant setting requires a high index of suspicion as the cases are often extrapulmonary and may present with minimal or atypical symptomatology. In addition, diagnostic tests perform poorly, and tuberculosis is also frequently associated with other infections, which may complicate the picture. It should be considered in any patient with fevers of unknown origin, constitutional symptoms, or pulmonary infiltrates. Sputum and biopsy specimens should be sent for acid-fast bacilli staining and culture. Since most cases do not involve cavitary lung disease, invasive procedures are often required to obtain a diagnostic specimen, such as bronchoscopy, mediastinoscopy, laparoscopy, and tissue biopsy. Cerebral spinal fluid (CSF) culture is the gold standard for diagnosing TB meningitis. Direct examination of specimens by means of an acid-fast stain provides supportive evidence of tuberculosis weeks before the culture and species identification may be available. Although microscopic examination is rapid, it is relatively insensitive. Culture is the gold standard, although results take weeks and approximately 20% of clinically suspected pulmonary Mtb infections remain culture negative. The false negative rate is likely to be even higher in extrapulmonary disease. Growth on solid media (such as Lowenstein-Jensen or Middlebrook agar) takes 3–6 weeks. Broth detection systems that detect early changes in the media due to growth of bacteria provide a more rapid turnaround time, often becoming positive after 2 weeks.

Since acid-fast staining and growth on solid or liquid media cannot distinguish Mtb from NTM, once an isolate is

recovered, further testing is required for species identification. Growth of a mycobacterial isolate after several days in culture excludes the diagnosis of Mtb, as it is invariably a rapid grower, most commonly *M. fortuitum*, *M. abscesses*, or *M. chelonae*. For slow-growing mycobacteria, molecular approaches can speed the process of species identification. These tests detect mycobacterial nucleic acids directly from clinical specimens. Thus, nucleic acid amplification tests are useful to quickly determine whether the acid-fast bacilli seen on smear or biopsy are a member of the Mtb complex weeks before cultures are available. In addition, nucleic acid amplification tests can detect Mtb in 50–80% of smear-negative, culture-positive specimens. Guidance on the use of such tests has been recently updated [128], which recommend that nucleic acid amplification tests be performed on at least one respiratory specimen from each patient in whom a diagnosis of TB is being considered but has not been established.

A new diagnostic test, Xpert MTF/RIF (Cepheid), uses PCR and molecular beacon technology to identify Mtb in sputum samples within several hours, while simultaneously detecting rifampin resistance [129]. Rifampin resistance is a marker of other drug resistance, so this allows a rapid way to identify suspected MDR cases, which would otherwise take months with conventional drug susceptibility testing. It is highly sensitive in smear-negative sputum samples, and the World Health Organization has endorsed its use as first line in HIV-infected patients in TB-endemic countries. It also appears promising for diagnosing extra-pulmonary disease [130]. One study showed a sensitivity of >85% from CSF, biopsy, urine, pus, and fine needle aspirates, although it may be lower (40–50%) in pleural and cavitary fluids. Further evaluation is necessary in extra-pulmonary disease and in the transplant setting, but it is likely to enter clinical practice given its high sensitivity, rapid turn-around time, and ability to quickly identify rifampin resistance. More novel diagnostic tests, such as TB ID/R [131], pyrosequencing assays [132], whole genome sequencing (WGS) [133], and next-generation sequencing [134, 135] are being configured in a low-cost platform to provide rapid diagnosis and drug susceptibility information.

Outcomes

The mortality rate associated with tuberculosis in transplant patients is 25–40% [81]. The high incidence of extrapulmonary disease and atypical presentations, coupled with the poor performance of diagnostic tests and the slow growth of the bacilli in culture result in diagnostic delays. At the same time, profound immunosuppression can lead to rapid disease progression. Predictors of mortality include disseminated disease, prior rejection, receipt of OKT3 or ATG, and presence of other opportunistic infections [83]. Treatment is complicated by drug interactions with immunosuppressive agents, particularly calcineurin inhibitors. Subtherapeutic immunosuppressive drug levels can result in organ rejection, and allograft loss has been reported in up to 33% of transplant patients on antituberculous therapy. In addition, side effects such as hepatotoxicity can be difficult to manage particularly in liver transplant patients [83]. Given the complexity of treatment and drug interactions, they are covered in detail in the therapeutic section.

Conclusion

Tuberculosis is an important cause of morbidity and mortality in the transplant patient. Our understanding of the basic biology of tuberculosis has made significant advances. It is clear that T cells, IFN-γ, and TNF-α play central roles in host defense against Mtb. On the bacterial side, work has pointed to the importance of the complex cell envelope and the type VII secretion system. Newer molecular techniques have made incremental improvements in diagnosis, although they have not been well studied in the transplant population. Despite these gains, the understanding of TB pathogenesis and host immunity has yet to translate into an efficacious vaccine, robust diagnostics for latent and active tuberculosis, or shorter and less toxic therapies. Therefore, tuberculosis is likely to remain a significant cause of disease in transplant patients for the foreseeable future.

Nontuberculous Mycobacterial Disease in Transplant Recipients

30

Julie V. Philley, Amar Safdar, and Charles L. Daley

Introduction

Nontuberculous mycobacteria (NTM) include over 170 species and subspecies many of which have been reported to cause disease in transplant recipients. The frequency of NTM disease among transplant recipients varies from center to center ranging from 1.4% to 22.4% [1–4] among lung transplant recipients; however, actual NTM disease occurs in less than 5% of patients [1, 2, 4]. Posttransplant infection can occur through several ways including reactivation of prior infection, donor-derived infection, contamination at the time of transplant, or posttransplant environmental contamination. The most common site of infection is the lung although these nearly ubiquitous mycobacteria can produce disease at any site in immunocompromised individuals, so a high index of suspicious is necessary in order to make an early diagnosis and initiate appropriate therapy promptly [5]. Treatment of NTM is complicated because of the multiple drugs required for treatment, drug-related toxicity, potential for drug-drug interactions, and long duration of therapy. Untreated NTM can produce significant morbidity and mortality with outcomes varying by mycobacterial species, drug resistance patterns, and type of transplant. This chapter will review the diagnosis and treatment of NTM disease among transplant candidates and recipients.

Epidemiology

The prevalence of NTM disease in the general population is increasing in many areas [6–10]. However, lack of mandated reporting and difficulty in distinguishing clinically significant disease from colonization or indolent infection make the prevalence of NTM disease hard to determine. The prevalence of NTM disease in transplant recipients is equally difficult to establish although case series and retrospective cohort studies have provided estimates of the prevalence of disease in this high-risk population.

The proportion of mycobacterial infections due to NTM varies depending on the prevalence of tuberculosis (TB). Among 7342 solid organ transplant (SOT) and 1266 hematopoietic stem cell transplant (HSCT) recipients at a center in South Korea where TB is prevalent, there were 152 patients identified with a mycobacterial infection of whom 22 (15%) had NTM isolated [11]. The overall incidence of TB was 257.4 per 100,000 patient-years compared to 42.7 per 100,000 patient-years for NTM. In areas with lower rates of TB, the proportion of mycobacterial infections due to NTM is typically 80–90% [3, 12, 13].

The type of transplant is an important factor determining the risk of NTM disease with higher rates of NTM disease reported among HSCT than SOT recipients in some studies [14]. For example, in a study from South Korea, the incidence of NTM in HSCT recipients was 258.7 per 100,000 patient-years, significantly higher than that seen in SOT recipients (27.1 per 100,000 patient-years) [11].

Solid Organ Transplants

The overall incidence of NTM disease among SOT recipients varies by the type of transplant with the highest rate among lung (0.46–8.0%) [2–4, 13, 15] and heart (0.24–2.8%) [16, 17] transplant recipients followed by kidney (0.16–0.38%) [18–24] and liver transplants (0.04–0.1%) [15, 25].

Lung Transplants

Lung transplant recipients have the highest rate of developing NTM infection after undergoing transplantation [26]. Much of the data concerning the epidemiology of NTM disease in lung transplants comes from large retrospective series, primarily from low TB prevalence areas. In general, between 3.8% and 22% of lung transplant recipients undergoing surveillance bronchoscopies have NTM isolated from bronchoalveolar lavage samples [2–4, 13]. However, most of these patients were not thought to have invasive NTM disease; only 10–14% of such patients were considered to have NTM disease [4, 27].

One of the first studies to describe the frequency of NTM in lung transplant recipients was published in 1999 and described a 12-year experience at a single center in Australia [13]. Of 261 transplants, there were 23 mycobacterial infections detected (8%) and all but two of whom had NTM isolated. The most common site of NTM disease was the lung (83%) and the most common causative organism was *M. avium* complex (MAC). Median time from transplant to diagnosis of NTM infection was 450 days and ranged between 50 and 3272 days [13]. A case series from the United States reported 34 patients with NTM disease over 7.5 years from all solid organ transplants. Nineteen occurred in lung transplants, 6 single and 13 bilateral allograft transplants [15]. The median time of occurrence was 8 months following transplantation procedure. In another series from the United States, 15 (22.4%) of 237 lung transplant recipients over a 15-year period developed NTM disease corresponding to an incidence of NTM isolation of 9 per 100 person-years and incidence rate of NTM disease of 1.1 per 100 person-years [4]. The most common NTM isolated was MAC (70%) followed by *Mycobacterium abscessus* (9%).

M. abscessus has become an increasingly common and challenging NTM infection in transplant recipients. An international survey of 31 of 62 transplant centers that responded reported that 17 of 5200 (0.33%) transplant recipients were identified to have *M. abscessus* after transplantation with two patients known to have pretransplant "colonization" [28]. Disease developed in the allograph in 12 patients, in the skin/soft tissue in 3 patients, and in both in 2 patients. Median time to diagnosis was 18.5 months, ranged between 1 and 111 months.

NTM can be isolated from 6% to 13% of patients with CF, and up to 20% of CF patients awaiting transplantation become infected [1, 29]. In several studies invasive NTM infections have been reported to occur in 0.5–3.4% of CF patients after undergoing lung transplantation [1, 28, 30]. In a review of both CF ($n = 60$) and non-CF ($n = 60$) lung transplants, mycobacteria were isolated from 7.2% and 9.1% of recipients, respectively [31]. *M. abscessus* is a particularly challenging pathogen to treat in patients with CF. Among 13 patients with pretransplant cultures positive for *M. abscessus*, all of whom met ATS criteria for disease, 3 developed posttransplant complications, and all 3 responded to treatment [32]. Survival posttransplant was 77% 1 year after transplantation, 64% at 3 years, and 50% at 5 years with no deaths related to *M. abscessus*. Additionally, there was no significant difference in survival when compared with other transplanted patients.

Other SOT

The frequency of NTM disease in other types of SOT is less common than with lung transplants. Among renal transplants, the incidence of NTM has been reported between 0.16% and 0.38% [12, 14, 15, 18–24, 33]. Of 3921 renal transplants between 1984 and 2002, 18 were identified as having mycobacterial infections after undergoing allograft transplantation, only 3 of which were due to TB. Thirteen of the patients were alive and well at a mean follow-up of 9.2 years since the infection diagnosis [12]. In Spain, between 1980 and 2000, there were 27 renal transplant patients (2.1%) with mycobacterial infections, 20 had TB, 5 had *M. kansasii*, and 2 patients had *M. fortuitum* infection [34].

The incidence of NTM infection among heart transplant recipients ranges between 0.24% and 2.8% [16, 35]. Novick and colleagues reported a 17-year experience at Stanford and noted that only 14 of 502 heart transplant recipients developed NTM infections over a mean of 3.5 years of follow-up [16]. The rate was higher among those receiving azathioprine and prednisone than cyclosporine alone. Additional heart transplant patients with pulmonary and extrapulmonary disease have been reported with various NTM species including *M. abscessus*, *M. xenopi*, and *M. scrofulaceum*. The estimates for NTM disease in liver transplants have been reported to be quite low at 0.1% [15, 25] although a recent study from Korea reported an incidence of 14.7 per 100,000 patient-years [11].

HSCT

The incidence of NTM infection among HSCT recipients has ranged from 0.4% to 4.9%; however, the reported incidence in allogenic stem cell graft recipients has been as high as 3–9.7% [36–41]. Among 6259 HSCT recipients at the University of Washington over a 20-year period, 40 were identified as having NTM infection (0.64%) of which 28 were considered to have invasive mycobacterial disease (0.44%) [37]. The median time to diagnosis was 251 days following transplantation. All three patients with definitive pulmonary disease were treated successfully.

A retrospective study from the University of Toronto reported that 4% of their 1097 allogenic HSCT patients had NTM isolated with 2.7% having NTM disease [42]. The median time to diagnosis was 343 days. All had pulmonary

NTM disease with 93% experiencing pulmonary-only involvement. In general, the rate of NTM disease in HSCT recipients has been higher than that in SOT recipients but not in all studies. A recent study from Korea reported an incidence of NTM in HSCT recipients at 258.7 per 100,000 patient-years, higher than that seen in SOT recipients (27.1 per 100,000 patient-years) [11].

Risk Factors for NTM Disease

Risk factors for development of NTM disease vary from study to study but recipients of lung transplant are at highest risk for NTM disease compared with other SOT recipients [15]. In a case-control study of 34 post-lung transplant recipients matched to 102 control patients, lung transplant was strongly associated with NTM disease (56% vs. 10%; OR 11.49) [15]. Among HSCT recipients a number of risk factors for NTM disease have been reported including a higher risk with allografts versus autografts, myeloablative versus nonmyeloablative transplants, matched unrelated donor over sibling allografts, underlying GVHD, use of steroids to treat GVHD, leukemia relapse, and the existence of bronchiolitis obliterans [36]. A recent study from Toronto reported that severe chronic graft-versus-host disease and CMV viremia were factors associated with an increased risk of NTM [42].

Immunologic Susceptibility to NTM Disease

Immunity to mycobacterial infection requires an effective interplay between the myeloid and lymphoid cells through the interleukin 12-interferon-gamma pathway [43]. A complicated cascade of events is set into effect following exposure to mycobacterial antigens, and organism-specific antigen primed T cells at the infection site orchestrate events leading to cell death of these intracellular pathogens. The critical effector cell for controlling NTM is the macrophage, which ingests mycobacteria, and once engulfed by the macrophage, the bacteria's fate is determined by the cell's state of immune activation, which is determined by interactions between cells in the TH1 pathway and their associated cytokines, particularly the IL-12/IFN-gamma axis [44]. Mononuclear phagocytes produce interleukin-12 which stimulates T cells and natural killer cells through the interleukin-12 receptor [43]. Signal transducer and activator of transcription (STAT)4 is activated leading to induction of interferon-gamma production which binds to its receptor causing activation and differentiation of macrophages [45, 46]. IFN gamma via cytokine receptor activates Janus kinase (JAK1 and JAK2) tyrosine-phosphorylation and stimulation of STAT1, which mediates activation of interferon-stimulated genes. In vitro experiments have shown that addition of IFN-γ promotes killing of microbes by upregulating T_H1 responses through neutrophils, monocytes, and macrophages [47]. IFN-γ activation of macrophages via T_H1 lymphocyte activation induces macrophages to overcome inhibition of mycobacteria containing phagolysosome maturation [48]. IFN-γ has also been noted to prime macrophages for enhanced microbial killing and activation of inflammatory response via Toll-like receptor (TRL) pathway [49, 50]. Furthermore, as a response to TLR signaling, IFN-γ alters epigenetic governance of macrophages, inducing and priming enhancers to increase transcriptional output [51].

The activated macrophages are then able to kill relatively avirulent intracellular organisms like NTM. Numerous other cytokines such as IL-18, IL-23, and IL-29, receptors like vitamin D receptor, and unidentified cofactors may also be important in garnering hosts' effective containment and elimination of immune-inflammatory response against NTM. Novel influences on macrophage lysosomal activity due to IL-12, IL-27, and STAT-3 were demonstrated by Jung et al. [52]. These adjunct cytokine and transcription signals promote enhanced trafficking of mycobacteria to lysosomes in human macrophages. This may have important implications in future approaches for effective containment of mycobacterial infection.

HIV-associated acquired immunodeficiency has demonstrated the critical role of CD4-positive T-helper lymphocytes (CD4+ cells) in maintaining host resistance to MAC and other NTM. CD4 cell decline is also associated with a cascade of dysfunction within the cell-mediated immune, or TH1 pathway, including alterations in cytokine levels and hosts' immune responsiveness [53, 54].

Interleukin-12 (IL-12) [55], IFN-γ, and tumor necrosis factor alpha are important for sustained macrophage activation and regulation of effective intracellular microbicidal activity. Reactive nitrogen and oxygen species are a family of toxic antimicrobial molecules derived from nitric oxide and superoxide, respectively. They assist in intracellular mycobacterial killing; IFN-γ is the principal cytokine in promoting nitrosative stress and bacterial cell death [56]. Recently, the important influence of restricted IFN-γ-mediated activation of pulmonary macrophages by the local suppressor of cytokine signaling (SOCS)1 was reported [57]. Additionally, this group showed that factors secreted by alveolar epithelial cells enhanced the microbicidal capacities of macrophages by mechanisms independent of reactive nitrogen species transcribed under the influence of IFN-γ; the clinical significance for such processes in physiologic clearance of environmental NTM that are routinely exposed to the human respiratory tract needs further investigation [57].

Transplant recipients are treated with immunosuppressive drugs in order to prevent and treat solid organ allograft rejection. In recipients of stem cell allograft, intragenic immune suppression is the mainstay of therapy for graft sustenance and treatment of acute or chronic graft-versus-host disease.

Immunosuppression is achieved through depleting lymphocytes, diverting lymphocyte traffic, or blocking their response pathways described above [58]. Besides the therapeutic effect of these drugs, there is also the undesirable effect of increasing the risk of infection from numerous pathogens including NTM.

Microbiology

NTM consists of over 170 species and subspecies that are found throughout the environment including from soil and water, both natural and treated. NTM are traditionally divided into two groups based on their rate of growth on subculture; rapid growers show visible growth by 7 days and slow growers after 7 days (Table 30.1). Many of these organisms have been reported to cause disease in transplant recipients. Most infections are caused by more virulent organisms such as *M. avium* complex, *M. kansasii*, and *M. abscessus*. Isolation of low-virulence mycobacteria is not uncommon, and in immunologically intact, nonsusceptible individuals, they frequently represent either laboratory/environmental contaminant or nondisease-associated colonization. However, in the setting of allogeneic transplantation, all organisms must be considered as potential pathogens until proven otherwise.

The most clinically important slowly growing NTM include *Mycobacterium avium* complex (MAC) and *Mycobacterium kansasii* although numerous other slow growers have been reported to cause disease in transplant recipients (Table 30.1). MAC currently consists of at least ten species; the most common to cause infection in humans are *M. avium*, *M. intracellulare*, and *M. chimaera* [59]. MAC isolates are usually susceptible to the macrolides like azithromycin and clarithromycin and clofazimine with variable susceptibility to rifamycins, ethambutol, amikacin, and streptomycin. *Mycobacterium kansasii* is a slowly growing organism that is considered one of the most virulent NTM. *M. kansasii* is usually susceptible in vitro to the first-line anti-tuberculosis agents except pyrazinamide as well as to the macrolides and fluoroquinolones [60–62].

Rapidly growing mycobacteria are particularly common among HSCT recipients and include *Mycobacterium fortuitum*, *Mycobacterium chelonae,* and members of the *Mycobacterium abscessus* complex. Rapid growers are more resistant to current antimicrobials than most slow growers and some species contain an erythromycin ribosomal methylase gene (*erm*) that can lead to inducible macrolide resistance [63]. *M. abscessus* is further subdivided into three subspecies (ssp) including ssp. *abscessus*, ssp. *massiliense*, and the least common ssp. *bolletii* [64, 65]. Approximately 80% of isolates of *M. abscessus* ssp. *abscessus* carry a functional *erm*(41*)* gene that results in inducible macrolide resistance in the presence of a macrolide; this resistance is not reflected by the initial 3-day in vitro MIC reported by some laboratories [63]. *M. abscessus* ssp. *massiliense* does not undergo inducible macrolide resistance as the *erm*(41) gene is nonfunctional and, hence, the disease is easier to treat [66–68]. Depending on the organism, the following antimicrobials show variable in vitro susceptibility: macrolides, aminoglycosides, clofazimine, fluoroquinolones, tigecycline, cefoxitin, and imipenem/meropenem [69].

Table 30.1 Nontuberculous mycobacteria reported to have caused disease in transplant recipients

Slowly Growing mycobacteria	Rapidly growing mycobacteria

M. marinum	
M. scrofulaceum	
M. szulgai	
M. terrae	
M. thermoresistable	
M. triplex	
M. xenopi	

Clinical Presentation

The clinical presentation of NTM disease in transplant patients varies depending on the type of transplant, degree of immunosuppression, patient comorbidities, and species of NTM involved [70]. Patients may present with pleuropulmonary, skin and soft tissue, bone and joint, catheter-related, as well as disseminated disease [5]. Among HSCT recipients, catheter-related infections are one of the most common infections followed by skin and soft tissue infections [36–41, 71, 72]. In lung transplant recipients, pleuropulmonary infections are most common ranging from 54% to 82% followed by skin and soft tissue infections [14, 73]. Cough and sputum production are common and more common in transplant recipients with NTM than TB. Skin, soft tissue, and disseminated infections are the most common types of NTM infections in heart and kidney transplants.

Time to presentation varies between types of transplants and tends to be longer for NTM than TB. A recent study from South Korea reported a median time to diagnosis of 24.2 months for NTM and 8.5 months for TB. For HSCT recipients the median time to presentation is 5 months and over 10 months for SOT [70]. Among SOT patients, the median time to diagnosis has ranged from 15 to 30 months for heart, 20 to 24 months for kidney, 15 months for lung, and 10 months for liver transplants [5, 33, 70].

Pulmonary Disease

Pleuropulmonary disease is the most common presentation in lung transplant recipients but occurs in other transplants as well [74]. In fact, pleuropulmonary infections account for about one-third of NTM infections in recipients of HSCT with MAC being the most common causative organism. Cough, with or without sputum production, is the most prominent symptom although weight loss, fatigue, hemoptysis, night sweats, dyspnea, and chills also occur [75]. Chronic lung disease is a well-recognized predisposing factor in immunosuppressed patients, including transplant recipients. The radiographic features suggestive of pulmonary NTM include small nodules, tree-in-bud opacities, and/or small cavitary lesions with bronchiectasis [2]. Infections due to *M. kansasii* frequently involve the upper-lung lobes, and thin-wall cavities are seen commonly. Other pleuropulmonary manifestations include empyema as well as chest wall and surgical wound infections [76].

Skin, Soft Tissue, and Musculoskeletal Infections

While most NTM disease affects the lung in lung transplant recipients, skin and soft tissue infections are also a major concern post surgically [4, 13, 25, 33, 77, 78]. In one series, 4 of the 53 lung transplant patients had soft tissue infections (3 with *M. abscessus* and 1 with *M. chelonae*) and 1 died from progressive disseminated disease [4]. Typical findings include painful to minimally painful erythematous to violaceous subcutaneous nodules usually on the extremities or near the site of surgical wounds [4, 77]. Lesions will often ulcerate and may follow lymphatic distribution resembling sporotrichosis. The most common species to cause skin and soft tissue involvement are the rapidly growing mycobacteria and *Mycobacterium marinum* [33, 79].

M. fortuitum produces skin and soft tissue infection in immunologically competent patients; most infections occur due to accidental inoculation. In transplant recipients, surgical sites and scars may become sites of infection. Most infections due to *M. chelonae* are seen in patients with underlying predisposing conditions such as chronic corticosteroid use, rheumatoid arthritis, lupus, and cancer [80, 81], while *M. abscessus* has notably caused surgical infections surrounding transplant sites [25, 77, 82]. Health-related infections occur sporadically and have been seen in patients after deep intramuscular injection, sternal wound infection following cardiac surgery, and after a variety of reconstructive and plastic surgical procedures including augmentation mammoplasty and chest wall reconstruction after tumor resection [83].

Musculoskeletal infections may present as septic arthritis, tenosynovitis, or osteomyelitis. These infections may involve noncontiguous sites due to disseminated disease. In one review of NTM in SOT recipients, 67% presented with soft tissue and musculoskeletal involvement with over 50% involving noncontiguous sites [25].

Catheter-Related Infections

Catheter-related infections have become the most common healthcare-related infections due to RGM with most infections occurring in patients with long-term indwelling intravascular catheters. In immunosuppressed patients, *M. chelonae* and *M. abscessus* are among the most common NTM isolates [84]. RGM species are increasingly reported in immunosuppressed patients with catheter-related infection and include uncommon NTM like *M. smegmatis* [85], *Mycobacterium neoaurum* [86], *Mycobacterium aurum* [87], *Mycobacterium lacticola* [88], and *Mycobacterium brumae* [89]. Catheter-related infections are the most commonly encountered infectious complication in HSCT recipients accounting for approximately one-third of all NTM infections in this setting and most are due to rapidly growing NTM. Median time to presentation is approximately 2 months [37]. It is important to emphasize that RGM are frequently isolated in hospital and laboratory water supplies, and numerous pseudo-outbreaks involving contaminated blood culture materials and fiberoptic bronchoscope sterilizing machine contamination have been described [90, 91].

Disseminated Disease

Disseminated disease has been reported with all types of SOT but is most common in kidney and heart transplant recipients [14, 25, 77, 92]. In some series, approximately half of patients with pulmonary disease have evidence of dissemination [14, 33]. Disseminated disease can involve almost any body site including skin, soft tissues, musculoskeletal sites, lymph nodes, blood, bone marrow, and lung. Patients may present with fever of unknown origin often with subcutaneous nodules. The rapidly growing mycobacteria are the most common species to disseminate followed by *M. kansasii* and *M. haemophilum*.

Diagnosis

Clinical Diagnosis

The diagnosis of pulmonary disease is based on the American Thoracic Society (ATS) and Infectious Diseases Society of America (IDSA) criteria (Table 30.2), which involve the assessment of clinical, radiographic, and microbiological factors [69]. Given the variable clinical presentation noted in transplant recipients with NTM disease, the clinician should have a high index of suspicion and send appropriate clinical specimens for culture and histopathologic examination.

Table 30.2 Clinical and microbiologic criteria for diagnosing nontuberculous mycobacterial lung disease [69]

Clinical (both required)
1. Pulmonary symptoms, nodular or cavitary opacities on chest radiograph, or a high-resolution computed tomography scan that shows multifocal bronchiectasis with multiple small nodules
and
2. Appropriate exclusion for other diagnoses.
Microbiologic
1. Positive culture results from at least two separate expectorated sputum samples. If results are nondiagnostic, consider repeat sputum AFB smears and cultures.
or
2. Positive culture result from at least one bronchial wash or lavage.
or
3. Transbronchial or other lung biopsy with mycobacterial histopathologic features (granulomatous inflammation or AFB) and positive culture for NTM or biopsy showing mycobacterial histopathologic features (granulomatous inflammation or AFB) and one or more sputum or bronchial washings that are culture positive for NTM.

Typical chest computed tomography findings of NTM pulmonary disease include the presence of bronchiectasis and centrilobular nodules with a tree-in-bud appearance [5, 70]. In the transplant setting, bronchiolitis obliterans and rejection may produce similar findings although the presence of nodules is more suggestive of NTM disease [93].

Laboratory Diagnosis

Laboratory diagnosis of NTM disease is based on isolation of these organisms from culture of clinical specimens. Both solid and broth media are recommended for growth of mycobacteria [69]. Slow-growing mycobacteria (SGM) take between 3 and 8 weeks to grow, whereas in the case of rapidly growing mycobacteria (RGM) growth often becomes evident within 7 days on subculture. Some organisms such as *M. genavense* can take up to 12 weeks of incubation to detect growth. For most NTM species, the optimal temperature for growth is 28 to 37 °C, although some species require either higher or lower temperatures for optimal growth. Specimens obtained from cutaneous sites should be incubated at 35 and 28–32 °C. In addition, some fastidious species such as *M. haemophilum* require addition of hemin or ferric ammonium citrate for growth.

The clinical usefulness of antimicrobial drug susceptibility testing remains unclear because of the lack of correlation between the in vitro activity of some antimycobacterial drugs and clinical outcomes. A broth-based culture method with both microdilution and macrodilution methods is considered acceptable for testing against MAC[69]. Initial isolates and treatment failures should be tested against clarithromycin because of the good correlation between identification of macrolide resistance and poor treatment outcomes. Recent studies also suggest correlation between amikacin and treatment outcomes with an MIC >64 ug/ml associated with lack of microbiologic response [94]. Isolates of *M. kansasii* should be tested for susceptibility to rifampin and if resistant, additional drugs should be tested such as macrolides and fluoroquinolones [69]. For rapidly growing mycobacteria, broth microdilution minimal inhibitory concentration determination is recommended [69].

Molecular methods such as gene sequencing and line probe assays are becoming increasingly available for rapid speciation and even identification of genetic mutations that confer drug resistance. A line probe assay is commercially available (Hain, Germany) that can detect several common NTM species and identify mutations which cause macrolide and aminoglycoside resistance [95]. While whole genome sequencing is the gold standard, the test remains expensive and not widely available.

Treatment

Treatment of NTM disease requires a multidrug regimen in order to achieve cure and prevent the emergence of resistance. In addition, surgical excision/debridement may be required in extrapulmonary disease and in some cases lessening of the immunosuppressive regimen is required [74]. The optimal combination of drugs (Table 30.3) and duration of therapy are not known for any NTM species. Given the high recurrence rate seen in non-immunosuppressed patients, the current ATS/IDSA recommendation to treat pulmonary NTM disease for 12 months of negative cultures should be considered the minimal duration [69]. Cutaneous and disseminated disease should be treated for a minimum of 6 months although longer durations may be required depending on the infecting species, site of disease, resistance pattern, and response to therapy [70]. Treatment of catheter-related infections includes prompt removal of infected devices and combination antimicrobial therapy for a minimum of 6–12 weeks [70]. Prolonged therapy greater than 12 weeks may be necessary depending on the infecting organism and clinical response to treatment. Lessening of immunosuppression increases the risk of solid organ graft rejection, stem cell graft compromise or graft loss, and potential worsening of graft-versus-host disease. Unlike patients with HIV/AIDS, immune reconstitution syndrome has not been a concern in transplant population.

As in non-immunosuppressed patients, isolation of an NTM from a clinical specimen does not necessarily indicate

Table 30.3 Commonly used drugs for nontuberculous mycobacterial infections

Drug	Route of administration	Dosage	Adverse reactions
Amikacin	Intravenous	10–15 mg/kg once daily or 15–25 mg/kg three times weekly	Nephrotoxicity, auditory-vestibular toxicity
Azithromycin	Oral	250–500 mg daily	Nausea, vomiting, diarrhea, auditory-vestibular toxicity Prolonged QT
Cefoxitin	Intravenous	50 mg/kg/dose 2–3 times daily	Fever, rash, cytopenias
Clarithromycin	Oral	500 mg twice daily	Hepatitis, taste disturbance, inhibits metabolism of rifabutin
Clofazimine	Oral	100 mg once daily	Discoloration of skin, enteropathy, nausea, vomiting, prolonged QT
Ethambutol	Oral	15 mg/kg/dose once daily	Optic neuritis, peripheral neuropathy
Imipenem	Intravenous	500–1000 mg 2–3 times daily	Nausea, vomiting, diarrhea, hepatitis, fever, rash
Isoniazid	Oral	5 mg/kg/dose once daily	Hepatitis, peripheral neuropathy
Linezolid	Oral, intravenous	600 mg once or twice daily	Cytopenias, peripheral neuropathy, optic neuritis
Minocycline	Oral	100 mg twice daily	Photosensitivity, nausea, vomiting, diarrhea, vertigo, tooth discoloration
Moxifloxacin	Oral	400 mg daily	Nausea, vomiting, diarrhea, insomnia, agitation, tendonitis, photosensitivity, prolonged QT
Rifabutin	Oral	300 mg daily	Cytopenias, orange discoloration of fluids, hepatitis, nausea, vomiting, diarrhea, hypersensitivity/flu-like syndrome, increased metabolism of many drugs, uveitis for rifabutin
Rifampin	Oral	600 mg daily	Cytopenias, orange discoloration of fluids, hepatitis, nausea, vomiting, diarrhea, hypersensitivity/flu-like syndrome, increased metabolism of many drugs
Tigecycline	Intravenous	50 mg once or twice daily	Nausea, vomiting, diarrhea, pancreatitis, hypoproteinemia, hepatitis
Trimethoprim-sulfamethoxazole	Oral	10–20 mg/kg/dose twice daily	Nausea, vomiting, diarrhea, cytopenia, fever, rash

that treatment is required. Studies in lung transplant recipients have reported that 75% or more of patients who have NTM isolated from the respiratory tract are "colonized" [2, 4, 26]. Repeated isolation of a more virulent species is more suggestive of NTM-related disease although in extrapulmonary disease it may not be possible to obtain additional samples for culture.

Despite the difficulties faced when treating NTM disease, most patients who have developed NTM disease after undergoing transplantation have survived and been cured with less than 5% of deaths related to the NTM disease. However, in many cases, treatment is prolonged and requires surgical debridement, and adverse reactions including hearing loss in those receiving aminoglycosides are common [33]. Consultation with an expert in the treatment of NTM disease is advised.

Slowly Growing NTM

Mycobacterium avium Complex

The ATS/IDSA recommend treatment with three to four drugs depending on the radiographic extent of disease (Table 30.4) [69]. For immunocompetent patients with nodular lung disease and bronchiectasis, three times weekly dosing of clarithromycin (1000 mg) or azithromycin (500 mg), ethambutol (25 mg/kg), and rifampin (600 mg) are recommended. However, for fibrocavitary or severe nodular/bronchiectatic disease, or in the transplant setting, medications should be administered daily instead of three times weekly with adjustment in doses where necessary (clarithromycin 500–1000 mg/day or azithromycin 250–500 mg/day, ethambutol 15 mg/kg per day, and rifampin 10 mg/kg per day (maximum 600 mg) or rifabutin 150–300 mg/day). For patients with cavitary changes or other severe forms of infection, amikacin or streptomycin given intravenously or intramuscularly at a dose of approximately 15–25 mg/kg three times weekly is recommended for the first 2–3 months [69]. Because of drug interactions (described below), rifabutin and azithromycin are preferred over rifampin and clarithromycin, respectively.

In the transplant setting, there are no specific recommendations for the duration of therapy. For pulmonary disease, the patient should be treated for at least 12 months of negative cultures although longer durations may be needed in transplant recipients. Patients are considered treatment failures if

Table 30.4 Treatment regimens for nontuberculous mycobacterial infections in transplant recipients

Organism	Example regimens	Dose	Alternative
M. avium complex *(noncavitary)*	Azithromycin Rifabutin Ethambutol	250–500 mg daily 300 mg daily 15 mg/kg daily	Moxifloxacin 400 mg daily Clofazimine 100 mg daily
M. avium complex *(cavitary)*	Azithromycin Rifabutin Ethambutol Amikacin	250–500 mg daily 300 mg daily 15 mg/kg/day per day 10–15 mg/kg once daily or 15–25 mg/kg three times weekly	Moxifloxacin 400 mg daily Clofazimine 100 mg daily
M. haemophilum	Azithromycin Rifabutin Moxifloxacin	250–500 mg daily 300 mg daily 400 mg daily	Ethambutol 15 mg/kg daily Clofazimine 100 mg daily
M. kansasii	Isoniazid Rifabutin Ethambutol	300 mg daily 300 mg daily 15 mg/kg per day	Azithromycin 250–500 mg daily Moxifloxacin 400 mg once daily Clofazimine 100 mg daily
M. marinum	Azithromycin Ethambutol	250–500 mg daily 15 mg/kg per day	Rifabutin 300 mg daily Moxifloxacin 400 mg daily Trimethoprim-sulfamethoxazole DS twice daily Doxycycline 100 mg twice daily Minocycline 100 mg daily
M. abscessus spp. *abscessus or bolletii*	Azithromycin Imipenem Amikacin Clofazimine	250–500 mg daily 500–1000 mg 2–3 times daily 10–15 mg/kg once daily or 15–25 mg/kg three times weekly 100 mg daily	Cefoxitin 12 gm in divided doses 3–4 times daily Tigecycline 50 mg 1–2 times daily Linezolid 600 mg 1–2 times daily
M. abscessus spp. massiliense	Azithromycin Imipenem Amikacin	250–500 mg daily 500–1000 mg 2–3 times daily 10–15 mg/kg once daily or 15–25 mg/kg three times weekly	Cefoxitin 12 gm in divided doses 3–4 times daily Clofazimine 100 mg daily Tigecycline 50 mg 1–2 times daily Linezolid 600 mg 1–2 times daily
M. chelonae	Azithromycin Imipenem Amikacin	250–500 mg daily 500–1000 mg 2–3 times daily 10–15 mg/kg once daily or 15–25 mg/kg three times weekly	Clofazimine 100 mg daily Tigecycline 50 mg 1–2 times daily Linezolid 600 mg 1–2 times daily
M. fortuitum	Imipenem Moxifloxacin Trimethoprim-sulfamethoxazole DS	500–1000 mg 2–3 times daily 400 mg daily 1 table twice daily	Cefoxitin 12 gm in divided doses 3–4 times daily Tigecycline 50 mg 1–2 times daily Doxycycline 100 mg twice daily Minocycline 100 mg twice daily Linezolid 600 mg 1–2 times daily

they have not responded after 6 months of appropriate therapy or achieved culture negativity of sputum after 12 months of therapy. Common factors in such patients include medication nonadherence, the use of inadequate regimens (e.g., clarithromycin with a fluoroquinolone only), and emergence of macrolide-resistant MAC isolates. Use of a macrolide alone or in combination with a fluoroquinolone is not recommended due to poor response and the frequent emergence of resistance [96, 97].

Mycobacterium kansasii

The ATS/IDSA guidelines recommend a daily three-drug regimen of isoniazid, rifampin, and ethambutol (Table 30.4) [69]. Although the role of isoniazid in this regimen is not clear (the MICs are 100x higher than with MTB), excellent results have been obtained in clinical studies using this regimen [60, 61]. Clarithromycin is highly active against *M. kansasii*, and clarithromycin-containing regimens have been associated with good treatment outcomes [98–100]. Rifabutin and azithromycin are preferred over rifampin and clarithromycin, respectively, because of drug interactions with some immunosuppressive medications.

The recommended duration of treatment is 12 months of negative cultures, although good results with 12 months of therapy have been reported [61]. As with MAC, a longer duration may be appropriate in the transplant setting but this has not been studied. Other drugs usually given in three-drug combinations are effective for the retreatment of disease that has become resistant to rifampin; they include macrolides, fluoroquinolones, trimethoprim/sulfamethoxazole, streptomycin, and amikacin [69]. At least in non-transplant populations, relapse after treatment with rifampin-containing regimens is uncommon.

Other Slow-Growing Mycobacteria

A number of other slowly growing mycobacteria have been reported to cause NTM disease in transplant recipients (Table 30.1). A detailed discussion of the treatment of these less common NTM is beyond the scope of this chapter. However, a few comments regarding treatment of *M. haemophilum* and *M. marinum* follow. *M. haemophilum* has been almost exclusively seen in patients with severe immune dysfunction either due to HIV-associated AIDS or in recipients of hematopoietic stem cell transplantation [101]. Disseminated infections are reported and predilection for tendon sheaths, bone, and joints is similar to infections seen with RGM. Drug susceptibility testing is not standardized and the correlation between susceptibility test results and clinical outcomes is uncertain. Current recommendations are to treat with a fluoroquinolone, macrolide, and rifamycin which has led to successful treatment (Table 30.4) [69, 102].

M. marinum is a slowly growing mycobacteria found in aquatic environments. Infection usually occurs when traumatized skin is exposed to water containing the organism. At least seven cases of *M. marinum* have been reported in transplant recipients including both SOT and HSCT patients [79, 103, 104]. Most have presented with erythematous tender cutaneous nodules on the extremities after exposure to fish tanks. Treatment regimens have included combinations of macrolides, rifamycins, fluoroquinolones, and cycline derivatives with cure in most patients including a patient with disseminated disease. The ATS currently recommends treatment of cutaneous disease with two active agents for approximately 1–2 months after resolution of the nodules (Table 30.4) [69]. However, most transplant recipients have been treated successfully for 3–9 months with one relapse after 6 months of ciprofloxacin and ethambutol.

Rapidly Growing NTM

M. abscessus Complex

Combination therapy including intravenous agents is necessary for clinically significant disease. Drug combinations including oral azithromycin, clofazimine, or linezolid/tedizolid plus intravenous cefoxitin, imipenem, tigecycline, or amikacin can be successful; however, refractory *M. abscessus* infections are common and remain difficult to treat (Table 30.4) [69]. Patients are begun on three or four of the above antibiotics during an initial multidrug intensive phase including intravenous antibiotics that are usually transitioned to a multidrug regimen of oral and possibly inhaled antibiotics. Long-term sputum conversion is difficult to achieve in patients with *M. abscessus ssp abscessus* lung disease with a functional *erm*(41) gene [68, 105, 106]. Sputum conversion rates among nonimmunocompromised patients with pulmonary disease due to *M. abscessus* ssp *abscessus* have been approximately 25% [66–68]. However, in patients infected with subspecies *M. massiliense* that lacks a functional *erm*(41) gene, culture conversion rates have reached over 80%. Among 16 patients with *M. abscessus* following lung transplantation that were treated, 11 (73%) had a radiographic or microbiologic response to treatment and 10 were considered cured [28]. Death was attributed to *M. abscessus* in two patients. Of note, the strains were not subspeciated so some patients may have been infected with the easier-to-treat *M. massiliense*.

M. chelonae

Mycobacterium chelonae causes skin and soft tissue disease similar to that of *M. abscessus* [69]. Unlike *M. abscessus* and *M. fortuitum*, *M chelonae* does not carry an *erm* gene and therefore effective therapy with a macrolide-based regimen may be more obtainable in these individuals [63]. *M. chelonae* is typically susceptible to macrolides, clofazimine, and tobramycin and resistant to cefoxitin with variable activity to fluoroquinolones, doxycycline, linezolid, and imipenem [81, 107]. Treatment usually involves a combination of three of the antibiotics above (Table 30.4).

M. fortuitum

Mycobacterium fortuitum is a rapid grower similar to *M. abscessus* and *M. chelonae*. It is a rare cause of lung disease, sometimes identified in patients with achalasia and other gastroesophageal reflux disorders [69, 108]. *M. fortuitum* isolates are usually susceptible to fluoroquinolones, doxycycline and minocycline, sulfonamides and trimethoprim/sulfamethoxazole, amikacin, imipenem, and tigecycline, and approximately one-half of the isolates are susceptible to cefoxitin [81, 107, 109]. Like *M. abscessus*, most *M. fortuitum* isolates have a functional *erm* gene so macrolides should not be counted on to treat this infection. Multidrug therapy with agents shown to be susceptible in vitro should be given for 12 months or until clinical resolution of the disease (Table 30.4).

Drug Interactions

Significant drug-drug interactions may occur between antimycobacterial drugs and immunosuppressive drugs used to prevent rejection (Table 30.5). Rifampin is a potent inducer of the CYPA3A4 pathway and thus can decrease the serum concentrations of calcineurin inhibitors and mTOR inhibitors such as sirolimus [70, 77]. Use of rifampin has been associated with acute rejection rates as high as 35% [110, 111]. Rifabutin, which is a less potent inhibitor of cytochrome p450, is the preferred rifamycin in these settings. Clarithromycin is an inhibitor of the CYP3A4 pathway and p-glycoprotein and thus raises the concentration of calcineurin and m-TOR inhibitors. In order to avoid this drug interaction, azithromycin is recommended over clarithromycin.

Table 30.5 Drug interactions between antimycobacterial and antirejection drugs[a]

Antibiotic class/ antibiotics	Cyclosporine	Sirolimus/everolimus	Tacrolimus
Azalide/macrolide			
Azithromycin	Possible mild increase in cyclosporine levels	No significant interaction	Possible mild increase in tacrolimus levels
Clarithromycin	Increase in cyclosporine levels	Increase in sirolimus/everolimus levels	Increase in tacrolimus levels
Fluoroquinolones			
Ciprofloxacin	No significant interaction	No significant interaction	No significant interaction
Levofloxacin	Possible mild increase in serum concentration	No significant interaction	No significant interaction
Moxifloxacin	No significant interaction	No significant interaction	No significant interaction
Rifamycins			
Rifampin	Decrease in cyclosporine levels	Decrease in sirolimus/everolimus levels	Decrease in tacrolimus levels
Rifabutin	Mild decrease in cyclosporine levels	Mild decrease in sirolimus/ everolimus levels	Mild decrease in tacrolimus levels

[a]Serum drug concentrations should be measured and doses adjusted as needed to effectively treat the NTM infection and avoid rejection or drug-related toxicity

Because of the many potential drug interactions, therapeutic drug monitoring should be strongly considered in order to maintain adequate serum drug concentrations and avoid unwanted toxicity [33].

When rifamycin is not used, an alternative drug should be selected. Studies in nontransplant populations have reported similar microbiologic outcomes in patients receiving a three-drug regimen including clofazimine instead of rifampin [112], and there is some evidence of activity in patients with refractory disease [113, 114]. A small study in five SOT patients reported good tolerance to clofazimine [115] although one pediatric bone marrow transplant patient has been reported to have developed an enteropathy [116].

Monitoring for Adverse Reactions and Treatment Response

Multidrug treatment regimens used for NTM infections are frequently associated with drug-related adverse events so monitoring of patients for toxicity is essential. The most common adverse reactions associated with antimycobacterial agents are included in Table 30.3. Transplant patients are often on other drugs that could have overlapping toxicities with antimycobacterial drugs; thus, close monitoring for adverse reactions is even more critical in this population. All patients who are being treated for NTM disease should have periodic assessment of complete blood counts, liver function tests, and creatinine. For patients receiving ethambutol or linezolid, a baseline assessment of visual acuity and color discrimination testing are recommended with periodic reassessments during the course of therapy. In addition, a baseline audiogram is needed for patients on an aminoglycoside and should be repeated during the course of treatment.

Response to treatment should be documented through periodic clinical, radiographic, and microbiologic evaluations. For pulmonary disease, treatment duration is based on the time of culture conversion so monthly cultures should be obtained to document the time of conversion. For patients with extrapulmonary disease, clinical and radiographic evaluation are most critical as resampling of extrapulmonary sites may not be possible or practical.

Survival

The impact of NTM infections on survival has varied between studies although in most the direct impact has been minimal. In a cohort of 237 lung transplant recipients from a center in the United States, NTM infection was not associated with an increased mortality [4]. In a retrospective cohort study to evaluate the impact of NTM on survival, 33 patients with NTM infection post-SOT were evaluated [92]. Surprisingly, there was not an increased mortality in patients with *M. abscessus* disease compared with other NTM disease. However, development of NTM infection during the first year after transplantation was strongly associated with decreased survival, independent of organ type. NTM infection was considered a contributing cause of death in only three of the nine patients whose death certificates were available for review. A recent study from a large Midwestern center reported that among 3338 SOT recipients, 50 (1.5%) had NTM infection, 43 of whom were lung transplant recipients. However, NTM infection was not associated with mortality in infected lung transplant recipients versus those not infected although NTM disease was associated with increased mortality compared with colonization in lung transplant recipients [26]. There was no difference in survival between NTM-infected

and NTM-uninfected lung transplant recipients: the former were more likely to develop bronchiolitis obliterans (80 vs. 52%, $p = 0.02$) although this finding was not noted in multivariate analysis. One study reported that NTM colonization and NTM pulmonary disease increased the risk of death after lung transplantation although NTM pulmonary disease was not considered the direct cause of disease [2]. The increased risk of death persisted even after adjusting for single-lung transplantation and presence of bronchiolitis obliterans.

Isolation of NTM Before Transplantation

Isolation of NTM during pretransplant period is not uncommon in patients undergoing lung transplant given their underlying lung disease, and pretransplant isolation of NTM has been associated with a greater risk of NTM disease after undergoing transplantation [1]. The International Society for Heart and Lung Transplantation (ISHLT) states that "chronic infection with highly virulent and/or resistant microbes that are poorly controlled pretransplant" is an absolute contraindication for transplantation [117]. However, "colonization or infection with highly resistant or highly virulent bacteria, fungi, and certain strains of mycobacteria…" is considered a relative contraindication. Furthermore, infection with multidrug resistant *M. abscessus* is considered a relative contraindication if the infection is "sufficiently treated" preoperatively and there is a reasonable expectation for adequate control postoperatively. Unfortunately, none of these recommendations provide clear guidance to providers or patients as it is difficult to distinguish "colonization" from indolent infection and active disease and sufficiently treated are not defined.

NTM are commonly isolated in patients with CF but the risk of NTM infections posttransplantation is not well defined. The Cystic Fibrosis Foundation (CFF), European Cystic Fibrosis Society (ECFS), and the ISHLT recommend that individuals with CF who are being considered for lung transplantation be evaluated for NTM pulmonary disease and the presence of current or previous history of respiratory tract samples with NTM should not preclude consideration for transplantation [117, 118]. Those who are found to have NTM lung disease should be started on treatment prior to transplant listing, and once they have achieved sequential negative cultures, they should be considered eligible for transplantation. This includes patients who have completed therapy. ISHLT states that progressive pulmonary or extrapulmonary disease secondary to NTM despite optimal therapy or an inability to tolerate optimal therapy is a contraindication for transplant listing; however, the CFF and ECFS state that even if the NTM cannot be cleared from the respiratory tract, this is not an absolute contraindication for transplant in patients with CF [118, 119]. Isolation of NTM prior to HSCT is also not a contraindication to transplant as patients have been successfully transplanted [14].

Prevention

Recent outbreaks of NTM infections in transplant patients and patients who have undergone cardiac surgery have highlighted the potential for nosocomial acquisition of NTM [120, 121]. Most nosocomial infections can be traced back to contamination with tap water containing NTM, so avoidance of tap water during and after transplantation surgery is critical. Person-to-person transmission of *Mycobacterium abscessus* ssp. *massiliense* may have occurred among patients with CF as described in two CF clinics in the United States and United Kingdom [122, 123], and a recent study suggested global transmission of two clones of *M. abscessus* and one of *M. massiliense* among CF patients [124]. To date, person-to-person transmission of NTM has not been described in other settings. Because of the possibility of transmission among CF patients, current CF foundation infection control and prevention guidelines should be adhered to [125].

Effective chemoprophylactic treatment including azithromycin, clarithromycin, and rifabutin has been demonstrated through randomized clinical trials to prevent disseminated MAC in advanced AIDS patients [126, 127]. Not surprisingly, some physicians have called for posttransplant prophylaxis with azithromycin for CF patients "colonized" with rapidly growing mycobacteria [77]. However, there is no evidence to support this practice and it is unlikely to be effective given the presence of an *erm*(41) gene in most *M. abscessus* complex strains. Multidrug treatment regimens to decrease the bacterial load as much as possible are likely to be more effective at preventing development of NTM disease in the posttransplant setting.

Summary

Nontuberculous mycobacteria (NTM) are common in the environment, being most often associated with soil and water sources. NTM isolation does not always portray clinically significant disease, albeit, in patients with severe immune dysfunction following allogeneic transplantation, these near-ubiquitous environmental bacteria may lead to serious and potentially life-threatening systemic disease. The true prevalence of NTM among transplant recipients is largely unknown. Correct laboratory identification of NTM species, adequate genetic analysis, and susceptibility testing are essential for identification of mycobacteria and are necessary in assembling effective antimicrobial treatment regimens. Reference laboratory evaluation may be required depending

on local laboratory capabilities. Antibiotic regimens are chosen according to NTM species, site of infection, and drug susceptibility profile, which can vary greatly according to the NTM species isolated. The treatment of NTM involves multiple antibiotics given for a prolonged period of time and is often accompanied by side effects and drug-drug interactions, especially in transplant patients on antirejection drugs and other agents given for suppressing hosts' immune response for prevention or treatment of graft-versus-host disease. Treatment by experienced NTM physicians is often necessary. It is essential for transplant providers to maintain a low index of suspicion in order to promptly and correctly diagnose NTM infections in the susceptible transplant population and provide host- and pathogen-specific treatment options.

Introduction

In the latter half of the twentieth century, considerable progress occurred in transplantation including improvements in donor selection and screening, surgical techniques, immunosuppression, and antimicrobial therapy. Despite these advances, infection persists as a common complication post-transplant and fungal infections in particular are associated with significant morbidity and mortality. The number of individuals receiving either a hematopoietic cell transplant (HCT) or solid organ transplant (SOT) continues to rise, resulting in an ever-expanding at-risk population for invasive fungal infections (IFIs). This chapter will provide a broad overview of the fungal pathogens affecting both the HCT and SOT populations inclusive of the changing epidemiology and unique considerations in the transplant recipient.

Fungal Pathogens in HCT and SOT

The list of fungi capable of affecting this population seems infinite with new pathogens continuing to emerge. For simplification, fungal pathogens can be classified into three categories: yeasts, filamentous molds, and endemic fungi. Yeasts are fungi that grow as single, rounded, or elongated cells and reproduce by budding or sometimes fission; chains of these elongated cells are called pseudohyphae. In contrast, molds are multicellular fungi with spores that germinate to produce branching hyphae. The third category, endemic fungi, are dimorphic fungi capable of existing as molds at room temperature and yeast or yeast-like forms at body temperature in the human host [1].

[a]List not inclusive
[b]Most authorities refer to disease as penicilliosis
[c]Sexual anamorph of *Pseudallescheria boydii*
[d]Some experts consider this a dematiaceous mold, recently reclassified as *Lomentospora prolificans*

The most common yeasts associated with infection in SOT and HCT are *Candida* species, although numerous other pathogens are seen including, but not limited to, *Cryptococcus*, *Hansenula*, *Malassezia*, *Rhodotorula, Saccharomyces*, and *Trichosporon* [2–5]. Non-*albicans Candida* species such as *C. glabrata*, *C. parapsilosis*, and *C. krusei* account for an increasing proportion of infections with evolving trends in antifungal resistance and are associated with worse outcomes in specific populations [6–9]. Infections with the encapsulated yeast *Cryptococcus* occur more frequently in SOT as compared to HCT. While *C. neoformans* var *grubii* (serotype A) is the predominant pathogen in both SOT and HCT populations, infections with *C. neoformans* var *neoformans* (serotype D) can be seen in Northern Europe, and *C. gattii* has emerged in both immunocompetent and immunocompromised hosts in Canada and the northwest United States and continues to cause disease in subtropical climates [10–12].

Molds include the hyaline and dematiaceous hyphomycetes as well as those from the subphylum *Mucormycotina*. Hyalohyphomycosis describes infections caused by the hyaline molds, a large group of septate molds that present as colorless or lightly pigmented hyphae in tissue. There are numerous molds in this group but the most common in the transplant population are *Aspergillus*, *Fusarium*, and *Scedosporium* species [13] (see Table 31.1). These molds are widely distributed and associated with an array of infections. Fungemia is a relatively rare occurrence with *Aspergillus* but is frequently seen in invasive fusariosis as it is capable of adventitious sporulation which probably aids its entry into the bloodstream. Other molds including *Acremonium*, *Scedosporium*, and *Paecilomyces* also demonstrate this phenomenon [14]. The dematiaceous fungi represent an assorted group of molds containing prominent amounts of melanin in their cell walls which contributes directly to their pathogenicity and is responsible for the light or dark brown color frequently seen in culture and/or histopathology [15]. Furthermore, these fungi are responsible for phaeohyphomycoses which often present as skin and soft tissue, ocular, and/or disseminated infections. *Alternaria*, *Bipolaris*, *Cladophialophora*, *Curvularia*, *Dactylaria*, *Exophiala*, and *Phialophora* are some of the more common black molds associated with infection in the transplant recipient [16, 17] (see Table 31.2). Many of these molds are also neurotropic and associated with severe and often fatal central nervous system (CNS) infections [2, 3]. Therefore, it is essential that there is proper and accurate identification of all molds from both sterile and non-sterile sites so prediction of disease and choice of therapy can be predicated on experience.

[a]List not inclusive
[b]Some experts consider this a hyaline mold, recently reclassified as *Lomentospora prolificans*

Mucormycosis refers to infection caused by molds in the order *Mucorales* in the subphylum *Mucormycotina* [18]. They are characterized by broad, irregularly branching hyphae with few septations in contrast to the more commonly seen narrow, regularly branching septate hyphae with *Aspergillus* and the other hyphomycetes [1]. Expert pathologists can generally tell the difference between these two groups of molds by histopathology. The genera most frequently associated with infections include *Rhizopus* and *Mucor*; however, infections with *Apophysomyces*, *Cunninghamella*, *Rhizomucor*, *Saksenaea*, and *Syncephalastrum* are reported [2, 19–21]. These molds are abundant in soil as well as decaying plant material and often gain entrance into the host via inhalation or direct skin penetration. They are associated with localized skin and soft tissue infections from trauma as well as rhinocerebral, gastrointestinal, and pulmonary infections from aerosolized or ingested spores and in the immunocompromised host have the ability to disseminate to other organs [21, 22].

The primary endemic mycoses include histoplasmosis, blastomycosis, and coccidioidomycosis and are an infrequent but important cause of transplant fungal infections particularly in the SOT population [23]. Inhalation serves as the primary mode of acquisition with clinical presentations ranging from isolated pneumonia to disseminated disease. Given their geographic predilection, obtaining a comprehensive exposure history in the transplant recipient remains critical to diagnosis as both primary infection and reactivation from prior infection can occur. Moreover, donor-derived infections have been reported with both histoplasmosis and coccidioidomycosis making links to exposure further complex in transplant patients [24–26].

A brief discussion of the immune reconstitution syndrome (IRS) is warranted in the introduction of fungal pathogens in transplantation. In an acute, life-threatening IFI in an immunocompromised host, it seems logical to attempt to restore the immune system to combat the infection. However, this must be approached in a careful and step-wise fashion as abrupt withdrawal of immunosuppression alongside institution of antifungal therapy has been associated with IRS in the transplant recipient with a number of fungal pathogens. It is most commonly reported in *Cryptococcus* and *Aspergillus* infections but has been associated with other IFIs including *Candida*, *Dipodascus capitatus*, and *Histoplasma capsulatum* [27]. The interactions are complex given the immunomodulatory effects of antifungals as well as the antifungal properties of certain immunosuppressives. However, in general the underlying pathogenesis involves a conversion of T-cell regulatory pathways to a proinflammatory state when antifungal therapy is initiated and immunosuppression is reduced. The net effect of this proinflammatory state is paradoxical worsening clinical signs and symptoms often misinterpreted as progressive infection in the transplant recipient as well as potential for allograft loss [28–30]. Presently guidelines detailing how to most appropriately manage these patients are lacking, but the challenging interplay of immunosuppressants and antifungals creates marked potential for future innovative strategies.

Epidemiology of IFIs in Transplantation

Inherent to understanding the epidemiology of IFIs is first an acknowledgement of the limitations of the available literature. For instance, studies in transplantation are often single-center, retrospective, and transplant organ-specific and lack uniform definitions of disease, thereby hampering epidemiologic assessments. However, attempts to optimize standardized definitions and incorporate study designs with detailed prospective data collection have advanced more recent estimations. The originally proposed definitions of IFIs applied only to patients with cancer and/or undergoing HCT but were revised to extend application to individuals with primary immunodeficiencies as well as SOT recipients [31, 32]. Current definitions include three categories, proven, probable, and possible IFIs, and attempt to incorporate the less common fungi and yet maintain the focus on patients with the highest likelihood of an IFI. While imperfect, these definitions serve as starting point with ongoing efforts in place to further refine. There is at least one major prospec-

tively maintained database to assist in defining the burden of IFIs in HCT and SOT. The Transplant-Associated Infection Surveillance Network (TRANSNET) [4, 5, 17, 23, 33] contains information regarding IFIs from 23 transplant centers in the United States. Published data from TRANSNET encompasses a 5-year period from 2001 to 2006 and provides the most recent and comprehensive prospective evaluation in the transplant groups regarding the characteristics and appearance of IFIs in this risk group. The Prospective Antifungal Therapy (PATH) [20, 21] Alliance is an additional large multicenter observational registry of IFIs inclusive of HCT/SOT recipients in North America.

Epidemiology in HCT

Incidence and Types of IFIs

Changes in the incidence of IFIs in HCT have occurred over the last few decades for a multitude of reasons including modifications in stem cell sources and conditioning regimens, utilization of hematopoietic growth factors, as well as advances in diagnosis, prevention, and treatment of infections [19, 34–40]. Previous studies report IFI incidence rates upwards of 15% [41, 42]. However, more recent data from TRANSNET found a 12-month cumulative incidence (CI) for any IFI of 3.4% (range 0.9–13.2%) in 15,820 patients undergoing HCT from March 2001 through September 2005 [5]. Among transplant types, the incidence was lowest in autologous HCT recipients (1.2%) when compared to rates of 5.8%, 7.7%, and 8.1% in allogeneic HCT recipients with matched-related donors (MRDs), unrelated donors (URD), and mismatched-related donors (MMRD), respectively.

Modifications in the practice of HCT have also resulted in shifts in the primary fungal pathogens associated with IFIs (see Table 31.3). While *Candida* maintains an imposing presence, it has been superseded by *Aspergillus* as the primary fungal pathogen in this risk group. Institution of antifungal prophylaxis directed against *Candida* species, increased utilization of alternate donor sources, and changes in HCT conditioning regimens are a few of the contributing factors for *Aspergillus* supplanting *Candida* as the most common IFI [43]. We can expect that as practices continue to change, the future will likely bring another group of leading fungal pathogens. For instance, alongside declining *Candida* infections since the early 1990s following institution of fluconazole prophylaxis in HCT patients, the concerning trend toward infections with more resistant non-*albicans Candida* species emerged [7, 44–50]. Invasive candidiasis (IC) typically manifests as bloodstream infections related to neutropenia and mucosal injury with the potential for dissemination. Hepatosplenic candidiasis, a distinct form of disseminated *Candida* infection seen in this population, is often referred to as chronic disseminated candidiasis as it can affect other organs in addition to the liver and spleen. Among *Aspergillus* species, *A. fumigatus* remains the most common pathogen in part due to specific virulence factors and its ubiquitous ecology [51]. However, non-*fumigatus* types are increasingly recognized to produce disease in the mammalian host including *A. terreus* which typically exhibits *in vitro* resistance to amphotericin B and *A. lentulus* which harbors *in vitro* and clinical resistance to most present antifungal therapies [52–54]. *Aspergillus* infections present as invasive pulmonary infections, rhinosinusitis, and disseminated disease involving the skin and/or CNS [55]. *Aspergillus* tracheobronchitis, an early presentation in the lung transplant recipient, is also reported, albeit rare, in HCT recipients [56, 57]. In the HCT recipient, neutrophil recovery can also be associated with worsening clinical and radiologic findings alongside declining serum *Aspergillus* galactomannan levels signaling the possibility of IRS associated with invasive aspergillosis (IA) treatment [58].

Non-*Aspergillus* molds, although less common, are emerging pathogens in HCT and unfortunately are often relatively resistant to most conventional antifungal agents. Marr et al. [59] retrospectively evaluated 5589 patients undergoing HCT at single center from 1985 to 1992 and of 144 proven

or probable infections with non-*Aspergillus* molds, *Fusarium* and *Scedosporium* were the most common. Surveillance data from TRANSNET confirm stable 12-month CI for both *Scedosporium* and *Fusarium* infections but increases in mucormycosis [5, 33]. Kontoyiannis et al. [60] also reported increasing rates of mucormycosis at a major cancer center in the late 1980s to 1990s. This same center later reported continued increases after the institution of voriconazole prophylaxis in their HCT population [61], and this report coincided with multiple reports of "breakthrough" mucormycosis at other institutions utilizing voriconazole [62–66]. As the increase was seen before and after the introduction of voriconazole, many propose this association is multifactorial, including changes in immunosuppression and patient survival, rather than a simple direct stimulatory effect on the fungus [5, 53]. Furthermore, similar breakthrough infections have been reported with other azole antifungals including posaconazole which has extended coverage against some but not all of the *Mucorales* species [67–69]. *F. solani* is the most commonly identified *Fusarium* species. Retrospective characterization of *Fusarium* infections in HCT recipients by Nucci et al. [70] at 2 US and 7 Brazilian transplant centers found an overall incidence of 5.97 cases per 1000 transplants with an approximate fourfold to tenfold increase in incidence when comparing autologous to allogeneic MRD and MMRD HCT recipients, respectively. The overall incidence of fusariosis did not differ between the two countries; however, Brazilian patients tended to be younger with underlying diagnosis of chronic myelogenous leukemia or aplastic anemia and received primarily MRDs as opposed to patients in the United States wherein AML (acute myelogenous leukemia) and non-MRD transplants predominated. Of the 61 cases identified, invasive fusariosis most often presented as disseminated disease including skin and pulmonary involvement with fungemia occurring in 28% of patients. *Scedosporium,* another prominent pathogen in HCT recipients, was first identified as a human pathogen in the early 1900s. Husain et al. [71] found that *S. apiospermum* complex (the sexual anamorph of *Pseudallescheria boydii*) infections occurred most commonly in all transplant groups, but infections with *S. prolificans* (recently reclassified as *Lomentospora prolificans*) and its presence in fungemias were clearly more common in the HCT as compared to the SOT population [72]. Moreover, severe presentations including sepsis-like syndromes with scedosporiosis were reported primarily in patients with hematologic malignancy or undergoing HCT.

The primary endemic mycoses, namely, histoplasmosis, coccidioidomycosis, and blastomycosis, are uncommon in HCT patients as evidenced by only six cases reported in TRANSNET [5, 23]. Data regarding histoplasmosis, the most common of this group, predominate in the form of case reports and series of pneumonia and disseminated infections [73–79]. However, Vail et al. [78] found no cases of histoplasmosis among 137 allogeneic HCT recipients at a single center in a "hyperendemic" region, 5% of which were identified with positive complement-fixation titers to *Histoplasma* antigens pre-transplant, suggesting it is not an overwhelming problem even in areas with substantial exposure. Coccidioidomycoses is the second most common endemic mycosis in the transplant population overall [76, 80–82]. Blair et al. [82] reported incidence rates of 0.9% and 2.1% in autologous and allogeneic HCT, respectively, in an endemic region where routine pre- and post-transplant recipient screening and prophylaxis is employed. In a separate report by this same group, 55 cases of coccidioidomycoses were described in patients with underlying hematologic malignancies. Pulmonary involvement was most common (95%) and 22% of the infections were disseminated [83]. Infections with blastomycoses are even more rare in HCT recipients [76, 84]. In sum, endemic mycoses must be considered in recipients, but they do not represent an overwhelming problem in the HCT population.

Risk Factors for IFIs

Multiple factors unique to HCT modify the IFI risk and typically depend upon the host, transplant, as well as post-transplant complications [40]. The impact of these variables is often time dependent, thereby preferentially increasing risks in the early or late post-transplant period. Early risk of infection is often mediated by abnormal mucosal barriers and neutropenia, whereas late infections following engraftment involve complications such as graft-versus-host disease (GVHD), cytomegalovirus (CMV), and delayed immune reconstitution. Identified risk factors for IFIs are most often directly applicable to *Candida* and *Aspergillus* infections and then extrapolated to other fungal pathogens with less precision. In addition, while we typically associate antineoplastic and other immunosuppressive therapy as additive in the risk of IFIs, it is important to recall that some of these agents may have antifungal properties. As an example, 5-flucytosine (5-FC), the precursor of 5-fluorouracil (5-FU), is used clinically for its synergistic effects with amphotericin B against *Cryptococcus* and less commonly against *Candida* species. Prior studies have also shown synergistic effects of agents such as 5-FU, methotrexate, mitomycin C, and doxorubicin when combined with polyenes against *Candida* species [85]. The antifungal properties of the calcineurin inhibitors (CNIs, e.g., tacrolimus and cyclosporine) and mammalian targets of rapamycin (mTOR) inhibitors (e.g., sirolimus) will be discussed further in the section on risks for IFIs in SOT.

Multiple host-related factors increasing IFI risk include (1) the recipient age, (2) underlying disease, (3) polymorphisms in host genes, (4) "biological factors," and (5) history of prior IFI(s). Older age at transplant is a well-established

risk factor impacting both the early and late transplant periods [34, 35, 59, 86, 87]. Autologous HCT recipients have less IFIs overall than allogeneic recipients. With respect to underlying disease, chronic myelogenous leukemia in chronic phase has been associated with fewer IFIs post-transplant [35, 59, 87]. Increased risks for IFIs including IA, mucormycosis, and fusariosis have been reported in patients with underlying multiple myeloma, aplastic anemia, AML, or myelodysplastic syndrome (MDS) [35, 59, 88]. Specific genetic polymorphisms in constituents of the immune system such as toll-like receptors (TLRs) 1–6, interleukin-10 promoter, tumor necrosis factor-alpha receptor, and plasminogen may play a role in susceptibility to IFIs [89–99]. Clearly the future will be to validate and quantitate these risks within the individual patient. "Biologic" host factors associated with increased IFI risk include iron overload and diabetes [100, 101]. Finally, patients undergoing evaluation for HCT are often heavily pre-treated with chemotherapy and other immunosuppressive modalities resulting in the development of IFIs prior to HCT. A previous IFI has already marked the patient for the potential of either reactivation or susceptibility to new IFIs. In a retrospective analysis of 48 HCT recipients with IA prior to transplant, Offner et al. [102] found evidence of relapse in 33% of patients with an associated 88% mortality. Given this and other reports of high rates of relapse or progression and potential increased mortality, in the past some centers considered pre-transplant IFIs a contraindication to HCT [102–104]. However, other centers have demonstrated that successful transplantation is feasible in patients with prior and even active IFIs and thus management of pre-transplant IFIs continues to evolve [105–114]. Remaining IFI risk factors associated with the transplant and post-transplant complications are summarized in Table 31.4 [115–127].

Table 31.4 Risk factors for invasive fungal infections in hematopoietic stem cell transplantation[a] [5, 7, 34, 35, 87, 88, 115–127]

Risk factor	Details	References
Transplant related		
Donor HLA similarity	Autologous < Allogeneic (MRD < MMRD/URD)	[5, 88, 115]
Stem cell source	Peripheral blood < bone marrow < cord blood; increased risk with T cell-depleted/CD34 selected cells	[35, 116–120]
Conditioning regimen	NMA < MA in early infections, NMA ≥ MA in late infections	[121–124]
Post-transplant related		
Neutropenia	Especially during early risk period	[7, 34, 35]
Viral illness	CMV (most commonly associated), RSV, parainfluenza, +/− influenza	[34, 35]
GVHD	Both acute (particularly grade III–IV) and chronic GVHD and associated treatment (e.g., corticosteroids, TNF-alpha blockers)	[87, 88, 125–127]

CMV cytomegalovirus, *GVHD* graft-versus-host disease, *HLA* human-leukocyte antigen, *MA* myeloablative, *MRD* matched-related donor, *MMRD* mismatched-related donor, *NMA* non-myeloablative, *RSV* respiratory syncytial virus, *TNF* tumor necrosis factor, *URD* unrelated donor

[a]List of risk factors not fully inclusive

Timeline and Outcomes for IFIs

For simplification, the timeline for infections post-HCT can be broken into three periods corresponding with an early (0–30 days), late (31–180 days), and very late (greater than 180 days) onset of infection (see Fig. 31.1) [4, 5, 128]. *Candida* infections tend to occur earliest, when neutropenia and mucositis predominate, but of course these IFIs can be seen throughout the transplant course with widespread use of antibiotics and foreign bodies such as catheters. Invasive candidiasis typically occurs earlier in autologous as compared to allogeneic HCT recipients as illustrated by PATH Alliance generated data with a median onset of IC at day 28 versus day 108, respectively [19]. Furthermore, in allogeneic HCT recipients, a myeloablative conditioning regimen tends to be associated with an earlier onset of IC (median 65 days) compared to a non-myeloablative regimen (median 590 days) with no differences seen among the donor types (e.g., MRD, URD, MMRD) [19].

Aspergillus infections are bimodal occurring in both the early and more commonly in the late post-transplant period with important implications for certain fungal diagnostics whose sensitivity vary pre- and post-engraftment. For example, invasion and thrombosis of the vasculature seen with angioinvasive fungi such as *Aspergillus* often result in a classic "halo" of surrounding ground-glass attenuation secondary to hemorrhage on computed tomographic imaging of the chest and are more commonly found in the neutropenic host [129]. In addition, screening diagnostics such as *Aspergillus* galactomannan, an enzyme-linked immunosorbent assay that detects galactomannan, a component of the fungal cell wall released during hyphal growth, has been found to be a more sensitive screening tool in the neutropenic versus non-neutropenic HCT recipient [130]. In general, IA occurs later than IC with a median onset of 99 days post-transplant in the TRANSNET cohort [5]. Similar to IC, an earlier onset was found in autologous versus allogeneic HCT recipients. Within the first month, 50% of the total IA cases in autologous HCT recipients had occurred compared to only 22% in allogeneic HCT recipients. Furthermore, the conditioning regimen and donor type have not consistently been shown to impact the timing of IA in the allogeneic HCT recipient [19].

Non-*Aspergillus* molds, including mucormycosis, *Fusarium*, and *Scedosporium*, also tend to occur later in the transplant period as compared to IC, although timing is variable dependent upon the pathogen and clinical scenario. For HCT recipients in the TRANSNET cohort, 67 (54.4%) of

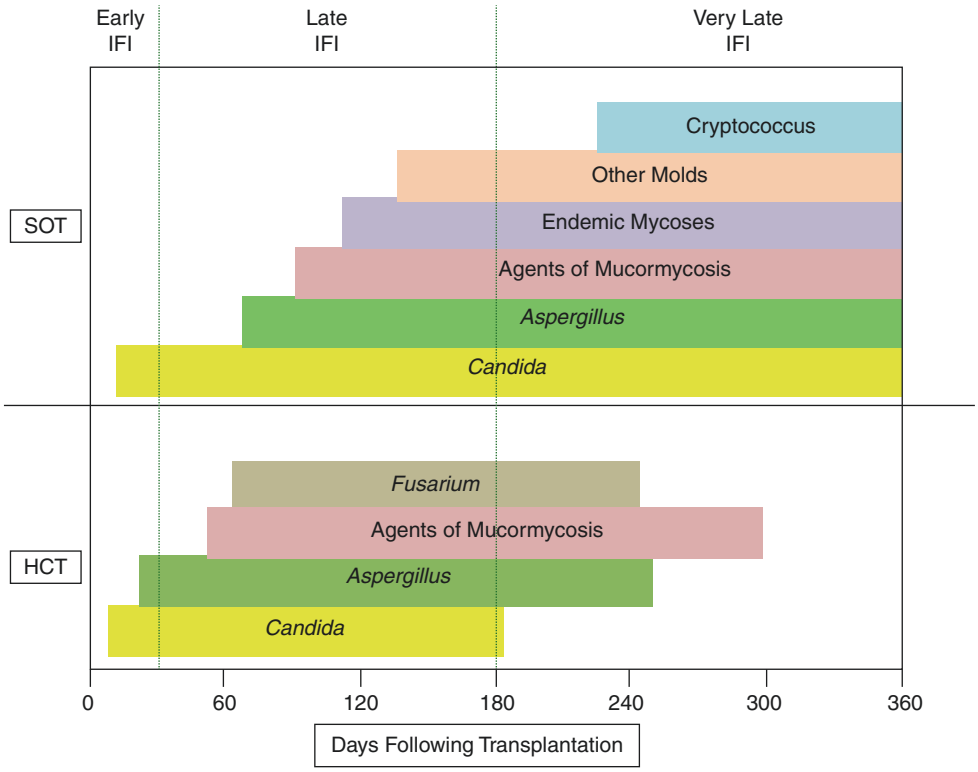

Fig. 31.1 Timeline of infections following hematopoietic and solid organ transplantation [4, 5, 128]. Based on Transplant-Associated Infection Surveillance Network (TRANSNET)-derived data for invasive fungal infections (IFIs) in solid organ transplantation (SOT) from Pappas et al. [4]) and hematopoietic stem cell transplantation (Kontoyiannis et al. [5]). (Adapted with permission from: Low and Rotstein [128]

invasive non-*Aspergillus* mold infections occurred within 6 months of transplant, though onset was quite delayed in some cases, with an appreciable number (13.8%) of infections with mucormycosis, *Fusarium*, and *Scedosporium* developing 2 or more years post-transplant [33]. In a smaller retrospective evaluation of *Fusarium* infections in HCT recipients involving nine transplant centers, Nucci et al. [70] described a trimodal timeline in allogeneic recipients wherein peak infections occurred a median of 16 days (pre-engraftment) and 62 days post-transplant with another peak after day 360. *Scedosporium* infections have been described earlier in the post-transplant course as well. For instance, in the study by Marr et al. [59] characterizing invasive mold infections in HCT recipients, the majority of *Scedosporium* infections occurred on or before post-transplant day 40 and Husain et al. [71] reported a median onset of 1.3 months after transplant with 75% of infections occurring within 6 months.

Outcomes in HCT continue to improve with the advances in transplantation and management of IFIs but remain suboptimal (see Table 31.3). In general, IC has been associated with the best survival outcomes followed by IA and the non-*Aspergillus* molds, but it is often difficult to differentiate the impact of the IFI versus the underlying disease on outcomes. However, clearly the IFIs contribute to morbidity and mortality. Pagano et al. [41] evaluated proven/probable IFIs in 3228 patients undergoing HCT from 1999 to 2003 and found an attributable mortality of 50% (IC), 72.1% (IA), and 65.3% (overall). Of note, among the cases of IC, non-*albicans* *Candida* infections were associated with the worst outcomes. Attributable mortality for IA was significantly higher in allogeneic (77.2%) compared with autologous HCT recipients (14.3%) whereas IC outcomes were similar among the two groups. Low survival associated with infections due to non-*Aspergillus* molds alongside possible increased frequency imparts significant concern for future trends. Neofytos et al. [19] evaluated 250 IFIs in adult HCT recipients and found the highest 12-week mortality rates with mucormycosis and other molds (inclusive of *Fusarium* species) at 64.3% and 80%, respectively. Husain et al. [71] similarly reported high overall mortality rates with *Scedosporium* infections, particularly *S. prolificans* (77.8%). In contrast to other studies, Neofytos et al. [19] found overall higher mortality rates with IC compared to IA, similar to findings in a more contemporary retrospective single-center review of IFIs by Corzo-León et al. [131], possibly related to the inherent difficulties in delineating true attributable mortality with specific pathogens in this complex patient population.

Epidemiology in SOT

Incidence and Types of IFIs

The spectrum of IFIs in SOT depends upon a multitude of variables including the transplanted organ(s). The section that follows will discuss selective epidemiologic characteris-

Table 31.5 Primary fungal pathogens in solid organ transplantation (SOT) [4, 33]

SOT group	12-month CI (%)[a,b]	Primary fungal pathogens (total % of IFIs)[b]

Liver	4.7	*Candida* (68) *Aspergillus* (11) Cryptococcus (6) Endemic mycoses (5) Agents of mucormycosis (2) Other molds (2)
Heart	3.4	*Candida* (49) *Aspergillus* (23) Cryptococcus (10) Endemic mycoses (3) Agents of mucormycosis (3) Other molds (7)
Kidney	1.3	*Candida* (49) *Aspergillus* (14) Cryptococcus (15) Endemic mycoses (10) Agents of mucormycosis (2) Other molds (3)
Pancreas	4.0[d]	*Candida* (76) *Aspergillus* (5) Cryptococcus (5) Endemic mycoses (6) Agents of mucormycosis (0) Other molds (3)
Small bowel	11.6	*Candida* (85) *Aspergillus* (0) Cryptococcus (5) Endemic mycoses (0) Agents of mucormycosis (0) Other molds (0)

[a]12-month cumulative incidence (CI) for first invasive fungal infection (IFI)
[b]Based on Transplant-Associated Infection Surveillance Network (TRANSNET)-derived data [4, 33]
[c]12-month CI reflects lung and heart-lung transplant recipients
[d]12-month CI reflects pancreas and kidney-pancreas transplant recipients

tics of the individual SOT groups, namely lung, liver, heart, renal, pancreas, and small bowel/multivisceral transplant. TRANSNET-generated data provide a broad overview of IFIs in this population [4] (see Table 31.5). A 12-month CI for the first IFI in the cohort of 16,459 SOT recipients was 3.1% overall and among SOT groups was highest in small bowel (11.6%) and lowest in kidney (1.3%) transplant recipients. Overall trends suggested an increase in IFIs in the SOT population driven primarily by the occurrence of IC.

With the exception of the lung transplant population, *Candida* remains the most common fungal pathogen in SOT recipients. In contrast to HCT in which non-*albicans Candida* predominated, *C. albicans* remained the most common yeast, accounting for 46% of the cases of IC in TRANSNET. However, increasing infections with non-*albicans Candida* species have been reported. The types of IC vary across SOT groups. In orthotopic liver transplantation (OLT), *Candida* often presents as intra-abdominal infections inclusive of peritonitis, recurrent cholangitis, and intra-abdominal abscesses with or without associated candidemia. Surgical site infections are also common [8, 132–134]. The spectrum of infections in lung transplantation includes isolated mucocutaneous involvement, candidemia, bronchial and aortic anastomotic infections, mediastinitis, empyema, and dissemination [135–138]. Schaenman et al. [139] reviewed 921 orthotopic heart transplant (OHT) recipients from a single center from 1980 to 2004 and found a decreasing overall incidence of IC (from 6.1% to 2.1%) with bloodstream (41%), disseminated (21%), gastrointestinal (14%), and urinary tract infections (UTIs) (11%) occurring most commonly. Although a sizeable number of infections were attributed to non-*albicans Candida*, the proportion did not change significantly over time. In renal transplantation, candiduria occurs commonly. Safdar et al. [140] reviewed 1738 renal recipients from a single center and found an 11% incidence of candiduria with *C. glabrata* predominating (53%). *Candida* infections of the renal allograft can also manifest as *Candida* arteritis of the renal and/or iliac arteries [141]. In pancreas transplant recipients, the site of IC varies based on multiple factors inclusive of transplant type and exocrine drainage site; however, intra-abdominal, surgical site, and UTIs predominate with or without accompanying bloodstream infections [142–146]. Finally, among all SOT groups, IC occurs most often in small bowel (SBT) and multivisceral transplant (MVT) owing to the heightened immunosuppression and altered gastrointestinal tract mucosa. One of the largest series in SBT and liver-SBT found that *Candida* bloodstream infections occurred most commonly followed by intra-abdominal infections [147].

Aspergillus is the second most common fungal pathogen overall and the lung transplant recipient remains most susceptible to this airborne pathogen. In lung transplantation, early infections can manifest as tracheobronchitis and often involve the bronchial anastomotic sites with the potential for devastating complications including bronchopleural fistulas. Later in the post-transplant period invasive pulmonary and disseminated *Aspergillus* infections predominate [138, 148–150]. IA in OLT consists primarily of pulmonary, cutaneous, and CNS disease with historically higher rates of dissemination, occurring in upwards of 50–60% of OLT recipients [55]. Singh et al. [151] compared OLT cohorts from 1990–1995 to 1998–2001 and despite improvements in transplantation techniques over time, the overall incidence of IA remained unchanged; however, significant reductions in CNS and disseminated IA were noted. IA occurs in up to 14% of heart transplant patients and pulmonary infections

predominate although extrapulmonary infection inclusive of mediastinitis and endocarditis as well as dissemination can occur [55, 152–157]. A descriptive analysis of IA in OHT at a single center over a 24-year period showed a decrease in overall incidence across time from 8.7% (1988–1999) to 3.5% (2000–2011) wherein pulmonary infections again predominated but later onset of infection (>3 months) in both cohorts was associated with a higher number of disseminated and/or atypical sites of infection [158].

Cryptococcal infections are more common in SOT as compared to HCT, but they remain overall infrequent constituting approximately 8% of IFIs in the TRANSNET dataset [4]. In SOT recipients, cryptococcal disease can manifest at multiple sites including pulmonary, skin, or soft tissue infections; however, over 50% of SOT recipients will have CNS involvement or disseminated disease, and cryptococcemia has been seen in roughly one-third of patients [28, 159]. Interestingly, lung transplant recipients may have an overall decreased burden of disease. They have been found to have lower rates of positive serum cryptococcal antigen testing in isolated pulmonary infections and have the lowest rates of dissemination of the SOT groups [159, 160]. It is possible that this is related to the removal of latent cryptococcal infections in the native lungs or earlier detection secondary to frequent pulmonary radiographic imaging and sampling, but this remains unanswered. Conversely, liver transplant recipients often have severe disease with dissemination and septic shock [160–162].

The non-*Aspergillus* molds, namely, mucormycosis, *Fusarium*, and *Scedosporium*, are increasingly recognized, together accounting for approximately 4% of IFIs in the TRANSNET surveillance cohort [33]. Mucormycosis is the most common of these pathogens and presentations in SOT range from isolated cutaneous infections due to direct trauma to invasive pulmonary and rhino-orbital-cerebral disease. Endobronchial anastomotic infections with potential for dissemination occur more commonly in the lung transplant recipient [163, 164]. Direct involvement of a non-pulmonary transplanted organ, such as a renal allograft, can occur with devastating consequences [165–167]. *Fusarium* infections in SOT range from isolated cutaneous and ocular involvement to severe pulmonary and disseminated infections with fungemia occurring in over 40% of reported cases [168]. Hussain et al. [71] evaluated 57 cases of *Scedosporium* infections in SOT and found pulmonary and disseminated infections occurring frequently. Moreover, SOT recipients with *S. prolificans* were more likely to have associated fungemia than those infected with the more commonly isolated *S. apiospermum* complex (40% vs. 4.7%, respectively).

Histoplasmosis is the most common endemic mycosis occurring in SOT, accounting for 75% of infections of this type in the TRANSNET-generated data, but overall IFIs with the endemic fungi are rare. Among SOT groups, renal transplant recipients are affected most often, with endemic fungal infections constituting 10% of IFIs in this SOT group [4, 23]. Disseminated disease in SOT is often seen with all of the endemic fungi. Cuellar-Rodriguez et al. [24] reviewed 3436 patients undergoing SOT in an endemic region for histoplasmosis and identified 14 patients with proven active infection and all had disseminated infection with pulmonary involvement. Gauthier et al. [169] reported 11 cases of blastomycosis in SOT recipients from a single center. Pulmonary infections occurred most commonly (82% of cases), and infections were often severe, with respiratory distress syndrome in 67% and dissemination in over one-third of patients. Blair et al. [170] reviewed the literature for cases of coccidioidomycosis in SOT and found incidence rates ranging from 3.8% to 8.7% in renal and heart transplant recipients from endemic regions. Pulmonary infection predominated and dissemination was seen in upwards of 75% in one case series, often to multiple sites, including the transplanted allograft, skin, meninges, genitourinary tract, and spleen.

Donor-derived fungal infections in SOT are rare but important considerations when caring for a transplant recipient. A donor source should at least be considered in early infections, particularly those involving the transplanted allograft. Multiple fungal pathogens have been associated with donor-derived infection and guidelines have been published by the American Society of Transplantation (AST) to guide both recognition and management [171]. Issues of transplant tourism may further impact the incidence of donor-derived IFIs [172, 173]. Donor-derived *Candida* infections are often a result of contaminated preservation fluid and are seen most commonly in the renal transplant population. Digestive tract disruption at the time of procurement is often identified. Resultant complications in the renal transplant recipient include *Candida* arteritis of the graft vasculature as previously mentioned [141]. Unrecognized candidemia in the donor may have significant impact on the graft including mycotic aneurysms with potential for rupture. In lung transplant recipients, heavy donor airway colonization with *Candida* has been associated with complicated early infections such as mediastinitis, empyema, and *Candida* arteritis involving the aortic anastomosis [174, 175]. Cases with *Aspergillus* have involved contamination of preservation fluid and unrecognized infection in the donor with complications including multiple renal abscesses and *Aspergillus* arteritis in the renal allograft as well as *Aspergillus* endocarditis with ultimate dissemination in a heart transplant recipient [171, 176, 177]. Rare reports of donor-derived infections in near-drowning accidents have also been reported with *S. apiospermum* complex and *Apophysomyces elegans* [178, 179]. Case reports of cryptococcal infection include transmission in a donor with unrecognized cryptococcal meningitis with resultant cryptococcemia and pneumonia and/or meningitis in the SOT recipients [180]. In addition, Sun et al. [181] described

five cases of early-onset (defined as less than 30 days post-transplant) donor-derived cryptococcal infections involving the allograft or surgical site. Finally, as previously mentioned, the endemic mycoses, namely histoplasmosis and coccidioidomycosis, have been transmitted from donors either from or with extensive travel to endemic areas inclusive of a rare case of *Coccidioides immitis* endocarditis [182].

Risk Factors for IFIs

Many IFI risks are relevant across transplant groups; however, some remain specific to the organ transplanted. In all SOT groups, the importance of rejection and resultant augmentation of immunosuppression and specific agents utilized therein cannot be underemphasized, increasing the risk across the spectrum of pathogens. However, as in HCT, it is important to keep in mind that some immunosuppressive agents used in SOT, such as CNIs and mTOR inhibitors, may impart a protective effect against IFIs. Calcineurin is a calcium- and calmodulin-dependent phosphatase involved in T-cell signaling and is the primary target of the CNIs (tacrolimus and cyclosporine). Based on their effects on the highly conserved mammalian and fungal calcineurin, these agents paradoxically possess both immunosuppressive and antifungal properties with the potential to both increase susceptibility to IFIs and reduce the severity and extent of fungal infections in the transplant recipient. The CNIs have been shown to impair fungal cell stress response, growth, and virulence and have demonstrated *in vitro* and *in vivo* synergistic activity with other antifungal agents against *Candida* and *Aspergillus* species [85]. In addition, the CNIs have been shown to impair the growth of *C. neoformans* at higher temperatures (e.g., body temperature) as well as inhibit hyphal elongation necessary for mating with resultant decreased infectivity. Moreover, tacrolimus has exhibited synergistic activity against *Cryptococcus* in combination with azoles and echinocandins [85, 183]. Clinically, the protective effects of CNIs were demonstrated by Singh et al. [160] in a multicenter, prospective study of *Cryptococcus* infections in SOT. In the 111 identified SOT recipients with cryptococcal infections, receipt of a CNI was independently associated with a lower mortality. Infections in those receiving a CNI also less frequently involved the CNS and were more often isolated to the lungs. These effects were more pronounced in the group receiving tacrolimus, perhaps at least partially explained by better penetration of the tacrolimus into the CNS as compared to cyclosporine. Rapamycin targets the kinase mTOR with a single homolog in humans, *Candida,* and *Cryptococcus* species. *In vitro* studies show fungicidal activity against both *C. albicans* and *C. neoformans* [184]; however, activity against *Aspergillus* is less clear with conflicting *in vitro* susceptibility results. Positive interactions were seen *in vitro* with disc-diffusion testing when used in combination with caspofungin against isolates of *A. fumigatus*, *A. flavus*, and *A. terreus* [185]. In addition, reports from *in vitro* testing against agents of mucormycosis (including both *Mucor* and *Rhizopus* species) with CNI and mTOR inhibitors in combination with antifungal agents suggest variable synergy against this fungal pathogen [186, 187]. These data support future studies examining potential therapeutic combinations for both prevention and treatment of IFIs in the transplant recipient.

In OLT, risks for IFIs in the pre-transplant period include prolonged intensive care unit stays, receipt of broad-spectrum antimicrobial therapy including spontaneous bacterial peritonitis antimicrobial prophylaxis, indwelling catheters, fungal colonization, and fulminant hepatic failure. Perioperative risks include prolonged operation times, significant intraoperative transfusion requirements, and choledochojejunostomy biliary anastomoses. Key post-transplant risks include renal failure (particularly the requirement of renal replacement therapy), early graft failure, retransplantation, and surgical re-exploration [8, 132, 151, 188–194]. As surgical techniques and procedures continue to advance, the perioperative risks have decreased in importance; however, post-transplant complications, particularly the need for retransplantation and renal failure requiring hemodialysis, remain prominent IFI risks [8, 195].

In lung transplantation, receipt of a single-lung transplant carries the unique risk of the remaining native lung serving as a nidus for fungal pathogens [150, 174, 196, 197]. However, double-lung transplant results in greater impairment in respiratory protective mechanisms and increased at-risk anastomotic area [138, 150]. The significance of airway colonization both pre- and post-transplant remains unclear as invasive disease can evolve with or without preceding colonization [198]. However, patients with cystic fibrosis developing IA post-transplant have been shown to be significantly more likely to have been colonized pre-transplant [199]. Furthermore, Cahill et al. [200] found that recipients with *Aspergillus* isolated from the airways in the 6-month period post-transplant were 11 times more likely to develop IA. Additional risk factors in lung transplantation for IFIs include advanced age, hypogammaglobulinemia, anastomotic airway stenosis and ischemia, and receipt of extracorporeal membrane oxygenation post-operatively [55, 150, 198–207].

Detailed evaluation of risk factors unique to heart transplant recipients is less robust than the previously discussed transplant populations. Munoz et al. [157] looked at risks for IA in 287 patients undergoing OHT between 1988 and 2002 confirming previously recognized factors such as re-operation and renal dysfunction and also demonstrating elevated risk with identification of an episode of IA in the heart transplant program within 2 months of the transplant. The latter finding signaled the

importance of center-specific environmental exposures, another shared risk in SOT groups [208]. A single-center cohort study of IFIs in heart transplant recipients from 1995 to 2012 identified further risks including delayed chest closure and the addition of OKT3, anti-thymocyte globulin, or daclizumab to standard corticosteroid induction [209]. Risks specific to the renal transplant recipient include prolonged pre-transplant hemodialysis, underlying diabetes, advanced donor age, delayed graft function, CMV infection, previous antibiotic exposure, and disruption of the intestinal and bladder mucosa [210–212]. In pancreas transplantation, enteric anastomotic drainage is particularly important in the context of intra-abdominal infections [142]. Finally, in SBT/MVT, the receipt of total parenteral nutrition and long-term antibiotic therapy both play a significant role [213]. These risk factors and epidemiologic characteristics are critical for each transplant program to review for both their diagnostic awareness and potential need for prophylactic or pre-emptive interventions.

Geographical differences in risk of IFIs are perhaps most notable among the endemic mycoses including blastomycosis, coccidioidomycosis, and histoplasmosis as infections typically occur in those residing in, or with extensive travel to, an endemic area. Knowledge of the geographic exposure in both patients and their donors is important in SOT given the potential for reactivation and donor-derived infections with these pathogens. *Blastomyces* species are found primarily in North America in midwestern, southern, and southeastern states, especially those bordering the Ohio and Mississippi river valleys, and in provinces bordering the Great Lakes and Saint Lawrence Riverway in Canada [214]. *Coccidioides* species are found in arid desert regions in the Western Hemisphere including California's south-central valley, southern Arizona and New Mexico, West Texas, and parts of Mexico and Central and South America [215]. *Histoplasma capsulatum* is endemic in North America, most notably the Ohio and the Mississippi River valleys within the United States, as well as Central and South America and areas in Africa and Europe [216].

Timeline and Outcomes of IFIs

As discussed in HCT, general periods of infection corresponding with early, late, and very late fungal infections ascribed to differing fungal pathogens are proposed in SOT (see Fig. 31.1). However, more recent epidemiologic data in SOT suggests a need to modify this timeline as the majority of IFIs tend to occur greater than 90 days post-transplant. Reasons for this shift to later in the post-transplant course are multifactorial and include utilization of antifungal prophylaxis, a topic discussed later in this chapter. The predominant IFIs early in the transplant course are IC and IA. Overall *Candida* infections occur earliest with a median onset of 130 days as compared to 184 days with IA based on the TRANSNET cohort [4]. Neofytos et al. found the median onset of IC post-transplant was earliest in lung (day 52) and heart transplant (day 67) and much later in renal transplant recipients (day 896) [20]. In contrast, IA occurred earliest in OLT with approximately 75% of OLT recipients developing infection within 6 months post-transplant. In lung transplant recipients, most cases of IA presented greater than 1 year post-transplant although infections at the tracheobronchial anastomoses are typically reported in the early transplant period.

Non-*Aspergillus* molds occurred later post-transplant with a collective median onset post-transplant of 467 days based on TRANSNET data. Combining IFIs with mucormycosis, *Scedosporium,* and *Fusarium*, only 37.8% occurred within 6 months of transplant with an additional approximate one-third occurring at 2 years and beyond. Similar to IA, OLT recipients had an earlier onset with these infections, with a median time to onset of 81 days as compared to 533 days for the non-liver SOT groups [33]. As in HCT, infections with *Scedosporium* may occur earlier than other non-*Aspergillus* molds. Husain et al. [71] reported a median post-transplant onset of 4 months in 57 SOT recipients with *Scedosporium* infections with over 60% occurring within 6 months. In general, IFIs associated with the endemic fungi and *Cryptococcus* tend to occur much later in the transplant course; the median onset of *Cryptococcus* is well beyond the first post-transplant year [4].

Survival outcomes with IFIs in SOT vary based on the pathogen, the host, and the site of infection. TRANSNET-generated data showed that 12-month survival rates, inclusive of all SOT recipients with IFIs, were lowest with IA (59%) followed by non-*Aspergillus* molds (61%), IC (66%), and cryptococcosis (73%) [4]. Among the SOT groups, Neofytos et al. [20] found the poorest overall survival outcomes in OLT recipients. Similar to IFI risks, the preponderance of outcomes-related data is with *Candida* and *Aspergillus* infections. When comparing outcomes specifically with IC among the groups, PATH Alliance data showed the highest 12-week survival rates in the lung transplant population; in contrast, OHT recipients fared the worst although not reaching statistical significance [20]. The increasingly common non-*albicans Candida* has been associated with decreased survival in OLT [8, 217]. In a multicenter, case-controlled study in 103 OLT recipients consisting of 34 cases with IC and 69 non-infected controls, Husain et al. [8] reported that infections with non-*albicans Candida* ($n = 12$) including *C. glabrata* (7), *C. tropicalis* (3), *C. parapsilosis* (1), and *C. guilliermondii* (1) were associated with higher mortality rates (58.3%) than those with *C. albicans* (22.7%). Similarly, in a more recent retrospective single-center evaluation of IFIs in OLT recipients, Raghuram et al. [217] reported 1-year survival rates of 27.8% and 50% in OLT recipients with *C. parapsilosis* ($n = 16$) and other non-*albicans Candida* [$n = 16$, *C. dubliniensis* (3), *C. glabrata* (10), *C. krusei* (2), and *C. tropicalis* (1)] infections,

respectively, in contrast to 75% with *C. albicans* infections (n = 15). The lower survival reported with *C. parapsilosis* in this study is surprising as *C. parapsilosis* has been shown to be less virulent in comparison to other *Candida* species in animal models and correspondingly has been associated with less severe outcomes in the clinical setting [7, 218]. However, all six isolates of *C. parapsilosis* in this study were fluconazole resistant, and the collective data beget the question of whether higher mortality associated with infections with non-*albicans Candida* reflects increasingly resistant and virulent organisms or is simply a surrogate marker for a more debilitated and complex transplant patient. Worse outcomes with IA are particularly seen in OLT recipients undergoing late retransplantation e.g., more than 30 days from the initial transplant, with a reported mortality of 100% [219]. In lung transplant, *Aspergillus* infections have been associated with mortality rates from 23% with isolated tracheobronchitis up to 82% in invasive pulmonary infections, and single-lung transplant recipients often have inferior survival outcomes [55]. Potential reasons for worse outcomes in the single-lung transplant recipient include older age at transplant as well as increased proportions of infections with invasive pulmonary aspergillosis as compared to tracheobronchitis with the native lung often serving as the source [55, 150]. *Scedosporium* and *Fusarium* infections have been associated with overall mortality rates of 54% and 33%, respectively, the latter much lower than reported rates in HCT [71, 220].

The impact of IFIs on overall graft function and survival is also a crucial consideration in SOT. In the lung transplant recipient, fungal pneumonias and even fungal colonization have been associated with the development of bronchiolitis obliterans syndrome and chronic allograft dysfunction [221, 222]. Albano et al. [141] conducted a multicenter, retrospective evaluation of graft site *Candida* infections in renal transplant recipients wherein 14 of the 18 infections were identified as *Candida* arteritis of either renal and/or iliac arteries. Local aneurysm developed in all but one patient, with three deaths due to rupture, and 82% of the remaining patients required nephrectomy. Based on their findings, the authors argue for empiric nephrectomy in this setting; however, varying reports with improved outcomes including retained graft function make management unclear [223]. Intra-abdominal fungal infections in pancreas transplant recipients were also associated with significantly lower 1-year graft survival rates compared to those without infection (17% vs. 65%, respectively) [142].

Antifungal Prophylaxis

Addressing fungal infections early, at the time of lowest fungal burden, is essential to the management of these infections and this is especially true with immunocompromised hosts. Given the present difficulties in early diagnosis of IFIs, prophylaxis has been a frequently utilized strategy in the transplant population. Antifungal prophylaxis in the HCT and SOT recipient is predicated on multiple variables including transplant and disease-related risk factors, prior history of fungal infections, screening strategies employed for early IFI diagnosis, and the local environment and epidemiology. In the future, additional risks that may be incorporated into the decision for antifungal prophylaxis include previously mentioned genetic polymorphisms in the transplant donor and recipient. For example, TLRs are proteins that reside on immune cells' surfaces and are important in fungal recognition and immune activation in response to infection. Bochud et al. [90] evaluated specific single-nucleotide polymorphisms in four TLR genes in HCT donors and recipients to assess whether they were associated with increased IA risk. In their initial discovery and subsequent validation cohorts they identified that the TLR4 haplotype S4 in the donor was associated with increased risk of IA in unrelated donor-recipient pairs. While research in this area remains ongoing, identification of genetic polymorphisms modifying risks for IFIs may significantly impact our future designation of the high-risk recipient meriting prophylaxis. Table 31.6 provides a summary of some of the genes wherein specific polymorphisms

Table 31.6 Genetic determinants of fungal risk[a] [97–99, 224, 225]

Gene	*Candida*	*Aspergillus*
CXCL10		Invasive aspergillosis
Dectin-1	Candida colonization	Invasive aspergillosis
DEFB1	Candida colonization	
IL-4	Chronic disseminated candidiasis Recurrent vulvo-vaginal candidiasis	ABPA (IL-4Rα)
IL-10	Candidemia/invasive candidiasis	Invasive aspergillosis
IL-12B	Candidemia/invasive candidiasis	
MBL2	Recurrent vulvo-vaginal candidiasis	Invasive aspergillosis Chronic pulmonary aspergillosis, ABPA
PLG		Invasive aspergillosis
PTPN22	Chronic mucocutaneous candidiasis	
TLR1/ TLR4	Candidemia/invasive candidiasis	Invasive aspergillosis
TLR2	Candidemia/invasive candidiasis	
TLR3	Chronic mucocutaneous candidiasis	Invasive aspergillosis
TLR6		Invasive aspergillosis

ABPA allergic bronchopulmonary aspergillosis, *CXCL10* C-X-C motif chemokine 10, *DEFB* beta defensin gene cluster, *IL* interleukin, *MBL* mannose-binding lectin, *PLG* plasminogen, *PTPN* protein tyrosine phosphatase nonreceptor, *TLR* toll-like receptor

[a]List is not fully inclusive

impact the risk associated with two common fungal pathogens, *Candida* and *Aspergillus* [97–99, 224, 225].

In general, prophylaxis consists of two types: primary prophylaxis occurs in patients at high risk but without prior history of an IFI, whereas secondary prophylaxis is given to patients with a prior IFI and impending heightened immunosuppression (e.g., transplantation) at increased risk for relapsed or new IFI. Strategies utilized by transplant centers include administration of prophylaxis to all patients (universal) versus those at increased risk (targeted). Limiting prophylaxis to a select high-risk population is important for a variety of reasons including reduced costs, drug interactions, drug toxicities, and the emergence of resistance. Data regarding prophylaxis in HCT and SOT continue to evolve and regimens are highly variable across centers but principles need to be explored and validated.

In HCT there are essentially two time points when prophylaxis is considered: early post-transplant when neutropenia predominates and following engraftment in high-risk patients with GVHD. Early prophylactic studies focused primarily on fluconazole. Goodman et al. [45] performed the first randomized controlled trial in HCT showing a reduction in superficial and systemic fungal infections with prophylactic fluconazole. Further evaluation by Slavin et al. [226] and Marr et al. [227] confirmed these findings along with both acute and long-term beneficial effects on survival, respectively. Epidemiologic changes in HCT, including the emergence of *Aspergillus* as the primary fungal pathogen and increasing non-*Aspergillus* molds and non-*albicans Candida* species, have expanded prophylactic considerations to echinocandins, polyenes, and the extended spectrum azoles (primarily posaconazole and voriconazole although data are likely to emerge with newly introduced agents such as isavuconazole) [228].

Robenshtok et al. [229] conducted the largest meta-analysis of antifungal prophylaxis in patients receiving chemotherapy or undergoing HCT. Sixty-four trials of prophylactic regimens inclusive of amphotericin B, fluconazole, itraconazole, posaconazole, voriconazole, and non-systemic antifungals were evaluated. Prophylactic therapy was associated with a reduction in all-cause and fungal-related mortality and total IFIs in allogeneic HCT patients but there was insufficient power to show significant benefit in the autologous HCT population. Ethier et al. [230] compared fluconazole with systemic mold-active prophylactic regimens (e.g., amphotericin B, caspofungin, micafungin, anidulafungin, posaconazole, itraconazole, voriconazole, and ketoconazole) in a meta-analysis which included 20 randomized controlled trials of antifungal prophylaxis in patients receiving chemotherapy or undergoing HCT. These authors found that mold-active regimens reduced proven or probable IFIs, IA, and IFI-related mortality when compared to fluconazole but did not significantly impact overall mortality and were associated with increased adverse effects. Data summarizing secondary prophylactic regimens are less common with no randomized controlled trials or meta-analyses to guide recommendations. However, a prospective, open-label, multicenter trial evaluated voriconazole for secondary prophylaxis in allogeneic HCT recipients with prior proven or probable IFI with a resultant 1-year cumulative incidence of IFI of 6.7 +/− 3.6% compared to prior clinical experience wherein relapsed infection occurred in 30–50% of patients suggesting overall benefit in this patient population [231, 232]. Certainly considerations for secondary prophylaxis are dependent on the previous offending pathogens, sites of infection, and available susceptibility data.

Guidelines available for antifungal prophylaxis in HCT include the Infectious Diseases Society of America (IDSA) [233], the European Conference on Infection in Leukemia [234], and the National Comprehensive Cancer Network [235]. For *Candida* infections, fluconazole remains a drug of choice before engraftment in allogeneic and high-risk autologous HCT recipients. Echinocandins are an alternative option and are often chosen due to their favorable side effect profile, lack of significant drug interactions, as well as their expanded antifungal coverage, particularly for patients known to be colonized or previously infected with non-*albicans Candida* species. In a randomized, double-blind, multicenter trial, micafungin was compared to fluconazole during the neutropenic phase following HCT and was superior to fluconazole in the primary endpoint of the absence of suspected, proven, and probable IFIs with overall fewer cases of IA in the micafungin arm [236]. In allogeneic HCT recipients at high risk for mold infections (e.g., those with GVHD), the guidelines support utilization of posaconazole. This recommendation is primarily based on the study by Ullmann et al. [237] comparing posaconazole to fluconazole which showed posaconazole was equivalent to fluconazole in IFI prevention and superior in prevention of proven and probable IA. Of note, the study did not show an overall survival advantage in the posaconazole arm. Posaconazole and isavuconazole have not yet been studied as primary prophylaxis in the early pre-engraftment period in the HCT population. However, posaconazole prophylaxis in patients with AML or MDS with prolonged neutropenia secondary to remission-induction chemotherapy was associated with a reduction in IFIs and improved survival [238]. Since these studies were published, posaconazole became available in an extended release tablet and intravenous formulation, thereby bypassing some of the previous concerns regarding overall posaconazole exposure with the suspension formulation. In addition, two studies evaluating voriconazole both pre-engraftment and during GVHD in allogeneic HCT recipients resulted in some advocating provisional use in this setting [239, 240].

In SOT, data for antifungal prophylaxis resides predominantly in liver and lung transplantation but continues

to emerge in other populations. In OLT, the primary pathogens targeted are *Candida* and *Aspergillus* and a variety of prophylactic agents have been utilized. Amphotericin B is among the first drugs studied for prophylaxis, and available data suggest that low-dose amphotericin B [e.g., 0.1 to 0.5 mg/kg/day amphotericin B or 1 mg/kg/day liposomal amphotericin B (LAMB) preparations] may not be effective, perhaps due to lack of adequate *Aspergillus* coverage [241–243]. However, treatment doses of LAMB (e.g., 3–5 mg/kg) have been shown to be effective in high-risk OLT recipients including a study in those requiring renal replacement therapy [244]. The frequently cited prophylactic study with fluconazole by Winston et al. [245] was a prospective, randomized, double-blind controlled trial comparing 10 weeks of fluconazole 400 mg daily to placebo and showed reductions in fungal colonization (from 70% to 28%) as well as significant reductions in proven IFIs in the prophylaxis arm without perceptible increases in colonization with non-*albicans Candida* species. Although prophylaxis did not impact overall mortality, there were fewer deaths due to IFIs. Utilization of echinocandin prophylaxis is appealing due to the lack of significant drug interactions or hepatotoxicity and potential activity against both fluconazole-resistant *Candida* and *Aspergillus* [246–249]. Saliba et al. [249] performed an international, multicenter, randomized, open-label trial of antifungal prophylaxis in high-risk OLT recipients comparing micafungin to institutional standard of care (fluconazole, LAMB, or caspofungin) and demonstrated non-inferiority with respect to the primary composite efficacy endpoint defined as the absence of a proven or probable IFI and no initiation of antifungal treatment at the end of prophylaxis. Furthermore, the side effect profile was comparable to standard of care with less renal toxicity during the course of prophylaxis.

With the trend of increasing non-*albicans Candida* infections in the setting of fluconazole prophylaxis alongside isolated reports of increased mortality associated with these infections in OLT recipients, the importance of targeted prophylactic therapy must be underscored [8]. Available IDSA and AST guidelines support the use of targeted prophylaxis in this population for patients with defined risk factors for *Candida* and *Aspergillus* infections [195, 250, 251]. As previously discussed, risk factors for *Candida* infections include choledochojejunostomy anastomoses, complicated surgical procedures (e.g., high intraoperative transfusion requirements, prolonged intraoperative times), and demonstrated colonization with *Candida* spp. Risks for both *Candida* and *Aspergillus* infections include the need for retransplantation, renal failure (particularly the need for renal replacement therapy), and reoperation. The duration of therapy and the most appropriate agents in this setting (e.g., fluconazole and extended spectrum azoles, amphotericin B products, and echinocandins) continue to be defined [250–253].

Most lung transplant centers utilize some form of prophylaxis in the early post-transplant period given the overall high level of immunosuppression applied and exposure of the transplanted organ to the outside environment [254–256]. Risks such as ischemia at the anastomotic site and pre- and post-transplant fungal colonization are among other considerations. However, consensus regarding the most appropriate strategy (targeted vs. universal), specific agents, and duration has not been reached. In the past the most common agents utilized were polyenes and azoles, namely, itraconazole and voriconazole, with increasing utilization now at some centers of posaconazole and the echinocandins [256]. Amphotericin B prophylaxis in the lung transplant population primarily consists of inhaled formulations owing to the potential to protect the transplanted organ without systemic drug exposure, thereby avoiding nephrotoxicity [257–261]. However, the localized nature of this therapy limits prevention of systemic complications such as pleural space infections. Lipid preparations of amphotericin B for nebulization were introduced to reduce the side effects associated with nebulized amphotericin B deoxycholate (ABD), namely wheezing and bronchospasm, as well as to optimize pharmacokinetic parameters including intrapulmonary concentration and half-life [262]. After the safety of nebulized amphotericin B lipid complex (ABLC) was demonstrated [259], Drew et al. [260] conducted the only available prospective, randomized controlled trial with nebulized ABLC comparing it to ABD. This study showed similar efficacy between the groups and significantly less adverse effects with nebulized ABLC. Both itraconazole and voriconazole alone and in combination with nebulized amphotericin have shown efficacy as IFI prophylaxis [263, 264]; however, concerns of increased voriconazole-associated hepatotoxicity are reported and issues around drug interactions as well as associated skin malignancies (e.g., squamous cell carcinoma) with long-term use are concerning [264, 265]. Robust studies evaluating agents such as posaconazole and echinocandins as primary prophylaxis within the lung transplant population are lacking. On the basis of available data, IDSA guidelines recommend antifungal prophylaxis in this group [250].

A final comment on prophylaxis for the endemic mycoses is to some extent applicable in both the HCT and SOT groups. The primary endemic mycosis for which routine screening and/or prophylaxis is performed in endemic areas is coccidioidomycosis; however, individual transplant centers vary in their screening practice as well as application and duration of prophylaxis. With coccidioidomycosis, risks are greatest among recipients with a prior history of infection or positive serologies, and donor exposure is also critical in decisions for initiating prophylaxis. Blair et al. [82] evaluated the impact of fluconazole prophylaxis at a single transplant center in an endemic region and found that prophylaxis contributed to a decrease in incidence of coccidioidomycosis

from historical rates of up to 9% down to 1% to 2% in the HCT and SOT transplant groups. The need for screening for histoplasmosis in recipients from endemic regions is less straightforward and is not routinely employed given the low rates of infection post-transplant and unclear benefit [266]. However, practice areas that remain controversial include appropriate prophylactic management in recipients with evidence of disease in the explanted organ and/or donor tissue and in recipients with recent active infection (e.g., within 2 years of transplantation). Cuellar-Rodriguez [24] reported their center's findings over a 10-year period during which they found 14 recipients with histopathologic evidence of histoplasmosis in either the explanted organ (ten cases) or donor tissue (four cases) and in whom long-term prophylaxis with either itraconazole (in lung transplant recipients) or fluconazole (in one liver transplant recipient) was administered. The authors found no evidence of active histoplasmosis in these patients after a mean of 13.5 months of follow-up and argue that long-term prophylaxis is necessary in this scenario. However, others cite experience in transplant patients with both serologic and radiographic evidence suggestive of prior histoplasmosis who did not develop infection despite lack of routine antifungal prophylaxis post-transplant suggesting therapy is not warranted [78]. In patients with recent active infection (e.g., within 2 years of transplant), present IDSA guidelines do not lend specific recommendations but suggest consideration of prophylaxis. In those with a history of completed treatment for histoplasmosis, recommendations are to check a urinary *Histoplasma* antigen prior to transplantation and to monitor frequently during the time of heightened immunosuppression with thorough investigation and potential therapy if increases in urinary antigen testing are appreciated [267]. The current recommendations regarding management for potential donor-derived infection with endemic mycoses including histoplasmosis and coccidioidomycosis in both living and deceased donors is beyond the scope of this chapter but is provided in the guidelines put forth by the AST on donor-derived fungal infections [171].

There are also important non-pharmacologic strategies utilized for preventing IFIs [233, 268]. Transplant recipients must incorporate healthy habits into their post-transplant routine and be counseled to identify and avoid high-risk activities and environments. The importance of maintaining good hand hygiene via frequent washing and/or alcohol-based rubs (for non-soiled hands) and the use of gloves and masks when in contact with substances such as soil and plants must be emphasized. Avoidance of smoking is also important, including tobacco and marijuana, particularly as the latter has been associated with pulmonary IFIs due to inhalation of fungal spores such as *Aspergillus*. Transplant recipients should attempt to avoid environments that may be associated with a high inoculum of fungal spores such construction sites, caves, horse barns, bird aviaries, and chicken coups. Limiting direct involvement in activities such as home remodeling, mulching, or spelunking is also important [268]. Certain beverages, spices, and foods associated with high quantities of fungal contamination should be avoided, particularly in neutropenic hosts. This list includes (but is not limited to) cold-brewed teas, pepper, unwashed raw fruits (particularly those with downy skins such as apricots and peaches), unroasted raw nuts, and many soft cheeses [233, 269]. The United States Department of Agriculture and the Food Safety and Inspection Service also have comprehensive food safety recommendations specifically for transplant recipients available online [270].

Conclusions

In summary, IFIs remain a vexing issue in HCT and SOT populations despite many advances in the field of transplantation. Multicenter collaboration with prospective monitoring and randomized controlled trials of diagnostics, prevention, and treatment are vital, particularly as we face new and increasingly resistant pathogens with less traditional presentations.

Candida Infections in Hematopoietic and Solid Organ Transplant Recipients

32

Alison G. Freifeld and Carol A. Kauffman

Introduction

Candida spp. are a major cause of morbidity and mortality among immunocompromised patients, especially recipients of hematopoietic stem cell transplant (HCT) or solid organ transplants (SOT). *Candida* spp. are the most common etiology of fungal infections in SOT recipients and the second most common among HCT recipients, after aspergillosis [1, 2]. Clinical signs of candidiasis range from mucosal colonization to invasive and/or systemic fungal disease. Candidemia is the most common manifestation of invasive candidiasis. Deep tissue *Candida* infections, including intra-abdominal abscesses, hepatosplenic, and urinary tract infections, are less common than candidemia, but they cause important syndromes in SOT and HCT patients. The immunosuppressive agents required to prevent organ rejection or graft-versus-host disease in transplant recipients can blunt immune responses to *Candida* spp. and predispose transplant recipients to developing invasive candidiasis. Other general risk factors include neutropenia, systemic antibiotic exposure, central venous catheters, parenteral nutrition, renal or hepatic insufficiency, a prolonged intensive care unit (ICU) stay, treatment with systemic corticosteroids, GVHD, immunosuppressive antirejection therapy, etc.

The diagnosis of invasive candidiasis is often hampered by the low sensitivity of traditional blood culture techniques for *Candida* spp. and by the lack of specific clinical findings associated with candidemia or deep tissue infection. Presenting clinical signs include fever, leukocytosis, and, less commonly, hypotension, none of which differentiate between *Candida* and bacterial infections. Furthermore, distinguishing *Candida* colonization, which is very common, from invasive disease complicates accurate diagnosis. Due to these confounding factors, reliable longitudinal incidence data about fungal infections have been difficult to obtain. The Mycoses Study Group (MSG) and the European Organisation for Research in Treatment of Cancer (EORTC) have provided consensus definitions for the diagnosis of invasive mycoses including candidiasis (Table 32.1) [3]. These definitions are now widely used and have greatly clarified epidemiologic, clinical, and drug susceptibility data, as they provide a common basis for diagnosing mycoses.

With the expanding repertoire of medical and surgical transplantation approaches that require adjunctive immunosuppression, it is not surprising that a recent study found that the incidence of systemic *Candida* infections has been rising in recent years [4]. Disturbingly, it was also found that despite the availability of potent antifungal agents, outcomes have not improved concomitantly. Candidemia remains one of the deadliest causes of bloodstream infection, with an attributable mortality rate ranging from 20 to 40% [5–7].The clinical manifestations, diagnostic methods, and antifungal prophylaxis and treatment approaches to *Candida* infections in transplant patients are reviewed herein to help clinicians in the management and prevention of these infections.

Pathogenesis and Risk Factors

Candida colonization of skin, gut, and mucosal surfaces is a frequent prerequisite for the development of invasive disease. *Candida* species colonize the oropharynx, axillary, groin, perineal skin folds, and genital and intestinal mucosa of 30–70% of healthy individuals, notably without causing any illness [8]. Effective and intact host immunological mechanisms prevent invasion and permit microorganisms to exist innocuously on mucosal and skin surfaces. Perturbations of this host-pathogen interaction at the mucosal surfaces can lead to oral thrush, colonic overgrowth, and

Table 32.1 MSG/EORTC definitions for the diagnosis of proven or probable invasive candidiasis [3]

Proven	Histopathologic, cytopathologic, or direct microscopic examination of a specimen obtained by needle aspiration or biopsy from a normally sterile site (other than mucous membranes) showing yeast cells, pseudohyphae, or true hyphae compatible with *Candida* spp. Recovery of a *Candida* spp. by culture of a sample obtained by a sterile procedure (including a freshly placed [<24 h ago] drain) from a normally sterile site showing a clinical or radiological abnormality consistent with an infectious disease process. Blood culture that yields *Candida* spp.
Probable	Disseminated candidiasis: at least one of the following two entities is identified after an episode of candidemia within the previous 2 weeks: Small, target-like abscesses (bull's-eye lesions) in the liver or spleen on CT and/or ultrasound Progressive retinal exudates on ophthalmologic examination

Modified from De Pauw et al. [3]

candiduria. These conditions are usually benign and readily treated, but further immunologic and physical impairments of skin or mucosal barriers may allow entry of colonizing yeast into the bloodstream or tissues.

Mucosal damage due to radiation or chemotherapy in HCT recipients and surgical wounds or incompetent anastomotic sites in SOT recipients are examples of barrier breaches that predispose to tissue infiltration by colonizing *Candida* spp. Indwelling intravenous catheters are ubiquitous in recently transplanted patients, and they create an important portal of entry for *Candida* into the bloodstream. The foreign materials comprising venous catheters appear to inhibit immune cell function, allowing uninhibited fungal growth on internal and external surfaces. Furthermore, *Candida* is able to produce a complex polysaccharide biofilm on these foreign surfaces, creating a protective matrix around the yeast and hyphal forms that grow inside [9, 10]. Parenteral nutrition via an indwelling venous catheter is linked to development of candidemia, perhaps due to enhanced yeast growth by component nutrients [11, 12]. *Candida* derived from contaminated organ preservative fluids postharvest is a rare source of infection in SOT recipients [13, 14].

Immunosuppressive drugs, particularly corticosteroids, are key risk factors for serious *Candida* infections [15–17]. They can significantly impair lymphocyte and neutrophil recognition and attack functions needed to eradicate *Candida* yeast and hyphal forms. Furthermore, co-colonizing bacteria at skin and mucosal sites appear to help control yeast numbers through competition for nutrients. Bacterial production of toxic substances such as hydrogen peroxide, lactic acid, and bacteriocins may also serve to keep local concentrations of colonizing *Candida* low [18]. However, when these resident bacterial populations are reduced by systemic broad-spectrum antibiotic treatment, as so often happens in transplant patients, yeast colonization increases, creating an increased opportunity for systemic invasion [9]. Other risk factors include renal insufficiency, dialysis, cytomegalovirus reactivation, overall severity of illness, mechanical ventilation, prolonged ICU stay, and malnutrition (Table 32.2).

Initial host responses to yeast invasion are mediated by the innate immune system. This rapidly active, evolutionarily ancient and conserved pathway is based on the broad recognition of fungal-specific small molecular targets (pathogen-associated molecular patterns, PAMPs) by host cell surface pattern recognition receptors (PRRs) that are located on phagocytes (granulocytes, monocytes/macrophages) and dendritic cells [19, 20]. Subsequent activation of intracellular signaling pathways and stimulation of inflammatory mediators then lead to an accumulation of inflammatory effector cells at the site of *Candida* invasion. Neutrophils and macrophages are the critical effector cells responsible for phagocytosis and killing of *Candida* through both oxidative and non-oxidative mechanisms. Accordingly, a lack of these key cells (i.e., neutropenia) occurring as a consequence of cytotoxic chemotherapy, underlying hematologic malignancy, or any other etiology is a strong risk factor for the development of invasive *Candida* infections [9].

Table 32.2 Risk factors for invasive candidiasis

Host factors	Medical interventions
Neutropenia	Cytotoxic cancer chemotherapy
Extremes of age	Dialysis
Renal failure	Central venous catheter or nasogastric tube
Trauma or burns	Prior antibiotic use
Bowel perforation	Prior surgery (especially abdominal)
High APACHE II score	Parenteral nutrition
Candida colonization	ICU stay >7 days

Epidemiology

Candida species are the fourth leading cause of hospital-acquired bloodstream infection (BSI) in the United States, accounting for nearly 10% of all healthcare-associated BSIs [21]. Data from the Transplant-Associated Infection Surveillance Network (TRANSNET), a consortium of 23 transplant centers in the United States that prospectively studied the epidemiology of invasive fungal infections in SOT and HCT recipients from 2001 to 2006, revealed that, in the SOT cohort, invasive candidiasis had the highest 12-month cumulative incidence (1.9%) followed by invasive aspergillosis (0.7%) [2]. Similarly, in the HCT TRANSNET

cohort, the cumulative incidence was 1.1% at 12 months for invasive candidiasis [1]. Crude mortality rates for *Candida* bloodstream infections, the most common form of invasive candidiasis, have often been reported to be more than 30% [6, 22–24]. Longitudinal studies indicate that despite advances in diagnosis and antifungal therapy, there has been no overall decline in either incidence or mortality associated with invasive candidiasis in the last decade [2, 4, 25, 26].

The timing and incidence of *Candida* infections vary by type of organ or hematopoietic cell transplant procedure, as well as by prior antifungal therapy, transplant center, time post-transplant, and aforementioned patient risk factors [1, 2, 15]. Most episodes of candidiasis occur early after SOT or HCT, generally within the first 2–3 months. Later episodes post-transplant are largely related to the use of corticosteroids and other immunosuppressive drugs for graft rejection in SOT or for graft-versus-host disease in HCT recipients [17, 27, 28].

Abdominal organ transplant recipients have the highest rates of invasive candidiasis among patients undergoing organ transplantation; rates of infection are highest in those receiving small bowel, liver, pancreas, or multi-organ transplants [29–33]. Candidemia predominates in this group and is often related to a vascular access device source [17]. Intra-abdominal candidiasis (e.g., peritoneal and biliary infection) is also common, however, and likely due to bile or intestinal fluid leakage during biliary anastomosis or translocation of intestinal flora into peritoneal fluid. Technical difficulty and prolonged time of abdominal surgery, primary graft failure, and early surgical re-exploration contribute to the risk of invasive candidiasis after abdominal organ transplantation [15, 31, 32]. Liver recipients appear to be especially susceptible to candidiasis, and higher risk is conferred by a number of pre- and postoperative factors, including choledochojejunostomy anastomosis, preoperative renal failure/dialysis, low serum albumin, CMV viremia, substantial infusions of intraoperative cellular blood products, as well as re-transplantation and surgical re-exploration after transplantation [29, 31, 32]. Enteric drainage in pancreas transplant recipients predisposes to a greater risk of invasive candidiasis than does bladder drainage [34]. Candidiasis is relatively infrequent among kidney transplant recipients, and it typically occurs later in the first year post-transplant [17]. A syndrome of early, within 1 month, graft-transmitted candidiasis resulting in fungal arteritis, with high morbidity and mortality after renal transplantation, is related to organ contamination during recovery of the donor kidney [13]. A recent study showed the overall incidence of candidiasis was 4.8% in heart and 8.3% in lung plus heart-lung transplant recipients and that the incidence has declined dramatically over the last 20 years. Candidemia was most often seen following heart transplant while tracheobronchitis due to *Candida* species was a more common manifestation in lung transplant recipients [35, 36].

The overall incidence of *Candida* infection, which is primarily candidemia, in HCT recipients is low, about 1% overall. Notably, the incidence is similar between autologous (1.2%) and allogeneic (0.8%) HCT [28]. The widespread use of antifungal prophylaxis may be credited with this reduction in invasive candidiasis in HCT populations over the last 20 years. In allogeneic HCT patients, two periods of risk for invasive candidiasis and other invasive fungal infections are identified: pre-engraftment and, subsequently, in the first 100 days post-engraftment. During the pre-engraftment period, mucositis, broad-spectrum antibiotics, and neutropenia are significant risk factors, but fluconazole prophylaxis effectively prevents most *C. albicans* infections. However, fluconazole prophylaxis clearly plays a significant role in the increase in breakthrough infections with non-*albicans* species that have lower azole susceptibility [26–28]. The second risk period is post-engraftment after allogeneic HCT, in the setting of GVHD. Corticosteroid use and CMV reactivation during GVHD treatment are both linked to increases in bacterial and fungal infections. In autologous transplantation, virtually all candidemias occur during pre-engraftment and are related to indwelling central venous catheters.

Candida albicans has traditionally been the most frequently isolated yeast pathogen. An important epidemiologic phenomenon over the last two decades has been the well-documented shift from *C. albicans* to non-*albicans Candida* as the most common infecting *Candida* species in some tertiary care centers [6, 37, 38]. This shift is especially prominent in immunosuppressed populations and is of great concern because *Candida glabrata* and *Candida krusei* are relatively or totally resistant to many azole agents, respectively. Increasing resistance to these agents limits their utility for both prophylaxis and treatment in immunosuppressed patients. Between 2001 and 2007 at MD Anderson Cancer Center, 75% of invasive candidiasis cases that occurred in patients with hematologic malignancy or undergoing HCT were due to non-*albicans Candida* species [26]. In the TRANSNET cohort, only 20% of isolates from HCT recipients were *C. albicans*. In this population, the majority of isolates were non-*albicans* species: *C. glabrata* (34%), *C. parapsilosis* (21%), or *C. krusei* (15%) [39]. *C. krusei* is intrinsically resistant to fluconazole but remains susceptible to voriconazole and to echinocandins. The routine use of azole prophylaxis in high-risk cancer populations, particularly in allogeneic HCT recipients, has been responsible for a decrease in invasive candidiasis, but it is also undoubtedly responsible for the rise in non-*albicans Candida* infections [26, 27, 40].

In the SOT population, *C. albicans* remains the most frequently isolated *Candida* species, although a shift toward more non-*albicans Candida* infections has been identified in two nationwide surveys [6, 39]. In the TRANSNET SOT cohort, *C. glabrata* accounted for 30%

of all isolates and *C. parapsilosis* for 9% [39]. Overall, 16% of the 915 *Candida* isolates from this SOT cohort, including several *C. tropicalis* and *C. albicans* isolates, were fluconazole resistant. Prior fluconazole use was a significant risk factor for nonsusceptibility to the drug. Clinicians should be especially aware of the relative or intrinsic fluconazole resistance patterns of *C. glabrata and C. krusei* in transplant populations. Since these and most other non-*albicans* isolates are typically susceptible to echinocandins, it is recommended that an echinocandin be initiated when yeast is isolated in blood cultures, pending species identification.

Clinical Manifestations

Candidemia

Candidemia simply means *Candida* species in the blood. Candidemia can be a transient event associated with colonization of an indwelling central venous catheter, but it is also the most common manifestation of disseminated infection involving multiple organs. The initial clinical presentation of these two different events may be similar; thus, one can never assume that an episode of candidemia is a transient event not requiring antifungal therapy. The clinical manifestations vary from mild fever to symptoms and signs of overwhelming sepsis that include hypotension, tachypnea, tachycardia, and confusion. The initial presentation is non-localizing, but focal signs later point to specific organ involvement. The appearance of multiple pustular skin lesions is a manifestation of widespread disseminated infection. Symptoms and signs associated with candidemia are the same, irrespective of the causative *Candida* species, and they mimic those seen with bacteremia. At autopsy, in severely immunosuppressed patients, widespread infection is characterized by microabscesses noted in many organs.

In SOT recipients, indwelling venous catheters and intra-abdominal processes related to surgery are likely sources for candidemia. In HCT patients, the greatest risk for candidemia is when neutropenia is present or during periods of maximum immune suppression during treatment of GVHD. Often, the source of the organisms is the gut because of damage to the mucosa from chemotherapy, but it can also be from indwelling central venous catheters that are present in almost all HCT patients.

A recent retrospective review of bloodstream infections in hospitalized patients found that mixed infections including bacteria plus *Candida* spp. are very rare, accounting for about 0.7% of all bloodstream infections. Outcomes from these mixed infections were similar to those with candidemia alone [41].

Hepatosplenic (Chronic Disseminated) Candidiasis

This form of invasive candidiasis is seen almost entirely in patients who have hematological cancers and who have been previously neutropenic. HCT recipients can manifest this form of candidiasis after engraftment when they have a return of their neutrophils, but more often, this syndrome occurs in the course of chemotherapy for acute leukemia before transplantation occurs [42]. *C. albicans* is the most likely pathogen, but all species have been found to cause this syndrome. The return of neutrophils triggers the symptoms of high fever, right upper quadrant discomfort, nausea, and fatigue. The symptoms can persist for weeks, but blood cultures usually remain negative. There may be documentation of a previous episode of candidemia, but in many patients, candidemia had not been documented. Imaging studies reveal the characteristic punched out lesions representing multiple small abscesses throughout the liver and the spleen. It has been postulated that hepatosplenic candidiasis could represent a form of immune reconstitution inflammatory syndrome (IRIS) because cultures from lesions often are negative, the illness begins when neutrophils return to normal levels, and symptoms respond to corticosteroids when they are added to antifungal agents [42].

Intra-abdominal Infections

Intra-abdominal infections with *Candida* species are usually seen in the immediate postoperative period in SOT recipients, especially those who received a liver, pancreas, or small bowel transplant [34, 43]. Infections are generally polymicrobial, involving facultative aerobic and anaerobic bacteria from the bowel, along with yeasts. *C. albicans* and *C. glabrata* are the yeasts most commonly isolated. The usual source is perforation of the bowel or mechanical problems with the anastomosis of the biliary tract in liver transplant recipients. The symptoms of intra-abdominal infection include fever, chills, abdominal pain, and distention; if the biliary tract is obstructed, nausea, vomiting, and jaundice occur. Signs of peritonitis may be present, especially with bowel perforation, and focal pain and fevers occur when a localized abscess is present. Imaging is essential to define the site of infection.

Biliary stents are often required after liver transplantation. When these devices remain in place for long periods, they are often colonized persistently with *Candida* species. A complication of this colonization is development of fungus balls, which can cause further obstruction and require revision of the stent [44].

Neutropenic enterocolitis is a life-threatening abdominal complication that occurs rarely after intensive chemotherapy

for acute leukemias and solid tumors. Gram-negative bacteria are the most common cause, but a recent review of published cases showed that the pooled frequency of fungal involvement in neutropenic enterocolitis from all reported patients was calculated to be 6.2% [45]. The vast majority was due to *Candida* spp. Antifungal coverage should be considered in the setting of neutropenic enterocolitis although bacteria are the predominant pathogens.

Urinary Tract Infections

Candiduria is common, but symptomatic urinary tract infections are uncommon in transplant recipients [46]. Many transplant recipients have candiduria in the postoperative period because of the use of indwelling urinary catheters and broad-spectrum antibiotics. The most common species found in the urine are *C. albicans* and *C. glabrata* [46]. Previously, it was thought that candiduria contributed to poor outcomes among kidney transplant recipients, and it was standard practice to treat with fluconazole when candiduria was documented. However, it has been shown in a large, nested, case-control study that those who had candiduria had a higher mortality rate, but the candiduria did not contribute to death, and treatment of candiduria had no effect on outcomes [47]. In this study, as in others, it was thought that candiduria merely was a marker for the severity of underlying illness [48].

Although most patients with candiduria have colonization of the bladder and do not require treatment, ascending infection leading to pyelonephritis can occur, especially in a kidney transplant recipient. In this case, symptoms of dysuria, frequency, and pain over the transplanted kidney will be present and may be accompanied by systemic signs of infection, such as chills, fever, and malaise. These patients require prompt treatment with an antifungal agent, almost always fluconazole. Patients who have candiduria and require ureteral stent placement are at increased risk for persistent *Candida* colonization of the stent and kidney infection.

An uncommon manifestation of *Candida* infection seen specifically in kidney transplant recipients is infection of the graft. This is manifested most often by fungal arteritis with aneurysm formation at the anastomosis site and less often as a graft site abscess [13]. In this circumstance, it has been shown that the kidney was infected at the time it was harvested from the donor, and this infection was directly transmitted with the organ to the recipient. The outcomes are poor with loss of the graft in the majority of patients.

The situation is different in HCT recipients who are neutropenic and who have candiduria. In these patients, candiduria may well be a marker for invasive candidiasis [49]. Symptoms are minimal if the patient is neutropenic and cannot be relied upon to define infection. In this circumstance, treatment is appropriate.

Pulmonary Candidiasis

Candida species rarely cause pneumonia. HCT patients who are markedly immunosuppressed can develop diffuse nodular infiltrates as part of widely disseminated candidiasis, but this is uncommon [50, 51]. In this type of patient, it is more common for pneumonia to be due to molds. Most patients have pulmonary involvement with *Candida* species discovered at autopsy. Sputum and bronchoalveolar lavage samples that yield *Candida* species have low specificity and should not be interpreted as evidence of invasive disease. Lung biopsy is needed to establish the diagnosis of *Candida* pneumonia [52].

Tracheobronchitis due to *Candida* species is the most common form of invasive candidiasis in lung and heart-lung transplant recipients [36]. Patients present with fever, productive cough, and shortness of breath; exam may reveal labored breathing and scattered rhonchi can be heard. Visualization of the airway by bronchoscopy and histologic confirmation are the usual methods of diagnosis.

Endophthalmitis

Endogenous *Candida* endophthalmitis occurs when the organism is hematogenously seeded into the highly vascular choroid layer of the eye [53]. It is not more common in the transplant population than in others who have been candidemic. The most common organism causing this infection is *C. albicans*, but all species have been reported to cause ocular infection [54]. Treatment is most effective if given early in the course of infection. Because the length of therapy and choice of antifungal agent for candidemia will vary if endophthalmitis is present, the Infectious Diseases Society of America (IDSA) guidelines for the management of invasive candidiasis recommend that a dilated ophthalmoscopic examination be performed on all patients who have candidemia to establish whether ocular involvement is present [7]. In patients who have neutropenia, it is recommended that a retinal examination be repeated after neutropenia resolves when lesions are more likely to be manifested [7]. Patients may have no complaints early in the course when typical white lesions are seen in the retina. If not found at this stage, patients seek attention later for changes in visual acuity; at this point, extension to the vitreous is common, and active vitritis is seen on examination. Treatment is more difficult, and the outcomes are less good at this stage of the infection.

Less Common Invasive *Candida* Infections

Endocarditis, osteomyelitis, and meningitis are uncommon complications of candidemia. None of these occur with greater frequency in transplant recipients than in other patients who have had candidemia. The clue to the presence of endocarditis is persistently positive blood cultures with or without manifestations of cardiac dysfunction or peripheral stigmata of endocarditis [55]. The vegetations tend to be large, and the disease may present with an embolus to a major vessel. All species have been implicated, but most commonly, endocarditis is due to *C. albicans* or *C. parapsilosis.* Echocardiographic studies are essential for establishing the diagnosis and defining valvular dysfunction and complications, such as paravalvular abscesses.

Osteomyelitis as a result of hematogenous spread usually involves the vertebral column [56]. The disc space is seeded during the course of candidemia, and then extension to the adjacent vertebral bodies occurs. Patients often do not develop symptoms until weeks after the candidemic episode, and then back pain is the main complaint. CT and MRI imaging studies are essential to identify infection, and needle aspiration or open biopsy, when feasible, are essential to define this process as due to *Candida*.

Candida meningitis, a common finding in neonates who have invasive candidiasis, is very uncommon in adults [57]. The manifestations vary from an acute presentation to a subacute process similar to that seen with cryptococcosis. This complication of invasive candidiasis can occur at the time of candidemia or several weeks later with the subacute form. Symptoms are headache, visual symptoms, and confusion; examination shows mild nuchal rigidity, occasionally papilledema, and lethargy, confusion, or stupor. Diagnosis is made by lumbar puncture after a CT or MRI scan to rule out an associated brain abscess.

Mucosal Candidiasis

Oropharyngeal candidiasis (thrush) is a superficial infection that used to be extremely common in transplant recipients, but is seen infrequently now because of the routine use of fluconazole for prophylaxis against fungal infections in these patients. Patients are often asymptomatic, but may complain of a cottony feeling in their mouth or pharyngeal pain when they swallow. Older patients who wear upper dentures are at increased risk for denture stomatitis due to *Candida*. Examination reveals white, plaque-like lesions on the buccal mucosa, tongue, and palate. Ulcerations are unusual and are usually due to mucositis or atypical herpes infections, and not *Candida.* Patients with denture stomatitis have erythema of the hard palate but no plaques.

Candida vaginitis is a very common infection in the general population and can be problematic in patients who are immunosuppressed. Vaginal discharge, vulvar pruritus, and dysuria are common manifestations. The discharge may be curd-like, but also can be thin. Examination shows vulvar erythema and plaque-like lesions on the vaginal mucosa.

Esophagitis is usually manifested by odynophagia; patients can generally point to a specific substernal area where they experience pain with swallowing. The patient may or may not have concomitant thrush. Endoscopy is diagnostic, but most physicians initiate treatment with an oral azole based on the clinical symptoms and make the diagnosis by noting a therapeutic response within several days.

Outcomes

Invasive candidiasis is associated with high crude mortality rates [6, 15, 22–24]. For many patients, *Candida* infection is a marker for serious underlying illness, but is not the cause of death. Attributable mortality has been difficult to evaluate, and estimates have varied from 30 to 62% in the general hospital population [58, 59]. Multicenter surveillance studies have provided crude, but not attributable mortality rates for candidiasis in transplant recipients [1, 2, 15]. A prospective observational study in French ICUs found that independent factors associated with mortality from invasive candidiasis included diabetes mellitus, immunosuppression, and mechanical ventilation [60], whereas a study that included all hospitalized patients in four medical centers in Sao Paulo, Brazil, found the highest risk factors were advanced age and high APACHE II score [24]. The association of a high APACHE II score and increased mortality in patients with candidemia has been noted by others, as has increased mortality with increasing age [22, 38].

Several studies have shown that prompt treatment of candidemia significantly decreases the mortality rate, and delay for as long as 48 h after the blood culture is performed is associated with increased mortality [61, 62]. A recent study noted a crude mortality rate of 63.5% among patients who had septic shock associated with candidemia [63]. In those in whom antifungal therapy was given within 24 h and who had adequate source control (removal of catheters, drainage of abscesses), the mortality rate was 52.8%; for those in whom these parameters were not met, the mortality was 97.6%.

Mortality appears to be higher in patients with candidemia due to *C. krusei,* but this likely reflects the fact that this species is seen most often in patients who have hematological malignancies or have received an HCT [6, 64]. *C. tropicalis* is known to be more virulent in animal models and has

also been associated with worse outcomes in immunosuppressed patients, especially those who have a hematological malignancy [65]. Mortality associated with candidemia due to *C. parapsilosis* appears to be consistently lower than that found with other species [22, 66, 67]. In some studies, mortality rates for patients who have *C. glabrata* fungemia have been noted to be higher than that seen with *C. albicans* [6], but in other studies, there was no difference or the rates were lower [22, 68, 69]. In general, the most important factors for outcome in transplant recipients are the extent of immunosuppression and the susceptibility of the organism to antifungal agents, rather than the virulence factors of the specific species causing infection.

Diagnosis

The diagnosis of invasive candidiasis requires clinical suspicion that *Candida* infection could be the cause of a patient's symptoms. The manifestations are similar to those seen with many bacterial infections, but several clinical clues should raise suspicion for candidemia and invasive candidiasis. The sudden appearance of non-tender, non-pruritic skin lesions is a strong clue to the presence of fungemia with *Candida* species. The lesions vary from a few millimeters to a centimeter in diameter and are usually manifested as a pustule on an erythematous base (Fig. 32.1). Similarly, a new complaint of focal muscle pain with tenderness noted on palpation should raise suspicion for the possibility of invasive candidiasis in an immunosuppressed host. Eye pain or visual loss should prompt an immediate workup for endogenous *Candida* endophthalmitis resulting from candidemia.

Fig. 32.1 Skin lesions that developed on the back of a 65 year-old man who was neutropenic after receiving an allogeneic stem cell transplant. Blood cultures yielded *C. albicans*

Cultures

By definition, candidemia is the presence of *Candida* species in the bloodstream, and this is usually established by growth of the organism in cultures obtained from blood. At least two sets of blood cultures from a peripheral vein should be obtained, and if the patient has a central venous catheter in place, blood also should be taken from the catheter for culture. The automated blood culture systems routinely used in most hospital laboratories are able to isolate *Candida* species, but it takes a minimum of 1–3 days for growth to occur. Overall, blood cultures are relatively insensitive, and invasive disease can be present without blood cultures yielding the organism.

After growth occurs in blood culture bottles, it generally takes another 1–2 days for the organism to be identified to the species level. This delay can be shortened with the use of several new techniques. One technique uses peptide nucleic acid fluorescence in situ hybridization (PNA-FISH), which can identify *C. albicans* and *C. glabrata* within several hours of a blood culture turning positive [70, 71]. Another technique uses mass spectrometry to quickly identify species of yeast once growth has occurred in blood culture bottles [72]. It is essential to identify *Candida* to the species level in all cases of candidemia and invasive disease because of differences in susceptibility to antifungal agents among the various species. It is especially important to identify *C. glabrata* and *C. krusei* because of resistance to fluconazole and other azoles [25, 73].

Candida species are part of the human microbiota, so that growth of yeasts from samples obtained from non-sterile sites documents only colonization. For example, sputum and bronchoalveolar lavage fluid cultures yielding *Candida* species cannot be used to establish a diagnosis of *Candida* pneumonia. However, finding organisms in lung tissue obtained by biopsy establishes the diagnosis. Growth of yeast from material aspirated through an indwelling drainage tube almost always reflects colonization of the tube and not what is in an abscess. In contrast, growth of *Candida* species from normally sterile body fluids, such as cerebrospinal fluid or synovial fluid, establishes a diagnosis of

invasive candidiasis. Material obtained by biopsy of a newly developed skin lesion or a muscle abscess should be submitted for culture and also for histopathological examination with special stains to detect fungi-invading tissues.

Non-Culture-Based Techniques

Substantial work has gone into the development of non-culture-based techniques to enhance the rapid diagnosis of candidemia and invasive candidiasis. These include antigen detection and DNA-based techniques.

Several different assays are commercially available to detect the presence of beta-D-glucan, a cell wall component of many fungi, not just *Candida* species. Many studies have been performed, and results show wide variations in sensitivity and specificity of this assay. A recent meta-analysis that included 16 studies with a total of 2979 patients who had probable or proven invasive fungal infections, not just *Candida* infections, calculated that the pooled sensitivity of the assay was 77% and specificity was 85% [74]. There was large heterogeneity among studies, including the use of different commercial products for the assay, different cutoff points for positivity, and different patient populations. When these investigators analyzed the 295 patients who were identified as having invasive candidiasis in 11 different studies, the sensitivity appeared to be 75%; it is not clear how many of these patients were transplant recipients. A study among 20 lung transplant recipients found modest sensitivity (71%) and poor specificity (59%) [75], and another in liver transplant recipients found poor sensitivity (58%) and moderately good specificity (83%) [74]. All studies have noted that this assay has poor positive predictive value and good negative predictive value.

Real-time PCR techniques continue to hold promise for rapid diagnosis, but to date, there is no standardized PCR test commercially available for the diagnosis of candidiasis [76]. Newer studies suggest that this technique may be more sensitive than both blood cultures and the beta-D-glucan assay for the diagnosis of invasive candidiasis [77]. A new more rapid system uses magnetic biosensor technology to identify different *Candida* species from whole blood [78].

Histopathology

Histopathology is used less often in the diagnosis of candidiasis than in the diagnosis of mold infections, most likely because *Candida* species are easily grown in the laboratory. Tissue biopsy with histopathological examination of skin lesions is useful for documenting disseminated infection

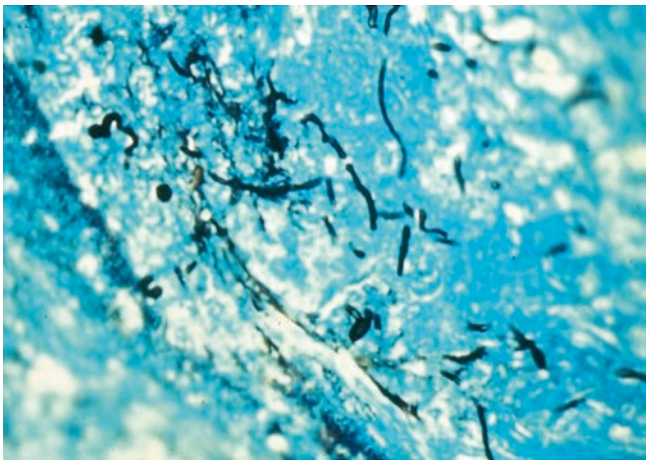

Fig. 32.2 Silver stain performed on the biopsy of a skin lesion shown in Fig. 32.1. Both yeast forms and hyphae, the typical picture noted with *C. albicans,* are present in the biopsy

(Fig. 32.2). Lung biopsy is essential for diagnosis of *Candida* pneumonia, and liver biopsy can document hepatosplenic *Candida* infection as cultures often fail to grow. Silver stains are used most often to visualize the yeast and hyphal elements that are usually both seen with tissue invasion. One cannot differentiate species of *Candida* by tissue biopsy, but it should be noted that *C. glabrata* remains a yeast in tissues and cannot produce hyphae.

Imaging Studies

In contrast to mold infections, imaging techniques are not useful in the diagnosis of infections due to *Candida.* The one exception is hepatosplenic candidiasis (chronic disseminated candidiasis), which occurs almost entirely in patients who are recovering from an episode of neutropenia. In this form of invasive candidiasis, ultrasound, computerized tomography (CT) scans, and magnetic resonance imaging (MRI) all are useful to establish the diagnosis [79]. The picture is characteristic, especially on CT scan, the modality used most often for this type of candidiasis. Multiple, discrete low-attenuation lesions representing small abscesses are typically seen in the liver, spleen, and, sometimes, kidneys and other organs (Fig. 32.3). Similarly, CT scans are useful for visualizing small abscesses that can occur in muscles during an episode of candidemia (Fig. 32.4).

Imaging studies are extremely useful for patients who have focal *Candida* infections. Examples include the use of transesophageal echocardiography to help establish the diagnosis and define the extent of disease in a patient with *Candida* endocarditis. CT or MRI scans are essential for evaluation

Fig. 32.3 Abdominal CT scan of a 25-year-old patient who had been neutropenic during induction therapy for acute leukemia and developed nausea, fever, and pain in the right upper quadrant. Discrete punched out lesions are evident throughout the liver, which is typical for hepatosplenic candidiasis

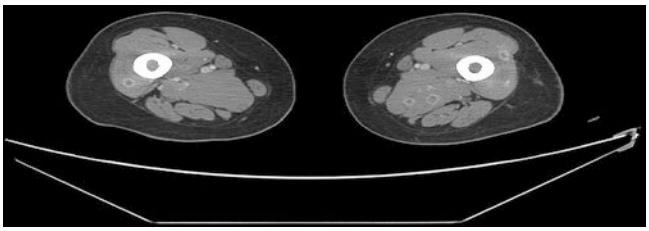

Fig. 32.4 CT scan of the thigh muscles of a 31-year-old woman who had undergone an allogeneic stem cell transplant and who developed muscle tenderness and persistent fever following *C. tropicalis* fungemia that was identified several days before. Multiple ring-enhancing lesions are noted

of abscesses and hydrocephalus in patients with central nervous system candidiasis and to define the presence of vertebral osteomyelitis due to *Candida* species. Additionally, ultrasound and CT scans are used routinely to define the location and response to therapy of polymicrobial bacterial/fungal intra-abdominal abscesses that occur in the postoperative period in recipients of small bowel, liver, or pancreas transplants.

Treatment

The treatment of *Candida* infections has changed markedly in the last 10–15 years. Amphotericin B is now rarely used, and most patients are treated with an echinocandin or an azole. As a result, toxicity is much less frequently seen. Guidelines for the treatment of candidemia and invasive candidiasis have been established by the IDSA, and these guidelines are applicable to transplant recipients, as well as other patient populations [7]. The American Society of Transplantation (AST) also has issued guidelines for treatment of *Candida* infections in SOT recipients [80].

Candidemia

All patients whose blood cultures yield *Candida* species should be treated with an antifungal agent for a minimum of 2 weeks after the blood cultures become negative. Removal of a central venous catheter is, by itself, not adequate therapy. Outcomes have been noted to be improved when antifungal therapy is begun as early as possible [61, 62]. Thus, in some patients, especially those who are severely ill, pre-emptive or empirical therapy with an antifungal agent is appropriate [81, 82].

Choice of Antifungal Agents

The choice of antifungal agents is usually either fluconazole or an echinocandin. Numerous randomized controlled trials have shown the efficacy of azoles and echinocandins, when compared with one another and when compared with amphotericin B [83–91]. When the infecting species is *C. glabrata* or *C. krusei*, the agent of choice is an echinocandin because of increasing resistance to fluconazole among *C. glabrata* isolates and the inherent resistance of *C. krusei* to fluconazole [64, 68, 69, 92, 93]. Cross-resistance to voriconazole is common among strains of *C. glabrata* that are fluconazole resistant, and for many strains, there is cross-resistance noted among all of the azoles when the isolate is shown to be resistant to fluconazole [25]. The cross-resistance to voriconazole does not occur in strains of *C. krusei*; they remain susceptible to this azole.

When empiric therapy in a high-risk transplant patient is deemed prudent before culture results are known, an echinocandin is the drug of choice [7]. After the organism has been identified and susceptibilities determined, therapy can be changed if needed. Switching to fluconazole from an echinocandin allows oral dosing and is less costly. In the transplant population, it is necessary to consider whether prophylactic antifungal agents had been given to the patient prior to the episode of candidemia. Prophylaxis has the potential to select out for species that are resistant to that class of drug.

Duration

The total length of therapy for candidemia without the development of other focal infections is 2 weeks from the time of the first negative blood culture. However, in patients who are neutropenic, therapy should be continued until the neutropenia has resolved [7]. Follow-up daily blood cultures should be obtained to document when candidemia has cleared.

Other Measures

All patients who have candidemia should have a dilated eye examination by an ophthalmologist. The presence of endophthalmitis will require longer therapy with drugs that achieve adequate levels within the posterior compartment of the eye. For neutropenic patients, it is important to repeat the retinal examination after their neutrophils return to normal levels when eye manifestations are more likely to be noted.

Management of Central Venous Catheters

The IDSA guidelines for both the management of invasive candidiasis and the management of intravascular catheter-associated infections recommend removing central venous catheters in patients with candidemia [7, 94]. Several small series and post-hoc reviews of clinical treatment trials for candidemia show faster clearance rates of candidemia and better outcomes when catheters are removed [67, 95, 96]. However, there are clinicians who believe that for certain patient groups, especially those who have received chemotherapy and are neutropenic, the source of the candidemia is likely to be the bowel and the catheter need not be removed [97]. A retrospective review of two randomized treatment trials showed that early removal of central venous catheters was not associated with improved treatment success and survival [98]. In contrast, a larger retrospective review of individual patient-level data from seven randomized treatment trials found that removal of a central venous catheter was associated with decreased mortality [67]. This subject remains controversial, but the strength of opinion and the recommendations of the guidelines are on the side of removing the catheter whenever feasible in a patient who has candidemia.

Hepatosplenic Candidiasis

For patients who have moderate to severe disease manifestations, it is recommended that therapy begin with a lipid formulation of amphotericin B, 3–5 mg/kg/day, or an echinocandin for several weeks and then go to step-down therapy with oral fluconazole, 400 mg daily [7]. Therapy should continue until there is resolution of the lesions on follow-up CT scans performed every 2–3 months. Importantly, if hepatosplenic candidiasis occurred prior to HCT, antifungal therapy must be continued throughout the period of engraftment and maximal immunosuppression in order to prevent relapse of the fungal infection.

The hypothesis that this syndrome is related to an IRIS phenomenon led to the use of oral glucocorticoids in addition to antifungal therapy [42, 99–101]. Patients given prednisone had prompt resolution of their fever and abdominal pain, and their inflammatory response markers more quickly returned to normal. However, lesions seen on CT scan did not resolve any faster. The dose of prednisone usually given has been 0.5–1.0 mg/kg daily for several weeks. However, the role of corticosteroids is still not established [7].

Intra-abdominal Candidiasis

An important factor in improving outcomes of patients who have an intra-abdominal abscess is either percutaneous or open surgical drainage. Antifungal therapy should be directed at the *Candida* species isolated from the abscess. When the patient has peritonitis or a diffuse phlegmon and a surgical procedure is not contemplated, antimicrobial therapy should be directed toward the most likely pathogens including *Candida* species. In the most common scenario in which *C. albicans* is isolated, either an echinocandin or fluconazole, 400 mg daily, can be used. If *C. glabrata* is isolated, the most appropriate therapy is with an echinocandin. Echinocandin doses used are micafungin, 100 mg daily; caspofungin 70 mg loading dose and then 50 mg daily; and anidulafungin, 200 mg loading dose and then 100 mg daily. Voriconazole should not be used until the isolate has been shown to be susceptible by in vitro testing. Treatment duration will be dependent on improvement of signs and symptoms and resolution of any abscesses noted on CT scan.

Treatment of candidiasis in liver transplant recipients who have biliary tract obstruction and indwelling stents is difficult. Colonization of the stent is common, and the major decision is to determine whether these organisms are causing infection. Just isolating yeast from a percutaneous drain is not adequate evidence that an antifungal agent is needed. If infection is deemed likely, then stent replacement, in addition to antifungal therapy, is usually required.

Urinary Tract Infections

Only patients in whom there is a high likelihood that symptomatic urinary tract infection is due to *Candida* species should receive antifungal therapy. Patients who are in hospital post-transplant and with an indwelling catheter rarely need to be treated for candiduria, which almost always reflects asymptomatic colonization of the catheter and bladder. When infection is present, fluconazole is the agent of choice as no other azoles and no echinocandins achieve adequate concentrations in the urine [102]. Most infections are due to *C. albicans* and respond nicely to oral fluconazole, 200 mg daily. In contrast, *C. glabrata* and *C. krusei* urinary tract infections are very difficult to treat. The agent of choice is amphotericin B deoxycholate, not a lipid formulation of amphotericin B. Therapy with as low as 0.3 mg/kg daily for just a few days may be adequate [7]. Regardless of the species and the agent used, if obstruction is present, therapy will likely fail. Ureteral stents that are colonized generally will have to be removed to eradicate candiduria.

Endophthalmitis

For *Candida* endophthalmitis, use of systemic antifungal agents that achieve adequate concentrations in the vitreous is recommended. The agents that achieve the best concentrations are fluconazole, voriconazole, and flucytosine [103]. Amphotericin B does not penetrate into the vitreous well, but there is a long experience using this agent in combination with flucytosine for *Candida* endophthalmitis [7]. However, for susceptible organisms, most clinicians use fluconazole, 400–800 mg daily, or voriconazole, loading dose 6 mg/kg bid for 1 day and then 4 mg/kg bid thereafter, rather than amphotericin B. The echinocandins and posaconazole do not achieve good intra-vitreal concentrations and are not recommended.

For patients who have *Candida* chorioretinitis with no vitreal involvement, systemic antifungal agents are appropriate as long as repeated examinations show no extension into the vitreous or the macula. Initial intravenous administration seems prudent to establish high concentrations in the vitreous [103]. When using voriconazole, serum concentrations should be monitored carefully to ensure that adequate levels have been achieved and to minimize toxicity.

For sight-threatening macular involvement and mild vitritis, in addition to systemic therapy, intravitreal injection of either voriconazole or amphotericin B deoxycholate should be performed to ensure immediate achievement of appropriate levels in the posterior compartment. For more extensive vitritis, in addition to systemic and intra-vitreal antifungal therapy, pars plana vitrectomy is recommended.

Mucosal Candidiasis

Oropharyngeal candidiasis can be treated with clotrimazole troches, nystatin swish and swallow suspension, or oral antifungal agents, such as fluconazole. Fluconazole is generally used as it is effective, simple to take once daily, more effective than local suspensions and troches in profoundly immunosuppressed patients, and inexpensive. The dose is 100 mg daily for 7 days. Other oral azole agents are also effective, but more costly and either absorbed less well or with more drug-drug interactions.

Vaginal candidiasis is almost always treated with oral fluconazole. Many local creams and vaginal suppositories are available, but patients prefer oral therapy, and it generally is more effective. Infection with *C. glabrata* is uncommon, but problematic to treat and requires consultation with an expert in the treatment of complicated vaginal candidiasis.

Esophagitis cannot be treated with local agents and requires systemic therapy. Fluconazole is the agent of choice at a dosage of 200 mg daily for at least 14 days. Echinocandins, voriconazole, and amphotericin B formulations are also effective, but generally only used if fluconazole fails to clear the infection.

Prophylaxis in Immunocompromised Hosts

Prevention of invasive candidiasis using antifungal agents during the pre-engraftment period is standard practice in patients undergoing allogeneic HCT [104]. Fluconazole is the most commonly used agent as it has a long track record of efficacy (Table 32.3). In a randomized double-blinded study, voriconazole proved to be no more effective than fluconazole in preventing invasive candidiasis among allogeneic HCT recipients [105]. Micafungin and presumably the other echinocandins are alternative prophylactic agents, comparable to fluconazole. However, their use is limited by the need for intravenous infusion and high costs [106]. Solid tumor patients undergoing autologous HCT generally do not require anti-yeast prophylaxis. However, many experts recommend that prophylaxis be given to the considerably larger population of patients who have underlying hematologic malignancies (e.g., lymphoma, leukemia, or myeloma). Other autologous HCT recipients for whom antifungal prophylaxis might be warranted are those who have or will have prolonged neutropenia and mucosal damage from intense conditioning regimens or graft manipulation, and those who have received purine analog therapy within the 6 months prior to HCT [104]. The choice of prophylactic agent ultimately depends on tolerability and cost. Fluconazole is the mostly widely used drug.

Guidelines for antifungal prophylaxis in SOT have been delineated by the American Society of Transplantation [80]. Antifungal prophylaxis against *Candida* should be provided to high-risk liver transplant recipients, specifically those with two or more of the following risk factors: prolonged surgical time, repeated abdominal surgery or re-transplantation, renal failure, high transfusion needs ($\geq$40 units of cellular blood products), choledochojejunostomy, and *Candida* colonization in the perioperative period. Fluconazole is the standard agent used (Table 32.3). A recent meta-analysis demonstrated that antifungal prophylaxis in these patients significantly reduced invasive candidiasis as well as fungal-related mortality, but not overall mortality [107]. Lower-risk liver transplant recipients do not require routine antifungal prophylaxis as their risk of invasive candidiasis is very low.

In contrast, patients receiving intestinal transplants have very high rates of *Candida* infection. Despite a lack of randomized clinical trial evidence, antifungal prophylaxis is recommended, especially for those who have graft rejection, increased immunosuppression or anastomotic incompetence. Pancreas transplant recipients whose transplants are drained via the enteric route or who have vascular thrombosis or

Table 32.3 Prophylaxis against *Candida* infections in solid organ transplant and hematopoietic cell transplant recipients

Transplant type	Risk factors	Antifungal prophylaxis	Notes/duration
Liver	Prolonged operation time Repeat operation Retransplantation	Fluconazole 400 mg/day *or* Lipid formulation of amphotericin B 3–5 mg/kg/day	Selected high-risk patients (see Risk Factors) should receive prophylaxis Up to 4 weeks of duration
Small bowel	Renal failure Choledochojejunostomy *Candida* colonization High transfusion requirement Graft rejection/dysfunction Enhanced immunosuppression	Fluconazole 400 mg/day *or* Lipid formulation of amphotericin B 3–5 mg/kg/day[a]	All recipients should receive prophylaxis At least 4 weeks of duration and/or healing of anastomosis and absence of rejection
Pancreas	Anastomotic disruption Abdominal reoperation Multivisceral transplantation Enteric drainage Vascular thrombosis	Fluconazole 400 mg/day *or* Lipid formulation of amphotericin B 3–5 mg/kg/day[a]	All patients should receive prophylaxis At least 4 weeks of duration
Allogeneic HCT	Neutropenia Mucositis Broad-spectrum antibiotics Hematologic malignancy	Fluconazole 400 mg/day *or* Micafungin 50 mg IV/day *or* Posaconazole 300 mg qd *or* Voriconazole 200 mg bid	All patients should receive prophylaxis up to day +75 Fluconazole is the drug of choice during pre-engraftment and post-engraftment Posaconazole is the drug of choice during therapy for severe GVHD; voriconazole is an acceptable alternative
Autologous HCT	Neutropenia Mucositis Broad-spectrum antibiotics Hematologic malignancy	Fluconazole 400 mg/day *or* Micafungin 50 mg IV/day	Prophylaxis is NOT routinely recommended Consider for patients who will have prolonged neutropenia (> 10 days) and/or extensive mucositis

[a]If high rates of non-*albicans Candida* sp. or risk factors for *Aspergillus*

postoperative pancreatitis are at higher risk for invasive candidiasis and should be considered candidates for antifungal prophylaxis [34].

Although the airways of lung and heart-lung transplant recipients are frequently colonized with *Candida* species, invasive infection is rare. Prophylaxis practices vary considerably among different centers, and there is no consensus. Candidiasis is relatively uncommon in heart and kidney recipients, and antifungal prophylaxis is not recommended as a routine practice in these patients [80].

Aspergillosis

33

Michael J. Satlin, Samantha E. Jacobs,
and Thomas J. Walsh

Introduction

Aspergillus species are ubiquitous, saprophytic fungi that are important causes of morbidity and mortality in transplant recipients [1]. Although their primary ecologic location is in soil and decaying environmental matter, *Aspergillus* produce small asexual spores called conidia or microconidia that disperse easily into the air and survive in a broad range of environmental conditions. Humans become infected with *Aspergillus* after conidia are inhaled and deposited in bronchioles, in alveolar spaces, and less commonly in paranasal sinuses [1].

Although there are approximately 250 species of *Aspergillus*, fewer than 20 cause human disease [2]. *Aspergillus fumigatus* is the most common cause of invasive aspergillosis in transplant recipients [3, 4] and other immunocompromised hosts [5]. However, the proportion of infections caused by other species is increasing [6]. In transplant recipients, *Aspergillus flavus* and *Aspergillus niger* are the next most common pathogens, followed by *Aspergillus terreus* [3, 4].

Pathogenesis and Host Defenses

Innate immunity plays an important role in preventing infection from inhaled *Aspergillus* conidia. Respiratory epithelial cells are the first lines of defense. These cells provide an anatomic barrier to invasion by *Aspergillus*, promote mucociliary clearance, and ingest inhaled conidia [7]. Conidia that are not removed by epithelial cells encounter alveolar macrophages [1]. These cells are responsible for phagocytosis and killing of mainly the metabolically active *Aspergillus* conidia with the potential for germination into filamentous tissue-invasive mold. These cells are also critical in initiating a proinflammatory response. Neutrophils are the primary inflammatory cells recruited by alveolar macrophages and serve as the dominant host defense against conidia that have evaded macrophage killing and have germinated to become hyphae, the tissue-invasive form of *Aspergillus* [7]. Histopathologically, invasive disease is characterized by progression of infection across tissue planes and vascular invasion with subsequent infarction and tissue necrosis [1].

The primary host deficiencies that are responsible for the increased risk of invasive aspergillosis in transplant recipients are neutropenia, corticosteroid-induced immunosuppression, and immune dysregulation resulting from graft-versus-host disease (GVHD). The absence of neutrophils allows unchecked proliferation of hyphae through tissue planes, including the walls of blood vessels. This leads to thrombosis and hemorrhage from rapid and extensive hyphal growth with scant inflammatory response [8]. Without neutrophil recovery, angioinvasion and dissemination to other organs via the bloodstream occur.

The pathology of invasive aspergillosis in non-neutropenic patients who are receiving corticosteroids is different from that of neutropenic patients. Invasive disease in these patients is typically not angioinvasive, but is instead characterized by only limited hyphal proliferation with neutrophilic and monocytic infiltrates, tissue necrosis, and excessive inflammation [8]. Corticosteroids impair the ability of phagocytes to kill *Aspergillus* conidia by interfering with phagocytosis, intracellular oxidative burst, production of cytokines and chemokines, and cellular migration [9]. Despite the deleterious effects of corticosteroids on innate immune cell function, phagocytes are typically successful in being recruited and preventing hyphal angioinvasion, but create an inflammatory environment that results in tissue injury and necrosis [8]. This exacerbated inflammatory response is generally regarded as the direct cause of pathology, in contrast to uncontrolled fungal growth observed in neutropenic hosts [1, 8]. Of note, the histopathologic patterns of non-neutropenic hematopoietic stem cell transplant (HSCT) recipients with invasive aspergillosis resemble that of neutropenic patients, with no influx of neutrophils into the lung tissue [8]. This lack of neutrophil migration may be related to delayed function of innate and adaptive immunity after HSCT, despite recovery of white blood cells [10].

Epidemiology

Aspergillosis is the most common invasive fungal infection in HSCT recipients [4]. The incidence of invasive aspergillosis after allogeneic HSCT ranges from 4% to 24%, with most centers reporting rates between 11% and 15% [6, 11]. In contrast, reported rates in autologous HSCT recipients are 1–2% [6, 11, 12]. Recent data suggest that although aspergillosis remains the most common invasive fungal infection after HSCT, its incidence may be lower than previously reported. In a study of 3288 adult HSCT recipients at 11 Italian sites from 1999 to 2003, the overall incidence of invasive aspergillosis was 6.3% after allogeneic transplant and 0.4% after autologous transplant [13]. In the Transplant-Associated Infection Surveillance Network (TRANSNET), a prospective study of 16,200 allogeneic and autologous HSCT recipients at 23 US sites from 2001 through 2005, invasive aspergillosis occurred within 6 months and within 12 months of transplant in 1.3% and 1.6% of patients, respectively [4]. These lower rates of invasive aspergillosis may be related to increasing use of broad-spectrum mold-active triazoles for prophylaxis and empirical therapy.

There are three distinct periods of risk for invasive aspergillosis after HSCT. The first period is during neutropenia before engraftment and is present after both allogeneic and autologous transplants. The next two periods, early post-engraftment in the setting of acute GVHD and late post-engraftment in the setting of chronic GVHD, pertain primarily to allogeneic transplants. Overall, the median time from transplantation to onset of invasive aspergillosis in TRANSNET was 99 days. However, this median time was shorter in autologous transplants and longer in allogeneic transplants. In autologous HSCT recipients, 50% of *Aspergillus* infections occurred within 1 month after transplant. In contrast, only 22% occurred during this time period after allogeneic transplant and nearly half occurred more than 4 months after transplant [4].

Baseline risk factors for invasive aspergillosis in allogeneic HSCT recipients include older age, mismatched or unrelated donor grafts, and use of cord blood or T cell-depleted grafts. Transplant complications that are independently associated with invasive aspergillosis include neutropenia, acute or chronic GVHD, use of high doses of glucocorticoids, cytomegalovirus (CMV) disease, and respiratory viral infections [6, 14].

Aspergillosis is less common after solid organ transplantation than after HSCT. While glucocorticoids predispose to invasive aspergillosis [9], calcineurin and mammalian target of rapamycin inhibitors are mechanistically less immunosuppressive in regard to the risk of aspergillosis [15, 16]. Calcineurin inhibitors may even exert an inhibitory effect against *Aspergillus* spp. [17]. However, aspergillosis is still the second most common cause of invasive fungal infection in solid organ transplant recipients, after candidiasis. The cumulative incidence of invasive aspergillosis in 11,014 solid organ transplant recipients in the Spanish Network for Research on Infection in Transplantation (RESISTRA) who had at least 18 months of follow-up was 1.4% [18]. Among 16,459 solid organ transplant recipients who were followed up in TRANSNET, the 12-month cumulative incidence of invasive aspergillosis was 0.7% [3]. The median time to development of invasive aspergillosis in TRANSNET was longer after solid organ transplantation than after HSCT (184 days vs. 99 days) and 20% occurred more than 3 years after transplant [3]. The exception to this timing is in liver transplant recipients, who are more likely to develop invasive aspergillosis early in the post-transplant period [18–20]. The major risk factors for aspergillosis after liver transplantation are re-transplantation and the need for renal replacement therapy, which each confer a 20- to 30-fold increased risk [21].

Risk factors for invasive aspergillosis after solid organ transplantation depend on the timing of infection. Independent risk factors for early invasive aspergillosis (during the first 3 months after transplant) are postoperative complications including re-operations, repeated bacterial infections, CMV disease, and renal failure. Risk factors for late invasive aspergillosis which is observed more than 3 months after transplantation procedure include older age, an immunosuppressed state because of chronic transplant rejection or allograft dysfunction, and renal failure [18].

Lung transplant recipients have a higher risk of aspergillosis than recipients of other organs, and aspergillosis is the most common invasive fungal infection in this population [3, 18]. Between 3% and 12% of lung transplant recipients develop invasive aspergillosis, compared to 1% and 8% of liver transplant recipients and less than 1% of kidney transplant recipients [3, 18, 22–24]. This relatively high incidence is likely related to continuous exposure of the transplanted organ to the environment and impaired mechanical defenses from decreased mucociliary clearance and blunted cough reflex [25]. Risk factors for invasive aspergillosis in lung transplant recipients include transplant of a single lung, CMV infection, rejection with augmented immunosuppression, and bronchiolitis obliterans [22, 26, 27].

Clinical Manifestations

Although *Aspergillus* infection has been reported at virtually all organs and sites, invasive aspergillosis most commonly occurs in the lungs. Clinical manifestations are nonspecific and include fever and nonproductive cough. The classic triad of fever, pleuritic chest pain, and hemoptysis is occasionally seen in neutropenic patients, but is rarely seen in non-neutropenic patients. In addition to invasive pulmonary disease, *Aspergillus* can also cause tracheobronchitis. This disease is most common in lung transplant recipients, but has also been described in other transplant recipients.

Common clinical manifestations of tracheobronchitis are productive cough and dyspnea, followed by fever, wheezing, and acute respiratory distress. Three different patterns of *Aspergillus* tracheobronchitis have been described: (1) obstructive bronchial aspergillosis, in which thick mucus plugs filled with fungal hyphae are found in the airways within minimal or no tissue invasion; (2) ulcerative tracheobronchitis, in which there is focal invasion of tracheobronchial mucosa by fungal hyphae; and (3) pseudomembranous tracheobronchitis, in which a pseudomembrane of necrotic debris and fungal hyphae overlie extensive inflammation and invasion of the tracheobronchial tree [28]. Chronic forms of pulmonary aspergillosis, such as aspergilloma, chronic necrotizing aspergillosis, and chronic cavitary pulmonary aspergillosis, are relatively uncommon in transplant recipients.

Inhalation of *Aspergillus* conidia can also lead to invasive rhinosinusitis. Common presenting symptoms include fever, facial pain, and nasal congestion. If disease progresses to the orbit, patients may develop blurred vision, proptosis, and chemosis. Facial numbness and diplopia can occur in the setting of cranial nerve involvement. It is essential to note, however, that findings may be subtle in neutropenic patients because of a blunted inflammatory response [29, 30]. Therefore, a high suspicion must be maintained in neutropenic transplant recipients with any of these symptoms or signs. Early endoscopic evaluation of the nares and oral cavity to look for areas of necrosis is essential to establish the diagnosis early and initiate timely therapy [31].

In the setting of angioinvasive disease, *Aspergillus* can disseminate from the respiratory tract to multiple organs, including the brain, eyes, skin, liver, and kidneys. Central nervous system (CNS) aspergillosis can occur in the setting of hematogenous dissemination or local extension from paranasal sinuses and should be considered in patients with acute onset of focal neurologic deficits or seizures. CNS aspergillosis can present as meningitis, encephalitis, brain abscess, subarachnoid hemorrhage, or mycotic aneurysm [32, 33]. *Aspergillus* endophthalmitis can be a presenting feature of disseminated disease and is typically associated with eye pain, visual changes, and destruction of multiple components of the eye [34]. Cutaneous aspergillosis can occur as primary disease in an area of skin breakdown or as multiple cutaneous lesions in the setting of disseminated disease [35, 36].

Diagnosis

General Considerations

Aspergillus conidia are ubiquitous and frequently inhaled into the airways. Many patients effectively clear these organisms without developing disease, and thus, culturing *Aspergillus* species from respiratory specimens does not necessarily indicate disease. Therefore, the diagnosis of invasive aspergillosis is not solely based on isolating the organism (or markers of the organism) but also on the probability that it is causing disease, which is a reflection on host's functional status and clinical presentation. Based on this uncertainty, the European Organisation for Research and Treatment of Cancer (EORTC) and the Mycoses Study Group (MSG) of the National Institute of Allergy and Infectious Diseases established definitions of "proven," "probable," and "possible" invasive aspergillosis. Disease is "proven" when hyphal invasion is identified in tissue. "Probable" disease requires presence of a host factor such as neutropenia, use of glucocorticoids or T-cell immunosuppressant, compatible clinical disease, and either detection of *Aspergillus* directly (e.g., culture, direct microscopy) or indirectly via detection of aspergillus galactomannan and/or [1 → 3]-β-D-glucan tests or both. Cases that meet criteria for a host factor and a clinical criterion, but for which mycological criteria are absent, are considered "possible" disease.

Importantly, these definitions were designed to maintain consistency in research studies and were not designed to drive clinical decision-making [37]. Notably, all recent allogeneic HSCT recipients, neutropenic autologous HSCT recipients, and most solid organ transplant recipients satisfy EORTC/MSG host criteria. Unfortunately, transplant recipients

often cannot undergo invasive procedures to obtain tissue and establish "proven" disease because of thrombocytopenia, advanced coagulation deficits, hemodynamic instability, or severe hypoxia.

Direct Examination and Culture

Respiratory specimens of patients being evaluated for aspergillosis should be stained where possible with calcofluor white, a fluorescent stain that binds to chitin, and 10% potassium hydroxide to detect the presence of fungal elements. Gomori methenamine silver (GMS) and periodic acid-Schiff (PAS) stains should be used on cytology preparations [38]. Organisms are typically seen as narrow as 3–6-micron-wide, septated hyphae with dichotomous acute angle branching [39]. Importantly, these characteristics are not diagnostic of *Aspergillus*, as they can be seen with other filamentous fungi, such as *Scedosporium* and *Fusarium* species.

Aspergillus grows rapidly in the laboratory and is often visible in culture within 1–3 days of incubation. Culture confirmation, where possible, is important to differentiate aspergillosis from other filamentous fungi, such as scedosporiosis and fusariosis. Identification to the species levels requires sporulation in order to examine the morphology of spore-bearing structures on lactophenol cotton blue wet mount preparations (Fig. 33.1a) [39].

Unfortunately, cultures of respiratory tract secretions lack sensitivity and specificity for invasive aspergillosis. *Aspergillus* is grown from sputum specimens in only 8–34% and from bronchoalveolar lavage (BAL) specimens in 45–62% of patients with invasive aspergillosis [40]. Thus, confirmation of invasive aspergillosis often requires histopathology. However, obtaining a biopsy is often not feasible in

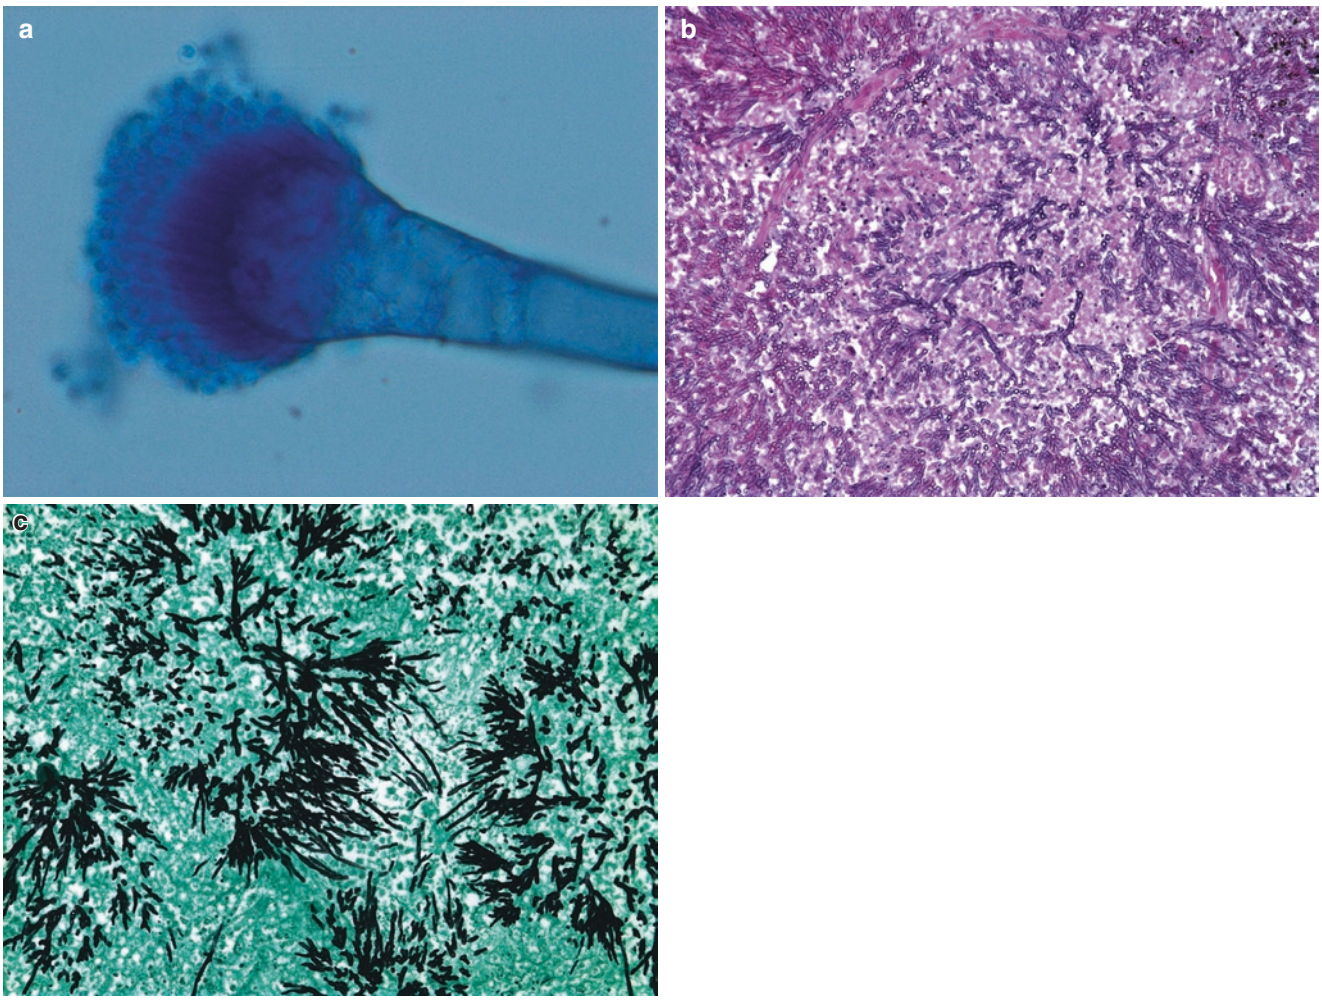

Fig. 33.1 *Aspergillus fumigatus*. (**a**) uniseriate vesicle with columnar phialides that encompass two-thirds of the vesicle on lactophenol cotton blue wet mount preparation (magnification ×100). (**b**) lung tissue demonstrating narrow, acutely branching septated hyphae and vascular invasion on hematoxylin-eosin stain; (**c**) lung tissue section showing narrow, acutely branching hyphae on Gomori methenamine silver stain. (All photomicrographs are courtesy of Audrey N. Schuetz, MD, MPH)

transplant recipients, particularly in HSCT recipients, because of thrombocytopenia. As such, negative fungal cultures should not preclude treatment in a clinical setting concerning for invasive aspergillosis. Although growth of *Aspergillus* from lower respiratory tract cultures does not necessarily indicate invasive infection, the positive predictive value of a positive lower respiratory tract culture is very high in HSCT recipients [41, 42]. Conversely, the positive predictive value in solid organ transplant recipients may be as low as 58% [41]. Of note, blood cultures have no role in the diagnosis of invasive aspergillosis and are negative even in the setting of disseminated infection.

Histopathology

The visualization of organisms on GMS or PAS stains of histopathology that resemble *Aspergillus* provides the strongest evidence of infection. As with direct microscopy, organisms are septated, hyaline hyphae with dichotomous, acute angle branching (Fig. 33.1b, c), features that can also be seen with other filamentous fungi. An important distinction is to differentiate *Aspergillus* from molds of the *Mucorales* order, because voriconazole is the treatment of choice against aspergillosis, but has no activity against the agents of mucormycosis. This distinction is usually possible from histopathology because, in contrast to *Aspergillus*, *Mucorales* typically appear as broad, nonseptate hyphae with right angle branching.

Serologic Markers

Given the limited sensitivities of microscopy and culture-based techniques and the difficulties of obtaining tissue histopathology in transplant recipients, the use of alternate modalities to diagnose invasive aspergillosis, such as serum biomarkers, is warranted. Galactomannan is a heteropolysaccharide found in the cell wall of *Aspergillus* species that is released into the serum and BAL fluid during hyphal growth and cell wall turnover. An enzyme-linked immunosorbent assay (ELISA) to detect galactomannan has been approved by the US Food and Drug Administration (FDA) for serum and BAL fluid. The assay is performed with an optical readout that is interpreted as a ratio relative to the optical density (OD) of a control, called the OD index. The FDA has recommended that an OD index of more than 0.5 should be considered a positive result. A meta-analysis demonstrates that the galactomannan serum ELISA has a sensitivity of 82% and specificity of 86% for invasive aspergillosis in HSCT recipients [43]. The performance of this test in solid organ transplant recipients has not been thoroughly evaluated. Among lung transplant recipients, the sensitivity appears to be lower, possibly because of a smaller fungal burden associated with infection in these hosts [44]. Conversely, in a study of 199 liver transplant recipients at high risk for invasive fungal infection who were randomized to fluconazole or anidulafungin for antifungal prophylaxis, the baseline serum galactomannan was positive in 47% of patients, suggesting poor test specificity in this population [45].

There are a number of limitations to the serum galactomannan assay. First, the sensitivity of the test is decreased by concurrent administration of mold-active antifungal therapy [46]. Second, there are a number of settings where false-positive tests may occur. False-positive results have traditionally been seen in patients receiving piperacillin-tazobactam and may persist for up to 5 days after discontinuation of the drug [47]. However, a recent study demonstrates that current preparations of piperacillin-tazobactam do not lead to false-positive galactomannan results [48]. False-positive results are common during the first 100 days after HSCT and in patients with chronic GVHD [49]. The likely explanation of these findings is that galactomannan in food or bacteria have cross-reactive epitopes and may translocate across intestinal mucosa in the setting of mucosal damage [50]. Third, fungi other than *Aspergillus*, such as *Penicillium* species, also have galactomannan on their cell walls [51]. A recent report demonstrated that nine of 11 hematology patients with *Fusarium* infection had positive serum galactomannan tests [52]. These limitations should be considered when using this assay to diagnose invasive aspergillosis in transplant recipients.

The galactomannan assay can also be performed on BAL fluid and provides additional sensitivity for the detection of pulmonary aspergillosis compared to culture and serum galactomannan. A study of high-risk hematology patients demonstrated that the sensitivity of BAL galactomannan to diagnose proven and probable invasive aspergillosis was 91%, compared to 50% and 53% for culture and microscopy, respectively [53]. Additional studies have confirmed the high sensitivity of BAL galactomannan in this population [54]. Data supporting the use of BAL galactomannan in solid organ transplant recipients are limited, but studies in lung transplant recipients have demonstrated sensitivities of 60–82% and specificities of 95–96% [55, 56].

(1 → 3)-β-D-glucan (BDG) is an integral component of the cell wall of many fungi, including *Aspergillus* and *Candida*, and can be detected in serum. The Fungitell assay is approved by the US FDA for the diagnosis of invasive fungal infections. This assay reports BDG concentrations as measured by optical density. Results are interpreted as positive (>80 pg/mL), intermediate (60–79 pg/mL), or negative (<60 pg/mL) [57]. In addition to aspergillosis and candidiasis, this test also detects infections caused by *Pneumocystis*, *Fusarium*, and *Trichosporon*. It does not detect mucormycosis, cryptococcosis, or mucosal candidiasis. A meta-analysis evaluating the use of serum BDG for the diagnosis of invasive

fungal infections demonstrated a sensitivity of 77% and specificity of 86% [58]. However, a more recent meta-analysis demonstrated a lower sensitivity (50%) and higher specificity (99%) in patients with hematologic malignancies, including HSCT recipients [59]. Its use in solid organ transplant recipients has not been well studied. A major limitation of the BDG assay is that false-positive results are seen in a number of settings. These include the use of hemodialysis with cellulose membranes [60], intravenous (IV) immunoglobulin [61], albumin [62] and amoxicillin-clavulanate [63], gauze packing of serosal surfaces [64], and bloodstream infections with certain bacteria, such as *Pseudomonas aeruginosa* [65].

Polymerase chain reaction (PCR) may be a powerful tool for early diagnosis of invasive aspergillosis, particularly in high-risk patients not receiving mold-active antifungal prophylaxis [66]. However, the lack of standardized and validated procedures for PCR detection of invasive aspergillosis remains a limitation of its wider usage [37].

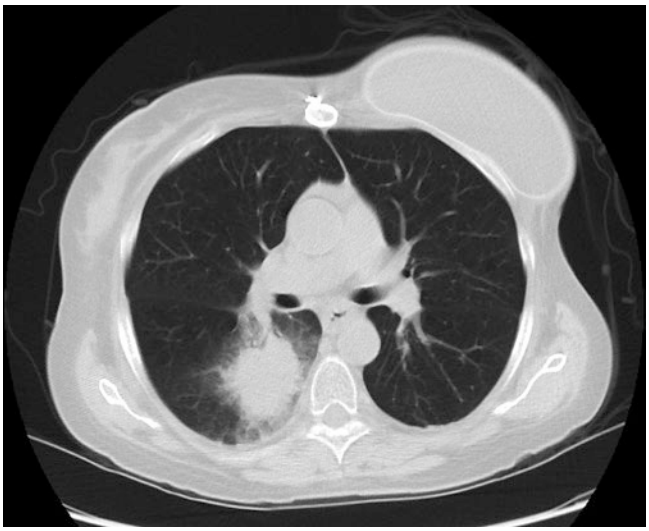

Fig. 33.2 Chest CT scan that demonstrates a halo sign (well-circumcised dense lesion with a surrounding area of ground-glass attenuation), a characteristic radiographic appearance of invasive pulmonary aspergillosis in a neutropenic patient

Imaging

Chest radiographs are insensitive for detecting the earliest stages of invasive pulmonary aspergillosis. On the other hand, computed tomography (CT) scanning of the lungs is an important and sensitive diagnostic screening method. Although radiographic abnormalities of invasive pulmonary aspergillosis are variable, focal lesions are typically seen on CT. In a review of baseline chest CT findings of 235 patients with invasive pulmonary aspergillosis, 94% had a nodule ≥1 cm in diameter, 61% had a halo sign, 30% had a consolidation including infarct (wedge)-shaped consolidations, and 20% had a cavitary lesion [67].

The CT halo sign is an area of ground-glass attenuation surrounding the circumference of a nodule or mass (Fig. 33.2) and was initially described in neutropenic patients with acute leukemia and invasive pulmonary aspergillosis [68]. Histopathologically, it represents a focus of pulmonary infarction as a nodule surrounded by hemorrhage represented as ground-glass attenuation. Although the halo sign may be seen in a variety of pulmonary infections, it is highly suggestive of aspergillosis in neutropenic patients with hematologic malignancies, including HSCT recipients [69–71]. The halo sign is commonly seen in early stages of invasive pulmonary aspergillosis but tends to disappear over time. In a study of 25 patients with hematologic malignancies, neutropenia, and invasive pulmonary aspergillosis who underwent serial CT scans, the prevalence of the halo sign on days 0, 3, 7, and 14 after initial diagnosis was 96%, 68%, 22%, and 19%, respectively [72]. The natural history of nodules caused by *Aspergillus* in neutropenic patients is to enlarge, even during appropriate therapy, and often cavitate. An air-crescent sign within a cavity is a finding that is highly suggestive of invasive aspergillosis. This finding results from air accumulation that separates necrotic tissue from normal lung parenchyma during cavitation [72].

Chest CT findings in solid organ transplant recipients with invasive pulmonary aspergillosis may differ from those of neutropenic patients. Among 92 solid organ transplant recipients who developed pulmonary aspergillosis in RESISTRA, nearly two-thirds presented with segmental areas of consolidation, rather than classic nodule progression to cavitation [18].

The role of CT pulmonary angiography for diagnosing invasive mold infections is unclear. One study found that this technique could distinguish between mold infections and other causes of pulmonary infiltrates, by virtue of detection of angioinvasion [73]. However, the study was small, conducted at a single center, and only included patients with hematologic malignancies. Given the risks associated with IV contrast and limited data to support its benefit compared to a noncontrast CT, the routine use of CT pulmonary angiography to diagnose invasive aspergillosis is not currently recommended.

Treatment

Primary Antifungal Therapy

Due to difficulties in obtaining an exact microbiologic diagnosis and the threat of clinical deterioration and death without treatment in immunocompromised transplant recipients, treatment of invasive aspergillosis should not be withheld

while conducting a diagnostic evaluation [74]. Typically, therapy is initiated based on risk profile, clinical presentation, imaging studies, and serological markers. This section will focus on therapy as it relates to the treatment of invasive aspergillosis. A treatment algorithm for suspected or documented invasive aspergillosis is shown in Fig. 33.3, and Table 33.1 reviews dosing, pharmacokinetic parameters, adverse effects, and notable drug interactions for antifungal agents used in the treatment of aspergillosis.

Triazoles, polyenes, and echinocandins all have in vitro and in vivo activity against *Aspergillus*. Voriconazole is recommended as the drug of choice for the initial treatment of invasive pulmonary aspergillosis by the Infectious Diseases Society of America (IDSA) [74]. This recommendation is based on a randomized, open-label trial of primary therapy of proven or probable invasive aspergillosis in 277 adult patients. The trial compared voriconazole 6 mg/kg IV every 12 h for two doses, followed by 4 mg/kg IV every 12 h for the first 7 days, followed by 200 mg twice daily thereafter to 1.0–1.5 mg/kg/day of IV amphotericin B deoxycholate [75]. Approximately 90% of patients had pneumonia, 30% were HSCT recipients, and 5% were solid organ transplant recipients. The treating clinician

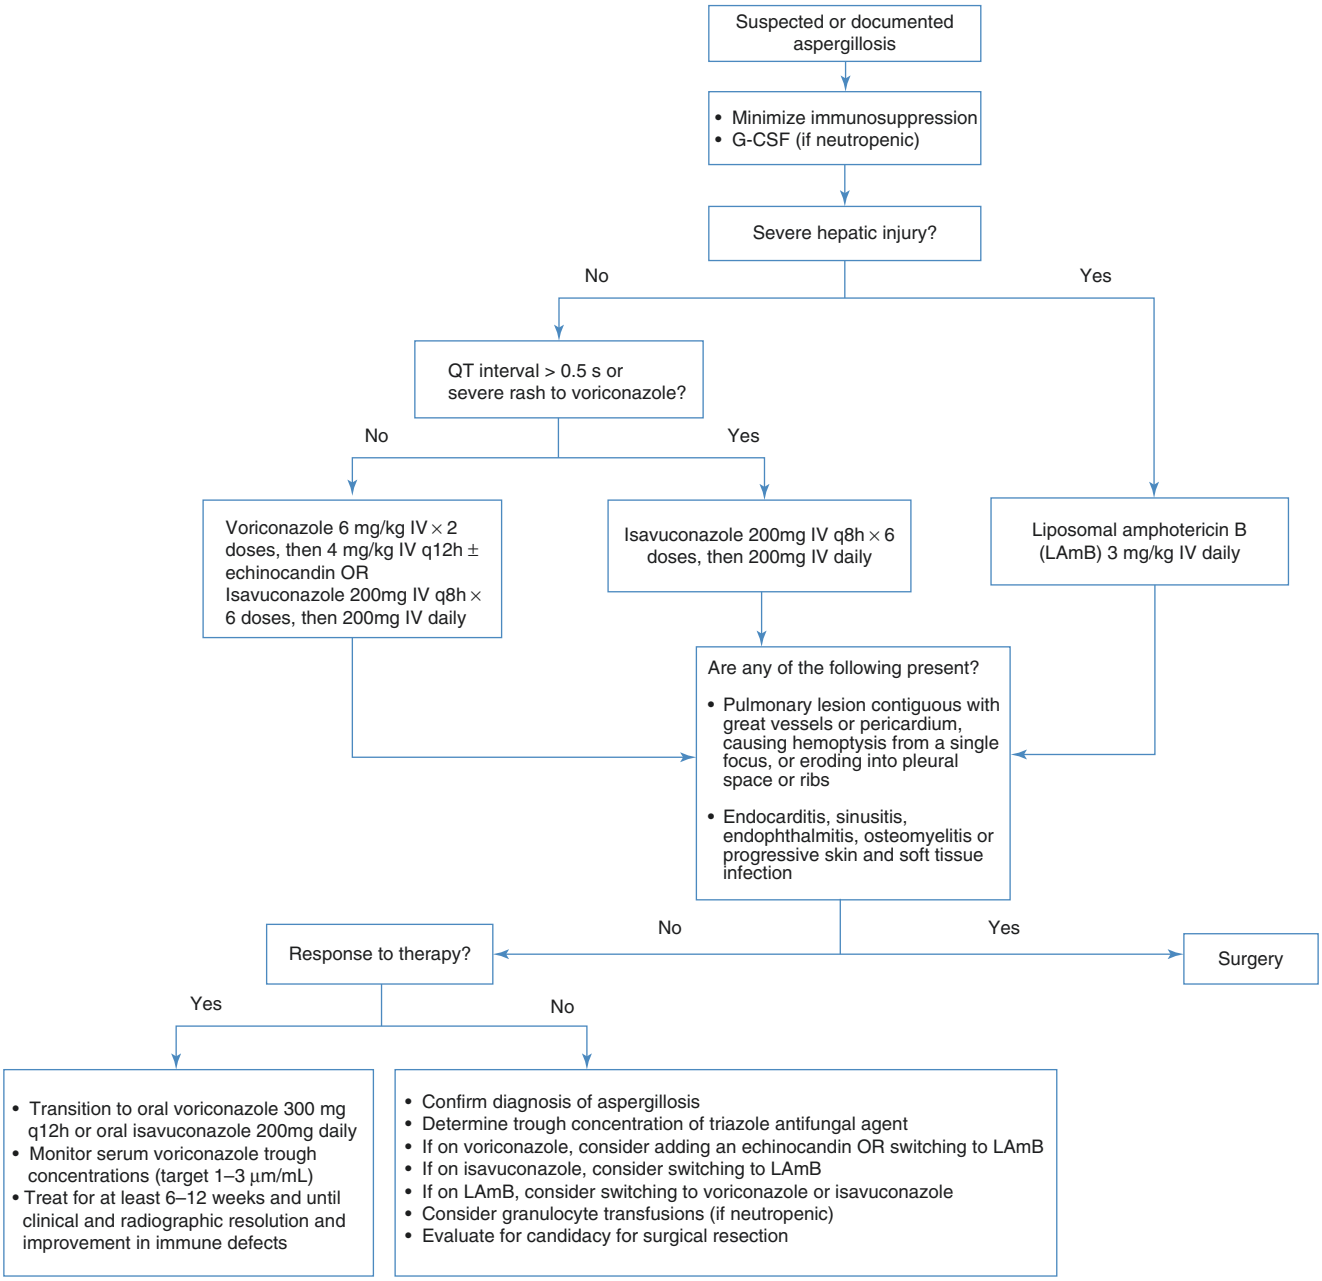

Fig. 33.3 Treatment algorithm for suspected or documented invasive aspergillosis

Table 33.1 Antifungal agents for aspergillosis

Antifungal agent	Adult dosing	Administration	Adverse effects	Notable drug interactions
First-line agents				
Voriconazole	IV: 6 mg/kg every 12 h ×2 doses and then 4 mg/kg every 12 h Oral: 300 mg every 12 h	IV: contains cyclodextrin, which may accumulate in patients with impaired renal function[a] Oral: absorption maximized if taken on an empty stomach (bioavailability up to 90%)	Hepatotoxicity Vision changes: photopsia, photophobia, or color changes Hallucinations Rash, photosensitivity QT prolongation Gastrointestinal Periostitis (prolonged use) Possible increased risk of squamous cell carcinoma and melanoma (prolonged use)	Rifampin and anticonvulsants (phenytoin, carbamazepine, phenobarbital): severely decrease voriconazole concentrations Warfarin, HIV protease inhibitors, simvastatin, atorvastatin, calcineurin inhibitors: voriconazole increases concentrations of these drugs Sirolimus: contraindicated with voriconazole
Isavuconazole	IV and oral: 200 mg every 8 h ×6 doses and then 200 mg daily		Gastrointestinal Hepatotoxicity Rash QT shortening	Similar to voriconazole Mycophenolate mofetil: isavuconazole may increase concentration
Liposomal amphotericin B (LAMB)	3 mg/kg IV daily	Acetaminophen, diphenhydramine, and low-dose hydrocortisone may limit infusion-related reactions 0.5–1 L of isotonic saline prior to drug administration may limit nephrotoxicity	Infusion-related reactions: Chest pain, dyspnea, hypoxia OR Severe abdominal, flank, or leg pain OR Rigors, chills, nausea, flushing, urticaria (less common) Nephrotoxicity: Azotemia (glomerular) Hypokalemia and hypomagnesemia (tubular) Metabolic acidosis (tubular)	Nephrotoxicity risk increases with concurrent use of other nephrotoxic agents Digoxin: Hypokalemia from amphotericin B may lead to digoxin toxicity
Second-line agents				
Echinocandins				
Caspofungin	70 mg IV ×1 dose and then 50 mg IV daily		Hepatotoxicity (rare: less common than with azole antifungal agents) Infusion and hypersensitivity reactions (very rare) Gastrointestinal (mild)	Cyclosporine: modestly increases caspofungin concentrations Rifampin and anticonvulsants: modestly decrease caspofungin concentrations (use 70 mg IV daily dose) Tacrolimus: caspofungin decreases tacrolimus concentrations by ~20%
Micafungin	150 mg IV daily		Similar to caspofungin	Cyclosporine and sirolimus: Caspofungin modestly increases concentrations of these drugs but does not affect tacrolimus concentrations
Anidulafungin	200 mg IV ×1 dose and then 100 mg IV daily		Similar to caspofungin	None
Amphotericin derivatives				
Amphotericin B lipid complex (ABLC)	5 mg/kg IV daily	Similar to LAMB	Infusion-related reactions: fever, rigors, nausea, and vomiting – higher rate than with LAMB Nephrotoxicity: rate likely higher than with LAMB	Similar to LAMB
Amphotericin B colloidal dispersion (ABCD)	3–4 mg/kg IV daily	Similar to ABLC	Similar to LAMB and ABLC, except higher rate of infusion-related reactions	Similar to LAMB

Table 33.1 (continued)

Antifungal agent	Adult dosing	Administration	Adverse effects	Notable drug interactions
Amphotericin B deoxycholate	1–1.5 mg/kg IV daily	Similar to ABLC	Higher rates of infusion-related reactions and nephrotoxicity than with LAMB or ABLC	Similar to LAMB
Posaconazole	IV: 300 mg every 12 h ×2 doses and then 300 mg daily Delayed-release tablet: 300 mg every 12 h ×2 doses and then 300 mg daily Oral suspension: 200 mg 4 times daily. Switch to 400 mg twice daily once disease has stabilized	IV: contains cyclodextrin, which may accumulate in patients with impaired renal function[b]; must be administered via a central venous catheter Tablet formulation preferred due to higher bioavailability, less food effect, fewer adverse effects Oral suspension must be taken with food, optimally with a high-fat meal, to ensure effective absorption	Hepatotoxicity Gastrointestinal	Drugs that increase gastric pH (proton pump inhibitors, histamine-2 receptor antagonists, and antacids) decrease absorption and serum concentrations (oral suspension only) Rifampin and phenytoin: severely decrease posaconazole concentrations Warfarin, HIV protease inhibitors, simvastatin, atorvastatin, calcineurin, and mTOR inhibitors: posaconazole increases concentrations of these drugs
Itraconazole	Capsule: 200 mg twice daily Oral solution: 2.5 mg/kg twice daily	Capsule: take with food and acidic beverages (cola or cranberry juice) to optimize absorption (55% bioavailability) Oral solution: take on an empty stomach to optimize absorption	Nausea, bloating, diarrhea, and weight loss (especially with the oral solution) Hepatotoxicity Hypertension, hypokalemia, and peripheral edema (use cautiously in patients with heart failure)	Drugs that increase gastric pH decrease absorption and serum levels of the capsule form, but not the oral solution Rifampin and phenytoin: severely decrease posaconazole concentrations Warfarin, HIV protease inhibitors, simvastatin, atorvastatin, calcineurin, and mTOR inhibitors: itraconazole increases concentrations of these drugs

mTOR mammalian target of rapamycin, *HIV* human immunodeficiency virus
[a]The clinical significance of the accumulation of cyclodextrin in patients with renal insufficiency is unclear

had the opportunity to switch to an alternate antifungal agent for drug intolerance or clinical failure. Patients who received voriconazole vs. amphotericin B deoxycholate had significantly improved survival (71% vs. 58%) and higher likelihood of complete or partial response (53% vs. 32%) at 12 weeks, respectively. They were also less likely to be switched to another antifungal agent because of intolerance or poor response (36% vs. 80%) and had significantly fewer drug-related adverse events. The results of this landmark trial demonstrated the superiority of voriconazole compared to amphotericin B deoxycholate for the treatment of invasive pulmonary aspergillosis.

The role and optimal dosing of oral voriconazole for invasive aspergillosis in transplant recipients are unclear. In the aforementioned trial, patients were eligible to receive 200 mg of oral voriconazole twice daily after 1 week of IV therapy. However, there is substantial variability in serum drug concentrations in patients receiving oral voriconazole. Serum trough concentrations at this dose are often <0.5–1 μg/mL (the minimum inhibitory concentrations at which, for most *Aspergillus* species, 90% of isolates are susceptible) [76, 77]. Trough concentrations ≤1 μg/mL have been associated with a lack of response to therapy, and concentrations >5.5 μg/mL have been associated with neurological toxicity. A randomized trial provides further support for monitoring voriconazole levels in patients receiving treatment for invasive aspergillosis [78]. One hundred ten patients receiving voriconazole for invasive fungal infection or empirical treatment were randomly assigned to therapeutic drug monitoring of voriconazole levels or no monitoring. In the monitored group, the dosage was adjusted to target a trough level between 1.0 and 5.5 μg/mL. Patients randomized to the therapeutic drug monitoring arm had a significantly higher rate of complete or partial response (81% vs. 57%) and a significantly lower rate of voriconazole discontinuation due to adverse events (4% vs. 17%) compared with patients randomized to no serum drug level monitoring.

The development of voriconazole represented a major advance in the therapy of aspergillosis. However, nonlinear pharmacokinetics, drug-drug interactions, adverse effects, and need for therapeutic drug monitoring may pose management challenges in immunocompromised patients with multiple

comorbid conditions. Isavuconazole is a new-generation azole with potent activity against *Aspergillus* species. Similar to other azoles, isavuconazole prevents fungal cell wall synthesis via inhibition of lanosterol 14α-demethylase. The thiazolyl cyanophenyl moiety of the active isavuconazole molecule allows greater avidity of isavuconazole for the binding pocket in the fungal cytochrome P450 51 protein, conferring broader antifungal spectrum. In animal studies and human trials, isavuconazole has comparable efficacy to voriconazole for the treatment of aspergillosis; yet, it has a more favorable safety, tolerability, and pharmacokinetic profile.

IDSA recommends isavuconazole as an alternative primary therapy for invasive aspergillosis based on the SECURE trial, a randomized, double-blind, noninferiority trial of isavuconazole versus voriconazole for the treatment of invasive fungal infections due to *Aspergillus* species and other filamentous fungi [79]. Adult patients with proven, probable, or possible invasive fungal infection according to EORTC/MSG criteria were randomized in a 1:1 ratio to treatment with isavuconazole given as 200 mg IV three times per day for six doses followed by 200 mg IV or orally daily thereafter or voriconazole administered as 6 mg/kg IV twice daily for two doses followed by 4 mg/kg IV twice daily or 200 mg orally twice daily thereafter. The primary outcome measure of the trial was day 42 all-cause mortality in the intention-to-treat (ITT) arm. The median durations of treatment were 45 and 47 days for patients receiving isavuconazole and voriconazole, respectively. All-cause mortality through day 42 in the ITT population of 516 subjects was 18.6% and 20.2% in the isavuconazole and voriconazole treatment groups, respectively, meeting the prespecified 10% noninferiority margin.

Treatment with isavuconazole is generally well-tolerated. The relatively greater safety and tolerability of isavuconazole as compared to voriconazole are key distinguishing features of this drug. The most common adverse events observed in clinical trials include nausea, diarrhea, vomiting, pyrexia, constipation, and hypokalemia [79, 80]. In the SECURE trial, significantly fewer drug-related treatment-emergent adverse events (TEAEs) occurred in patients treated with isavuconazole (42%) versus voriconazole (60%; $P < 0.001$). In particular, fewer adverse events occurred in the following system organ classes in patients receiving isavuconazole versus voriconazole: hepatobiliary disorders (9% versus 16%), eye disorders (15% versus 27%), and skin and subcutaneous tissue disorders (33% versus 42%). Permanent drug discontinuation due to drug-related TEAEs was 8% and 14% in patients taking isavuconazole and voriconazole, respectively. Also, of note, isavuconazole causes QTc shortening, as opposed to most triazoles that are associated with QT prolongation. The clinical significance of this observed QT shortening is unknown; in clinical trials, no ventricular arrhythmias were observed, and no medical interventions were required.

In patients who are intolerant of triazoles or have contraindications to their use, liposomal amphotericin B is a valid alternate option for initial treatment of invasive aspergillosis [74]. This recommendation is based on a randomized, double-blind trial of 201 adult patients with proven or probable invasive mold infection who received liposomal amphotericin B at either 3 mg/kg or 10 mg/kg per day for 14 days, followed by 3 mg/kg per day [81]. Invasive aspergillosis accounted for 97% of cases and 90% were pulmonary infections. Approximately 20% of patients were HSCT recipients and only one had received a solid organ transplant. A favorable response was achieved in 50% and 46% of patients in the 3- and 10-mg/kg groups, a difference that was not statistically significant. However, in the 3 mg/kg arm, there was a trend toward overall improved survival (72% vs. 59%; $P = 0.09$) and significantly lower rates of hypokalemia and renal failure. The results of this trial demonstrate the efficacy of 3 mg/kg of daily liposomal amphotericin B as first-line therapy for invasive aspergillosis, yielding similar outcomes to those of the pivotal trial that established the efficacy of voriconazole [75]. This study also establishes that increasing the dose of liposomal amphotericin B beyond 3 mg/kg daily for invasive pulmonary aspergillosis yields no additional clinical benefit, but higher rates of nephrotoxicity.

Unfortunately, there are no randomized comparisons of liposomal amphotericin B and voriconazole or isavuconazole for invasive aspergillosis and few between lipid formulations of amphotericin B and conventional amphotericin B deoxycholate. A randomized trial of 66 patients with neutropenia-associated invasive fungal infections, of which 40 had pulmonary aspergillosis, demonstrated that liposomal amphotericin B had a strong trend toward improved response rates and significantly lower mortality and renal failure compared to amphotericin B deoxycholate [82]. Another study randomized 174 patients with invasive aspergillosis to receive amphotericin B colloidal dispersion (ABCD) versus amphotericin B deoxycholate [83]. Patients randomized to either arm had poor, but similar, complete or partial response rates of 18% and 23%, respectively. Patients who received ABCD had lower rates of nephrotoxicity (25% vs. 49%) but higher rates of infusion-related chills and fevers. Lipid formulations of amphotericin B are less nephrotoxic than conventional amphotericin B deoxycholate, and amphotericin B lipid complex and liposomal amphotericin B have fewer infusion-related side effects [82–84]. This improved side effect profile, combined with data that suggest superior efficacy [81, 82], provides a strong rationale for using lipid formulations of amphotericin B instead of amphotericin B deoxycholate for invasive aspergillosis.

Second-Line Antifungal Therapy

Alternate antifungal agents for patients who are intolerant of or not responding to voriconazole, isavuconazole, or liposomal amphotericin B include amphotericin B lipid complex,

posaconazole, itraconazole and echinocandins. Amphotericin B lipid complex has not been compared in a randomized trial to liposomal amphotericin B for the treatment of aspergillosis. However, a randomized comparison for empirical therapy of prolonged fever and neutropenia and an observational study suggest that amphotericin B lipid complex may be associated with greater rates of infusion-related reactions and nephrotoxicity [85, 86]. Posaconazole demonstrates activity comparable to amphotericin B in animal models, and clinical data are consistent with these laboratory findings [87, 88]. In an open-label study of 107 patients with invasive aspergillosis refractory to or intolerant of amphotericin B or itraconazole, treatment with posaconazole given as 800 mg/day oral suspension in divided doses was successful in 42% of patients [89]. This response rate was greater than that of 86 historical controls with similar demographic and disease features and is similar to those observed with other agents in the salvage setting. Posaconazole was approved in Europe for salvage treatment of patients with invasive aspergillosis who are refractory to amphotericin B or itraconazole, but not for patients refractory to voriconazole.

Itraconazole is a second-line agent for the treatment of aspergillosis and has less intrinsic activity against *Aspergillus* than voriconazole [90]. IDSA guidelines do not recommend using itraconazole for salvage therapy in patients with invasive aspergillosis that is refractory to primary therapy with voriconazole because of its inferior in vitro activity, bioavailability, and toxicity profile, compared to voriconazole [74].

Caspofungin is the only echinocandin approved by the US FDA for the treatment of invasive aspergillosis in patients intolerant of or refractory to standard therapy [91]. A study of 83 patients with invasive aspergillosis who were mostly refractory to amphotericin B or a triazole demonstrated a favorable response rate of 45% [92]. Although not FDA-approved for salvage therapy, micafungin and anidulafungin are at least as potent as caspofungin in vitro against *Aspergillus* [93]. Studies using micafungin alone for salvage therapy are small but show similar response rates to that of caspofungin [94, 95].

Although not formally investigated in a clinical trial, when a change in antifungal therapy is considered necessary because of refractory disease, switching to a different class is prudent. Given suboptimal response rates to salvage therapy using single-agent therapy, combination therapy is often employed. Combination therapy using an echinocandin and a triazole is an attractive option because this combination inhibits both cell wall and cell membrane biosynthesis and both drug classes have favorable toxicity profiles. Furthermore, this combination demonstrates a synergistic interaction in neutropenic animal models of pulmonary aspergillosis [96, 97]. A study of 47 patients with invasive aspergillosis who failed therapy with amphotericin B compared outcomes of those who switched to voriconazole alone to that of those who switched to the combination of voriconazole and caspofungin [98]. Salvage therapy with this combination was associated with improved 3-month survival in multivariate analysis.

An antifungal combination that is not recommended is the use of amphotericin B and triazoles. Antagonism between these agents has been demonstrated both in vitro and in animal models [99]. A proposed mechanism for this antagonism is that amphotericin B binding to fungal cell membranes is reduced in the setting of triazole inhibition of the ergosterol biosynthetic pathway. Confirmatory clinical data of the significance of this antagonism are limited, but one observational study demonstrated no benefit to adding itraconazole to a lipid formulation of amphotericin B [100].

Combination Antifungal Therapy for Primary Treatment

The aforementioned in vitro, animal, and clinical observational data that suggest the potential benefit of combining a triazole and an echinocandin provided rationale for testing this hypothesis in a clinical trial [96–98]. A multicenter, randomized, double-blind trial compared outcomes among patients with invasive aspergillosis who received primary therapy with combination voriconazole and anidulafungin versus voriconazole alone [101]. The study population consisted of allogeneic HSCT recipients (32%) and patients with hematologic malignancies with proven or probable invasive aspergillosis. Voriconazole was given for a minimum of 1 week intravenously, after which the investigator could switch to 300 mg of twice daily oral voriconazole. After 2 weeks, patients in the combination therapy arm could have been switched to voriconazole monotherapy, to complete 6 weeks of antifungal treatment. Mortality at 6 weeks was 19.3% in the combination arm and 27.5% in the monotherapy arm and at 12 weeks was 29.3% in the combination arm and 39.4% in the monotherapy arm. The *P* value for these differences was 0.09 and 0.08, respectively. The rate of adverse events was not higher in the combination arm.

Although these findings did not reach statistical significance, the strong and consistent trend toward a mortality benefit with combination therapy, combined with the apparent lack of significant added toxicity and supportive in vitro and laboratory animal data, provides a compelling rationale for adding an echinocandin to voriconazole as initial therapy for invasive aspergillosis. Assuming that the survival differences are not due to chance, then this trial suggests that for every 12 patients who have an echinocandin added to voriconazole in their initial regimen, one life will be saved. It is unclear how long the echinocandin should be continued in the trial; it was given for 2–4 weeks, and it is reasonable to discontinue it upon discharge from an inpatient setting.

Extrapulmonary Aspergillosis

The optimal treatment of aspergillosis at sites other than the lungs has not been well studied because most patients in randomized trials had pulmonary aspergillosis. The trial comparing voriconazole to amphotericin B deoxycholate included 37 patients with extrapulmonary infection [75]. Of these 37 patients, successful outcome occurred in 43% of those randomized to voriconazole, compared to 13% of those randomized to amphotericin B ($P < 0.05$). Based on these data, the IDSA recommends voriconazole for the primary treatment of extrapulmonary manifestations of invasive aspergillosis [74].

Aspergillus dissemination to the CNS is a devastating complication of invasive aspergillosis. Unlike amphotericin B, echinocandins, and itraconazole, voriconazole achieves therapeutic levels in the cerebrospinal fluid (CSF) and brain tissue [102–104]. The CSF penetration of isavuconazole is not well studied. Mortality rates for CNS disease prior to the availability of voriconazole were >90% [105, 106]. In contrast, 35% of patients with CNS aspergillosis who received voriconazole combined with surgical intervention had a complete or partial response, with long-term survival observed in 31% of patients [107]. These findings provide strong rationale for using voriconazole as the cornerstone of therapy for CNS aspergillosis.

The sinuses are also common sites of extrapulmonary aspergillosis. Therapy for invasive sinus aspergillosis often consists of systemic antifungal therapy and surgical debridement. Although voriconazole is recommended for invasive sinus aspergillosis, amphotericin B formulations should be used until sinus mucormycosis has been excluded by culture or histopathologic examination [74]. Because of its high degree of water solubility, voriconazole is also a reasonable option for endophthalmitis, peritonitis, and joint infections. A detailed discussion of site-directed treatments can be found in the IDSA guidelines [74].

Antifungal Resistance

The vast majority of *Aspergillus* isolates are susceptible to amphotericin B, voriconazole, isavuconazole, posaconazole, itraconazole, and echinocandins. However, there are exceptions that make identifying the species from growth of a clinical specimen helpful in deciding on treatment. Most isolates of *Aspergillus terreus* are resistant to amphotericin B, but susceptible to voriconazole [108]. Furthermore, observational data and data from animal models demonstrate poor efficacy of amphotericin B against infections caused by *Aspergillus terreus* compared to voriconazole [109, 110]. Therefore, amphotericin B derivatives should not be used for antifungal resistance to treat infections due to *A. terreus*.

Certain uncommon *Aspergillus* species such as *A. lentulus* and *Neosartorya udagawae* have decreased in vitro susceptibility to antifungal resistance in antifungal agents commonly used for aspergillosis [111, 112]. Recently, *Aspergillus fumigatus* isolates with elevated minimum inhibitory concentrations of voriconazole have been reported [113]. However, these isolates are extremely rare and the vast majority of clinically significant *Aspergillus* antifungal resistance isolates remain highly susceptible to voriconazole [114].

Duration of Antifungal Therapy

Antifungal therapy for invasive aspergillosis should be continued for at least 6–12 weeks, until all signs and symptoms of infection have resolved and until all radiographic abnormalities have stabilized [7, 74]. Transplant recipients with invasive aspergillosis may need to remain on therapy for longer periods of time because of persistent immune defects. Long-term therapy is facilitated by the excellent bioavailability of oral voriconazole and isavuconazole.

Adjunctive Therapies

Reversal of immunosuppression is an important component of the treatment of invasive aspergillosis. In a review of 405 HSCT recipients with invasive aspergillosis, neutropenia and receipt of high doses of corticosteroids were independently associated with mortality [115]. Dose reduction or discontinuation of corticosteroids is recommended, when feasible. In neutropenic patients, recovery of bone marrow function is essential for control of the infection [116]. Granulocyte colony-stimulating factors (G-CSF) shorten the duration of chemotherapy-induced neutropenia and lead to fewer episodes of fever and neutropenia and infection [117, 118]. Although it is not clear that G-CSF improves response rates or decreases mortality in patients with invasive fungal infections, IDSA guidelines support their use in neutropenic patients with aspergillosis [74].

The role of granulocyte transfusions in the management of neutropenic patients with aspergillosis is not well defined, but favorable responses have been reported [119]. The Resolving Infection in Neutropenia with Granulocytes (RING) trial was an open-label, multicenter, randomized trial to investigate the efficacy and safety of granulocyte transfusions for bacterial and fungal infections in patients who were neutropenic (absolute neutrophil count <500 cells/μL) due to chemotherapy, HSCT, or underlying disease [120]. The primary outcome was clinical success, defined as survival at day 42 and clinical response of the study-qualifying infection. This endpoint was met in 20/48 (42%)

and 21/49 (43%) of patients in the granulocyte and control arms, respectively. Twenty percent of patients had transfusion reactions of grade 3 and 4 severity including hypoxia (n = 7), tachycardia (n = 1), hypotension (n = 1), and an allergic reaction (n = 1). No deaths were attributable to transfusion reactions. Unfortunately, this study had low subject accrual, enrolling less than half of its intended sample size of 118 patients per study arm; therefore, statistical power was limited to detect a difference in the primary outcome if one truly existed. In persistently neutropenic patients with invasive aspergillosis who are not responding to medical and (when appropriate) surgical therapy, administration of granulocyte transfusions from G-CSF-stimulated healthy donors may be considered.

Surgical resection of a pulmonary lesion of aspergillosis can provide a definitive diagnosis and eradicate a localized infection. Surgery may be indicated in the setting of recurrent hemoptysis from a single cavitary lesion, lesions contiguous with the great vessels or pericardium, or lesions that invade the chest wall (Fig. 33.3) [74]. Surgical resection may also be considered in appropriate HSCT candidates prior to transplant. Multiple case series suggest that surgery can be safely and effectively performed in patients with localized infections, even during neutropenia [121, 122].

Surgery is essential for the treatment of *Aspergillus* endocarditis and should be strongly considered in endophthalmitis, osteomyelitis, and necrotic, progressive skin and soft tissue infections [74]. Neurosurgical interventions have been independently associated with survival in CNS aspergillosis and should be pursued when feasible [107]. Similarly, surgical debridement of infected tissues is an important component of the management of invasive sinusitis [123].

Prevention

Antifungal Prophylaxis

Primary prophylaxis against *Aspergillus* and other mold infections is not indicated in autologous HSCT recipients because of the low rate of these infections in this population [13]. Current data are inconclusive as to whether antimold prophylaxis should be routinely administered to allogeneic HSCT recipients. A randomized, double-blind trial of 600 allogeneic HSCT recipients compared the efficacy of voriconazole to that of fluconazole in preventing invasive fungal infections after myeloablative transplant [124]. These agents were administered for either 100 or 180 days after transplant, depending on the risk of invasive fungal infection, and serum galactomannan was routinely monitored until day 100. There were no significant differences between groups in rates of invasive fungal infection, survival, or toxicities, although there was a trend toward a lower rate of invasive aspergillosis in the voriconazole arm (3% vs. 6%; P = 0.09). Another blinded study randomized 882 HSCT recipients of autologous and allogeneic stem cell grafts to intravenous micafungin or fluconazole during the neutropenic phase after transplant [125]. Patients randomized to micafungin had less use of empirical antifungal therapy and a trend toward fewer cases of aspergillosis (1 vs. 7; P = 0.07), but there were no differences in the rate of breakthrough fungal infection. These studies suggest that mold-active primary prophylaxis may not be necessary for allogeneic HSCT recipients in the setting of empirical antifungal therapy for prolonged fever and neutropenia and structured galactomannan screening. However, many experts favor the use of a mold-active agent for prophylaxis in high-risk HSCT recipients with anticipated prolonged neutropenic periods, such as cord blood transplant recipients or those with lengthy duration of neutropenia immediately prior to HSCT [74].

HSCT recipients with GVHD are at high risk of invasive mold infections and merit consideration for prophylaxis with mold-active agents [6, 14]. In a double-blind trial, 600 patients with GVHD who were receiving immunosuppressive therapies were randomized to 112 days of posaconazole (200 mg three times daily) or 400 mg of daily fluconazole for antifungal prophylaxis [126]. Patients randomized to posaconazole had a lower rate of invasive aspergillosis (2.3% vs. 7.0%; P = 0.006) and death from an invasive fungal infection (1% vs. 4%, P = 0.046) and a strong trend toward a lower rate of invasive fungal infection overall (5.3% vs. 9.0%; P = 0.07). The incidence of treatment-related adverse events and overall mortality were similar in both arms. Voriconazole has also been shown to be effective in preventing invasive aspergillosis in HSCT recipients with GVHD who are receiving glucocorticoids [127]. These data support the use of prophylactic posaconazole or voriconazole, instead of fluconazole, in patients with GVHD who are receiving corticosteroids.

Patients with prior invasive aspergillosis are at high risk for relapse of fungal disease after HSCT [128]. Secondary prophylaxis with voriconazole is effective in preventing relapse after transplantation and is recommended for this indication by the American Society for Blood and Marrow Transplantation (ASBMT) [129, 130].

Aspergillosis is generally less common after solid organ transplantation than after HSCT, and prophylaxis against aspergillosis is not routinely recommended in this population [3, 25]. However, mold-active prophylaxis may be warranted in high-risk patients, such as lung, heart, and heart-lung transplant recipients. Prophylaxis options in these patients include nebulized amphotericin B and oral mold-active triazoles. The administration of nebulized amphotericin B delivers drug to the site of *Aspergillus* exposure, with minimal systemic drug exposure, and its use has been associated with lower rates of invasive aspergillosis in observational studies [131, 132].

Common adverse effects of nebulized amphotericin B include nausea, vomiting, taste alterations, and bronchospasm. Nebulized lipid formulations of amphotericin B may also be effective in preventing aspergillosis and have better lung penetration and longer half-lives than conventional nebulized amphotericin B deoxycholate [133]. In a randomized trial, nebulized amphotericin B lipid complex was as effective as nebulized amphotericin B deoxycholate and associated with fewer adverse events [132]. The primary disadvantage of using nebulized amphotericin for prophylaxis against aspergillosis is that it does not prevent systemic fungal infections, such as candidemia, and pleural space infections [134]. A retrospective study showed that voriconazole is also effective in preventing pulmonary aspergillosis in lung transplant recipients [135]. However, liver enzyme abnormalities developed in over 40% of patients who received voriconazole. Regular monitoring of liver enzymes and serum concentrations of calcineurin inhibitors is required when using voriconazole as primary prophylaxis in solid organ transplant recipients.

Mold-active prophylaxis may also be warranted in high-risk liver transplant recipients. The American Society of Transplantation recommends consideration of targeted prophylaxis in patients who are receiving a second or third liver transplant, receive renal replacement therapy, require reoperation involving the thoracic or intraabdominal cavity, or are transplanted for fulminant hepatic failure [25]. Both lipid formulations of amphotericin B and echinocandins appear to be effective for this indication [136, 137], whereas voriconazole has not typically been used because of concerns of hepatotoxicity.

Limiting Exposures

Invasive aspergillosis among transplant recipients results from respiratory exposure to and direct contact with fungal spores. Transplant recipients should avoid construction, excavation, and other dust-laden environments during at-risk periods [130, 138]. Physical barriers should be used in the hospital to prevent airborne transmission of *Aspergillus* from construction sites to transplant wards [23]. The use of high-efficiency particulate air (HEPA) filters has been shown to reduce the incidence of aspergillosis in neutropenic patients [139]. The ASBMT recommends the use of HEPA filters and at least 12 air exchanges per hour in all rooms housing HSCT recipients [130]. The need for HEPA filters in rooms of solid organ transplant recipients is not well established [23].

Prognosis

In a study of 642 patients in TRANSNET who developed invasive aspergillosis from 2001 through 2006, the 12-week all-cause mortality rate was 58% in HSCT recipients and 34% in solid organ transplant recipients [140]. Factors independently associated with mortality in HSCT recipients included persistent neutropenia, renal or hepatic insufficiency, onset of disease within 30 days of transplant, and corticosteroid use. Factors independently associated with mortality in solid organ transplant recipients included hepatic insufficiency, malnutrition, and CNS disease. Use of an amphotericin B formulation for treatment was associated with increased mortality in both groups. Other studies of HSCT recipients with invasive aspergillosis have found that poor pulmonary function prior to transplant, use of human leukocyte antigen-mismatched stem cells, and disseminated disease are associated with increased mortality and that survival has improved in recent years [115, 141, 142].

The serum galactomannan assay may also have prognostic value. A meta-analysis of 27 studies showed a strong correlation between the galactomannan index level at the time of diagnosis and mortality [143]. Other studies have confirmed the prognostic value of the initial serum galactomannan and demonstrated that the rate of galactomannan decline after starting antifungal therapy is also correlated with survival [144, 145].

Mucormycosis

34

Brad Spellberg and Johan Maertens

Taxonomy

Previously, the class *Zygomycetes* encompassed both fungi of the order *Mucorales* and *Entomophthorales*. However, recent reclassification has abolished the class *Zygomycetes* and placed the order *Mucorales* in the subphylum *Mucoromycotina* and the order *Entomophthorales* in the subphylum *Entomophthoromycotina*, both in the phylum *Glomeromycota* [1] (Table 34.1). Therefore, infection caused by the *Mucorales* is most accurately referred to as mucormycosis, although the term zygomycosis may be still used by some sources. Infections caused by the *Entomophthoromycotina* are referred to as entomophthoromycosis, but may be clinically indistinguishable from cases of mucormycosis.

Fungi belonging to the order *Mucorales* are distributed into six families, all of which can cause clinical infections [2]. These families include (1) the *Mucoraceae* (genera *Rhizopus, Mucor, Cokeromyces*), (2) the Lichtheimaceae (genera *Lichtheimia* [formerly *Absidia*]), *Rhizomucor*), (3) the *Cunninghamellaceae* (genus *Cunninghamella*), (4) the *Mortierellaceae* (genus *Mortierella*), (5) the *Saksenaeaceae* (genera *Saksenaea, Apophysomyces*), and (6) the *Syncephalastraceae* (genus *Syncephalastrum*). The latter three families are rare causes of infection and are more frequently encountered in highly immunocompromised patients, such as in the transplant setting [3].

Table 34.1 Taxonomy of Mucormycosis Etiologic Fungi; Subphylum *Mucormycotina*, Order *Mucorales*

Family	Genus (species listed for some)
Mucoraceae	*Rhizopus oryzae* *Rhizopus microsporus* *Rhizomucor* *Mucor* *Actinomucor*
Lichtheimaceae	*Lichtheimia* (formerly *Mycocladus,* formerly *Absidia*)
Cunninghamellaceae	*Cunninghamella*
Thamnidiaceae	*Cokeromyces*
Mortierellaceae	*Mortierella*
Saksenaeaceae	*Saksenaea* *Apophysomyces*
Syncephalastraceae	*Syncephalastrum*

Species belonging to the family *Mucoraceae* are isolated more frequently from patients with mucormycosis than those of any other family. Among the *Mucoraceae*, *Rhizopus oryzae* (*Rhizopus arrhizus*) is by far the most common cause of infection [2, 4]. Other less frequently isolated species of the *Mucoraceae* family that cause a similar spectrum of infections include *Rhizopus microsporus* var. *rhizopodiformis, Lichtheimia* spp., *Apophysomyces elegans, Mucor* species, and *Rhizomucor pusillus* [2–4]. It is important to emphasize that the syndrome name, mucormycosis, derives from the order *Mucorales* and family *Mucoraceae*, not from the genus *Mucor*, which itself is a rare cause of infection. Increasing cases of mucormycosis have been also reported due to infection with *Cunninghamella* spp. [4–8]. As mentioned, to date, rare case reports have demonstrated the ability of species belonging to other families to cause mucormycosis [2, 3, 9–12].

Incidence

Mucormycosis is far less common than other opportunistic fungal infections, such as those caused by *Candida* and *Aspergillus spp*. An older population-based study estimated

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_34

the incidence of mucormycosis to be 1.7 cases per million people per year, which translates to approximately 500 cases per year in the United States [13]. In autopsy series, the prevalence of mucormycosis has ranged from 1 to 5 cases per 10,000 autopsies, making the infection 10–50 fold less common than invasive *Candida* or *Aspergillus* infections [14–16]. Most recently, a 10-year study of mucormycosis in France based on the International Classification of Diseases, 10th Revision (ICD-10) codes, found a doubling of incidence, from 2001 to 2010, to 2.1 cases per million population [17].

In recent years, the epidemiology of mucormycosis has shown an alarming trend. Mucormycosis, formerly virtually always community-acquired and often in the setting of diabetic ketoacidosis (DKA), has rapidly become a nosocomial infection in patients with malignancy or undergoing organ transplantation or HSCT [18]. Indeed, in patients undergoing allogeneic bone marrow transplantation, the prevalence of mucormycosis has been described to be as high as 2–3% [19, 20]. However, rates as low as 0.4% have also been reported [21].

Epidemiology and Risk Factors

While in previous years poorly controlled diabetes mellitus was the most common risk factor, more recent series have found that in developed countries, immunocompromise caused by transplantation, prolonged corticosteroid courses, and neutropenia are collectively more common risk factors than diabetes mellitus [22–25]. However, in underdeveloped countries, diabetes mellitus remains the most common risk factor [26, 27].

At transplant centers, the incidence of mucormycosis has been rising since the late 1990s, although rates still remain low relative to other fungal infections [28, 29]. For example, at the Fred Hutchinson Cancer Research Center, Marr et al. described a doubling in the number of cases from 1985–1989 to 1995–1999 [30]. Kontoyiannis et al. described a greater than doubling in the incidence of mucormycosis in transplant patients over a similar time span [31]. Similarly, a single-center study from Belgium found a marked increase in probable or proven mucormycosis (from 0.019 to 0.148 cases per 10,000 patient-days) between 2000 and 2009, driven mostly by changes between the years 2005 and 2009 [25]. The increase in cases in the latter study was most likely explained by an increase in the at-risk population, rather than other factors (e.g., changes in antifungal prophylaxis, etc.).

In patients undergoing hematological stem cell transplantation, mucormycosis develops at least as commonly in non-neutropenic periods as in neutropenic periods. For example, more than half the cases of mucormycosis occur more than 90 days after transplantation [19, 21, 30]. Nevertheless, mucormycosis remains relatively uncommon in the setting of solid organ transplantation (SOT). For example, in the recent, multicenter, TRANSNET study, the incidence of mucormycosis in recipients of solid organ transplants in the United States was less than 1 per 1000 (0.07%) at 1 year of follow-up [32], and mucormycosis accounted for only 2% of invasive fungal infections in this setting (versus >50% for invasive candidiasis and nearly 20% for invasive aspergillosis) [33].

The major risk factors for mucormycosis in the transplant setting include underlying myelodysplastic syndrome (possibly due to iron overload from repeated blood transfusions) and graft-versus-host disease (GVHD) treated with steroids [19, 28, 30, 34, 35]. Administration of antithymocyte globulin may also be a risk for mucormycosis [28]. Although less than half of these patients are neutropenic at the time of disease onset, prolonged neutropenia is a risk factor for mucormycosis in this setting [36], as are diabetes mellitus and steroid use [36].

The possible role of antifungal prophylaxis in predisposing patients to developing mucormycosis is increasingly being described, but remains uncertain. Prophylaxis with either itraconazole [36] or voriconazole [20, 29, 37–39] has been implicated in predisposing to mucormycosis, and these cases have typically presented with disseminated mucormycosis, the most lethal form of disease. However, other studies have indicated that the primary factor driving increased cases is the increased population at risk, rather than exposure to specific prophylactic regimens [25].

Mucormycosis of the lung occurs most commonly in leukemic patients who are receiving chemotherapy or in patients undergoing HSCT. Indeed, the pulmonary form of the disease is the most common form found in neutropenic or stem cell transplant patients [30, 40]. In contrast, soft tissue infections occur in patients with disrupted cutaneous barriers, either as a result of traumatic implantation of soil, maceration of skin by a moist surface [41, 42], or in nosocomial settings via direct access through intravenous catheters or subcutaneous injections [43–45]. Contaminated surgical dressings and linens have also been implicated as a source of outbreaks of cutaneous mucormycosis [46–49]. Cutaneous mucormycosis has also occurred in the context of contaminated tape used to secure an endotracheal tube in a ventilated patient [41]. Recently, an iatrogenic outbreak of gastric mucormycosis occurred due to contamination of the wooden applicators used to mix drugs that were poured down the patients' nasogastric feeding tubes [50]. These patients presented with acute severe gastric bleeding. The diagnosis was established by demonstration of the pathogen in cultures of samples taken from gastric aspirates and the box of wooden tongue depressors.

Clinical Manifestations

In large studies, the median time to onset of mucormycosis after SOT has been reported to be 5–7 months [21, 32, 51], underscoring that the disease most commonly occurs after the immediate post-transplant period, often in association with corticosteroid therapy for GVHD. Based on clinical presentation and the involvement of a particular anatomic site, mucormycosis can be divided into at least six clinical categories: (1) rhinocerebral, (2) pulmonary, (3) cutaneous, (4) gastrointestinal, (5) disseminated, and (6) miscellaneous [4, 22, 24, 27, 31, 51–53]. These categories of invasive mucormycosis tend to occur in patients with specific defects in host defense (Table 34.2). For example, patients with DKA typically develop the rhinocerebral form of the disease and much more rarely develop pulmonary or disseminated disease. In contrast, pulmonary mucormycosis occurs most commonly in leukemic patients who are receiving chemotherapy or in patients undergoing HSCT.

Table 34.2 Risk factors and clinical manifestations of mucormycosis

Clinical risk factor[a]	Immune defect	Typical disease manifestation
Diabetes mellitus[b]	Increased available iron Increased expression of host receptor for *Mucorales* invasion [58] Possible phagocytic defects	Rhino-orbital-cerebral
Neutropenia	Disruption of predominant innate immune host defense mechanism against the fungus (phagocytic killing)	Pulmonary disease, occasionally disseminated
Corticosteroids	Suppression of phagocytic defense mechanisms Unmasking or inducing diabetes mellitus	Rhino-orbital-cerebral, pulmonary, or disseminated
Iron overload states and deferoxamine therapy during renal failure	Elaboration of free iron to enhance fungal growth	Disseminated or local
Injection drug use	Bypassing anatomical barriers to directly access the bloodstream	Cerebral or disseminated
Trauma or cutaneous breakdown	Bypassing anatomical barrier	Subcutaneous or deeper to fascia and muscle
Severe malnutrition	Unclear	Gastrointestinal

[a]Multiple risk factors are often coexistent. For example, patients with malignancy or undergoing transplantation are often treated with corticosteroids which cause diabetes mellitus. Such patients are also often neutropenic and undergo multiple blood transfusions which can create iron overload and also have multiple areas of skin disruption (via catheters, tape, etc.)

[b]Contrary to historical teaching, the predominant mechanism by which diabetes mellitus predisposes to mucormycosis is not acidosis, since the majority of diabetic patients with mucormycosis do not present with acidosis. Diabetes disrupts normal iron sequestering mechanisms, and hyperglycemia upregulates expression of a host receptor used by *Mucorales* to penetrate into epithelia. Acidosis exacerbates the likelihood of infection by further disrupting iron sequestration

Rhinocerebral mucormycosis is the most common form of the disease generally, but is less common than lung disease in the transplant setting [33, 35]. Most rhinocerebral mucormycosis cases occur in patients with diabetes, although such cases are increasingly being described in the transplant setting, likely due to corticosteroid use. The initial symptoms of rhinocerebral mucormycosis are nonspecific and include eye or facial pain and facial numbness, followed by the onset of conjunctival suffusion, blurry vision, and soft tissue swelling. Fever may be absent in up to half of cases, while white blood cell counts are typically elevated, as long as the patient has functioning bone marrow. If untreated, infection usually spreads from the ethmoid sinus to the orbit, resulting in loss of extraocular muscle function and proptosis, typically with chemosis. Onset of signs and symptoms in the contralateral eye, with resulting bilateral proptosis, chemosis, vision loss, and ophthalmoplegia, is an ominous sign that suggests the development of cavernous sinus thrombosis.

Upon visual inspection, the infected tissue may appear normal during the earliest stages of spread of the fungus. The infected tissue then progresses through an erythematous phase, with or without edema, before onset of a violaceous appearance, and finally the development of a black, necrotic eschar. Infection can sometimes extend from the sinuses into the mouth and produce painful, necrotic ulcerations of the hard palate, but this is a late finding and suggests extensive, well-established infection.

Pulmonary mucormycosis is the most common manifestation in the setting of SOT [35], accounting for more than half of mucormycosis cases in some series [25, 33, 54]. Symptoms of pulmonary mucormycosis include dyspnea, cough, and chest pain; fever is often, but not invariably, present. Fungal invasion of blood vessels results in thrombosis and subsequent tissue necrosis, cavitation, resulting in potentially life-threatening hemoptysis. Lobar consolidation, isolated masses, nodular disease, cavities, or wedge-shaped infarcts may be seen on chest radiography. High-resolution chest CT scan is the best method for determining the extent of pulmonary mucormycosis and may demonstrate evidence of infection before it is seen on the chest x-ray. In the setting of cancer, where mucormycosis may be difficult to differentiate from aspergillosis, multiple pulmonary nodules (i.e., $\geq$10), pleural effusion, or concomitant sinusitis makes mucormycosis more likely [55]. It is critical to distinguish mucormycosis from aspergillosis as rapidly as possible, as treatments for these infections differ. Indeed voriconazole, the first-line treatment for aspergillosis, exacerbates the severity of mucormycosis in mouse and fly models [56, 57].

Cutaneous mucormycosis may occur as a result of external implantation of the fungus or, conversely, as a result of hematogenous dissemination. External implantation infection has been described from soil exposure resulting from trauma (e.g., motor vehicle accident), penetrating injury with plant material (e.g., thorn), injections of medications (e.g., insulin), catheter insertion, contaminated surgical dressings, and use of tape to secure endotracheal tubes. Cutaneous disease can be very invasive, penetrating into the muscle, fascia, and even bone. Mucormycosis necrotizing fasciitis has a mortality rate approaching 80%. However, isolated cutaneous mucormycosis (i.e., not disseminated disease) has a favorable prognosis and a low mortality rate with prompt, aggressive surgical debridement. In contrast, necrotic cutaneous lesions in the setting of hematogenous dissemination are associated with an extremely high mortality rate.

Gastrointestinal mucormycosis has been seen in premature neonates in association with disseminated disease and necrotizing enterocolitis; more rarely, it has been described in adults with neutropenia or other immune-compromised states. It has also been described as a nosocomial process after administration to patients of medications mixed with contaminated wooden applicator sticks. Nonspecific abdominal pain and distention associated with nausea and vomiting are the most common symptoms. Gastrointestinal bleeding is common, and fungating masses may be seen in the stomach at endoscopy. The disease may progress to visceral perforation, with extremely high mortality rates.

Hematogenous dissemination of mucormycosis may originate from any primary site of infection. For unclear reasons, patients receiving liver transplants are at higher risk for dissemination [51]. The most common site of dissemination is the brain, but metastatic lesions may also be found in any other organ. The mortality associated with dissemination to the brain approaches 100%. Even without central nervous system involvement, disseminated mucormycosis has a mortality rate of >90%. Miscellaneous mucormycosis may affect any body site including the bones, mediastinum, trachea, kidneys, and peritoneum associated with dialysis.

Diagnosis

A high index of suspicion is required to make the diagnosis of mucormycosis. The median time to diagnosis after onset of symptoms in the setting of SOT was 6 weeks in the retrospective study from France [24]. A concept that is frequently poorly grasped by clinicians inexperienced with mucormycosis is that the initial imaging study is frequently negative or has subtle findings [52]. Radiographic findings are often not in pace with clinical progression of mucormycosis, and a negative imaging study result does not provide a rationale to delay a more aggressive diagnostic approach including tissue biopsy via sinus endoscopy or bronchoscopy in appropriate at-risk transplant recipients.

Disease manifestations of invasive aspergillosis and mucormycosis may be similar, and both diseases affect similar populations of high-risk cancer or transplant patients. However, it is critical to determine if antifungal coverage for mucormycosis must be included, since therapy for mucormycosis tends to be active against aspergillosis, but therapy for aspergillosis is not necessarily active against mucormycosis (discussed below). In this regard, Chamilos et al. performed a retrospective comparison of cancer patients who developed pulmonary mucormycosis or pulmonary invasive aspergillosis to determine if clinical or radiographic findings could distinguish the two diseases [55]. By logistic regression analysis, cancer patients with concomitant invasive sinusitis were 25-fold more likely to have pulmonary mucormycosis than aspergillosis, and patients receiving voriconazole prophylaxis were almost eightfold more likely to have mucormycosis. On the initial pulmonary CT scan, the presence of multiple nodules or pleural effusion imparted a 20-fold or fivefold increased risk of mucormycosis compared to aspergillosis, respectively. No other clinical or radiographic findings could distinguish the two diseases, not even the so-called reverse halo-sign on chest CT scan. Galactomannan, particularly from bronchoalveolar lavage (BAL) in a patient with lung infection, appears to be able to distinguish invasive aspergillosis (positive galactomannan) from mucormycosis (negative galactomannan) [59]. However, a recent case report of positive galactomannan in a patient with infection caused by *Lichtheimia* underscores that false-positive results may occur or the patient may have concurrent polymicrobial fungal disease [25, 60]. The true specificity of galactomannan in cases of potential mucormycosis is not well defined.

Because the *Mucorales* are environmental isolates, establishing a definitive diagnosis requires a positive culture from a sterile site (e.g., needle aspirate, tissue biopsy specimen, or pleural fluid) or histopathological evidence of invasive mucormycosis. A probable diagnosis of mucormycosis can be established by culture from a non-sterile site (e.g., sputum or bronchoalveolar lavage) in a patient with appropriate risk factors and clinical and radiographic evidence of disease. However, given the urgency to administer therapy early, therapy should be given while awaiting confirmation of the diagnosis from pending studies.

Biopsy with histopathology remains the most sensitive and specific modality to definitively establish the diagnosis (Fig. 34.1). The biopsy should demonstrate the characteristic-wide (e.g., ≥6–30 μm in diameter), thick-walled, ribbonlike, aseptate, hyphal elements that branch at right angles. Other fungi including *Aspergillus, Fusarium,* or *Scedosporium* spp. have septae, are thinner, and branch at acute angles. The width and ribbonlike form of the fungus is most reliable to

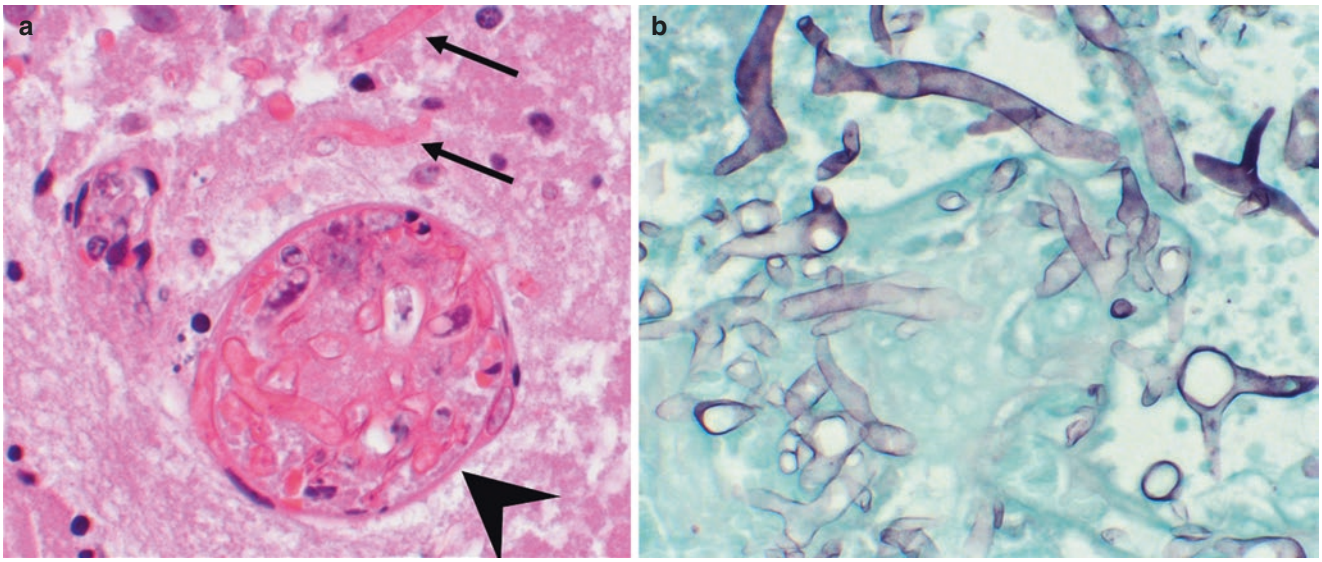

Fig. 34.1 Histopathology sections of *R. oryzae* in infected brain. (**a**) H&E stain of the brain showing broad, ribbonlike, non-septate hyphae in parenchyma (arrows) and a thrombosed blood vessel with extensive intravascular hyphae (arrowhead). (**b**) Gomori methenamine silver (GMS) stain of the brain showing extensive broad, ribbonlike hyphae invading the parenchyma

distinguish mucormycosis, since artificial septae may be apparent due to folding of the tissue during processing, which may also alter the appearance of the angle of branching. The *Mucorales* are visualized most effectively with periodic acid-Schiff (PAS) or methenamine silver stain and, if the organism burden is high, with hematoxylin and eosin (H&E) stain (Fig. 34.1). While histopathology can identify *Mucorales*, species identification can only be made from positive cultures. PCR is under investigation as a diagnostic tool and may be available at certain sites, but it is not yet approved by the US Food and Drug Administration as a diagnostic test for mucormycosis and is not generally available. A recent intriguing study suggested that immune-based assays may be available to detect mucormycosis in the future [61].

Unfortunately, cultures are positive in less than half of cases of mucormycosis. Nevertheless, the *Mucorales* are not fastidious organisms and tend to grow quickly (i.e., <48 h) on culture media. The likely explanation for the low sensitivity of culture is that the *Mucorales* form long filamentous structures that are killed by tissue homogenization, the standard method for preparing tissue cultures in the clinical microbiology laboratory. When processing tissues for culture, the microbiology laboratory should be advised that a diagnosis of mucormycosis is suspected and the tissue should be cut into sections which are placed in the center of culture dishes, rather than being homogenized.

Imaging techniques often have subtle findings which underestimate the extent of disease. For example, the most common finding on CT or MRI scanning of the head or sinuses in a patient with rhino-orbital mucormycosis is sinusitis which is indistinguishable from bacterial sinusitis [62]. It is also common to detect no abnormalities in sinus bones despite clinical evidence of progressive disease. MRIs are more sensitive than CT scans for detecting orbital and CNS involvement [62]. CT scans are useful for early detection of pulmonary mucormycosis, particularly in patients with cancer. By logistic regression, pulmonary mucormycosis in patients with cancer could be distinguished from aspergillosis on the basis of sinusitis, presence of multiple (≥10) nodules by CT scan, and pleural effusion [55]. Endoscopy and/or surgical exploration with biopsy of the areas of suspected infection should always be performed in high-risk patients. If mucormycosis is suspected, initial empiric therapy with a polyene antifungal agent should begin while the diagnosis is being confirmed.

Treatment of Mucormycosis

The successful treatment of mucormycosis requires four steps [52]: (1) early diagnosis; (2) reversal of underlying predisposing risk factors, if possible; (3) surgical debridement where applicable; and (4) prompt antifungal therapy.

Early Diagnosis

A recent study from Chamilos et al. quantified the benefit of early initiation of polyene antifungal therapy in the setting of hematologic malignancies [63]. They reported that if treatment was initiated within 5 days of diagnosis of mucormycosis, survival was markedly improved compared to initiation

of polyene therapy at ≥6 days after diagnosis (83% vs. 49% survival). Hence establishing an early diagnosis of mucormycosis is critical to enable early initiation of active antifungal therapy. Given the overlap of clinical syndromes caused by mucormycosis and other pathogens or noninfectious syndromes in the lung and other body sites, a high index of suspicion is required to enable an early diagnosis.

Reversal of Underlying Disease

It is critical to reverse/prevent underlying defects in host defense when treating patients with mucormycosis. Immunosuppressive medications, particularly corticosteroids, should be dose reduced or stopped if at all possible. Aggressive management to rapidly restore euglycemia and normal acid-base status is critical in diabetics in ketoacidosis. Administration of iron should be avoided, as it exacerbates the severity of infection in animal models of mucormycosis [64–66]. For the same reason, it may be advisable to minimize blood transfusions [67], if feasible. Deferoxamine use should also be avoided due to its ability to exacerbate mucormycosis [64, 65, 68–70].

Surgical Management

Blood vessel thrombosis and resulting tissue necrosis during mucormycosis can result in poor penetration of antifungal agents to the site of infection. Therefore, debridement of necrotic tissues may be critical for complete eradication of mucormycosis. In a recent study, surgery was found to be an independent variable by logistic regression for favorable outcome in patients with mucormycosis [4]. Furthermore, in multiple case series, patients who did not undergo surgical debridement of mucormycosis had a far higher mortality rate than patients who underwent surgery [31, 34, 42, 71–76]. While there is potential selection bias in these case series, as patients who did not undergo surgery likely differed in disease severity or comorbidities from those who did, these data support the concept that surgical debridement is necessary to optimize cure rates.

The extent and timing of surgical debridement necessary to maximize outcomes of mucormycosis has never been defined. Data from a recent retrospective review of patients with rhino-orbital-cerebral mucormycosis [62] support the use of intraoperative frozen sections to delineate the margins of infected tissues so that uninvolved tissues can be spared from debridement. The use of calcofluor fluorescence microscopy has also been reported to increase the sensitivity of frozen sections for guiding the extent of surgical revision [77].

Antifungal Therapy

First-Line Monotherapy Options

In general, primary antifungal therapy for mucormycosis should be based on a polyene, if possible (Table 34.3). While amphotericin B deoxycholate (AmB) was the cornerstone of mucormycosis therapy for decades, lipid formulations of AmB are significantly less nephrotoxic and can be safely administered at higher doses for a longer period of time than AmB [62, 78]. Furthermore, treatment of mucormycosis with liposomal amphotericin B (LAmB) was associated with a 67% survival rate, compared to 39% survival rate when patients were treated with AmB (p = 0.02) [79]. Multiple other, more recent case series also found initial therapy with LAmB to be substantially more effective than other options, particularly in transplant settings [51, 80, 81]. Therefore, most experts now prefer to use lipid polyenes rather than AmB for the treatment of mucormycosis. Indeed, lipid polyenes are recommended as first-line therapy in the recently released European treatment guidelines for this disease [82].

Available data indicate advantages of LAmB over ABLC for the treatment of central nervous system (CNS) mucormycosis. For example, LAmB levels achieved in rabbit brain were fivefold above ABLC levels [83]. Furthermore, while similarly effective in neutropenic mice, LAmB was markedly superior to ABLC in mice with induced diabetic ketoacidosis (DKA) who were infected with *R. oryzae*, primarily due to superior clearance of fungus from the brain [84]. These animal studies are complemented by a recent, relatively small retrospective case series, in which the outcomes of patients with rhino-orbital-cerebral mucormycosis were found to be worse when ABLC was used as initial therapy versus AmB or LAmB [62]. In contrast, a recent murine study found that ABLC achieved superior lung levels compared to LAmB, resulting in superior clearance of fungus from the lungs [85]. When a higher dose of LAmB was used than that of ABLC, the efficacy was similar. No clinical studies are available yet to validate these intriguing murine data.

In the absence of definitive data on dose selection, 5–7.5 mg/kg/day of lipid polyenes are reasonable for most cases of mucormycosis. A recent randomized study of 339 patients with various mold infections found no clinical benefit of LAmB dosed at 10 mg/kg/day versus 3 mg/kg/day [86]. However, there were only five total cases of mucormycosis in the study, none of which involved the CNS. Given the low CNS penetration of polyenes, some experts prefer dose escalation to 10 mg/kg/day of LAmB for CNS mucormycosis. Doses of LAmB higher than 10 mg/kg/day do not result in pharmacokinetic advantage [87].

Recently, a new triazole, isavuconazonium sulfate, was approved for the treatment of mucormycosis in the United

Table 34.3 First-line antifungal options for mucormycosis

Drug	Recommended dosage	Advantages and supporting studies	Disadvantages
Primary antifungal therapy			
Liposomal amphotericin B (LAmB)	5–10 mg/kg/day	Less nephrotoxic than AmB Better CNS penetration than AmB and ABLC Improved outcomes vs. AmB in murine models and a retrospective clinical review	Expensive
Amphotericin B lipid complex (ABLC)	5–7.5 mg/kg/day	Less nephrotoxic than AmB Murine and retrospective clinical data suggest benefit of combination therapy with echinocandins	Expensive Possibly less efficacious than LAmB for CNS infection
Primary combination therapy[a]			
Caspofungin plus lipid polyene	70 mg IV load, then 50 mg/day for ≥2 weeks 50 mg/m^2 IV in children	Favorable toxicity profile Synergistic in murine disseminated mucormycosis Retrospective clinical data suggested superior outcomes with combination caspofungin-lipid polyene therapy for rhino-orbital-cerebral mucormycosis	Clinical data of combination therapy are very limited
Micafungin or anidulafungin plus lipid polyene	100 mg/day for ≥2 weeks Micafungin 4 mg/kg/day in children Micafungin 10 mg/kg/day in low-birth-weight infants Anidulafungin 1.5 mg/kg/day in children	Favorable toxicity profile Synergistic with LAmB in murine model of disseminated mucormycosis	No clinical data

Primary therapy should generally include a lipid formulation polyene. Non-polyene-based regimens may be appropriate for patients who refuse polyene therapy or for patients with mild disease in relatively immune-competent hosts that can be surgically eradicated (e.g., isolated suprafascial cutaneous infection)

[a]Prospective, randomized trials are necessary to confirm the suggestion of benefit of combination therapy from animal and small, retrospective human studies of mucormycosis. Also, dose escalation of any of the echinocandins is not recommended based on paradoxical loss of benefit of combination therapy at echinocandin doses ≥3 mg/kg/day

States (US) and for salvage treatment in Europe. Isavuconazole does have in vitro activity against the *Mucorales,* but with MICs that are about fourfold higher than those of posaconazole (discussed below); however, blood levels achieved are more than fourfold above those of posaconazole [88–92]. The FDA approval as therapy of mucormycosis was based on the positive results of a 37-patient, open-label, single-armed study in which isavuconazole was used to treat patients with mucormycosis [93]. Outcomes were compared to a historical cohort treated with polyenes and were similar in the open-label isavuconazole cohort and the historical cohort. While these results provide reassurance that isavuconazole has merit as a therapeutic agent for mucormycosis, the study design cannot establish isavuconazole as a first-line option [94, 95]. The trial was small, underpowered, and inherently subject to bias in the absence of an active control group [94]. Furthermore, most patients in the open-label study had been pretreated with lipid polyenes. Thus, isavuconazole may be best considered as a second-line option in patients intolerant of lipid polyenes, for salvage therapy or possibly for combination therapy (as discussed below).

Fluconazole, voriconazole, and itraconazole do not have reliable activity against mucormycosis [20, 29, 36–39, 96–100]. The reported in vitro MIC_{90} of posaconazole against the *Mucoromycotina* has ranged from 1 to ≥4 μg/ml [96, 101–104]. However, in patients with febrile neutropenia or invasive fungal infections, posaconazole oral solution dosed at 400 mg twice daily resulted in serum levels <1 μg/ml, with considerable variability [105–107]. These data raise concerns about the reliability of achieving adequate in vivo levels of posaconazole to treat mucormycosis. Furthermore, posaconazole is relatively ineffective for the treatment of mucormycosis in preclinical animal models [98, 108–110]. The efficacy of posaconazole as a treatment option is further called into question by reports of mucormycosis developing as a breakthrough infection while on posaconazole prophylaxis [111–113]. Thus, posaconazole cannot be recommended as a first-line treatment for mucormycosis.

In contrast, Van Burik et al. reported 60% response rates (45% partial response, 15% complete response) for salvage therapy in patients with mucormycosis who were refractory to or intolerant of polyenes [114]. Greenberg et al. reported similar results [115]. Hence, posaconazole is an option for salvage therapy for these infections. Given its variable absorption, therapeutic drug monitoring for posaconazole should be considered, although precise therapeutic or toxicity targets have not been defined [116, 117]. Some experts have recommended serum levels of 0.7 μg/ml [117].

Combination Antifungal Therapy for Mucormycosis

Among patients with mucormycosis in the setting of hematologic malignancies, a recent retrospective study used propensity matching to assess if patients who received combination therapy had improved survival compared to those who received monotherapy [118]. Among 106 patients, 44% received monotherapy and 56% received combination therapy. By propensity matching, patients who received combination therapy did not have superior survival compared to patients who received monotherapy. These data cast some doubt on the role of combination therapy in patients with hematologic malignancy. However, the study was retrospective, and various combination therapy regimens were evaluated, and so it is not possible to say if one combination regimen might be more favorable than others. Definitive answers regarding the role of combination therapy await prospective randomized trials.

Among combination regimens, the one with the most promising preclinical and retrospective data is lipid polyenes with echinocandins. It is now known that *R. oryzae* expresses the target enzyme for echinocandins [119]. In DKA mice infected with *R. oryzae*, combination caspofungin plus ABLC therapy markedly improved survival compared to either monotherapy or placebo [120]. Combination therapy with LAmB plus either micafungin or anidulafungin was also synergistic in either neutropenic or DKA mice with disseminated mucormycosis [121].

In a recent retrospective review from two institutions, combination polyene-caspofungin therapy was associated with significantly improved outcomes in patients with rhino-orbital and rhino-orbital-cerebral mucormycosis compared to polyene monotherapy [62]. Most of the patients were diabetic, although there were patients with neutropenia or status post solid organ transplant in the series. In multivariate analysis, only combination therapy was significantly associated with superior outcomes (OR = 10.9 for success vs. monotherapy, $p = 0.02$).

Echinocandins have extremely favorable toxicity profiles. Furthermore, at an average hospitalization cost of ~$100,000 per case of mucormycosis [122], addition of an echinocandin at ~$100 per day for 2–4 weeks would increase hospital costs by a small amount (i.e., < 3%). Thus, neither toxicity nor cost is a compelling reason to avoid combination polyene-echinocandin therapy for patients with mucormycosis. If used as combination therapy, echinocandins should be administered at standard doses—dose escalation is not recommended, due to paradoxical loss of efficacy during murine mucormycosis at doses ≥3 mg/kg/day [119, 121, 123]. A large-scale, definitive, phase III clinical trial is necessary to determine if combination lipid polyene-echinocandin therapy is superior to monotherapy.

The central role of iron in pathogenesis of mucormycosis has been confirmed based on in vitro, in vivo animal models and retrospective human studies [64, 66, 70, 124, 125]. The requirement for iron acquisition for *R. oryzae* growth and pathogenesis suggested that abrogation of iron uptake could be an important therapeutic adjunct for mucormycosis infections. Unfortunately, despite promising preclinical [66, 70, 125] and observational clinical data in the setting of diabetes mellitus [126, 127], a recent randomized, double-blinded, placebo-controlled trial found that patients treated with iron chelation therapy plus LAmB had higher mortality rates than patients treated with LAmB plus placebo [128]. These data do not preclude an advantage of iron chelation therapy in the setting of diabetes mellitus since no patient enrolled had isolated diabetes mellitus as a risk factor [128], but they preclude routine use of adjunctive iron chelation therapy in the setting of active malignancy.

There are few clinical data to address the role of combination azole-polyene therapy for mucormycosis. However, two recent preclinical studies evaluated the efficacy of posaconazole combination therapy during murine mucormycosis. In the first study, Rodriguez et al... found that combining posaconazole with AmB enhanced the survival of neutropenic mice infected with *R. oryzae* only when compared to a subtherapeutic dose of AmB monotherapy (0.3 mg/kg/day) [109]. In contrast, combination therapy was of no advantage compared to AmB monotherapy at a standard dose (0.8 mg/kg/day). Similarly, we recently reported that combination posaconazole plus LAmB was of no benefit compared to monotherapy with LAmB alone in either neutropenic or DKA mice with mucormycosis [110]. Based on available data, posaconazole does not have a clear role as adjunctive therapy in combination with lipid polyenes. Whether isavuconazole combinations with lipid polyenes are of advantage is not known.

Ben-Ami et al. recently reported that the antibacterial agent, colistin, has activity against the *Mucorales* [129]. Colistin was cidal in vitro, although regrowth of the fungus occurred unless subinhibitory AmB was added for synergy. Colistin mechanism of action appeared to involve disruption of the cytoplasmic and intracellular vacuolar membrane integrity. The drug had limited activity as a prophylactic agent during inhalational challenge, but did not have systemic therapeutic activity. Its potential role as a second agent in a combination regimen merits further study.

Proinflammatory cytokines, such as IFN-γ and GM-CSF, enhance the ability of granulocytes to damage the agents of mucormycosis [130]. Adjunctive immune therapy with recombinant G-CSF and GM-CSF, or with recombinant IFN-γ, has been used successfully in conjunction with lipid formulations of amphotericin B in the treatment of mucormycosis [131–133]. Whether recombinant cytokines have a role in the primary treatment of mucormycosis in immunocompromised patients is not well defined.

G-CSF-mobilized granulocyte transfusions have been increasingly used for refractory mycoses, including mucormycosis [134]. While the reported experience in the management of mucormycosis with granulocyte transfusions is limited, such transfusion use may contain the infection and

be lifesaving in persistently neutropenic hosts with this infection. Finally, based on limited experimental and clinical data, hyperbaric oxygen therapy may be also useful in centers with the appropriate technical expertise and facilities, although the precise mechanism by which hyperbaric oxygen would be effective is not well described [135].

Salvage Therapy

Posaconazole and deferasirox are reasonable salvage options for patients with mucormycosis refractory to or intolerant of polyene or isavuconazole therapy. Substantially, more clinical data are available for posaconazole in this setting [114, 115]. Posaconazole appears to be quite safe despite dosing for months to years of administration [114, 115].

Deferasirox is cidal against *Mucorales*, killing the fungi by inducing iron starvation [66]. Deferasirox cannot be used by *Mucorales* as an iron siderophore as is deferoxamine, to which the fungi bind and from which they strip iron. This explains why deferasirox kills *Mucorales* while deferoxamine actually enhances growth [70]. There is limited experience with deferasirox as salvage therapy. However, in case series and case reports, its addition to patients progressing on previous therapy has resulted in favorable outcomes without substantive toxicity [126, 127, 136]. Nevertheless, the majority of patients treated with deferasirox in these studies did not have active malignancy and had not undergone hematopoietic stem cell transplantation. If deferasirox is used as salvage, it should be limited to patients with diabetes mellitus or possibly steroid therapy in the setting of solid organ transplantation, and it should be used cautiously and with regular monitoring of renal and hepatic function. Administration at a dose of 20 mg/kg/day for 2–4 weeks is reasonable for salvage therapy, since in preclinical studies of non-iron-overloaded primates, deferasirox toxicity increased beyond 4 weeks of therapy [137].

G-CSF-mobilized granulocyte transfusions may provide additional support for persistently neutropenic patients until recovery from neutropenia. Administration of GM-CSF or IFN-γ may further augment host response and antifungal effect in non-neutropenic patients with refractory infection. In a recent murine study, addition of GM-CSF to LAmB therapy, but not IFN-γ, improved the survival of mice with mucormycosis [138].

Cryptococcus Infections in Transplant Recipients

35

Raymund R. Razonable and Pearlie P. Chong

Introduction

Cryptococcus species are group of closely related basidiomycetous encapsulated yeasts. Distributed worldwide, there are over 50 species belonging to the genus *Cryptococcus*. However, only *Cryptococcus neoformans* (which includes *C. neoformans* var *grubii* and var *neoformans*) and *Cryptococcus gattii* (formerly known as *C. neoformans* var *gattii*) are well known pathogens causing human illness [1, 2]. There have been only few reports of human disease due to other members, such as *Cryptococcus albidus* and *Cryptococcus laurentii*, especially in immunocompromised hosts [3–5].

C. neoformans var. *grubii* and var. *neoformans* are present in soil, especially enriched with droppings of birds, including pigeons and chickens [6]. These fungi have been cultured from roosting sites of pigeons and from rotting vegetation [7]. *C. neoformans* var *grubii* and var *neoformans* account for the large majority of human cryptococcosis in the United States and other temperate climates of the world [1]. On the other hand, *C. gattii* is endemic in tropical and subtropical regions of Africa and Australia, Southeast Asia, and Brazil. *C. gattii* has been cultured from eucalyptus (red gum) trees in Australia [8]. Recently, *C. gattii* has been reported in the Pacific Northwest of the United States and Canada, as a cause of an outbreak of human cryptococcosis [2, 9]. *C. gattii* has been cultured from trees native in California and British Columbia [2, 9].

Cryptococcus species cause infections in immunocompetent and immunocompromised individuals. Most serious infections, however, occur in individuals with defective cell-mediated immunity, such as patients with acquired immunodeficiency syndrome (AIDS) and transplant recipients [10, 11]. *C. neoformans* causes most infections occurring in immunocompromised hosts, while most infections due to *C. gattii* has been reported in immunocompetent hosts [9].

Epidemiology of Cryptococcosis After Transplantation

Cryptococcosis is the third most common fungal infection after solid organ transplantation (SOT), following *Candida* and *Aspergillus* species. In a recent multicenter epidemiologic study, cryptococcosis accounts for 8% of all invasive fungal infections after SOT [12, 13]. However, the overall incidence of cryptococcal disease after SOT ranges from as low as 0.2% to as high as 5%, depending on the type of organ transplant and the duration of follow-up [12, 13]. In contrast to the SOT population, cryptococcal disease is rarely seen among hematopoietic stem cell transplant (HSCT) recipients. The TRANSNET database reported that cryptococcal disease occurred in 0% of the HSCT recipients, while it accounted for 8% of all invasive fungal infections in SOT recipients [13, 14]. This difference is probably due to the widespread use of *Cryptococcus*-active azole prophylaxis routinely given to the recipients of hematopoietic stem cell transplantation such as fluconazole for the prevention of invasive candidiasis or voriconazole and posaconazole for the prevention of invasive mold disease among high-risk transplant recipients [15].

Transmission and Patterns of Disease After Transplantation

Transmission of *Cryptococcus* sp. occurs through inhalation of the fungus, either in yeast form or as basidiophores, from an environmental source such as bird droppings or soil. Following inhalation, the fungus may remain localized in the lungs or it may disseminate hematogenously, with particular predilection to infect the central nervous system (CNS).

Three patterns of cryptococcal infection occur in transplant recipients. First, it may result from the reactivation of subclinical (and latent) cryptococcus infection [16]. This pattern of infection was suggested in a study where pre- and post-transplant cryptococcal serology was evaluated with the risk of fungal disease [17]. Transplant recipients with detectable pretransplant serum cryptococcal antibodies had an earlier onset of cryptococcal disease indication for the potential of reactivation of previously acquired infection [17]. The factors associated with reactivation of latent cryptococcal infection are not yet defined, although it may reflect an overall net state of immunosuppression and fungal burden. Second, de novo acquisition of cryptococcal infection may occur after transplantation, as a result of natural transmission via inhalation of the fungus [18, 19]. The majority of de novo cryptococcal disease occurs after the first year following transplantation, and the median time to the onset of cryptococcal disease ranges from 16 to 21 months [13, 20, 21]. Third, cryptococcus may rarely be acquired from the donor (i.e., donor-derived cryptococcus) [22–24]. Donor-derived cryptococcus infection manifests early, and the symptoms generally occur between 14 and 24 days after transplantation [22]. Hence, donor-derived cryptococcal disease should be considered in any transplant recipient with diagnosis within 30 days after transplantation. Occurrence of donor-transmitted cryptococcal disease in one transplant recipient should alert surveillance and management of possible disease in the other organ recipients from the same donor. Occurrence of cryptococcal disease in multiple recipients from a single donor raises the suspicion for donor-derived infection. Donor-derived cryptococcal disease is however so infrequent that routine screening of donors for latent cryptococcal infection is not recommended [10].

Risk Factors and Pathogenesis

Transplant candidates with liver cirrhosis and end-stage liver disease have impaired host defenses, including compromised cell-mediated immunity, phagocytic dysfunction, decreased antibody and immunoglobulins, and complement deficiency that may increase their risk of cryptococcosis [25]. Indeed, liver cirrhosis is a recognized risk factor for the development of cryptococcal disease [25]. Mortality in liver cirrhotic patients with cryptococcosis is high, and previous studies have reported this to range from 81% to 100% [26, 27]. Patients with pretransplant cryptococcal disease should be treated aggressively. Improvement of clinical signs and symptoms of cryptococcal disease, stable and improving cryptococcal antigen titers, and sterility of fungal cultures should be demonstrated before these patients are considered for organ transplantation.

The primary host defense against cryptococcal infections is cell-mediated immunity, of which T helper CD4+ cells play a central role [10, 11]. Impairment in cell-mediated immunity may therefore predispose to cryptococcal disease. An over-immunosuppressed state is generally considered as a risk factor for cryptococcal disease. Use of lymphocyte-depleting drugs such as alemtuzumab and antithymocyte globulin has been associated with cryptococcosis [28, 29]. Use of high doses of corticosteroids has also been suggested as a risk factor for cryptococcal infection [30, 31]. In contrast, use of calcineurin inhibitors appears to influence the clinical manifestation of cryptococcosis. For example, patients on tacrolimus or other calcineurin inhibitors were less likely to have disseminated cryptococcal disease and more likely to present with disease localized to the lungs or skin. Tacrolimus has anticryptococcal activity at temperatures of 37–39 °C but not at environmental temperatures. This property could account for the higher ratio of skin and soft tissue infections compared to CNS infections in patients receiving tacrolimus-based immunosuppressive regimens [32].

Cryptococcal disease is rarely encountered in HSCT recipients. In one review, there have only been nine HSCT patients identified in the literature [12]. In this small cohort, there were more autologous that allogeneic HSCT recipients with cryptococcal disease. The precise reasons for this observation are largely unknown. Prophylaxis with cryptococcus-active azoles may account for this difference, since it is given for longer periods of time in allogeneic HSCT recipients. In the same context, the routine use of antifungal prophylaxis in HSCT recipients may also account for the lower incidence of cryptococcosis in HSCT compared to SOT recipients. In our review of invasive fungal infections after lung transplantation, where prolonged universal azole prophylaxis is provided, no cases of cryptococcal disease was observed [15].

Clinical Disease and Its Manifestations

Cryptococcus neoformans may affect any organ system, but it most commonly involves the lungs and CNS as shown in Table 35.1. Disseminated invasive disease is a very common presentation and was documented in up to 61% of SOT recipients with cryptococcal infection, especially liver recipients [21]. Pulmonary disease is the most common organ

Table 35.1 Clinical manifestations of cryptococcosis

Respiratory	Nodules Infiltrates (lobar, interstitial) Cavitation Effusions/empyema Adenopathy (mediastinal, hilar) Acute respiratory distress syndrome Pneumothorax Endobronchial lesions
Neurologic	Meningitis Encephalitis Cryptococcoma (more common with *C. gattii* infection) Hydrocephalus Spinal cord granuloma
Cutaneous	Nodules (classically with central umbilication) Vesicles Plaques Purpura Ulcers Cellulitis
Other organs	Musculoskeletal (arthritis, myositis, osteomyelitis) Ocular (keratitis, chorioretinitis, endophthalmitis) Genitourinary (prostatitis, renal abscess) Gastrointestinal (hepatitis, peritonitis, mucosal ulcers) Cardiovascular (endocarditis, cryptococcemia) Lymph (lymphadenopathy)

involved with cryptococcus infection in transplant recipients [33–35]. It may present as an asymptomatic infection that is detected incidentally on chest radiograph [33, 34] or as a severe pneumonia and respiratory failure [35]. Depending on the pulmonary syndrome, patients may present with fever, cough, sputum production, pleurisy, and weight loss. Radiographic findings vary depending on the syndrome and may include an isolated pulmonary nodule, nodular infiltrates, consolidation, or pleural effusions [33–35].

Extra-pulmonary involvement is common in transplant patients with cryptococcosis, and the CNS is the most common extra-pulmonary site [20, 21, 36]. Accordingly, transplant recipients with cryptococcal infection should undergo spinal fluid examination. Cryptococcal meningitis or meningoencephalitis is the most frequent CNS disease, and it may have an acute or subacute clinical presentation with headache, fever, neck pain, nuchal rigidity, altered mental status, lethargy, coma, cranial nerve palsies, and memory loss. An isolated CNS parenchymal lesion is observed less frequently. However, focal parenchymal mass lesions may be observed in neuroimaging studies of 10–25% of patients with cryptococcal meningitis. Findings consistent with meningeal enhancement, hydrocephalus, and cerebral edema may occur in 15%, 10%, and 3%, respectively [37]. CNS parenchymal lesion is reported to be a more common presentation of *C. gattii* compared to *C. neoformans* infection.

Skin and soft tissues is the third most common organ involved in cryptococcal disease. Eight percent of patients with cryptococcosis have skin, soft tissue, or osteoarticular involvement [21]. Cutaneous involvement is generally indicative of a widely disseminated disease, and the skin was involved through hematogenous dissemination from a primary pulmonary focus. Rarely, primary cutaneous cryptococcosis may occur as a result of direct inoculation or exposure from the environment, and these skin lesions may serve as foci for hematogenous dissemination. The typical cryptococcal skin lesion is characterized as a papule or maculopapule with central umbilication (that is easily mistaken for molluscum contagiosum). However, cryptococcus may produce almost any type of skin lesion, including nodules, cellulitis, and ulcerations [38]. The diagnosis is confirmed by demonstrating the fungus on skin biopsy, either using histopathology or fungal culture.

Other sites of the body may be involved in cryptococcosis, usually as part of a disseminated disease. Cryptococcal disease affecting the prostate gland, kidney, liver, tendons, bones, and joints has been observed [39]. Kidney and prostatic involvement may be indicated by detection of cryptococcus in urine [40]. Systemic spread from the prostate may occur during urologic manipulation and with a longer duration of antifungal treatment in patients with prostatic involvement since the organ may serve as a sanctuary site. Ocular cryptococcosis may also occur, although it is rare [41]. The two distinct clinical patterns of ocular cryptococcosis are rapid and slow visual loss. Rapid visual loss is due to optic neuritis resulting from the direct invasion of the optic nerve by *C. neoformans*. This illness is rapidly progressive, with a clinical course of as short as 12 h [42]. Slow visual loss occurs later, often during antifungal therapy, secondary to raised intracranial pressure. Endophthalmitis has also been reported in patients with disseminated cryptococcosis [43]. Cryptococcal peritonitis has been reported in patients undergoing peritoneal dialysis and those with underlying liver disease and cirrhosis [27, 44].

Diagnosis of Cryptococcal Infection

Transplant recipients and candidates suspected to have cryptococcal disease should undergo thorough clinical evaluation to confirm the diagnosis and to ascertain the extent of the disease. The evaluation may include blood and urine culture and antigen detection in clinical samples such as blood, respiratory secretions, tissues, and cerebrospinal fluid (CSF). Lumbar puncture to detect cryptococcal meningitis should be performed in all patients with documented cryptococcosis. The opening pressure should be obtained (to evaluate for hydrocephalus) and the CSF should be evaluated for pleocytosis (white cell count), protein, glucose, and microbiology including cryptococcal antigen [10]. Imaging studies such as brain CT or MRI may be performed to determine the pres-

ence of mass lesions or hydrocephalus [10]. MRI is more sensitive that CT scan in detecting cerebral cryptococcomas, which may be present in up to 33% of patients with CNS disease [10]. Biopsy of affected tissues such as the prostate or kidney should be performed if feasible when cryptococcus infection is suspected in these sites [10].

Several methods are available for the diagnosis of cryptococcal infection. Isolation of the fungi for culture of clinical specimens is considered the gold standard for diagnosis of cryptococcal infection. *Cryptococcus* species grows easily, usually within 3–7 days on most bacterial and fungal culture media. Colonies of *C. neoformans* usually appear within 48–72 h after plating a specimen on routine laboratory agar media. Macroscopically, they appear as white- to cream-colored opaque colonies which usually become mucoid in appearance with prolonged incubation.

Detection of cryptococcal antigen in the serum and CSF, using either latex agglutination or enzyme immunoassay method, is an accurate and rapidly available method for the detection of cryptococcal infection. The sensitivity and specificity with either method is more than 90% [45]. In a review of SOT recipients, the serum cryptococcal antigen had a sensitivity of 88–98% in patients with cryptococcosis, while the CSF cryptococcal antigen has a sensitivity of 98–100% in patients with cryptococcal meningitis [46]. The mean titers have ranged from 1:2 to 1:512 [46]. The sensitivity of cryptococcal antigen testing over culture (33–39%) has been demonstrated [46], and several studies reporting cases of cryptococcal meningitis in which CSF cryptococcal antigen is detected before CSF culture is positive [20, 21, 47]. Cryptococcal antigen is also more sensitive compared to India Ink preparation (50–80%) in the diagnosis of cryptococcal meningitis [46]. Cryptococcal antigen testing relies on the detection of capsular polysaccharide antigens from *Cryptococcus* species, which allows for its detection in lower fungal burden states and earlier in the course of the infection. Serum cryptococcal antigen may be negative in cases of isolated pulmonary cryptococcosis [47]. However, a positive serum cryptococcal antigen should trigger evaluation for extrapulmonary disease, including the CNS. In patients at high risk for dissemination, such as transplant recipients, a lumbar puncture should be performed even if neurologic symptoms are absent. Early spread to the CNS may be asymptomatic and be manifested only by a positive CSF fungal culture or cryptococcal antigen. Indeed, CSF cryptococcal antigen may be useful in detecting early CNS cryptococcal disease, before there is sufficient fungal burden to result in a positive fungal culture.

Measurement of cryptococcal antigen titers carries prognostic information. A high initial cryptococcal titer indicates high fungal burden, disseminated disease, poor host immunity, and higher likelihood of treatment failure [20, 21, 47]. In one review, the serum cryptococcal antigen titer was higher in patients with symptomatic pulmonary cryptococcosis compared to those with asymptomatic or incidentally detected cases (1:128 versus 1:32) [35]. Notably, the titers are usually lower in patients with *C. gattii* compared to *C. neoformans* infections [2]. Cryptococcal antigen titers are also generally useful in following antifungal treatment responses. However, this may not be as reliable as fungal culture in differentiating clinical disease progression due to treatment failure versus immune reconstitution inflammatory syndrome (IRIS) [10, 48]. A rising cryptococcal antigen titer is generally indicative of clinical progression, while it is stable or decreasing antigen levels in patients with IRIS, although this is not generally the case (see below). Other fungal antigen tests such as serum galactomannan or the (1- > 3) ß-D-glucan tests are not reliable for the detection of cryptococcus and should not be used for diagnosis of and monitoring cryptococcosis.

Several stains are used to identify cryptococcus in biopsy samples and other clinical specimens. Traditionally, India ink preparation was used as a readily available tool for the rapid diagnosis of cryptococcal infection. *Cryptococcus* species are yeasts, measuring 5–10 μm in diameter, that contain a polysaccharide capsule that appears as clear halo or space in specimens treated with India ink stain. The sensitivity of India ink preparation is only in the 50% in patients with cryptococcal meningitis in the non-AIDS population [49]. Alcian blue stains are also used and may provide better specificity for cryptococcus infection. Mucicarmine staining will stain the cryptococcal capsule to rose or burgundy color [49]. Gram stain usually shows poorly stained Gram-positive yeast, while Gomori methenamine silver (GMS) fungal stain may demonstrate the narrow-based budding oval yeast of cryptococcus in tissue specimens [49].

Treatment of Cryptococcal Disease in Transplant Recipients

Treatment of cryptococcal disease in transplant recipients entails the use of antifungal drugs and reduction in pharmacologic immunosuppression. The antifungal drugs that are recommended for the treatment of cryptococcal disease in transplant recipients are amphotericin B products, preferably lipid formulations, flucytosine, and fluconazole (Table 35.2) [10, 50]. Voriconazole, itraconazole, and posaconazole are also active against cryptococcus, but they offer no additional benefit compared to fluconazole and have higher potential for drug-drug interactions, especially drugs used for prevention of graft rejection and prevention and treatment of GVDH [5, 43]. The basis of the treatment recommendations in transplant recipients is extrapolated from retrospective studies in SOT recipients and from clinical trials performed in patients with AIDS [10, 50]. There are no randomized, prospective clinical treatment trials in transplant recipients with cryptococcosis.

Antifungal susceptibility testing is not generally recommended in cryptococcosis, unless there is persistent infection and relapsed infection or the infection is due to *C. gattii*, which may sometimes be associated with high minimum

Table 35.2 Treatment of cryptococcosis in transplant recipients

Therapy	Drug and dose	Duration
Asymptomatic pulmonary disease	Fluconazole, 400 mg per day	6–12 months
Mild to moderate isolated pulmonary disease	Fluconazole, 400 mg per day	6–12 months
All other cases, including CNS disease, severe pulmonary disease, and disseminated disease		
Induction therapy		
(a) Preferred therapy	Liposomal amphotericin B, 3–4 mg/kg per day; or amphotericin B lipid complex, 5 mg/kg per day, plus flucytosine, 100 mg/kg per day	Minimum of 2 weeks
(b) Alternative therapy	Liposomal amphotericin B, 3–4 mg/kg per day, or amphotericin B lipid complex, 5 mg/kg per day	Minimum of 4–6 weeks
Consolidation therapy	Fluconazole, 400–800 mg per day	8 weeks
Maintenance therapy	Fluconazole, 200–400 mg per day	6–12 months

inhibitory concentration to fluconazole [51–53]. In vitro *resistance* to amphotericin B and fluconazole among cryptococcal isolates is very uncommon [53].

With the exception of mild-to-moderate pulmonary cryptococcosis, all other cryptococcal diseases in transplant recipients should be treated using induction therapy with fungicidal liposomal amphotericin B (3–4 mg/kg per day) or amphotericin B lipid complex (5 mg/kg per day) and flucytosine (100 mg/kg per day) for a total of 14 days (Table 35.2) [10, 50]. This combination therapy should be used to treat patients with CNS disease, disseminated disease, or severe respiratory disease. Lipid formulations of amphotericin B are preferred over amphotericin B deoxycholate, as it confers survival benefit and is less nephrotoxic, especially in transplant patients who are already receiving several nephrotoxic medications [54]. Mortality at 90 days is lower in SOT patients with cryptococcosis treated with lipid formulation compared to the deoxycholate formulation of amphotericin B [54]. Flucytosine is an essential component of induction therapy. The lack of flucytosine use and its use for <14 days have been associated with treatment failure at 2 weeks and 90 days, respectively [55, 56].

The 2-week induction phase with amphotericin B plus flucytosine should be followed by a consolidation phase using oral fluconazole (400–800 mg per day) for 8 weeks and finally maintenance therapy phase using oral fluconazole (200–400 mg per day) for at least 6–12 months [10, 50]. The duration of antifungal treatment may be prolonged as guided by serial serum cryptococcal antigen monitoring [50]. Transplant clinicians generally continue treatment for a duration that exceeds the time of positive cryptococcal antigen in the blood.

Patients with isolated (localized) mild-to-moderate pulmonary disease have lower fungal burden and may be treated upfront with fluconazole (400 mg per day) for 6–12 months. The duration of treatment may be prolonged until the serum cryptococcal antigen is negative [10]. Prior to embarking on this treatment regimen, disseminated cryptococcal disease should be excluded with a lumbar puncture and culture of the blood and urine [10].

Monitoring of drug levels during antifungal therapy may be needed to avoid drug-associated toxicities. Flucytosine is a common cause of bone marrow suppression, especially in the setting of renal impairment. Therefore, routine monitoring of flucytosine levels is recommended, with the goal of 2-h postdose level being 30–80 μg/mL. The potential for drug-drug interaction should be considered when fluconazole is used, since azoles are potent inhibitors of CYP 3A4, which decreases hepatic metabolism of calcineurin inhibitors, thereby resulting in supratherapeutic levels of tacrolimus and cyclosporine. Voriconazole, itraconazole, and posaconazole have greater potential for drug-drug interactions compared to fluconazole and do not offer additional benefit compared to fluconazole [5].

Cryptococcal meningitis causes significant inflammation with the development of a film that prevents the absorption of the CSF, and this may result in the elevation of the intracranial pressure. Patients with cryptococcal meningitis should therefore have routine measurement of the intracranial pressure during lumbar puncture. Patients with initial opening pressure >25 mmHg should have therapeutic lumbar punctures to reduce the intracranial pressure to <20 mmHg [10]. If the intracranial pressure remains high, either a lumbo-peritoneal or an external ventricular drain can be placed as a bridge to eventual ventriculoperitoneal shunt placement. Uncontrolled and prolonged raised intracranial pressure from cryptococcal meningitis may lead to hydrocephalus, blindness, and death [57].

Cautious reduction in immunosuppression is another component of therapy that is essential in the successful management of cryptococcal disease. However, there should be gradual reduction of net immunosuppression during antifungal therapy, since drastic reduction has been associated with organ rejection for SOT recipients, worsening of graft-versus-host disease in HSCT recipients, and development of IRIS [10].

Cryptococcal Immune Reconstitution Inflammatory Syndrome

Cryptococcal IRIS may occur in some patients treated for cryptococcal disease, especially if there is an abrupt restoration of host immunity. IRIS is characterized clinically by

exacerbation of the signs and symptoms, and it has been mistaken as treatment failure or clinical relapse [37]. The incidence of cryptococcus-associated IRIS in SOT recipients is estimated to be 5–10% [58]. The pathogenesis of cryptococcus-associated IRIS represents an intricate relationship between the fungus, immunosuppressive agent, and the type of host inflammatory immune response. Experimental studies have shown that *C. neoformans* has immunomodulatory characteristics and preferentially inhibits Th1 while inducing Th2 responses. Immunosuppressive agents used to maintain graft function such as tacrolimus, cyclosporine, and corticosteroids suppress the production of cytokines stimulated by Th1 cells to a varying degree. Withdrawal of these agents, especially tacrolimus, may lead to an increase in proinflammatory cytokines and subsequent development of IRIS.

Cryptococcus-associated IRIS often presents clinically between 4 and 6 weeks upon initiation of antifungal therapy [58]. Risk factors include potent baseline immunosuppression and disseminated cryptococcal disease. In one study, the risk of IRIS was higher in patients receiving triple immunosuppressive regimen [59]. Clinical manifestation is highly variable, and this may include exacerbation of hydrocephalus, aseptic meningitis, cerebral mass lesions, pulmonary nodules, cellulitis, and lymphadenitis [37]. The clinical manifestation may be so severe that it may cause significant morbidity. There are currently no laboratory markers or clinical criteria that can reliably distinguish IRIS from worsening cryptococcosis. However, IRIS may be considered if there is (1) new or worsening appearance of clinical manifestations, (2) symptoms occurred during receipt of appropriate antifungal therapy and could not be explained by a newly acquired infection, and (3) negative results of cultures for *C. neoformans* during the diagnostic workup for the inflammatory process [48]. An increase in serum cryptococcal antigen titer and/or visualization of cryptococcus in histopathology specimens are not strictly indicative of treatment failure, as both have been described in SOT recipients with crypto-associated IRIS [58]. Maintaining a high index of clinical suspicion for IRIS is crucial to avoid unnecessary adjustments and changes in antifungal therapy. Ultimately, the key feature that distinguishes cryptococcal IRIS from treatment failure is the persistently negative fungal cultures with IRIS.

The management of cryptococcal-associated IRIS in transplant recipients is similar to that in nontransplant patient population and is symptom centric. If symptoms are minor, they usually resolve spontaneously within a few weeks. Corticosteroids (e.g., prednisone 0.5–1 mg/kg) may be considered for more severe manifestations of pulmonary and other sites, especially if the CNS involved. If used, the corticosteroids are generally tapered over 6–8 weeks [10].

Prognosis of Cryptococcal Disease in Transplant Recipients

The overall mortality rates in SOT recipients with cryptococcosis is about 14% [21], although other studies have reported as high as 33–42% [20]. In HSCT recipients, the assessment of outcomes is limited due to a small number of reported cases. Long-term outcomes were only reported in four of nine HSCT patients; two were alive and two had died at the end of the follow-up, suggesting a mortality rate of 50% [12].

The mortality rate varies according to extent of organ involvement; it may be as high as 49% in patients with CNS involvement, while it can be as low as 2.8% in isolated pulmonary cryptococcal disease [20]. Risk factors for higher mortality are altered mental status, absence of headache, and liver and renal failure [47]. For CNS disease, patients with brain parenchymal lesions had a mortality rate of 50%, while those with leptomeningeal lesions had a mortality rate of 12.5% [37, 60]. Serum and CSF cryptococcal antigen titers have not been found to correlate with outcomes. Patients on calcineurin inhibitors appear to be at lower risk of death [61].

Conclusions

Cryptococcosis is the third most common invasive fungal infection in SOT recipients, whereas seldom seen in HSCT recipients. Most infections in transplant recipients are due to *C. neoformans*. Pulmonary disease is the most common clinical presentation, although extrapulmonary disease such as CNS infection is a well-recognized extrapulmonary complication of cryptococcosis. Diagnosis can be confirmed with the use of culture and antigen testing. Depending on disease severity and extent of infection, treatment consists of lipid formulations of amphotericin B, flucytosine, and fluconazole. Reduction in immunosuppression should also be considered as an important component of infection management. This, however, should be approached with some caution due to the concern for the potential risk of cryptococcus-associated IRIS.

Histoplasmosis, Coccidioidomycosis, and Diseases Due to Other Endemic Fungi in Transplant Recipients

36

Pascalis Vergidis, Chadi A. Hage, and L. Joseph Wheat

Introduction

Endemic mycoses are a diverse group of fungal infections that can cause disease in both healthy and immunocompromised individuals. Histoplasmosis, coccidioidomycosis, and blastomycosis are the three major endemic mycoses encountered in North America. Paracoccidioidomycosis is endemic in South America and penicilliosis in Southeast Asia. Sporotrichosis, typically a lymphocutaneous infection, can disseminate in the immunocompromised host. Endemic fungi occur naturally in the environment in specific geographic areas and are thermally dimorphic; they exist as molds at ambient temperature and as yeasts or spherules in the case of coccidioidomycosis, at body temperature.

Among transplant recipients, endemic mycoses are less commonly encountered compared to infection caused by opportunistic fungi. Based on data from the Transplant-Associated Infection Surveillance Network (TRANSNET), 1208 invasive fungal infections occurred among 1063 solid organ transplant (SOT) recipients in 15 US centers for the period 2001–2006 [1]. Of those, 18.8% were caused by *Aspergillus* spp. and 5.3% by endemic fungi. Among hematopoietic stem cell transplant (HSCT) recipients, endemic mycoses are less common. Based on the TRANSNET database, 983 invasive fungal infections occurred among 875 HSCT recipients in 22 centers [2]. Of those, 43% were caused by *Aspergillus* spp. and only 0.6% by endemic fungi. Because each endemic fungal infection is unusual outside of a specific geographic area, a careful travel and residence history should be obtained, preferably at the time of pretransplant evaluation. Otherwise, the diagnosis may be missed and appropriate treatment may be delayed or not given.

Histoplasmosis

Histoplasma capsulatum is the causative agent of histoplasmosis. There are two varieties causing human disease: var. *capsulatum* and var. *duboisii*. These vary in their geographic distribution. In the mold phase, septate hyphae produce microconidia and macroconidia. Tuberculated macroconidia with their thick wall and radial, fingerlike projections are used for identification of the organism in culture. Budding yeast cells of *Histoplasma* are small (2–4 μm), narrow, and ovoid in shape.

Epidemiology

Soil contaminated with bird droppings or excrements of bats is the common natural habitat. The disease is endemic in the Mississippi and Ohio River valleys, Central America, the Caribbean, several countries in South America, and parts of Southeast Asia and Africa. *H. duboisii* is the cause of African histoplasmosis. Histoplasmosis is the most common endemic mycosis among transplant recipients in North America. This may be explained by the large geographic area that harbors the mold. However, even in endemic areas, the incidence is low and has been estimated to be 1 case per 1000 transplant-person-years [3]. In 586 patients undergoing solid organ or allogeneic bone marrow transplantation in Indianapolis, a hyperendemic area, none of them developed histoplasmosis after a mean follow-up period exceeding 16 months [4]. On the other hand, during two large outbreaks that occurred in Indianapolis between 1978 and 1981, rates of 2.1% were reported among allograft recipients [5].

Pathogenesis

Cell-mediated immunity provides the primary host defense against *H. capsulatum*, explaining the severity of disease in transplant recipients who receive potent T-cell immunosuppressants. Following transplantation, histoplasmosis is predominantly acquired from the environment via inhalation of molds. As the organism remains in tissue for prolonged periods following infection, it has been proposed that disease can occur following endogenous reactivation. However, there is no clear evidence supporting this mechanism of disease acquisition. In a study of autopsy specimens, *Histoplasma* could not be grown from calcified pulmonary granulomas in which yeast cells were seen and granulomas failed to cause histoplasmosis when injected into mice [6]. Rather than reactivation, conversion of latent infection-acquired pretransplant into symptomatic disease is a plausible mechanism of posttransplant histoplasmosis. Far less commonly, infection may be derived from the allograft if the disease went unrecognized in the donor [7].

Clinical Manifestations

Respiratory disease presents with fever, chills, cough, and dyspnea, which can progress to severe hypoxemia. Imaging usually reveals miliary or diffuse reticulonodular infiltrates. Mediastinal and hilar adenopathy is rarely seen in immunosuppressed patients. Disseminated disease is more likely to develop in the immunocompromised host. Besides fever and chills, manifestations include malaise, anorexia, and weight loss. Hepatomegaly and splenomegaly are common physical findings. Gastrointestinal manifestations include painful, nonhealing mucosal ulcers, abdominal pain, and diarrhea. Cutaneous manifestations include erythematous macules, necrotic or hyperkeratotic papules, and nodules. Central nervous system (CNS) involvement occurs in 5–10%, presenting as chronic meningitis or focal brain lesions. Patients with severe infection may present with shock, respiratory failure, or disseminated intravascular coagulation. Laboratory abnormalities include pancytopenia due to bone marrow involvement and elevated liver enzymes, particularly alkaline phosphatase. Symptom onset may range from months to years after transplantation [3, 8]. If the donor has unrecognized active histoplasmosis at the time of transplantation, disease in the recipient typically manifests within months after transplantation [7].

Among transplant recipients an immune reconstitution inflammatory syndrome (IRIS) has been described, mainly in association with cryptococcal infection [9]. Patients present with new or worsening clinical or radiographic manifestations or an inflammatory mass while receiving appropriate antifungal therapy [10]. Culture results are negative and biomarker levels are stable or decreasing. For histoplasmosis, the syndrome has been described among patients with AIDS initiating antiretroviral treatment and patients discontinuing tumor necrosis factor-α blocker therapy. Among transplant recipients, IRIS associated with histoplasmosis could occur after reduction in potent immunosuppressive therapy.

Diagnosis

Diagnosis is established by growing the organism from respiratory secretions, blood, other body fluids, or biopsy tissue. Typically culture methods require up to 4 weeks for growth and hence do not provide a rapid diagnosis. The yield from blood cultures is enhanced by using the lysis-centrifugation system (Isolator tube system) [11]. Automated blood culture systems have a lower yield and take a longer time to show growth. Cutaneous, oral, or gastrointestinal lesions may also be sources for isolation of the fungus. Detection of yeast cells on tissue biopsy allows for rapid identification. Periodic acid-Schiff stain or methenamine silver stain should be used in biopsy specimens. Appropriate tissues include lung, mucocutaneous lesions, liver, and bone marrow. For direct detection from respiratory specimens, calcofluor white staining can be used. This binds with chitin and allows for detection of fungi using fluorescent microscopy. Potassium hydroxide is added to hasten clearing of viscous specimens. Yeast cells may also be detected using Wright's stain in peripheral blood smears within polymorphonuclear cells and/or monocytes.

The *Histoplasma* enzyme-linked immunoassay (EIA) can detect the cell wall polysaccharide antigen in serum, urine, bronchoalveolar lavage (BAL) fluid, or cerebrospinal fluid (CSF), and has become a useful diagnostic tool, especially in immunosuppressed patients who may not be able to mount an immunologic response. Results are available within 1–2 days after collection of the specimen allowing for rapid diagnosis. To increase the yield of the assay, both serum and urine should be tested in suspected cases. Repeated testing is recommended in patients with suspected disease progression, if initial results are negative. In a multicenter study, antigenuria was present in 91.8% of 158 patients with disseminated disease and 96.3% of patients who had undergone solid organ transplantation [12]. Urine antigen was detected more often and at higher levels in immunosuppressed patients and those with severe disease.

Cross-reactivity in the *Histoplasma* antigen assay can occur in infections due to other endemic fungi, such as *Paracoccidioides brasiliensis*, *Penicillium marneffei*, *Blastomyces dermatitidis* [13], and *Coccidioides immitis* [14]. Of note, *Histoplasma* and *Blastomyces* antigens are immunologically identical. In patients with disseminated histoplasmosis, false-positive reactions with the *Aspergillus*

galactomannan assay have been reported [15]. There have been no reports of false-positive *Histoplasma* antigen in the serum of patients with invasive aspergillosis, but 8.3% of BAL fluid specimens positive for *Aspergillus* galactomannan were positive for low levels of *Histoplasma* antigen (below the limit of quantification) [16]. Patients with histoplasmosis may have a positive beta-D-glucan assay [17]. Hence, *Histoplasma* antigen should be determined in patients with positive results for *Aspergillus* galactomannan or beta-D-glucan assays if they have a relevant epidemiologic history.

Antibody detection by means of immunodiffusion (ID) or complement fixation (CF) is a useful diagnostic tool. In the ID test, results are reported as M or H precipitin bands. Most patients will develop an M band. The H band is seen in less than 20% of patients, mainly in those with disseminated infection, chronic cavitary pulmonary histoplasmosis, or more severe acute pulmonary histoplasmosis. The M band becomes positive sooner than the H band and persists longer [18]. The CF test uses antigen from the yeast and mycelial forms. Titers of 1:32 or higher are highly suggestive of active infection. With the currently used immunosuppressive regimens, antibody is detected in only 18–33% of infected SOT recipients [3, 12]. Antibodies may persist for several years following recovery and may not indicate active disease. Furthermore, cross-reactions are possible in patients with other endemic mycoses.

Molecular detection methods are not standardized and their role remains limited. Using two nested PCR assays, *H. capsulatum* was detected in 20/29 (68.9%) formalin-fixed, paraffin-embedded tissue specimens [19]. Using a real-time PCR assay, the organism was directly detected in 11/15 (73.3%) clinical specimens, but in only 2 of 6 (33.3%) specimens of BAL fluid [20]. Finally, PCR is less sensitive than *Histoplasma* antigen. PCR was positive in urine in 7.8% [21], BAL fluid in two of nine (22.2%), serum in none of ten, and CSF in none of ten patients with positive *Histoplasma* antigen in the respective body fluids [22].

Treatment

The Infectious Disease Society of America (IDSA) has published guidelines for the treatment of histoplasmosis [23]. Antifungal agents are presented in Table 36.1. Treatment should be initiated with a lipid formulation of amphotericin B.

Table 36.1 Antifungal agents used for the treatment of endemic mycoses

Antifungal agent	Dosage and duration of treatment	Comment
Liposomal AmB	3 mg/kg/d for 1–2 weeks For CNS disease: 5 mg/kg/day for 4–6 weeks Dose adjustment not needed for renal dysfunction	Lipid formulations are preferred in transplant recipients due to the lower risk of nephrotoxicity After a favorable clinical response to AmB, treatment can be transitioned to an oral azole
AmB lipid complex	5 mg/kg/day for 1–2 weeks Dose may be adjusted for acute renal dysfunction	
AmB deoxycholate	0.7–1 mg/kg/day If renal dysfunction, one may need to reduce dose or take the dose every other day to reduce risk of further nephrotoxicity	
Itraconazole capsule or oral solution	Loading dose 200 mg po q8h for the first 3 days, followed by 200 mg po q12h thereafter Higher doses may be used based on serum concentrations Dose unchanged for Cl_{cr} > 10 mL/min $Cl_{cr} \leq$ 10 mL/min: 50% of normal dose Prophylaxis: 200 mg/day	Preferred agent for histoplasmosis and blastomycosis Administer capsule with food or acidic beverage Target serum concentration (random): 1–10 μg/mL (combined itraconazole and hydroxy-itraconazole) by HPLC or 3–10 μg/mL by bioassay
Fluconazole	200–800 mg po daily Consider loading with 2× maintenance dose Cl_{cr} 50–80 mL/min: Dose unchanged Cl_{cr} 10–49 mL/min: Usual load and then 50% of normal dose Cl_{cr} < 10 mL/min: Usual load and then 25% of normal dose	Preferred agent for central nervous system coccidioidomycosis Drug-level monitoring is typically not required
Voriconazole	≥40 kg: 200 mg po q12h (increase to 300 mg q12h if inadequate response) <40 kg: 100 mg po q12h (increase to 150 mg q12h if inadequate response) Dose unchanged for renal dysfunction	Drug-level monitoring recommended, target trough concentration: 1–5 μg/mL
Posaconazole	600–800 mg po daily in 2–4 divided doses Dose unchanged for renal dysfunction Prophylaxis: 200 mg three times daily	Obtain with fatty meal Drug-level monitoring recommended, target trough concentration: 0.5–1.5 μg/mL
Echinocandins	Not indicated for endemic mycoses	Their role in combination with other antifungals against endemic mycoses has not been established

AmB amphotericin B, *Cl_{cr}* creatinine clearance, *HPLC* high-performance liquid chromatography

In a randomized controlled trial, the liposomal formulation was more effective and less nephrotoxic than amphotericin B deoxycholate in patients with AIDS [24]. In a recent case series of posttransplant histoplasmosis, 94% of patients treated with amphotericin B had a favorable response [3, 8]. Nephrotoxicity remains a problem even in patients treated with the lipid formulations**.**

After intravenous therapy, transition to an azole antifungal can be made if the patient is afebrile, clinically stable, and able to take oral medications. Itraconazole is the treatment of choice and is available in capsule form and as oral solution. Capsules require food and an acidic gastric pH for solubilization. Absorption can be increased by concurrent ingestion of cola or cranberry juice and is impaired by drugs that interfere with gastric acidification (such as proton pump inhibitors). The oral solution has better bioavailability but is more commonly associated with gastrointestinal upset. Serum concentrations should be measured after achieving steady-state levels (typically after the second week of therapy). Because of the long half-life of itraconazole, serum samples may be obtained independent of the drug administration time. Concentrations are determined by high-performance liquid chromatography (HPLC) or bioassay. Combined drug concentrations (parent drug and hydroxy-itraconazole metabolite) as determined by HPLC of at least 1 mcg/mL and lower than 10 mcg/mL are recommended. Concentrations determined by bioassay vary among different laboratories and are higher than the concentrations determined by HPLC. Concentrations of at least 3 mcg/mL determined by bioassay are recommended. Serum concentration should be measured after starting treatment and repeated if initial values are low, if the dose is modified, and if there is concern about compliance, absorption, or relapse. Of note, itraconazole may increase the levels of cyclosporine, tacrolimus, and sirolimus. Monitoring immunosuppressant concentrations is recommended.

Fluconazole is a second-line agent and should be used only in patients who cannot tolerate itraconazole or are unable to achieve therapeutic concentrations. Voriconazole and posaconazole are active in vitro and have been studied in a few patients intolerant of or who have failed other therapies [25, 26]. Their effectiveness in comparison to itraconazole is unknown. Of note, *Histoplasma* may develop resistance to fluconazole and voriconazole during therapy [27]. Echinocandins are not active and should not be used [28, 29].

Most patients respond quickly to appropriate antifungal therapy. High mortality rates may be related to delays in timely disease recognition. Antigenemia declines during the first month of treatment, followed by a decline in antigenuria [8, 30]. Monitoring antigen concentration is useful in assessing response to treatment and diagnosing relapse. Antifungal treatment is recommended for at least 12 months, but may not be required for life. The safety of discontinuation of life-long suppressive therapy has been demonstrated in patients with AIDS. In patients who have responded to antiretroviral treatment with an increase in their CD_4 count above 150 cells/mm^3, and have no clinical or laboratory signs of histoplasmosis, itraconazole therapy can be safely stopped [31]. The safety of treatment discontinuation has not been established in transplant recipients, but feasibility has been reported [8]. Decisions should be based on appraisal of the net state of immunosuppression in individual patients.

Prevention

Transplant recipients should be informed about activities that carry a high risk of acquiring histoplasmosis. These include excavation, demolition, or remodeling of old buildings, cleaning debris from attics or barns, shoveling bird or bat manure, cutting or burning wood, tearing down structures on which birds and bats may have roosted, and spelunking [32].

Candidates for transplantation who reside or have traveled to areas endemic for histoplasmosis should be carefully evaluated for a history of pneumonia or systemic illness characterized by fever and weight loss. Radiographic abnormalities consistent with histoplasmosis form the basis for further testing. If the clinical and laboratory findings indicate active disease during the 2 years preceding transplantation, itraconazole treatment for a few months before transplantation, if feasible, and 6–12 months following transplantation should be considered. Studies in SOT and HSCT recipients have shown that pretransplant recipient serologies or radiographic findings of prior infection (such as pulmonary nodules or calcified mediastinal lymph nodes) are not associated with posttransplant histoplasmosis [4, 33]. As such, routine pretransplant screening in the absence of history of active disease is not recommended.

Potential living donors should be evaluated before organ donation. If there is prior history of histoplasmosis, undiagnosed pneumonia in the last 2 years, clinical or radiographic findings suggestive of disease, further testing should be performed. The presence of an H band, CF titers of 1:32 or higher, antigenuria, or antigenemia suggest active infection. M bands and CF titers of 1:8 to 1:16 may represent active or inactive infection. In the presence of active disease, the donor should be treated for 3–6 months before organ donation. Antifungal therapy and close monitoring for 1 year following transplantation should be considered in the recipient. For deceased or living donors, organs should be inspected for the presence of granulomas at the time of procurement (Fig. 36.1). Suspicious lesions should be examined by histopathology and fungal culture. Additionally, antigen and antibody testing of the donor should be performed. If cultures or

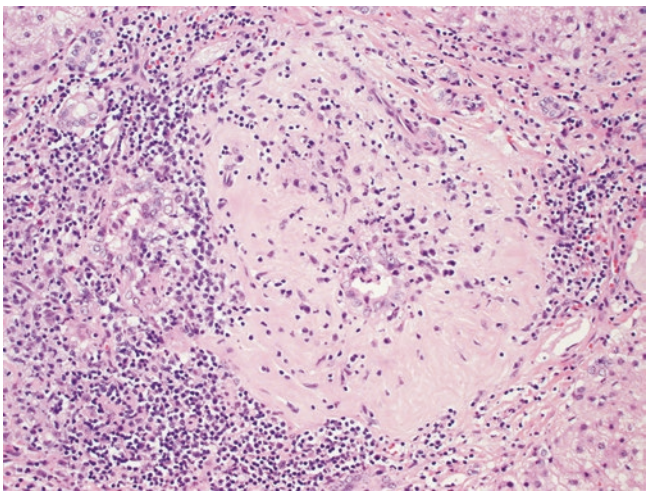

Fig. 36.1 Donor liver biopsy demonstrating scattered non-necrotizing granulomas (hematoxylin and eosin stain, ×200). No yeast cells were detected. The recipient developed disseminated histoplasmosis 1 month posttransplant

antigen tests are positive, the recipient should be treated for 12 months. If cultures and antigen tests are negative but antibodies are detected, a 3–6-month course of itraconazole is recommended.

Coccidioidomycosis

The genus *Coccidioides* contains two species, *C. immitis* and *C. posadasii*. These are morphologically identical but genetically and epidemiologically distinct. Hyphae and arthroconidia are produced at ambient temperature. Hyphae are hyaline, septate, and thin. Arthroconidia are thick-walled and barrel-shaped. At body temperature, large, round, thick-walled spherules (10–80 μm in diameter) filled with endospores (2–5 μm in diameter) are observed.

Epidemiology

Coccidioides is found in soil particularly at warm and dry areas with low rainfall, mild winters, and high summer temperatures. It is endemic in the desert Southwestern United States (mainly southern Arizona and Central California), Northern Mexico, and certain areas in Central and South America. *C. immitis* is the predominant species in California. *C. posadasii* is mainly found in the remainder of the endemic areas. Infection is common as the organism is easily dispersed by desert winds. Skin test positivity rates of 30% were reported in a study conducted between 1977 and 1979 in Tucson [34]. The rate of reported coccidioidomycosis in Arizona has increased from 21 cases per 100,000 population in 1997 to 91 cases per 100,000 in 2006 [35]. Besides mandatory reporting, this increase in incidence may be explained by climatic changes.

From 1970 to 1979, coccidioidomycosis occurred in 6.9% of renal transplant recipients residing in Arizona [36]. After 1999, the overall infection rate among transplant recipients was 1.5% (1.3% in renal, 2.1% in allogeneic bone marrow, and 2.5% in liver transplant recipients), which is similar to the estimated rate among all residents of the endemic area [37]. Among 37 liver transplant recipients who received their allograft at an area of low endemicity and moved to an endemic area, only one (2.7%) developed coccidioidomycosis within at least 1 year of follow-up [38]. Disease has also been reported in transplant recipients who visited endemic areas [39, 40], but the actual risk is unknown.

Pathogenesis

Infection is acquired by inhalation of the spores (arthroconidia) that transform into spherules within the airways. The rupture of mature spherules releases endospores, which can settle in the lung parenchyma or spread via blood circulation. Disease progresses as each endospore forms a new spherule. In the normal host, disease is usually self-limited and results in long-lived immunity, which protects from a second infection. For unclear reasons, individuals of Filipino or African ancestry have a higher risk of developing disseminated disease. Patients with impaired cell-mediated immunity, such as transplant recipients, are also at increased risk for dissemination. Disease may occur after primary infection and reactivation or may be transmitted from the donor.

Clinical Manifestations

In the normal host, disease is usually asymptomatic or manifests as a mild respiratory illness. In the immunocompromised host, pulmonary disease presents with high fever, cough, dyspnea, and hypoxemia. Skin rash may be accompanied by muscle and joint pain. Disease may progress to fulminant respiratory failure. Typical radiographic findings include diffuse reticulonodular infiltrates. Cavitary lesions may be seen. Some patients may present with fatigue, anorexia, and weight loss. The most frequently involved extrapulmonary sites are the skin, osteoarticular structures, and meninges. Skin lesions include papules, pustules, or nodules that commonly ulcerate. Meningeal involvement results in headache, cranial nerve palsies, and signs of increased intracranial pressure. Hydrocephalus may occur, especially in children. The most feared complication is CNS vasculitis leading to cerebral ischemia, infarction, and hemorrhage.

In the transplant recipient, disease can occur at any time but is more common during the first year after transplantation [41]. Donor-derived disease has been reported within the first posttransplant month in patients not receiving antifungals, as the disease was not recognized in the donor [42–44]. Donor-transmitted infection has also been manifested after antifungals were discontinued [45].

Diagnosis

Diagnosis is established by growing the organism from sputum, BAL fluid, blood and other body fluids, or biopsy tissue. *Coccidioides* usually grows on routine laboratory media within 7 days. When coccidioidomycosis is suspected, the clinician should alert the microbiology laboratory since the organism is highly contagious. In respiratory specimens, spherules can be detected using calcofluor white staining. Spherules can be detected in tissue biopsy using hematoxylin and eosin or special stains such as methenamine silver. Notably, spherules do not take up Gram stain.

Anti-coccidioidal antibody titers, although specific, may take several weeks or months to rise after the onset of illness, especially in patients with impaired immunity. Moreover, in immunosuppressed patients with disseminated disease, serologic tests may remain negative. ID methods for both IgM and IgG antibodies are commonly used. Available assays are qualitative and quantitative [46]. A positive qualitative test should be confirmed with CF or quantitative ID. Tube precipitin-type antibodies, considered to be IgM, develop relatively early during infection (within the first 3 weeks of symptoms). Complement-fixing antibodies, considered to be IgG, are typically detected later in the course of the disease. Antibody detection in CSF is useful in diagnosing meningitis. Finally, an EIA for IgM and IgG antibodies is highly sensitive, but less specific than ID [47]. Combining the results of serologic tests can increase the diagnostic yield. Among 62 immunosuppressed patients with coccidioidomycosis, 84% were seropositive using all methods [48].

For moderate to severe disease, detection of urine *Coccidioides* antigen by means of an EIA was found to have a sensitivity of 70.8% [49]. Cross-reactions with other endemic mycoses can occur. The role of molecular methods has not been established. A real-time PCR assay has been validated in clinical specimens [50] and is offered in reference laboratories. The assay demonstrated a sensitivity of 75% and specificity of 99% compared with culture of respiratory specimens [51].

Treatment

The Infectious Diseases Society of America has published treatment guidelines [52]. Clinicians who practice in the Southwestern United States are familiar with this disease. Seeking advice from a specialist with experience in treating coccidioidomycosis may be of benefit. All transplant recipients should receive antifungal treatment (Table 36.1). The choice of intravenous versus oral therapy depends on the degree of respiratory compromise or rate of disease progression. The use of amphotericin B is favored in more severe disease. Lipid formulations are preferred due to the lower risk of nephrotoxicity, even though these agents have not been specifically studied for coccidioidomycosis in clinical trials. After a favorable clinical response, treatment can be transitioned to an oral azole. In a randomized trial of oral itraconazole (200 mg twice daily) versus oral fluconazole (400 mg daily) for the treatment of nonmeningeal progressive coccidioidomycosis, there was a trend toward greater efficacy with itraconazole at 12 months [53]. Regarding fluconazole use, higher doses (800 mg daily) are preferred and are generally well tolerated. Even for widespread disease, there is no evidence that combination treatment with amphotericin B and an azole is superior to treatment with a single agent. There are anecdotal reports of successful use of voriconazole for the treatment of coccidioidomycosis [54–56]. In small series, posaconazole has been used for refractory disease [57–59]. Overall, experience with the newer triazoles is limited in transplant recipients. Echinocandins should not be used. Patients should receive antifungal treatment for at least 1 year. Lifelong azole prophylaxis to prevent disease relapse should be considered.

For meningeal disease, the treatment of choice is fluconazole. Currently, most experts treat with daily doses of 800 mg or higher. In clinical trials, the dose used was 400 mg per day [60]. Some experts combine azole treatment with a lipid formulation of amphotericin B on the basis of the belief that responses are more prompt with this approach. In a small series of patients with refractory disease, itraconazole therapy was also found effective [61]. Patients who respond to azole therapy should continue this treatment indefinitely [62]. Hydrocephalus, a complication which frequently requires shunt decompression, does not per se indicate the need for alternative antifungal treatment.

Clinical and laboratory follow-up at frequent intervals to assess treatment response is advised. Fluconazole has high oral bioavailability and predictable pharmacokinetics; hence, serum drug concentrations are rarely obtained. If itraconazole is used, concentrations of at least 1 μg/mL by HPLC (combined itraconazole and hydroxy-itraconazole) and 3 μg/mL by bioassay are recommended. If serology was positive at diagnosis, response to treatment should be monitored using quantitative ID or CF assays. Coccidioidomycosis can be fatal, especially in transplant recipients who are at risk for dissemination. As the number of infected recipients is small, mortality rates have varied widely. In a single-center retro-

spective study (1999–2007), mortality was 13% (2/15) among liver transplant recipients [41]. In a literature review (1966–2002), mortality was 55% (18/33) among renal transplant recipients [63].

Prevention

Exposure to dust is an established risk factor for coccidioidomycosis. Activities related to disturbance of the soil, such as agricultural work, appear to be associated with development of disease, and transplant recipients should be informed about the risk. However, exposure to contaminated dust cannot be totally prevented in areas of endemicity.

For the transplant candidate diagnosed with active disease, transplantation should be postponed until clinical manifestations and radiographic abnormalities have resolved with antifungal treatment. Ideally, CF titer should decrease to 1:2 or less before considering transplantation. If there is evidence of active disease at the time of transplantation, antifungals should be continued lifelong. There is no clear consensus about the optimal posttransplant prophylactic strategy for recipients residing in an endemic area who do not have a history of active disease. Some experts recommend universal prophylaxis for all patients in endemic areas while others base it on evidence for active disease including seropositivity. Evidence is not available to determine if prophylaxis prevents posttransplant coccidioidomycosis. At the Mayo Clinic in Arizona, targeted antifungal prophylaxis was administered to those with a history of coccidioidomycosis or positive serologic studies at the time of transplantation. Using this approach, de novo coccidioidomycosis developed in 3% of liver transplant recipients who did not meet the criteria for targeted prophylaxis [41]. More than half of the cases occurred in the first posttransplant year. The authors currently recommend universal antifungal prophylaxis for 6–12 months for those residing in endemic areas.

Potential living donors with a history of travel to or residence in an endemic area should be evaluated for active or past infection. Serologic studies (EIA, CF, and ID), cultures of respiratory secretions, and chest imaging should be obtained. If there is evidence of active infection, the donor is not suitable for organ procurement. Lung transplant recipients from a seropositive donor require long-term antifungal prophylaxis due to the high likelihood of a quiescent granuloma in the lung parenchyma. For deceased or living donors, organs should be inspected for the presence of granulomas at the time of procurement. Suspicious lesions should be examined by histopathology and fungal culture. Serologic studies should also be obtained. If there is evidence of active disease in the donor, fluconazole should be administered indefinitely in the recipient.

Blastomycosis

Blastomycosis is a pyogranulomatous systemic mycosis caused by *Blastomyces dermatitidis*. In the mold phase, narrow branching septate hyphae bear small conidia on a short stalk. The yeast cell (8–15 μm in diameter) has a doubly refractile thick wall and produces a characteristic single, broad-based daughter bud. Two serotypes have been identified based on the presence of the A-antigen.

Epidemiology

The organism exists in warm, moist soil enriched by organic debris including decaying vegetation and wood. Endemic areas include the Southern, Central, and Midwestern United States, especially areas around the Great Lakes and the Ohio and Mississippi River valleys. It also occurs in Canadian provinces that border the Great Lakes and St. Lawrence River. Outside North America, blastomycosis is most common in Africa (typically A-antigen negative strains). Fewer cases have been reported from Central and South America and Western Europe. Blastomycosis is commonly associated with recreational or occupational activities that take place around rivers or lakes. In endemic areas, disease commonly occurs in dogs. Owning an infected pet may provide a useful diagnostic clue, as the dog and its owner may inhale conidia from the same source. Disease transmission to humans following dog bites has been reported [64]. The disease is rarely reported after solid organ transplantation. In two retrospective studies, the cumulative incidence was 0.13% (1996–2008) [65] and 0.14% (1986–2004) [66], respectively. Newly acquired infection typically occurs long after transplantation when patients resume their normal activities.

Pathogenesis

As with other endemic mycoses, the disease occurs after inhalation of conidia from the environment. The lungs are the primary site of involvement. Hematogenous spread can cause focal manifestations at a distant site or disseminated infection. Patients with defective cell-mediated immunity are at highest risk for severe disease. In transplant recipients, blastomycosis may result from conversion of latent infection-acquired pretransplant into symptomatic disease. Donor-derived infections have not been reported but could potentially occur.

Clinical Manifestations

In the normal host, pulmonary disease typically presents with a non-specific flu-like syndrome. In the immunocom-

promised host, multilobar disease is more common and may progress to adult respiratory distress syndrome (ARDS) which is associated with high mortality. Extrapulmonary manifestations usually involve the skin, osteoarticular structures, or the genitourinary system. The disease presents with pustular, nodular, or ulcerative skin lesions. The typical verrucous cutaneous lesions of blastomycosis are not seen in immunosuppressed patients. Osteomyelitis may occur contiguously to or separately from cutaneous lesions. Prostate infection presents with dysuria, perineal pain, or obstructive symptoms. CNS infection typically presents with lymphocytic meningitis. Other manifestations include epidural abscess and intracranial mass lesions [67].

Diagnosis

Blastomyces grows within 2–5 weeks on most culture media at room temperature. The fungus is isolated from respiratory secretions in most cases of pulmonary infection [68]. Direct specimen examination allows for rapid diagnosis. Respiratory specimens should be treated with potassium hydroxide or calcofluor white or stained with Papanicolaou stain. Similarly, exudate from cutaneous or subcutaneous lesions should be examined by wet prep or special stain. Direct CSF examination typically does not reveal the organism in cases of meningitis. Diagnosis can be established by detection of yeast cells consistent with *Blastomyces* in pulmonary or extrapulmonary tissue specimens. These may be difficult to identify with routine hematoxylin and eosin stains. Special stains, such as methenamine silver or periodic acid-Schiff, should be used. The presence of pyogranulomas on biopsy should raise the suspicion for blastomycosis.

Serologic testing includes techniques for detection of antibody to the A-antigen. CF and ID methods lack both sensitivity and specificity. EIAs have shown improved sensitivity, but there are insufficient clinical data to recommend their use as a routine diagnostic tool [69, 70]. Detection of the cell wall polysaccharide antigen by means of an EIA is available. Antigen can be detected in urine, serum, and other body fluids. The sensitivity of the quantitative urine antigen assay is 90% [71–73]. Antigen concentrations are highest in patients with ARDS. Specificity is 99% in patients with nonfungal infections and healthy subjects. The assay shows cross-reactivity with other fungi, particularly *H. capsulatum*, which is endemic in the same areas as *Blastomyces*. Similar to *Histoplasma* antigen, levels decline with successful treatment and increase with disease relapse.

Molecular methods are not widely available and have not been studied extensively. In a real-time PCR assay, detection directly from clinical specimens (mainly respiratory secretions and pleural fluid) demonstrated a sensitivity of 86% and a specificity of 99% [20]. The assay provides a rapid method for the detection of *B. dermatitidis*. Molecular methods may prove useful in detecting the organism from formalin-fixed paraffin-embedded tissue [74].

Treatment

The Infectious Diseases Society of America has published guidelines for the treatment of blastomycosis [75]. All immunocompromised patients should be treated. For moderately severe to severe pulmonary or disseminated disease, treatment should be started with amphotericin B. In transplant recipients, lipid formulations of the drug are preferred due to the lower risk of nephrotoxicity. Treatment can be transitioned to oral itraconazole after clinical improvement. In immunosuppressed patients, antifungal therapy is recommended for at least 12 months. Indefinite treatment may be needed in patients who remain on immunosuppressive agents or those who experience relapse. For CNS disease, a lipid formulation of amphotericin B should be administered for 4–6 weeks followed by an oral azole. Itraconazole is the preferred azole [76]. Fluconazole (400–800 mg daily) is an alternative agent [77, 78]. The newer triazoles are active in vitro. The successful use of voriconazole [65, 79, 80] and posaconazole [81] has been reported in small series or case reports. As with other endemic mycoses, echinocandins are not active. Large abscesses should be drained and devitalized tissue should be debrided in the setting of extensive osteomyelitis. Surgical resection of residual pulmonary cavities is not indicated. In the two published case series, overall mortality among transplant recipients was approximately 36% [65, 66], reaching 67% (4/6) in SOT recipients with ARDS.

Prevention

Transplant recipients should be educated about the risk associated with recreational or occupational activities along waterways in areas of endemicity. Due to the rarity of disease in transplant recipients, the role of pretransplant screening and posttransplant antifungal prophylaxis to prevent blastomycosis has not been defined. In the absence of robust data, an approach similar to the one followed for histoplasmosis seems reasonable.

Other Endemic Mycoses

Paracoccidioidomycosis is a systemic fungal infection caused by *Paracoccidioides brasiliensis*. The organism is endemic in areas of Central and Latin America.

Most cases have been reported from Brazil, particularly among individuals involved in agricultural activities [82]. The lungs are the primary site of involvement but disease can disseminate. Ulcerated painful mucocutaneous lesions are characteristic. Radiographically, diffuse alveolar and interstitial pulmonary infiltrates are seen in acute disease. Paracoccidioidomycosis has been described in single case reports among kidney transplant recipients [83–85]. The organism may be visualized in direct specimens or biopsy tissue. Antibody and antigen detection are useful tools in diagnosing disease and following treatment response [86, 87]. Sulfonamides, amphotericin B, and itraconazole are active against *Paracoccidioides*. The rarity of the infection among transplant recipients may be explained by the routine prophylactic use of trimethoprim-sulfamethoxazole.

Penicilliosis is caused by *Penicillium marneffei*, a dimorphic fungus endemic in most countries in Southeast Asia, Southern China, Taiwan, and Northeast India. Patients may present with pulmonary involvement, diffuse lymphadenopathy, hepatomegaly, and splenomegaly. Skin lesion characteristics of the disease are found on the face, upper trunk, and extremities. Papules may have a necrotic center which gives an umbilicated appearance. The disease has been well described in HIV-infected individuals. Cases of penicilliosis have been reported in renal transplant recipients [88–90]. As with HIV-infected patients, disease has been reported in a transplant recipient after a brief visit to an endemic area [91]. Diagnosis is established by culture and histopathology. Standard treatment involves a formulation of amphotericin B followed by azole therapy.

Sporothrix schenckii is a dimorphic fungus with worldwide distribution. Most commonly, infection presents with ulcerated, verrucous, or erythematous skin nodules which can spread locally via the lymphatic route. Pulmonary involvement, systemic dissemination, and meningeal involvement may occur in the immunocompromised host. Lymphocutaneous infection results from inoculation of the organism into the skin and subcutaneous tissues. Pulmonary disease is acquired via inhalation of arthroconidia. Activities such as landscaping, gardening, or farming have been associated with sporotrichosis. Recurrent systemic disease [92] and urinary sporotrichosis [93] have been reported in renal transplant recipients. Diagnosis is established by culture and histopathology. Treatment guidelines have been published by IDSA [94]. Itraconazole is the treatment of choice for lymphocutaneous and osteoarticular disease. For meningeal, severe pulmonary, and disseminated disease, a lipid formulation of amphotericin B should be used. After the initial clinical response, treatment with itraconazole is recommended.

Cytomegalovirus

37

Amar Safdar and Donald Armstrong

Introduction

Cytomegalovirus (CMV) is a herpesvirus, and similar to other viruses in this group, after an acute infection, the virus establishes lifelong asymptomatic residency referred to as "viral latency". Primary or initial infection in the general population with intact immune response is often a brief and mild illness that requires no therapy. Individuals with latent CMV infection may experience subclinical viral reactivation and unwittingly shed the virus in bodily fluids, such as saliva, tears, semen, breast milk, and urine. In the United States, by the age of 40 years, more than half of adults show serologic evidence of prior CMV infection (www.CDC.gov) [1]. CMV is not considered highly contagious, although the common mode of viral transmission within the members of a shared household, close contacts including children in daycare centers, is via exchange of saliva; it is important to recognize that CMV infection may be acquired after sexual intercourse. Cytomegalovirus infection during pregnancy is a leading cause of permanent birth defects (www.CDC.gov) [1].

Only 8 herpesviruses among more than 100 discovered so far cause disease in humans. These include herpes simplex virus types 1 and 2, varicella-zoster virus, cytomegalovirus, Epstein-Barr virus, human herpesvirus 6 variants A and B, human herpesvirus 7, and Kaposi's sarcoma virus or human herpesvirus 8 that also causes primary effusion lymphomas and the rare multicentric Castleman's disease. A simian virus, called B virus, occasionally infects humans.

Patients with dysfunctional adaptive immune response are at a higher risk for severe CMV infection and end-organ disease [2, 3]. Since it is a common childhood infection, most viremia in immunocompromised patients represents reactivation of a remotely acquired latent infection [2]. End-organ viral disease poses an existential threat for patients with severe immune dysregulation and/or suppression of adaptive cellular immune response [4]. A newly acquired CMV infection in seronegative transplant recipients from an allograft harvested from CMV-seropositive donor has emerged as the most serious risk for post-transplant CMV infection and disease after blood or marrow hematopoietic stem cell or solid organ allograft transplantation (HSCT and SOT, respectively) [3, 5].

In transplant recipients, viral infection or recurrence of a remotely acquired infection is a well-recognized risk factor for end-organ disease that has the potential to involve any organ system. In patients undergoing HSCT, viral pneumonitis, myelosuppression, encephalitis, enterocolitis, hepatitis, and rarely retinitis or adrenalitis may be encountered [3]. CMV organ disease may occur in patients despite effective anti-CMV prophylaxis. Stem cell graft compromise or loss of allograft is another life-threatening complication resulting from direct virus-induced suppression of hematopoiesis. In addition, CMV infection was noted to elevate the risk for graft-versus-host disease (GVHD) [6]. In solid organ allograft recipients, CMV infection and end-organ disease is a well-recognized and serious post-transplant complication that has far-reaching impact on the allograft function and survival [5].

CMV infection is increasingly recognized to influence and elicit multifaceted modifications in hosts' immune response. This appears to be more pronounced in yet unpredictable select group of individuals that undergo allograft transplantation. The virus-induced immune dysregulation has been implicated in fostering vulnerability for secondary fungal and bacterial infections, which additionally influence poor transplant outcomes [7].

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_37

In this chapter, a comprehensive review of cytomegalovirus is presented with pertinent aspects of this opportunistic viral pathogen in patients undergoing transplantation procedures.

CMV Structure

CMV is a double-stranded DNA virus encased in an icosahedral capsid and belongs to the beta (β) subfamily of the *Herpesviridae*. The viral DNA is composed of nearly 230,000 base pairs that encode for approximately 200 proteins [8]. CMV genes are named after their position within each segment of the genome like UL97 is the 97th open reading frame in the unique long segment.

CMV tegument or matrix is composed of a cluster of proteins that lines the space between the envelope and nucleocapsid.

In laboratory cell line cultures, diploid human fibroblasts, endothelial cells, and macrophages support CMV growth ex vivo, whereas, during infection, CMV is found in a variety of cells such as endothelial cells, epithelial cells, smooth muscle cells, and peripheral blood neutrophils [9]. The diverse hosts' tissue tropism for cytomegalovirus plays an important role in viral disease involvement of a wide spectrum of hosts' organ systems.

Like other herpesviruses, CMV persist within the cells in a latent state for the life span of the host and periodically replicated resulting in low-level viremia and viral shedding at various body sites. Latent CMV virus has been shown to exist within neutrophils and monocytes [10, 11]. It is possible that the virus also maintains latent residency in other tissues and abdominothoracic viscera.

CMV Cell Entry

CMV infection of human fibroblasts and epithelial cells requires glycoprotein complexes composed of gB and gH/gL/gO. In addition, for epithelial cell infection, the viral envelope pentamer complex consisting of gH, gL, UL128, UL130, and UL131A is required. Data from vaccine development showed that neutralizing antibodies to gB or gH epitopes can interfere with CMV entry in fibroblasts and epithelial cells [12]. It was interesting that neutralizing antibodies targeting conformational epitopes such as UL128/130/131A that are important components of the viral unit that interacts with hosts' immune receptors did not prevent viral entry into the fibroblasts, although these antibodies were able to cease viral entry into epithelial cells [12]. However, the envelope pentamer complex is highly immunogenic in eliciting neutralizing antibody response against UL128/130/131A subunits and gH, which can effectively block CMV entry into both epithelial cells and fibroblasts [12]. This has been an area of keen interest in designing a novel immunogen construct for effective and durable CMV vaccine.

CMV Immunity

Innate Anti-CMV Immunity

CMV triggers cellular inflammatory cytokine production via TLR pathway. It is known that viral glycoproteins B and gH that are also a part of CMV envelope pentamer complex cause TLR2 activation [13, 14]. Certain genetic polymorphisms in TLR2 were explored to identify potential host vulnerabilities for the risk of CMV infection. In patients undergoing orthotopic liver transplantation, a multivariate Cox hazard model demonstrated a possible link between higher risk of CMV disease after transplantation in patients exhibiting homozygous TLR2 Arg753Gln polymorphism (hazard ratio, 1.9) [15]. This risk for cytomegalovirus remained after adjusting for age, CMV serostatus, and allograft rejection [15].

TLR3 and TLR9 are important in eliciting innate immune defense against CMV replication and infection in mice [16, 17]. In the murine CMV experiments, TLR9 assures rapid antiviral response; this was in concert with other TLR-dependent and TLR-independent innate immune events assisting to garner subsequent adaptive anti-CMV response in the animals studied [17].

Natural killer cells are marrow-derived lymphoid cells that play an integral role in hosts' innate immune response needed to contain an infection after the initial exposure. NK cells are also constituent in orchestrating adaptive immune response. It has been known for some time that patients with various deficiencies in NK cell function are predisposed to serious herpesvirus infections that include CMV and EBV [18, 19]. Activating killer Ig-like receptor (aKIR) plays a central role in NK cell-mediated anti-CMV immunity, and certain stem cell donor aKIR genotypes appear to modify risk for post-transplant CMV infection [20, 21]. One hundred and fifty-two patients with CMV reactivation were compared with 59 with no viral reactivation after HSCT [22]. Presence of specific aKIR haplotypes in the donor, but not in the recipient, were significantly associated with protection from CMV reactivation and the degree of CMV viremia during post-transplant period [22]. A donor aKIR profile exhibiting aKIR2DS2 and aKIR2DS4 predicted low risk of CMV reactivation after transplantation; this was independent of CD4 and cytotoxic T cell-mediated CMV protection [22]. It needs to be further investigated if pre-transplant selection of donor aKIR haplotypes may optimize the risk of post-transplant CMV infection, especially in patients undergoing stem cell

transplantation that are known to have high risk for CMV infection and end-organ disease after transplantation.

NK cells have recently been shown to exert regulatory effect on antiviral T cell response. In part, this is achieved by direct NK cell-mediated killing of activated, CMV-targeted T cells for the purpose of modifying risk of tissue injury from an untamed antiviral cellular immune response [23]. NK cells modify antiviral immune response by destroying dendritic cells, which also serves to restrain continuous antigen presentation and T cell activation in patients with persistent viral infection [24]. It is likely that overall or net immunoregulatory NK cell function is contingent up on the location and extent of inflammation elicited by adaptive antiviral immune response [25].

NK cells are the first lymphoid cells to repopulate after allogeneic HSCT. Innate immunity is axiomatically thought to lack recall or memory function. It was therefore interesting and unexpected to see reports that certain NK cell subsets (Ly49H) exhibit memory following re-exposure to pathogens like cytomegalovirus [26].

In addition, the association between post-transplant risk of CMV reactivation and disease and presence of simple genetic aberrations in chemokine receptor 5, IL-10, and monocyte chemoattractant protein 1 is intriguing and needs further clinical verification [27].

Adaptive Immunity

CD8 cytotoxic T lymphocyte (CTL) response is an important feature of adaptive immune response against cytomegalovirus [28]. CTL responses against viral epitopes like UL123 (IE-1), UL122 (IE-2), and UL83 (pp65) are most prominent and robust [28–31]. The clinical significance of CMV cellular immunity in controlling viral replication is demonstrated in studies that show causal relationship between viremia and lack of CMV-specific CTLs, whereas post HSCT reconstitution and recovery of CMV-specific cytotoxic T cell provide protection from CMV infection and end-organ viral disease [32–34].

CMV-specific CD4 helper T cells also play an important role in protection from CMV disease in patients undergoing allogeneic stem cell transplantation [35–37]. In patients with late post-transplant CMV infection, inadequate CMV-specific helper T cell responses were noted as a risk for late CMV disease and death [38]. Since cytotoxic response forms the backbone of adaptive cellular immunity against CMV infection and disease, it was proposed that a virus-specific helper T cell in most part assists in sustaining a forceful cytotoxic antiviral response [34]. The emerging role of gamma delta (γδ) T cells in protection against CMV infection is of interest and needs to be explored further [25].

The role of humoral immunity against CMV disease in patients after allograft transplants remains uncertain. Following naturally acquired CMV infection, antibodies are produced against various viral proteins, and anti-gB and anti-gH antibodies are thought to limit the extent of CMV disease progression after the initial infection [39, 40]. However, anti-CMV antibodies thus far have shown to play a limited or no role in containment or prevention of CMV disease after stem cell allograft transplantation.

CMV Immune Evasion

Cytomegalovirus has developed and refined a number of evolutionary mechanisms to elude and avoid mammalian immune surveillance. In the past three decades, a number of sophisticated viral methods have come to light. Some of the salient functional features of CMV genes to achieve this goal include (a) impede apoptosis of CMV infected [41], (b) MHC-I restricted antigen presentation [42], and (c) blocking interferon-assisted antiviral response [43–45].

CMV also encodes proteins that are homologues to hosts' cellular proteins. Among them, proteins that resemble MHC Class-I molecules, IL-10, TNF receptors, and chemokines including CXC-1 help CMV to dodge hosts' immune surveillance [46–51].

NK cells are effective deterrent against viral infection, although CMV among other herpesviruses have developed means to avoid NK cell attack by pirating MHC-like domains, thereby attenuating an important element of host's innate antiviral immune defense [52]. It is important to note that CMV has the capability to modulate NK cell functions including cell maturity; and possibly recall or memory after the initial viral exposure, the later obervation needs further investigation [53].

CMV and Hematopoiesis

Since early 1990, CMV DNA could be isolated from the marrow cells in healthy CMV-seropositive individuals being considered for stem cell harvest [54]. It was also shown that CMV can render severe and potentially irremediable damage to the bone marrow stroma, crippling the rate of regeneration of pluripotent stem cell necessary for repopulation and engraftment hematopoiesis [55]. Others in the late 1980s showed that CMV can impair hematopoiesis either through infection of bone marrow stromal cells influencing hematopoietic growth factor production or by a direct viral infection of myeloid cells and their precursors [56].

CMV Diagnosis and Viral Surveillance

CMV IgG and IgM are measured to assess acute or latent infection due to cytomegalovirus. These tests probe the potential risk for post-transplant CMV infection and disease;

however, by itself serology provides no meaningful information for the presence of infection (viremia) or end-organ disease. The ex vivo cultures cannot be clinically relied upon due to slow viral growth in cell lines that may take weeks to identify virus-induced cytopathic effects. It is important to note that culture-proven viremia is highly predictive of CMV disease and probably a reflection of high viral load at the time specimens were collected [57]. The limited utility of CMV cultures has yielded to innovative assays such as shell vial test, which is now seldom used due to lack of sensitivity; however, shell vial when positive could provide evidence of viable replicating cytomegalovirus in the clinical sample, and results could be available within 18–24 h [58, 59].

Tissue samples when obtained may exhibit characteristic "owl's eye" CMV nuclear inclusions, although more sensitive immunohistochemical techniques are now routinely used to identify CMV antigens within the infected cells. It is not uncommon to find intracellular CMV antigens by immunohistochemical test in samples that do not exhibit intracellular or intracytoplasmic viral inclusions.

Advances in molecular techniques that are independent of viral growth in tissue cultures have boosted ability to diagnose CMV infection. Identification of CMV tegument phosphoprotein that is 65 kilodalton in weight (pp65; UL83) in peripheral blood leukocytes by fluorescent anti-pp65 antibodies has become a standard clinical practice for rapid diagnosis of CMV infection, especially in high-risk transplant recipients. CMV pp65 antigenemia assay has adequate sensitivity and specificity, with reliable predictive values. The number of positive cells over the total number of leukocytes per slide provides a semi-quantitative estimation of the CMV viral load in the peripheral blood. A positive CMV pp65 antigenemia has reliable predictive value for end-organ CMV disease in patients undergoing allogeneic HSCT [60]. Conditions with low-peripheral blood leukocyte counts including pre-engraftment severe neutropenia or other post-transplant disorders with low blood neutrophils limit this test's utility. CMV antigenemia test is not valid for diagnosis of CMV infection in other bodily fluid such as CSF, BAL, pleural, and peritoneal aspirate samples. Use of pp65 antigenemia to assess treatment response should include the forethought that once neutrophils are infected by cytomegalovirus, the viral antigens will remain present through the lifespan of these cells and may not be construed as an indicator of real-time viral kinetics in the peripheral blood. Therefore, a decline in pp65 antigenemia may lag behind actual resolution of viremia while on anti-CMV therapy.

Quantitative PCR relies on quantitative amplification of viral DNA. This test has now become the standard for assessing level of CMV viremia in whole blood or plasma. CMV DNA PCR is also used in CSF along with other routine viral PCR for HSV and VZV. PCR is the most sensitive method for detecting CMV viremia and may capture cases where pp65 antigenemia either cannot be performed due to severe neutropenia or provides false-negative result [61]. The results are usually available within 24 h, and the test shows high specificity for presence of cytomegalovirus. It is a direct measurement of viral load and illustrates oscillations in CMV viremia that could reliably predict the risk for CMV end-organ disease [62].

In patients with suspected CMV pneumonitis, CMV PCR in BAL fluid appears to be a sensitive test with good negative predictive values. Due to limited specificity for viral lung disease and inability to distinguish CMV lung disease versus asymptomatic respiratory tract viral shedding, use of CMV PCR in BAL samples is discouraged [63].

Nucleic acid sequence-based amplification (NASBA) is a new technology that measures early-immediate CMV mRNA and appears to be comparable to DNA PCR or pp65 antigenemia for the diagnosis of viremia; providing real-time guidance for preemptive antiviral therapy in patients following stem cell allograft transplantation [64]. Most transplant centers, however, still use pp65 antigenemia or CMV DNA PCR assays. A detailed review of diagnosis of CMV infection and disease is provided in Chaps. 47 and 49.

Risk Factors

Hematopoietic Stem Cell Transplantation

Allograft Stem Cell Transplants

Despite universal screening for CMV viremia and the institution of prophylactic or preemptive antiviral therapy in patients undergoing allogeneic HSCT, a small number of patients end up developing CMV end-organ disease during post-transplant period [65]. Donor and recipient CMV serostatus continues to be an essential factor in selection of stem cell grafts, with an appreciation for potential variability in engraftment kinetics, preparatory conditioning regimens, GVHD prophylaxis, and the underlying malignant versus non-malignant disorders.

The lowest risk of CMV infection and disease during post-transplant period is among seronegative donor and recipient (D−/R−) allograft transplantation. The highest risk (~30%) of newly acquired CMV infection is among seronegative patients undergoing HSCT from a CMV (+) donor (D+/R−). Primary CMV infection that is not transmitted via allograft now rarely occurs in patients given blood and blood products from CMV (+) donor(s) or acquired by natural transmission. It is important to recognize that heightened awareness and strict adherence to CMV screening, antiviral prophylaxis and preemptive therapy protocols, and recent addition of effective and safe antiviral drugs all contribute favorably toward improved outcomes in these high-risk (D+/R−) transplant

recipients. However, in a study, mortality due to bacterial and fungal infections was noted to be significantly higher in this group (18%; D+/R−) compared with 10% mortality due to such infection observed in patients undergoing allograft stem cell transplantation with a low risk of newly acquired CMV infection (D−/R−) [66].

Patients with D+/R+ CMV serostatus often exhibit a complex dynamic of CMV transmission from the donor; it was interesting to note that in such patients transmission or reactivation of multiple CMV strains can occur [67]. Clinical significance of viremia due to newly acquired donor-specific viral strain(s) and reactivation of recipients' latent viral strains, or both, may influence outcome in a yet uncertain manner. The genetic variety and potential for a wide-ranging phenotypic viral variance may potentially influence viral kinetics, risk for end-organ disease, and importantly risk of drug resistance and response to antiviral drug therapy. Further investigation is needed.

Up to 80% of CMV-seropositive stem cell allograft recipients may have viral infection if no antiviral prophylaxis is given. The overall risk of CMV infection in allogeneic transplant recipients has been between 20% and 35%; however, it is important to underscore that advancement in risk estimation and intervention with preventive strategies has significantly modified such a risk [68]. Despite these highly effective interventions to prevent CMV disease in seropositive HSCT recipients, several investigators have reported that non-cancer relapse mortality remains high compared with CMV-seronegative recipient [69, 70]. The impact of donor CMV serostatus in seropositive HSCT recipients continues to be tendentious. Some studies have reported a beneficial effect of having seropositive donor with regards to a reduction in cancer relapse or non-cancer relapse mortality, whereas other studies have found no such advantage [71–79]. Despite the controversy for non-cancer relapse mortality and overall survival, transplantation in D−/R+ patients has resulted in delayed CMV-specific immune reconstitution, increased risk of CMV reactivation, CMV recurrence during late transplant period, and risk for end-organ CMV disease [80–85].

Patients undergoing mismatched or unrelated donor graft transplants, indication for HSCT (cancer vs. other disorders), T cell depletion, acute GVHD, and high-dose (1 mg/kg per day) corticosteroid use are all recognized as factors that promote risk for CMV infection in this population [86–90]. Similarly, it is uncertain if the source of stem cell graft either from peripheral blood or marrow-derived stem cells makes a significant impact on the risk for CMV infection in the post-transplant period. There are reports of CMV risk divergence based on the source of allograft; however, others have controverted such findings [85, 87, 90–92]. Mechanistic target of rapamycin such as sirolimus appears to modify cellular signaling pathways that are influenced or assimilated by CMV-encoded viral proteins; use of sirolimus for GVHD prophylaxis has been observed to protect against CMV infection and disease [85, 93].

Late CMV Infections

In the era of preemptive ganciclovir therapy during early (<100 days) transplant period, CMV infections are gaining increasing, albeit, dubious recognition during the late (≥100 days) transplant period [94, 95]. CMV infection 100 days after transplantation was strongly associated with the risk for non-cancer relapse mortality [84]. In 15–30% of allogeneic HSCT recipients, late CMV infection may occur if no antiviral measures are put in place, resulting in CMV end-organ disease in approximately 6–18% of such patients [96–98]. Those at risk for late CMV infection are (a) patients who developed CMV infection or disease within first 100 days after transplantation, (b) patients exhibiting a lack of CMV-specific immune reconstitution, (c) patients with presence of persistently low lymphocytes in the peripheral blood, and (d) patients with acute or (e) chronic GVHD [84, 88, 99, 100]. In select group of patients with such risk factors, anti-CMV prophylaxis may be extended beyond 100 days after transplantation. It is also imperative to continue weekly viral surveillance using pp65 antigenemia or CMV blood PCR, and in patients with the evidence of continued viremia, preemptive therapy may reduce the burden of late transplant CMV disease [98, 101].

Nonmyeloablative Transplants

The risk of CMV infection and disease in the early post-transplant period is substantially lower in patients undergoing nonmyeloablative conditioning in preparation for matched, related donor stem cell graft compared with patients given conventional myeloablative preparatory regimens [101, 102]. However, the risk of CMV infection and disease appeared to be similar among nonmyeloablative and myeloablative groups after the first year following transplantation [101, 102]. It is important to recognize that in T cell depletion and transplantation using matched, unrelated donor grafts, the risk reduction for early CMV infection becomes unnoticeable between nonmyeloablative and myeloablative transplantation procedures [101, 103].

Autologous Stem Cell Transplantation

It has long been recognized that cytomegalovirus infection influences engraftment capacity of autografts during the aplastic period. A significant predictive relationship was

shown between CMV infection and delay in granulocyte recovery, whereas such a relationship was not evident for the recovery in platelet counts after autologous transplantation. In nearly 40% of CMV-seropositive patients undergoing autologous transplantation, CMV can be detected by pp65 antigenemia or viral DNA in the peripheral blood [104, 105]. However, despite these high rates of CMV viremia, end-organ disease is seldom seen in patients undergoing autologous SCT [106–108]. In this group, when CMV pneumonia does occur, the outcome for such a devastating viral lung disease is similar to that seen in allogeneic HSCT recipients [109]. CD34+ selected grafts, treatment with high-dose corticosteroids, and conditioning regimen with fludarabine or total-body irradiation increases the risk for CMV disease following autologous SCT [91]. CMV does not pose a serious risk for patients undergoing autologous SCT and routine antiviral prophylaxis, and viral surveillance is therefore not recommended. However, a select group of high-risk patients following autologous stem cell transplant may benefit from routine surveillance and preemptive anti-CMV therapy.

Cord Blood Stem Cell Transplants

Umbilical cord blood provides a novel source of stem cell for suitable recipients [110]. Such allografts are virtually always CMV-negative. Among CMV-seropositive recipients of cord blood stem cell transplantation (CBT), lack of antiviral prophylaxis would result in an unacceptable rate of CMV infection, which is reported between 40% and 80% although in one report, all patients undergoing such transplants developed CMV reactivation [111–115]. High-dose valacyclovir prophylaxis was shown to reduce increased CMV risk after cord blood transplantation to what has been known for patients undergoing peripheral blood or marrow stem cell allograft transplantation [116].

In a report of 100 CBT, the overall incidence of infection was 2.4 times higher in adults compared with children undergoing transplants with cord blood stem cell allografts [117]. In adults, overall infection risk was significantly higher in the presence of severe neutropenia (3 × higher) and GVHD (1.9 × higher). Late (>100 days) cytomegalovirus infections occurred only in children with chronic GVHD [117]. Multivariate analysis showed that resolution of lymphocytopenia (≥1000 cells/ml) and successful stem cell engraftment were significantly protective against the risk of serious infection (hazard ratio 0.71 and 0.20, respectively) [117]. Due to the substantial risk and potential burden of CMV infections in patients undergoing CBT, continued viral surveillance, especially in patients with acute or chronic GVHD, necessitates optimized CMV prevention and preemptive treatment strategies.

CMV Disease in HSCT

CMV infection in transplant patients implies presence of CMV in blood by direct qualitative or quantitative measurement of viral DNA or by measurement of viral surrogate like pp65 antigenemia. It is also important to recognize that transplant patients similar to general population, despite having a noteworthy vulnerability for viremia and end-organ disease, may develop asymptomatic viral shedding at various body sites. Therefore, isolation of cytomegalovirus DNA in bodily fluids such as urine, tears, nasal, upper respiratory tract secretions, and orointestinal tract may not necessarily indicate viral organ disease. This is in contrast to viral isolation in CSF and BAL culture samples in patients with a compatible clinical illness [118]. It is important to note presence of CMV DNA by PCR in CSF and especially BAL samples are of value due to its high negative predictive value that may assist in ruling out CMV infection or end-organ viral disease.

CMV can cause disease in almost any organ system, although CMV disease designation should be approached with great caution as other infections and non-infectious complications may be misconstrued as CMV disease. This is further complicated by the fact that protean clinical presentation of cytomegalovirus infection most commonly presents as a nonspecific febrile illness.

The first step is to identify hosts' immunologic susceptibility for end-organ CMV disease. In such patients, isolation of cytomegalovirus in tissue cultures is important; for example, in patients suspected to have CMV-related loss of stem cell graft, culture isolation of the virus in marrow aspirate or biopsy sample is highly suggestive, whereas a positive PCR for CMV DNA is not considered adequate to establish viral causality for the loss of stem cell graft [119].

CMV pneumonitis in symptomatic patients with a suggestive radiographic presentation of viral interstitial pneumonitis or, at times, nodular infiltrates needs to be differentiated from other pulmonary infections such as common respiratory tract viral infections, drug toxicity, and PCP, in addition to the growing recognition of various syndromes associated with pulmonary GVHD. Detection of CMV by viral culture in lower respiratory tract samples such as bronchoalveolar lavage fluid is encouraged. Lung biopsy samples are seldom available in stem cell transplant recipients due to severe thrombocytopenia and dysregulation in coagulation pathways, or limited functional respiratory reserve; although these potential contraindications for lung biopsy do not exist in most SOT patients in whom CMV pneumonitis may be suspected. Presence of CMV by (+) PCR is not adequate; diagnosis of CMV pneumonitis requires isolation of virus in lower respiratory tract fluid or tissue culture samples along with evidence of viral inclusions and/or immunohistochemical viral confirmation in lung biopsy samples [119]. It has been proposed that in HSCT recipients, isolation of other opportunistic pathogens

like filamentous fungi in the setting radiologic features consistent with IFD probably indicates fungal pneumonia rather than CMV pneumonia, when such a diagnosis is based on (+) CMV PCR alone [119]. The authors would like to emphasize that various immunologic aberrations and compromised structural respiratory tract barrier as a consequence of cytomegalovirus infection promote the risk for secondary superimposed bacterial and fungal lung disease that may occur concurrently or sequentially after viral lung infection.

Suspected viral eye disease including retinitis requires detailed examination by an ophthalmologist or a specialist in retinal disease. Similarly, in patients with orointestinal CMV disease, the diagnosis is predicated upon isolation of cytomegalovirus in tissue cultures along with histologically compatible disease with immunohistochemical confirmation. Detection of CMV by PCR by itself is considered insufficient for the diagnosis of CMV gastrointestinal disease [119].

CNS disease should be suspected in patients with acute or chronic changes in mentation or cognition, persistent headaches, and other symptoms eluding to intracranial disease process. Isolation of CMV in CSF cultures is highly suggestive although most experts agree that isolation of CMV DNA by PCR in CSF sample in a susceptible patient with clinical and radiographic features consistent with CMV encephalitis or myelitis is adequate for diagnosis. In certain patients, brain biopsy may be approached to confirm diagnosis, especially in individuals with localized or focal brain lesions. This is attempted to exclude other potential causes like neurotropic molds, dimorphic fungi, tuberculous or nontuberculous mycobacteria, *Nocardia*, parasite like *Toxoplasma gondii*, and among noninfectious conditions like primary CNS lymphoma or metastatic cancers.

CMV Pneumonia

Cytomegalovirus lung infection that often presents as multifocal interstitial pneumonitis is an important CMV disease in patients undergoing high-risk blood and marrow stem cell transplantation and is historically associated with an unacceptably high mortality rate ranging between 60% and 90% [120].

The incidence and risk for developing fatal CMV pneumonia were assessed after a review of 999 autopsies [121]. Twenty-five patients who died with CMV pneumonia were compared with 34 similar patients. The incidence of CMV pneumonia was 3.5% during 1990–1997 at a major Comprehensive Cancer Center in the United States; a sizeable decline in the incidence of CMV pneumonitis (0.8%) during 1997 through 2004 was encouraging [121]. Sustained and prolonged lymphopenia was a well-recognized risk factor for CMV infection and disease. Routine anti-CMV prophylaxis in susceptible population and preemptive antiviral treatment approach based on sensitive new-generation quantitative viral assays have greatly improved the overall incidence of end-organ CMV disease including viral lung disease [122].

Most patients present with fever, cough without sputum production, dyspnea and hypoxia on exertion that subsequently progresses to disabling shortness of breath at rest. Onset of symptoms are usually insidious; if the diagnosis and treatment is delayed, the disease in vast majority of cases progresses to severe hypoxemia and respiratory failure requiring assisted ventilatory support within 1–2 weeks after the process commenced. Chest rays are not sensitive for the diagnosis of CMV pneumonitis [123]. A high-resolution CT scan without IV contrast may show early interstitial viral infiltrates (Fig. 37.1a, b) [124]. Rarely, pulmonary nodules

and cavitary pneumonia are attributed to cytomegalovirus lung disease, especially in severely immunosuppressed individuals (Fig. 37.2a, b).

The diagnosis of CMV pneumonia requires demonstration of viable, replicating virus in BAL or lung biopsy samples by shell vial or cultures. In the event biopsy is a possibility, presence of CMV in the lung tissue by immunohistochemical assays is considered diagnostic. CMV shedding in the lower respiratory tract is not uncommon among transplant population and should not be used for the diagnosis of CMV pneumonia.

In a randomized, controlled trial of ganciclovir prophylaxis for CMV pneumonia in patients undergoing HSCT, strongest predictors of CMV pneumonia was CMV-positive culture in BAL and blood samples [125]. Nearly two-thirds of asymptomatic patients developed CMV pneumonia subsequently [125]. As mentioned earlier, performing CMV DNA PCR in BAL fluid samples for the purpose of diagnosing CMV pneumonia is discouraged. A negative BAL CMV DNA PCR carries high negative predictive value which may assist in ruling out CMV as a cause of pneumonia [63].

CMV Retinitis

Major ocular complications in allogeneic HSCT recipients include chronic GVHD, dry eye syndrome in the absence of GVHD, corneal ulcers, cataract, and glaucoma [126]. CMV retinitis, varicella zoster virus, and fungal endophthalmitis are rare but devastating infections. It is also interesting that in some patients allergic conjunctivitis may be acquired from atopic donors and may be mistaken for acute viral infection, since the recipient had no prior history of allergic conjunctivitis before undergoing transplantation [126].

In CMV retinitis, though uncommon in allogeneic HSCT recipients, clinical presentation is not dissimilar to that observed in patients with advanced HIV/AIDS. CMV eye disease presents with gradual and progressive loss of vision; however, sudden blindness has also been reported. CMV, like varicella zoster virus posterior eye chamber involvement, includes retinitis, retinal hemorrhage, vitritis; whereas, anterior chamber infection presents as uveitis, or iridocyclitis. Patients with initial single eye involvement have greater than 50% risk for contralateral eye to become involved, if not treated preemptively [127]. Most cases of CMV retinitis are seen after 100 days following transplantation and often associated with the evidence of GVHD, delayed lymphocyte engraftment, and early (<100 days) CMV reactivation [127].

In 2014, five cases of CMV retinitis were a significant increase in children undergoing allogeneic HSCT at a transplant center in the United States [128]. These sporadic cluster of cases may occur from time to time, although there have been no reports of systematic increase in the incidence of CMV retinitis in HSCT population. Continued ophthalmic assessment and screening are part of routine comprehensive care provided for transplant recipients.

CMV Hepatitis

CMV hepatitis like other viral infections such as adenovirus, HHV6, and EBV among others is difficult to distinguish clinically from non-infectious causes of liver injury includ-

ing drug toxicity, and GVHD [129, 130]. Among allogeneic HSCT recipients, high-dose corticosteroids, T cell-depleted graft, acute and chronic GVHD, and mismatched or unrelated donor stem cell grafts are well-recognized risk factors for CMV infection and end-organ disease. Diagnosis requires histologic and CMV identification by immunohistochemical stain performed on liver tissue biopsy samples. As obtaining liver biopsy may not be always feasible, a high degree of suspicion, along with presence of CMV viremia, that have coincided with acute hepatocellular injury may provide an indication for possible CMV etiology in patients with acute hepatitis. Post-transplant reactivation of chronic, latent HBV and HCV infections should always be an essential part of such investigations.

CMV Encephalitis

Viral encephalitis is most notably seen during the late post-transplant period. The median time from HSCT to diagnosis was recently reported as 145 days [131]. In a report from China, RSV was the most prominent pathogen (50%), whereas cytomegalovirus (7%), and HHV6 and HSV (3% each) were less common. Clinical presentation included alterations in mentation and new-onset seizures. Neuroimaging showed abnormality in close to 80% of patients. Elevated protein in cerebral spinal fluid was present in 60%, whereas pleocytosis and elevated or normal glucose levels were noted in less than one-third of patients. Multivariate analyses revealed high-grade acute GVHD, presence of CMV viremia, and engraftment syndrome as significant risk factors for viral encephalitis [131].

The classic histologic feature of CMV brain infection is non-lethal cytotoxic edema due to intracellular viral inclusions (Figs. 37.3 and 37.4). This edema forms the basis of highly suggestive long-lasting diffusion restriction findings noted in brain MRI scans in patients with CMV cerebritis [132].

Punctiform lesions on diffusion-weighted MRI images appear to have a clear ventricle wall tropism, validated on classical autopsy findings in patients with CMV encephalitis [132].

Subependymal and periventricular punctiform-restricted diffusion lesions on IV contrast-enhanced MRI in patients with clinical features of meningoencephalitis are highly suggestive of CMV encephalitis [132].

It is important to note that encephalitis due to other neurotropic viruses like adenovirus, EBV, VZV, HSV, and HHV-6 may elicit a clinical syndrome that is difficult to distinguish from CMV brain disease. HHV6 encephalitis is mostly seen during early post-transplant period and patients appear to have high-grade HHV6 viremia [133].

CMV Myelosuppression

CMV-induced myelosuppression or hematopoietic stem cell graft failure needs to be distinguished from recipients' immunologic rejection of the stem cell allograft, myelotoxicity resulting from a cornucopia of drug cocktails given to patients following transplantation. Furthermore, alternative causes of myelosuppression like (a) recurrence of hematologic malignancy, (b) bone marrow infiltration due to lymphoproliferative disorders among others, and (c) infection

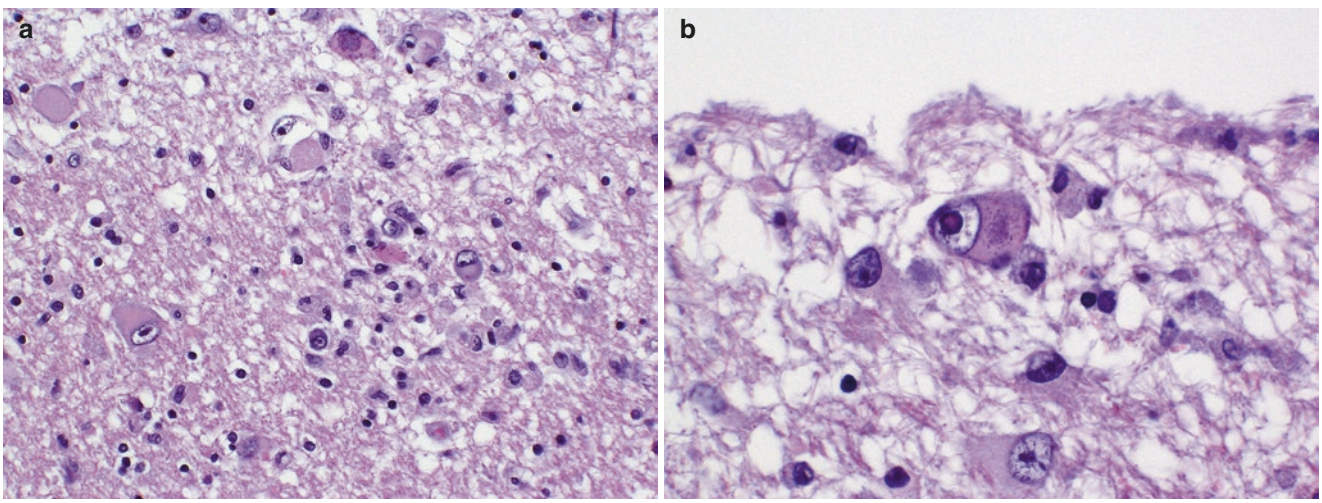

Fig. 37.3 Hematoxylin and eosin stain of subependymal white matter, the lower power (**a**; 40×) showing multiple enlarged astrocytes with prominent inclusion bodies in the nuclei. There is also lymphocytic infiltration in the tissue indicating inflammation. The higher power (**b**; 100×) emphasizes an enlarged astrocyte bearing both a large intranuclear inclusion and basophilic stippling of the cytoplasm representing cytoplasmic inclusions also characteristic of cytomegalovirus encephalitis. (Images courtesy of Dr. Marc K. Rosenblum of Memorial Sloan-Kettering Cancer Center, New York, NY)

The higher magnification shows antibody labeling of both the intranuclear inclusion and the viral inclusions in the cytoplasm. (Images courtesy of Dr. Marc K. Rosenblum of Memorial Sloan-Kettering Cancer Center, New York, NY)

due to myelotoxic viruses like HHV6, EBV, adenovirus, and parvovirus B19 should be part of such an evaluation. Patients with severe peripheral blood pancytopenia thought to result from CMV-associated graft failure need demonstration of (a) bone marrow hypoplasia, (b) detection of cytomegalovirus in marrow sample culture, (c) exclusion of stem cell graft rejection, and (d) recurrence of cancer [119].

CMV Gastrointestinal Tract Disease

CMV can affect any part of orointestinal tract. Viral esophagitis similar to HSV or *Candida* esophagitis may occur without significant disease in the oral cavity. Difficulty in swallowing, substernal chest pain, and epigastric discomfort are common clinical features. On endoscopic examination, confluent or nonconfluent pseudomembranous lesions, confluent or nonconfluent deep mucosal ulcers that may be more pronounced in the distal esophagus are prominent findings.

Patients with CMV enteritis and colitis may present with abdominal pain, diarrhea, and abdominal distention; these patients are often febrile. Presence of hematochezia heralds underlying severe ulcerative CMV colitis. In such patients, viral ulcers may extend deep into the submucosa. Clinically, and by visual inspection on endoscopic examination, gastrointestinal viral disease is difficult to distinguish from GVHD. Diagnosis require culture isolation of CMV in tissue biopsy samples and immunohistologic evidence of viral disease; albeit both of these diagnostic approaches lack sensitivity. Diagnosis of CMV gastrointestinal disease is further complicated as patients may not have evidence of CMV viremia or antigenemia at the time of clinical presentation [134, 135]. CMV gastritis, gastric and duodenal viral ulcers, when suspected, also require biopsy of the affected site for viral culture and immunohistologic assessment.

Solid Organ Transplantation

Risk Factors

A recent report of CMV infection using the Scientific Registry of Transplant Receipts data published between 2005 and 2014 showed the overall rates of donor and recipient CMV seropositivity have remained constant over the reported period. It was encouraging that among living donor transplantation, there were more CMV-seronegative donors and recipients over the span of this data registry [136]. This probably reflected a donor selection bias and a preference for CMV-seronegative living donors for seronegative patients awaiting transplantation with stable end-stage organ disease.

Patients receiving calcineurin inhibitor, mycophenolate mofetil, and corticosteroid-based regimens intended for solid organ allograft preservation have high susceptibility for CMV infection and disease. The drugs that inhibit mechanistic target of rapamycin (mTOR) such as sirolimus and everolimus exhibit indirect protection against cytomegalovirus. This has propelled the hypothesis for use of such agents in calcineurin inhibitor-sparing antirejection regimen to reduce the risk for CMV infection and disease, especially among at risk population. A recent review of existing literature regarding potential benefit of mTOR inhibitors on the risk for opportunistic viral infection after transplantation showed a favorable impact on the risk of CMV, polyomavirus, and HHV8 infections, whereas there was no advantage noted for post-transplant infections due to EBV and HCV [137].

Presently, calcineurin inhibitor-based regimen is preferred, specifically for patients considered at high risk for allograft rejection. However, calcineurin inhibitor-sparing regimen that includes mTOR inhibitor with various permutations including or excluding mycophenolate mofetil, corticosteroids, and thymocyte globulins are under investigation.

It was recently demonstrated that in patients undergoing solid organ allograft transplantation, risk of post-transplant CMV reactivation and disease can be measured by evaluating subpopulation of active CMV-specific CD8 cells that produce IFN-γ [138]. Patients who exhibited ≥0.25% CMV-specific active CD8 cells prior to transplantation and 0.15% or 0.25% 2 and 4 weeks following transplantation, respectively, had adequate control of CMV infection and were purposed to require less viral monitoring. Others have also reported that monitoring CMV-specific T cell kinetics, especially against CMV major early immediate protein (IE-1) before and after transplantation in patients receiving CMV discordant (D+/R−) renal allograft, may provide a better risk stratification for appraising the risk of post-transplant CMV infection [139]. The authors reported that pre- and post-transplant declining or undetectable CMV IE1-specific T cells identified a subgroup of patients that have high frequency of CMV viremia (81%) after kidney transplantation, in whom graft was harvested from CMV-seropositive donor ($P < 0.001$) [139].

Heart & Lung Transplants

In lung transplant recipients, infections are a significant complication. Within first year after transplantation, infections are the leading cause of death [140]. In lung transplant reipients, allograft rejection also continues to be an important challenge that presents as either acute graft failure or chronic allograft dysfunction due to bronchiolitis obliterans syndrome. Nearly half of long-term transplant survivors develop bronchiolitis obliterans syndrome within 5 years after undergoing lung transplantation [140]. CMV infection remains a serious complication in SOT population; recipients of pulmonary allograft are regarded as a high-risk group. It is daunting to ascertain a delicate balance between iatrogenic antirejection drug-induced, cumulative immunosuppression, which is necessary for the allograft preservation, and, on the other hand, an attempt to preserve hosts' adaptive immune surveillance needed to protect against opportunistic infections among whom, CMV leads the stage as the protagonist. This is certainly the case in patients after high-risk allograft transplantation and those who need aggressive treatment for moderate to severe allograft rejection.

In 378 consecutive heart transplant recipients, CMV infections were significantly more common in older patients [141]. Treatment with rabbit thymoglobulin or with T-cell acute lymphoblastic leukemia cell line Jurkat-derived ATG-Fresenius had twofold higher risk for CMV infection compared with patients in whom such induction regimens were not used [141]. Everolimus compared with azathioprine or mycophenolate significantly lowered the risk of CMV infection (OR 0.19; $p < 0.0001$). It is also pertinent to note that other major opportunistic infections were significantly more common in patients with CMV infection or viral end-organ disease following heart transplantation [141].

In lung transplant recipients, mycophenolate-sparing antirejection regimen with everolimus was noted to reduce the incidence of CMV infection [142]. These patients also had lower rates of lower respiratory tract infection, leukopenia, post-transplant bronchiolitis obliterans syndrome, and biopsy-proven acute pulmonary allograft rejection [142]. The increased dropout rate in everolimus treatment group was in most part due to drug intolerability.

Liver Transplantation

A recent meta-analysis included 21 retrospective observational studies that included over 8000 patients and showed no survival benefit in hepatic graft donor/recipient ABO blood group concordance [143]. However, patients undergoing orthotopic liver transplantation from AOB blood type incompatible donor had significant high risk for CMV infection (OR = 2.6), incidence in antibody-mediated rejection (OR = 74), risk of chronic rejection (OR = 2.3), overall biliary (OR = 1.5), and hepatic artery complications (OR = 4.2) compared with patients given liver graft from ABO compatible donor [143].

HHV6 infections in liver transplant recipients are known to cause hepatitis, encephalitis, and graft dysfunction. The indirect effects of HHV6 infection in this population were reported to increase risk for (a) CMV disease, (b) post-transplant HCV progression, (c) greater fibrosis scores, and (d) death [144].

Kidney and Pancreases Transplant

As with other visceral allograft transplantation, donor and recipient CMV discordance (D+/R−) is the most important determinant for CMV infection and organ disease following transplantation. In early antiviral prophylaxis trials, 48–67% of kidney transplant recipients that were randomized in the placebo group developed CMV disease within first year after transplant procedure [145, 146]. The risk was highest among D+/R− (48%) compared with D+/R+ (6%) renal allograft recipients [145]. Additionally, more than half of the patients without antiviral prophylaxis developed acute graft rejection within 6 months after transplant surgery [145, 146].

In a large prospective study that assessed 609 kidney and kidney-pancreas recipients, 18% developed CMV viremia after a median 5.6 months after transplantation [147]. Patients were given standardized CMV prophylaxis, and close to 90% of patients with CMV infection were asymptomatic [147]. In multivariate analysis, D+/R− serostatus,

older donor age more than >50 years, high tacrolimus, and mycophenolic doses were significant risk factors for CMV infection [147]. As expected, D−/R− status yielded lowest risk for CMV infection after transplantation. Patients who did develop symptomatic CMV disease had 3.5 times higher risk for allograft loss [147]. As noted with other transplants, pooled analysis of randomized controlled trials found that risk of CMV viremia and end-organ disease was significantly reduced in patients given mTOR inhibitors versus mycophenolate [148].

A similar CMV disease rate was observed in patients undergoing pancreas transplants. The overall CMV infection rate in this group was 24% among 130 pancreas-kidney or pancreas after kidney allograft recipients, in whom antiviral prophylaxis was continued for a median of 49 days [149]. CMV-seronegative recipient status (D+/R−) was associated with the highest risk (44%) for CMV infection during the post-transplant period, whereas only 8% had CMV infection in pre-transplant CMV-seropositive group [149].

In 407 pancreas allograft recipients, the incidence of CMV infection was highest in D+/R− (20%), followed by 17% in D+/R+ and 5% in D−/R+, and lowest (3%) when transplants were performed in seronegative donor and recipients [150]. Most infections occurred 90 days after transplantation, and despite no reduction in immune suppression in most patients (72%), none of these patients experienced adverse outcomes that included CMV-related deaths or loss of the allograft [150].

Intestinal and Multivisceral Transplant

Intestinal transplant recipients are especially vulnerable to serious CMV-related complications. The incidence of CMV infection is close to 40%, and most infections are seen within 60 days after transplantation [151]. A vast majority (81%) of CMV disease affects intestinal allograft. Risk of CMV disease is greater in (a) D+/R−, (b) isolated intestinal transplant recipients, patients with high net state of immune suppression resulting from (c) high tacrolimus serum levels, and (d) higher cumulative corticosteroid dose [151]. It is important to note that over half of the patients with clinical and histopathologically proven CMV visceral disease did not have detectable CMV viremia by DNA PCR analysis [151].

In children undergoing intestinal transplantation, incidence of CMV is lower (24%) compared with adults following similar allograft transplants [152]. Most infections are also noted within 2 months after transplantation, and 90% CMV disease involves the visceral transplanted allograft [152]. In children, no CMV disease was noted when both donor and recipients were seronegative [152]. As with adults, high cumulative corticosteroid dose was associated with greater risk of CMV disease in children [152]. Recent studies have shown a lower incidence of CMV infection (18%) and disease (7%) in pediatric transplant recipients [153]. As noted, most end-organ CMV disease in patients undergoing intestinal transplantation involve the transplanted allograft, and disease recurrence occurs in 50–86% of patients, in whom an initial response to antiviral therapy was observed [152, 153]. Presence of CMV disease increases the risk of death by 11-fold in patients undergoing intestinal transplantation and, indirectly, enhances their vulnerability for EBV infection and PTLD [153].

Face, Limbs, and Integument Transplant

CMV infection in patients receiving composite tissue allotransplantation has evolved as one the most important infection challenges during the post-transplant period [154, 155]. Seronegative receipts following allograft harvested from seropositive donor are at the greatest risk for CMV infection and disease. Due to elevated iatrogenic immune suppression needed in such patients, response to anti-CMV therapy is often erratic; infection and viral disease relapse are common [154, 155].

Biologics and Risk of CMV

The risk of CMV infection in patients receiving conventional chemotherapy for hematological malignancies is low [156]. Therefore, routine CMV screening in the asymptomatic patients receiving fludarabine, hyperfractionated cyclophosphamide, vincristine, doxorubicin and dexamethasone, or rituximab is not recommended. In non-HSCT patients, rate of CMV infection or viral reactivation ranges between 2% and 67% [157]. Some of the prominent although putative risk factors include treatment with high-dose corticosteroids, advanced malignancy, poor performance status, and treatment with alemtuzumab, fludarabine, Velcade, and rituximab [157]. CMV prophylaxis and preemptive therapy are reserved for only high-risk patients and not given routinely in non-transplant patients undergoing treatment with biologic immune suppressive agents.

Alemtuzumab (Campath)

Alemtuzumab is a recombinant DNA-derived humanized monoclonal antibody directed against CD52, a cell surface glycoprotein. It is used in the treatment of chronic lymphocytic leukemia, T cell prolymphocytic leukemic, cutaneous T cell lymphoma, and T cell lymphoma. CMV reactivation after Campath usually occurs within 3–6 weeks following therapy and the incidence ranges between 10% and 66% [158, 159]. Up to one-third of CMV infections in patients after Campath therapy are symptomatic and may present with a nonspecific febrile illness [160]. Patients at risk for CMV reactivation being treated with Campath may benefit

from anti-CMV drug prophylaxis. The data regarding valganciclovir is encouraging. In a randomized trial, 35% of patients given valacyclovir (500 mg daily) prophylaxis developed CMV reactivation, where none had CMV reactivation in valganciclovir (450 mg bid) treatment group [161]. Valganciclovir three times a week was also reported to be effective in preventing CMV reactivation [162].

Preemptive anti-CMV therapy instead of prophylaxis is another approach, which is similar to all preemptive antiviral regimens and requires close monitoring for early and sustained viral reactivation using pp65 antigenemia or viral DNA PCR in blood [163]. CMV monitoring should be continued for 8 weeks after treatment with Campath has been discontinued [164]. In patients with evidence of CMV viremia during Campath therapy, it is suggested to withhold further treatment with the biologic agent until viremia has resolved. A thorough assessment for possible end-organ CMV disease should be undertaken and treated according to the established standards [165].

Pancreas-kidney dual organ transplant recipients in whom alemtuzumab induction therapy was compared with historical controls that received induction with basiliximab at a single transplant center in the US. There was no difference in patients, renal, or pancreas allograft survival, or renal allograft delayed graft function, incidence of PTLD, and sepsis in the two groups [166]. Infections due to EBV or BKV were not significantly dissimilar in the cohorts studied [166]. It is, however, important to note that the incidence of CMV infection was significantly higher in the alemtuzumab-treatment group vs. patients in whom basiliximab induction was given [166]. This observation resulted in modification of induction protocol at this center from two-dose alemtuzumab to a single 30 mg-dose induction therapy [166]. Alemtuzumab was still considered desirable due to low drug cost and few acute drug-related toxicities during induction for abdominal visceral transplantation.

Rituximab

Rituximab is a human-mouse chimeric monoclonal antibody that has been successfully used to treat B-cell non-Hodgkin's lymphoma, certain autoimmune diseases, and dermatologic disorders like Pemphigus vulgaris, post-transplant B-cell-mediated allograft rejection, and PTLD which are among other constantly emerging uses for this effective anti-CD20 biologic immune-modulatory drug.

The risk of cytomegalovirus infection is considerable in allogeneic HSCT and solid organ transplantation recipients receiving high-dose rituximab therapy. However, it was interesting to note that in 49 patients with primary post-transplant CMV infection, 32 patients received low-dose rituximab therapy and exhibited no clinical or immunologic difference compared with 17 such patients in whom rituximab was not given [167].

In a literature review, 64 reported cases of serious viral infection after rituximab therapy in patients with lymphoma, the median time from the start of rituximab treatment and diagnosis of viral infection was 5 months and ranged between 1 and 20 months [168]. Infections due to HBV (39%), CMV (23%), and varicella-zoster virus (9%) were the three prominent viral infections. Among HBV-seropositive patients, just over half of the patients had developed fatal liver failure. In contrast, nearly one-third of the patients with other severe systemic viral illness following rituximab therapy including CMV, had died [168]. The cause of death in the latter group could not be fully attributed to CMV or varicella zoster disease.

In allograft CMV-seropositive transplant patients undergoing rituximab therapy, risk for CMV infection and disease is much higher than in patients undergoing autologous SCT [169]. In a report of nearly 1000 autologous SCT recipients, 239 patients had clinical suspicion for symptomatic CMV reactivation. Among these, only 3% had confirmation of CMV viremia that developed after a median of 32 days following transplantation [169]. CMV viremia was detected in 4% of patients in whom rituximab was given, whereas 2% in patients without rituximab therapy. In this report, rituximab therapy in autologous stem cell graft recipients did not contribute to significant increase in CMV reactivation, end-organ disease, or death [169].

In 182 patient experience following T cell depleted matched unrelated or haploidentical donor stem cell transplant was recently reported [170]. In this high-risk group, half of the patients developed CMV viremia, whereas end-organ viral disease was noted in 6% of the patients. High-grade acute GVHD, D−/R+ CMV serology, and cancer as an indication for transplantation were prominent risk factors for CMV viremia. Treatment with rituximab significantly reduced risk for EBV reactivation in whom high B cell-containing stem cell grafts were given. The authors reported an increase in the rate of CMV viremia following TCR-α/β and CD19-depleted stem cell allografts; however, rituximab therapy did not result in unfavorable survival or risk for end-organ CMV disease. Furthermore, in this group, use of CD19-depleted allografts and rituximab combination in select high-risk patients eliminated the risk of PTLD [170].

CMV antiviral drug prophylaxis is not routinely recommended for transplant patients undergoing treatment with rituximab. It is however recommended that in high-risk allogeneic stem cell graft recipients, a greater degree of vigilance for CMV reactivation and viremia, or both should be maintained during and 3 months after completing anti-CD20 antibody therapy. As with any other at-risk transplant group, clinical suspicion for viral end-organ disease should prompt appropriate investigation and commencement of effective antiviral drug therapy.

Basiliximab

Basiliximab is a chimeric mouse-human monoclonal antibody that has high affinity against CD25, the α chain of the IL-2 receptor expressed on T lymphocytes. It is indicated for the prevention of acute renal allograft rejection. Basiliximab was shown to significantly reduce acute renal allograft rejection compared with cyclosporine and corticosteroids or triple antirejection therapy [171]. The efficacy of basiliximab was similar to that of equine antithymocyte globulin and daclizumab and perhaps superior to muromonab-CD3. The incidence of adverse events had been similar in basiliximab-treated patients versus those given conventional induction. Secondary malignancies and PTLD after transplants were rare and were similar in basiliximab vs. the control group [171]. It is important to note that incidence of CMV infection did not increase after basiliximab preparatory antirejection therapy compared with conventional dual or triple drug combinations [171]. The incidence of CMV infection was also similar with basiliximab, compared with patients given induction therapy using equine or rabbit antithymocyte globulin [171].

In heart transplant recipients, the results of 22 randomized clinical trials were systematically assessed for immunosuppressive T cell antibody induction; these trials had data in 1427 heart-transplant recipients [172]. Chronic allograft vasculopathy, renal dysfunction, PTLD, and risk of other cancers were not significantly dissimilar across these studies. There was also no noteworthy difference in the risk of infections, including CMV infection and risk of death [172]. It was important to note that acute cardiac allograft rejection occurred less frequently when IL-2 receptor antagonist was given (33%) compared with no induction (45%; RR 0.73) [172].

CMV Prevention

CMV Risk Reduction

CMV-seronegative patients should ideally receive an allograft from a CMV-negative donor. This is true for patients awaiting hematopoietic blood or marrow stem cells or solid organ allograft transplantation. In patients undergoing allogeneic stem cell transplantation, major human leukocyte antigen compatibility is regarded as of greater significance than discordance between donor and recipient CMV serostatus (D+/R−). However, taking into account the risks that newly, graft-acquired CMV infection poses in such patients, some experts have questioned the current practice and advocated that CMV-negative donor being more preferential than graft concordance based on minor HLA antigen such as allele-mismatches or mismatches for HLA-C, DQ, or DP. CMV-seronegative donor status has also been considered more important than other risk factors such as advanced donor age or blood group disparity. Clinical validation for these largely anecdotal although plausible recommendations still need validation via prospective randomized trials that should include ethnically diverse cohort of patients.

Newly acquired CMV infection in D−/R− HSCT recipients was less likely due to naturally acquired infection in the adult life, whereas CMV transmission via transfusion of unscreened blood and blood products was reported as an important source of infection in older studies [173]. Use of blood products from CMV-seronegative blood donors is of foremost significance in prevention of newly acquired CMV infection during the post-transplant period. Reports of leukocyte-reduced or filtered blood products were an alternative approach to mitigate risk of CMV infection from blood transfusions in CMV + donor pool [174, 175].

In authors' opinion, all CMV-seronegative transplant recipients should receive adequately screened blood and blood products from CMV-seronegative donors, as newly acquired CMV infection via transfusion poses a devastating complication in this vulnerable population.

CMV Drug Prophylaxis

Ganciclovir prophylaxis was a major breakthrough in prevention of CMV infection and end-organ viral disease in patients undergoing HSCT. Though it was well tolerated in most patients, drug toxicity, selection of drug-resistant viral mutants after prolonged exposure with low drug dose, subsequent risk for breakthrough, and often difficult-to-treat infections and potential for end-organ disease became limiting concerns. Valganciclovir was a welcome addition.

A search for more potent antiviral drugs with a low likelihood for the risk of breakthrough CMV infections, infections due to drug-resistant viral stains, has propelled research in the past decades. After a less than stellar performance by maribavir in phase III trials [176], the recently concluded trial using a new anti-CMV agent was an encouraging gain in the existing antiviral drug armamentarium. Letermovir is a novel antiviral drug that inhibits the CMV-terminase complex. In phase II dose escalation trial, a significant benefit was noted in incidence of CMV infection and end-organ disease plus lower discontinuation of prophylaxis for any reason at 240 mg daily dose vs. 60 mg, 120 mg, or when no drug prophylaxis given [177].

A phase III trial in CMV (+) adult HSCT recipients with no evidence of CMV infection and/or disease, letermovir prophylaxis with 480 mg, or half that daily dose in patients taking cyclosporine was assessed for 14 weeks after patients underwent transplantation [178]. The primary end point was the proportion of patients in whom clinically significant CMV infection became evident within 24 weeks after transplant. Patients were followed through week 48 after HSCT. In 495 patients, 38% randomized to receive high-dose letermovir prophylaxis developed clinically significant CMV infec-

tion, whereas a significantly higher proportion of patients (61%) developed such episodes in the group given placebo [178]. Letermovir was well tolerated; no episodes of drug-related myelotoxicity or renal dysfunction were observed. Vomiting, edema, and atrial fibrillation or flutter were low-grade adverse events that were possibly attributed to letermovir prophylaxis. All-cause mortality, 48 weeks after transplantation, was 21% in letermovir group compared with 26% in patients randomized to receive no anti-CMV prophylaxis [178]. This trial has provided a much-needed new approach for preventing CMV infection in patients undergoing allogeneic stem cell transplantation.

Immunoprophylaxis

Use of intravenous immune globulin (IVIG) has shown variable efficacy in prevention of CMV viremia during post-transplant period, especially among at-risk population. In addition, even target-specific, enriched anti-CMV hyperimmunoglobulins or CMV-specific monoclonal immunoglobulins have also been disappointing in this regard [179–181].

The lack of therapeutic efficacy of IVIG in reducing CMV risk after D+/R− and D+/R+ allogeneic HSCT was known in earlier studies and was validated in a recent meta-analysis [182]. Use of enriched or monoclonal CMV antibodies is a high-price alternative for antiviral drug prophylaxis and currently not recommended for routine use in prevention of post-transplant CMV infection [183, 184].

In patients undergoing solid organ transplantation, treatment with hyperimmunoglobulins or target-enriched immunoglobulins, especially for CMV and HBV infections, may have ancillary immune modulatory effect(s) [185]. It was interesting to note in orthotopic liver transplant recipients, HBV hyperimmunoglobulin prophylaxis had an unexpected favorable influence on the risk of graft rejection resulting in improved graft and patient survival compared with patients given antiviral drug therapy alone [185]. Similarly, anti-CMV hyperimmunoglobulin prophylaxis in patients following lung transplantation had resulted in reduced frequency of bronchiolitis obliterans syndrome [185]. These additional host-immune-modifying events attributed to hyperimmunoglobulin prophylaxis given during early post-transplant period may not be a direct treatment-induced modification of allograft recipients' immune-inflammation response. It could be contended that such benefit, if valid, arises from an indirect effect from suppression of opportunistic, possibly immune-modulating viral infections.

Preemptive Therapy in HSCT

Prevention of CMV end-organ disease in patients with early and sustained CMV viremia has spearheaded the evolution of preemptive therapy in the last three decades. Implementation of effective preemptive anti-CMV therapy that reduces the need for universal antiviral drug prophylaxis relies upon predictor(s) that confidently portend CMV disease risk in patients undergoing allogeneic transplantation. Such preemptive strategies in a select group of allogeneic transplant recipients have been a notable intervention that resulted in a considerable decline in early post-transplant CMV disease and reflected upon improved patient survival [61].

However, the premise of anti-CMV drug prophylaxis, as with prevention strategies for other opportunistic infections, is to routinely provide antimicrobial drug, often given in lower doses during high-risk periods. Unlike preemptive therapy, prophylaxis is administered regardless of the evidence of CMV infection (antigenemia or viremia). Empiric therapy is regarded as systemic full-dose anti-CMV therapy given in patients when CMV end-organ disease is suspected and confirmation is either pending or not attainable.

A suitable agent for prophylaxis must (a) have favorable toxicity profile, (b) be easy to administer, (c) not require frequent dose administration, (d) demonstrate efficacy in prevention of infection and tissue invasive disease, and importantly (e) have low potential to influence emergence of drug-resistant mutants or (f) breakthrough infections due to organisms inherently nonsusceptible to the class of drug being used for prophylaxis. Another important consideration is reliable bioavailability of such an agent that would make routine blood/serum drug monitoring dispensable. CMV prophylaxis, unlike preemptive approach, is offered to all at-risk transplant patients and not selected for patients that demonstrate CMV infection, therefore exposing a subgroup of low-risk patients to systemic toxicity of ganciclovir or foscarnet, in whom post-transplant CMV infection or disease would not have occurred. Unlike preemptive approach, in patients given drug prophylaxis, routine viral monitoring is not required. Both strategies have demonstrated comparable efficacy in preventing CMV end-organ disease [61]. It was therefore considered desirable to opt for preemptive approach using CMV pp65 antigenemia or viral DNA PCR techniques to avoid more generalized use of an antiviral drug prophylaxis, especially in transplant receipients with suboptimum restitution of post-trasnplant antiviral immune surveillance [186, 187].

Assessing CMV-specific immune reconstitution after allogenic stem cell allograft transplantation is a novel approach to objectively stratifying patients at risk for CMV infection and end-organ disease. The utility of CMV-specific adaptive T cell response as a guide for withholding preemptive anti-CMV therapy was assessed in 58 patients 3–6 months after allogeneic HSCT [188]. In 19 CMV episodes, this strategy was applied, treatment was deferred in 5/19 patients and none of these five patients developed CMV disease [80]. This approach has not become the standard of care at most transplant centers barring cost, feasibility, and limited clinical experience.

The current approach for preemptive therapy after allogeneic HSCT is based on regular, once a week measurement of

CMV pp65 antigenemia, or viremia by new-generation sensitive PCR DNA analysis, or RNA amplification using nucleic acid sequence-based amplification (NASBA). These measurements are performed during first 100 days after transplantation and may be extended beyond 100 days in patients with sustained risk for late CMV disease. It is important that patients assigned to receive preemptive anti-CMV therapy should be periodically assessed for subclinical or modestly symptomatic end-organ viral disease.

A short 2- to 3-week course of ganciclovir is frequently adequate in resolving CMV viremia although close to one-third of patients given short anti-CMV preemptive therapy will have infection recurrence [189]. Currently, preemptive therapy is given for 6–8 weeks or for 100 days after engraftment [190]. In patients with persistent viremia or pp65 antigenemia after 2 weeks of anti-CMV therapy, treatment needs to be extended until viral clearance is achieved. A gradual decline in CMV viremia after institution of preemptive antiviral therapy was noticeable as an important prognosticator of CMV disease during the late transplant period [191].

In authors' opinion, in patients in whom, rise in CMV PCR or antigenemia is observed for 2 consecutive weeks after commencing ganciclovir preemptive therapy, a genetic drug mutation analysis should be performed. This is especially pertinent for patients with prior and extensive exposure to ganciclovir. A change to an alternative antiviral drug should also be considered without delay in patients with the earliest clinical and/or radiographic evidence of CMV end-organ disease, while receiving ganciclovir preemptive therapy. However, it should be emphasized that a number of patients will exhibit protracted or gradual response to anti-CMV preemptive therapy, which is more a reflection on patients' ineffective T cell antiviral immune response and possibily, yet undermined, hosts' minor genetic polymorphism(s) that curtails ability to suppress viral replication during the post-transplant period. It has also been sugested that such immune vulnerablity for CMV infection may only become clinically evident, after an allogenic transplantation procedure has been undertake.

Management of CMV Disease

CMV sporadically activates from viral latency in most non-immunosuppressed individuals with or without periods of physical and/or immunologic stress with no certain clinical consequence. Even in immunosuppressed patients, diagnosis for CMV end-organ disease requires fulfilment of certain criteria, such as (1) isolation of cytomegalovirus in viral cultures, (2) clinical and radiologic features of CMV disease, (3) identifying susceptible transplantation population, and, most importantly, (4) demonstration of cytomegalovirus in tissue biopsy samples.

Gastrointestinal Disease

For gastrointestinal CMV disease, induction parenteral drug therapy with intravenous ganciclovir is given for 2–3 weeks followed by 4–6 weeks of low-dose maintenance therapy, which needs to be continued well after resolution of CMV viremia and clinical and/or radiographic evidence of viral disease. Historically, short course (≤2 weeks) antiviral therapy was associated with the risk of treatment failure and viral disease relapse [192]. In patients with orointestinal CMV disease, tissue damage is a direct result of virus-mediated cell damage; therefore, immunomodulation with adjunct IVIG for harnessing or modifying immune-inflammatory response is not recommended [193].

Nearly one-third of HSCT recipients may experience disease recurrence after demonstrating a clinical response to anti-CMV drug therapy. The authors suggest a reinduction with systemic antiviral drug given for 3–4 weeks and maintained until precipitating risk factors, if present, such as high-grade acute or chronic GVHD, graft rejection, high-dose anti-GVHD or allograft rejection therapy, and treatment for cancer recurrence including donor lymphocyte infusion mediated severe immune suppression has improved. Despite limited data, prolonged suppression with oral valganciclovir was encouraged in patients with end-organ CMV disease, including recurrent CMV enteritis or colitis. It is important to assess for potential malabsorption state even in the setting of well-controlled chronic enteric GVHD or visceral graft rejection. In such circumstances, drugs even with otherwise high oral bioavailability like valganciclovir may fail to achieve adequate therapeutic drug concentration.

CMV Pneumonitis

Response to antiviral drug therapy by itself for treatment of CMV pneumonia, particularly in patients undergoing allogeneic HSCT, has been disappointing. CMV pneumonia has dual components, direct virus-mediated cytopathic effects on pneumocytes, and additional virus-elicited tissue damage via an exaggerated hosts' inflammatory response. Therefore, combination therapy has long since become the standard of care that comprises of an effective anti-CMV drug like ganciclovir or foscarnet along with IVIG [194, 195]. This approach has resulted in a substantial improvement yeilding good clinical response and improved patient survival compared with historic outcomes following antiviral drug therapy alone. It was not unexpected that no additional benefit occurred by substituting CMV-enriched immune globulin compared to pooled IVIG from community blood donors [196]. In patients with pulmonary edema and circulatory volume overload that may be exacerbated by IVIG, a reduced volume CMV-enriched immunoglobulins may exert less intravascular oncotic pressure and can be substituted in select clinical situations.

Immunopathogenesis of CMV pneumonitis is predicated on hosts' exaggerated inflammatory response triggered by cytomegalovirus infection involving the lungs [197]. Systematic review in a number of studies has provided support for IVIGtherapy in recipients of allogeneic HSCT with CMV pneumonitis; ergo addition of IVIG is presently regarded as standard of care, despite limited controversies that may surface periodically.

CMV Retinitis

Treatment of CMV retinitis involves systemic treatment with an antiviral drug like ganciclovir, foscarnet, or cidofovir. Intraocular, posterior chamber instillation of ganciclovir via injections or implantation of slow drug-release devices has evolved as the mainstay of therapy for this devastating CMV disease that threatens to compromise vision and in some patients resulting in permanent blindness, despite best possible, intensive multimodality treatment measures [198, 199]. It is also important to recognize that initially uninvolved contralateral eye is at risk for CMV disease in most patients with CMV retinitis initially involving a single eye.

Cidofovir has permitted biweekly maintenance therapy. Local ophthalmic treatment options such as intraocular devices for sustained ganciclovir delivery or intravitreal instillation of cidofovir, fomivirsen, and ganciclovir have been used to circumvent systemic drug toxicity while maintaining high drug concentration at the site of viral disease [200]. The intraocular cidofovir is desirable due to its long half-life, and patients may be spared from implantation of intraocular devices that are needed for ganciclovir sustained local delivery. Safety and pharmacokinetics of the cidofovir prodrug was evaluated in rabbits [201, 202]. The drug was well tolerated, and gradually dissolved, yielding free drug accumulation in the retina and vitreous; half-life of 25 days. The status of future development of cidofovir prodrugs for potential clinical use is presently not known.

It is important to recognize that acute uveitis may complicate systemic cidofovir therapy, similar to ophthalmic toxicity noted with rifabutin. Discontinuation of the offending drug and topical steroids along with mydriatic cycloplegic agents are ameliorative in most patients [203]. Since patients commonly present with painful red eye and signs of anterior segment inflammation accompanied by fibrinous exudate and possibly vitritis, a lack of awareness of this drug-induced toxicity that may rarely complicate cidofovir therapy may misdirect a cumbersome and fruitless exploration for possible infection.

Ocular hypotony is another rare complication of systemic cidofovir therapy [204]. Anterior uveitis or iridocyclitis and ocular hypotony are a result from a direct interaction between cidofovir and the ciliary body [205]. Most reports of this cidofovir ophthalmic toxicity is reported in patients with HIV/AIDS receiving treatment for CMV retinitis. Alternatively, inflammation of anterior eye chamber and vitreous body may be a reflection of immune restoration in patients with AIDS and not a direct consequence of cidofovir on the ciliary apparatus [206].

Fomivirsen is a phosphorothioate oligonucleotide that inhibits CMV replication via an antisense mechanism that targets mRNA encoded by CMV. This drug is approved as second-line intraocular instillation therapy for CMV retinitis in patients with HIV/AIDS [207]. Therapeutic feasibility and efficacy of fomivirsen in treatment of CMV retinitis in non-HIV patients, especially those undergoing allograft transplantation is not certain.

Other Organ Diseases

CMV hepatitis, encephalitis, myelitis/myeloradiculitis, and adrenalitis are not common, and management with an antiviral agent like ganciclovir is often adequate. It has been proposed, barring adequate clinical experience, that intravenous foscarnet may penetrate physiological blood-brain barrier better than that occurs after intravenous ganciclovir therapy. The potential superiority of one drug versus the other has not been systematically studied and at best is regarded as anecdotal opinion. In transplant patients with CMV disease, high degree of clinical suspicion, early and correct diagnosis, and appropriate supportive care is what determines a favorable outcome along with the implementation of effective and well-tolerated anti-CMV drug therapy.

Antiviral Agents

Drugs that are active against cytomegalovirus are given for infection prevention and preemptive therapy prior to development of end-organ cytomegalovirus disease. These agents are also effective for the treatment of CMV disease. In patients undergoing transplantation, all resources are focused on identifying patients at risk for CMV organ disease such as high risk transplant procedures, and post-transplant complication that increase vulnerability for this devastating potentially life-threatening complication.

Acyclovir

Acyclovir is active against herpes simplex viruses and regarded as the cornerstone of antiviral prevention and treatment since its approval by FDA in 1982. The initial critical step in intracellular drug activation is dependent on phosphorylation by viral thymidine kinase that exhibits >3000 times higher avidity for acyclovir than mammalian host enzymes; cellular thymidine kinase then converts acyclovir to triphosphate form, which is a potent inhibitor of viral DNA polymerase. Acyclovir despite showing less than optimal anti-CMV activity in vitro tests, when given to patients

undergoing stem cell transplantation was noted to reduce the overall risk for CMV infection and perhaps favorably influenced the risk for CMV organ disease [208].

Valacyclovir

Valacyclovir is a valine-ester prodrug of acyclovir with a greater than 50% oral bioavailability compared with 10–20% oral bioavailability achieved with traditional oral acyclovir therapy. Valacyclovir is converted to acyclovir after first-pass hepatic metabolism by hosts' esterase enzymes yielding a high-serum drug concertation. It was therefore, not unexpected that prophylaxis with valacyclovir was more effective than acyclovir in reducing the risk of CMV infection, as noted by a decline in the need for ganciclovir preemptive therapy in patients undergoing allogeneic HSCT [209]. The impact of valacyclovir prophylaxis on overall survival after allogeneic HSCT remains uncertain. It is recommended that allogeneic transplant recipients at risk for CMV disease, while on valacyclovir prophylaxis should undergo routine surveillance for CMV infection and be treated preemptively with appropriate anti-CMV drug should there be evidence of CMV antigenemia or viremia [210].

Ganciclovir

Ganciclovir is competitive inhibitor of deoxyguanosine triphosphate and interferes with the incorporation of this essential nucleoside into viral DNA. Ganciclovir is a synthetic nucleoside analogue 9-(1,3-dihydroxy-2-propoxymethyl) guanine (DHPG) that is converted to ganciclovir monophosphate by a CMV gene (UL97)-encoded phosphotransferase. Further phosphorylation of ganciclovir monophosphate into the active triphosphate form is undertaken by hosts' cellular enzymes. Presently, ganciclovir is regarded as the first-line drug for prevention and preemptive treatment of CMV infection in patients undergoing transplantation. Intravenous ganciclovir significantly reduces the risk of CMV disease in patients undergoing allogeneic HSCT [211, 212].

One of the major treatment limiting toxicity of ganciclovir is suppression of marrow granulocytopoiesis; the resultant peripheral blood neutropenia is noted in nearly one-third of the stem cell allograft recipients being treated with ganciclovir [213]. As expected, presence of drug-induced severe neutropenia (ANC < 500 cells/ml), if it remains unabated, significantly increases the risk for secondary superimposed bacterial infections and tissue invasive fungal disease [213].

Ganciclovir dose reduction and additional support with recombinant myeloid growth factor may help mitigate this potential life-threatening complication, although in a number of patients the drug may have to be discontinued. Most often, such patients are switched over to foscarnet. Ganciclovir serum drug concentration analysis may help guide drug dosing in select patients, especially those with renal impairment, although this is not a common practice in transplant centers in the United States and elsewhere. Another important observation in clinical trials showed a lack of overall survival benefit from ganciclovir prophylaxis or preemptive therapy; this was noted despite a significant reduction in the risk for end-organ CMV disease.

Valganciclovir

Oral valganciclovir has better bioavailability compared with oral ganciclovir; in HSCT recipients, serum drug levels may be comparable to those seen after intravenous ganciclovir therapy [214]. The efficacy and tolerability of valganciclovir preemptive therapy are now regarded as analogous to intravenous ganciclovir therapy in patients undergoing allogeneic stem cell transplantation [215, 216].

In patients following solid organ transplantation, oral valganciclovir showed a safe, easy to administer, and potentially effective option for CMV therapy nearly comperable to intravenous ganciclovir [217]. It was cautioned that in allograft recipients with specific organ transplants that were not represented in the comparison trials, extrapolating valganciclovir feasibility data in such transplant recipients should be approached with caution [217]. The VICTOR trial showed comparable efficacy of oral valganciclovir vs. intravenous ganciclovir for the treatment of CMV disease in recipients of solid organ transplantation [218]. Oral anti-CMV therapy is now recommended in SOT patients for the treatment of CMV disease. VICTOR biobank was used in a series of post hoc analyses that yielded important information regarding treatment of CMV disease in SOT population. These included the following: (a) modifying antiviral therapy with the initial CMV viral load, (b) the effect of immune suppression on anti-CMV treatment outcomes, and (c) importantly, for prevention of disease recurrence and emergence of drug resistance, antiviral treatment should be continued until CMV viral load has become undetectable [218].

A multicenter randomized study assessed intravenous ganciclovir in patients undergoing alemtuzumab reduced intensity conditioning HSCT vs. oral valganciclovir; 67% of 27 patients cleared CMV viremia after a median 14 days of therapy [219]. By measuring serum ganciclovir levels, bioavailability of oral valganciclovir was 73%. It was interesting to note that average drug exposure was higher in the valganciclovir group compared with patients given ganciclovir intravenously (37 ± 15 and 28 ± 7 μg h/ml, respectively).

Taking into account the existing data, systemic drug exposure and safety of valganciclovir has emerged as comparable to traditional intravenous ganciclovir given preemptively in both solid organ and hematopoietic stem cell allograft recipients. An important exception includes the lack

of such data in high-risk HSCT recipients and those with CMV infection while undergoing treatment for severe GVHD or visceral allograft cellular immune rejection.

Foscarnet

Foscarnet, trisodium phosphonoformate, is a pyrophosphate analog that binds reversibly near the pyrophosphate-binding site of viral DNA polymerase or reverse transcriptase. Foscarnet unlike nucleoside analogues does not require modification for antiviral activity. Foscarnet binding with viral DNA polymerase, blocks DNA chain elongation. Foscarnet selectively inhibits viral DNA polymerase; cross-over inhibition of mammalian DNA polymerase would require 100-fold greater drug concentration than that needed for blocking CMV replication. It is active in vitro against herpes viruses, HBV and HIV. Foscarnet is presently used as a second-line agent for the treatment of CMV infection in transplant patients intolerant to ganciclovir or those with ganciclovir nonsusceptible or unresponsive CMV, HSV, and VZV infection. In vitro activity and limited clinical data also foster use of foscarnet in patients with end-organ disease due to human herpesvirus 6A and 6B [220].

Foscarnet is considered as effective as ganciclovir for preemptive anti-CMV therapy in patients undergoing allogeneic stem cell transplantation [221, 222]. However, as all currently licensed antiviral drugs, breakthrough infection is not unique to treatment with foscarnet. In most such cases, lack of clinical response reflects a combination of less drug-susceptible viral strains and viral escape due to profound hosts' cellular immune dysfunction.

In 20 high-risk HSCT recipients including unrelated donors, or T cell-depleted stem cell grafts, and/or transplant for advanced malignancy, foscarnet prophylaxis was assessed during first 100 days after transplantation [223]. CMV pp65 antigenemia was seen in 80% of patients with low dose and less than 20% with high-dose foscarnet prophylaxis. CMV disease occurred in 33% receiving lower two-dose schedule, where none of the patients assigned to high two-dose approach developed end-organ viral disease. Increased serum creatinine was noted in 75% of these patients, and in nearly half, the drug needed to be stopped. Authors reported dose-dependent prophylactic effect of foscarnet in prevention of CMV antigenemia, and despite high incidence of nephrotoxicity, it was reversible after the treatment was discontinued [223].

Compared with ganciclovir, foscarnet anti-CMV therapy is given preemptively to individuals undergoing allogeneic blood or marrow stem cell transplantation. In this randomized study involving 213 patients, the primary efficacy endpoint was the occurrence of CMV disease or death from any cause within 180 days after transplantation [190]. The event-free 180-day survival estimates were similar in the two treatment groups. As anticipated, significantly more patients (11%) developed severe neutropenia in ganciclovir group versus 4% in those receiving foscarnet prophylaxis. Renal impairment was not significantly different among the two groups; 5% in foscarnet-treated patients and 2% in the ganciclovir-treated patients. Ganciclovir was discontinued in 6% of patients due to hematopoietic toxicity such as neutropenia or severe thrombocytopenia, whereas no such treatment interruptions were noted in foscarnet-treated group.

A report in 39 patients in whom 22 had undergone SOT and 17 HSCT received foscarnet for treatment of ganciclovir-resistant CMV infection (n = 15) and other exhibiting lack of clinical response to ganciclovir therapy. Patients were given foscarnet for well over a month (median 32 days). Virologic failure occurred in 33%, and viremia relapsed in 31% of the patients. More patients died (31%) in HSCT group compared with SOT, whereas significantly more SOT recipients had ganciclovir-resistant CMV virus [224]. It was not unexpected to see that nearly half of the patients (51%) developed impaired renal function by the end of foscarnet therapy. It is important to take into account that end-organ CMV disease was documented in 28% of the 39 patients [224].

Drug treatment refractory CMV viremia, viral recurrence, and risk of end-organ disease are more of a reflection on hosts' genetic and immunologic viral susceptibility, type of allograft transplantation, and post-transplant complication(s) resulting in hosts' immune dysregulation. This concept has given way to handling CMV infection in transplantation population with novel approaches such as adaptive cellular immunotherapy and search for vaccine candidates and constructs that may yield effective and durable anti-CMV immune response.

Cidofovir

Cidofovir or hydroxyphosphonylmethoxypropylcytosine (HPMPC) is a phosphonate containing cyclic cytosine analogue. Cidofovir phosphonate group mimics deoxycytidine monophosphate. This drug does not require viral kinases for phosphorylation to furnish its antiviral potential [225]. Therefore, cidofovir is active against the viral mutants that are deficient in viral kinase including ganciclovir-resistant CMV strains. Hosts' cellular enzymes phosphorylate cidofovir twice to its active form. The resulting cidofovir diphosphate remains within the cells for an extended duration. The diphosphate cidofovir competitively inhibits incorporation of deoxycytidine triphosphate into viral DNA by viral DNA polymerase. Incorporation of the drug in viral DNA disrupts further chain elongation [225]. Tenofovir and adefovir are two related phosphonate-containing drugs that are acyclic deoxyadenosine analogue and are active against HIV and HBV. The mechanism of antiviral activity of these drugs is similar to that of cidofovir against CMV.

Acute renal tubular necrosis is a major drug toxicity that can be, in part, muted by optimizing intravascular hydration before and after cidofovir infusion to maximize glomerular filtration,

and probenecid is given to reduce active cidofovir secretion in proximal renal tubules. Despite these measures, acute renal failure limits first- or second-line use of cidofovir in most transplant recipients with CMV infection and/or disease.

Cidofovir is a broad-spectrum agent that exhibits in vitro activity against a variety of human pathogenic viruses including human herpesviruses, adenovirus, HPV, polyomaviruses, and human poxviruses [226]. Potential clinical application other than the standard indication for CMV retinitis in patients with AIDS is not presently approved. Intravenous cidofovir has been used as salvage therapy for treatment of progressive multifocal leukoencephalopathy and Kaposi's sarcoma. Intraocular injection for treatment of CMV retinitis, intralesional cidofovir injections for treatment of respiratory papillomatosis, topical application for treatment of aggressive molluscum contagiosum, anogenital condyloma acuminata, and recurrent genital herpes have been used with some success. Topical ophthalmic instillation of cidofovir for treatment of viral keratoconjunctivitis has also been well tolerated and with good results [227].

Maribavir

Maribavir is a benzimidazole l-riboside compound with potent activity against CMV including ganciclovir-resistant viral strains. The mechanism of action against ganciclovir-resistant CMV isolates include drug-induced inhibition of UL97 kinase and viral DNA synthesis [228]. Viral UL97 kinase is involved in viral DNA synthesis and viral capsids' exit from cell nuclei. Maribavir shows in vitro activity against ganciclovir- foscarnet-and cidofovir-resistant strains of CMV [228].

In a study, clinical CMV isolates and laboratory viral stains exhibiting mutations in UL97 and UL54 DNA polymerase were tested in vitro by plaque reduction assay. All 17 CMV stains resistant to ganciclovir (n = 11), foscarnet (n = 4), and cidofovir showing UL97 and UL54 DNA polymerase mutations were susceptible to maribavir [229]. A laboratory mutant CMV virus with UL97 L397R mutation showed high-level maribavir resistance; however, this strain was sensitive to other three antiviral drugs tested. Maribavir demonstrates rapid absorption after oral administration and linear pharmacokinetics and has effective in vivo activity against cytomegalovirus [230]. In phase I trials, based on urinary drug recovery, 25–45% of maribavir was noted to be absorbed when given orally [231].

In a phase II dose-ranging trial conducted in patients following HSCT, CMV infection and disease were reduced with all three drug doses tested, although this antiviral benefit was not evident in phase III trial among patients randomized to receive maribavir 100 mg twice daily [232]. Inadequate low-dose maribavir was thought to be a potential flaw in this phase III trial [232].

In 120 patients following stem cell or solid organ transplantation, safety, antiviral activity, and pharmacokinetics of different oral doses of maribavir for up to 24 weeks for treatment of CMV infections resistant or refractory to treatment with ganciclovir, valganciclovir, or foscarnet were studied. A number of participants with confirmed undetectable plasma CMV within 6 weeks after being randomized to receive 400 mg, 800 mg, and 1200 mg twice daily dose was 70%, 63%, and 71%, respectively. Serious adverse events were not widely different among the three groups (70%, 68%, and 65%, respectively) (clinicaltrials.gov NCT01611974).

Another phase II European randomized dose-ranging trial to assess safety and efficacy of maribavir vs. valganciclovir for the treatment of CMV infection in transplant patients without CMV end-organ disease has ended in 2014 (EudraCT: 2010-024247-32); results from this trial are not known. Overall, Maribavir has been safe and well tolerated; alteration in taste was the most frequently reported adverse event.

Letermovir

Letermovir is a novel antiviral drug that inhibits the CMV-terminase complex that can be given orally or intravenously. In vitro data has shown letermovir remains active against drug-resistant CMV mutant strains. Limited clinical experience for treatment of multidrug-resistant CMV infection or disease in allograft transplant recipients was encouraging [233]. In a phase II dose-escalation study in 131 CMV (+) stem cell HLA-matched allograft recipients, letermovir was given at doses of 60, 120, or 240 mg daily and compared with similar patients that were given placebo. Prophylaxis and placebo were continued for 12 weeks after stem cell engraftment. The primary end point was "all-cause prophylaxis failure" which was defined as stopping study drug due to CMV antigenemia or viremia, viral end-organ disease, or any other cause [177]. The "all-cause prophylaxis failure" was 48% in patients given 60 mg dose versus 64% in the placebo group. It was 32% in patients given 120 mg (P = 0.01) and 29% in patients given 240 mg letermovir daily dose (P = 0.007). A difference in time-to-onset for prophylaxis failure for letermovir 240 mg daily dose vs. placebo was a significant finding (P = 0.002) [177]. There were no episodes of drug-induced hematologic or renal toxicity. The drug was well tolerated, and the safety profile of letermovir was comparable to patients who were randomly assigned to receive placebo.

In a phase III trial in adult CMV (+) HSCT recipients without CMV viremia, letermovir prophylaxis 480 mg daily, or half that dose in patients taking cyclosporine, was assessed during the first 14 weeks after transplantation. In 495 patients, 24 weeks after transplantation, 38% randomized in letermovir treatment group developed clinically significant CMV infection, whereas such events were observed in 61% among the placebo group ($P < 0.001$) [178]. Letermovir was well tolerated, with no drug-related myelotoxicity or renal dysfunction. Vomiting, edema, and atrial fibrillation or flutter

were low-grade adverse events possibly associated with letermovir use. The 48-week all-cause mortality in letermovir group was 21% comparted with 26% in patients who did not receive this anti-CMV drug for prophylaxis [178].

Brincidofovir

Brincidofovir (CMX-001) is a lipid acyclic nucleoside phosphonate prodrug of cidofovir that exhibits excellent oral bioavailability and expected long half-life allowing twice-weekly dosing schedule. Brincidofovir crosses cell membrane via facilitated and passive diffusion; once inside the cell, it is converted into cidofovir after cleavage from its lipid moiety and phosphorylated to cidofovir diphosphate by intracellular kinases [234]. In experimental CMV infections, brincidofovir is 400 times more potent than cidofovir [235]. The spectrum of antiviral activity of this cidofovir prodrug includes all five families of DNA viruses that causes human disease including the herpesviruses and adenoviruses [236, 237]. Brincidofovir has shown potent activity against Ebola virus in vitro, and in experimental Ebola virus disease results were cautiously encouraging [238]. Unlike cidofovir, brincidofovir is not a substrate for the human organic anion transporters, which favorably contributes to its low nephrotoxicity potential [239].

A phase II dose-escalation study in HSCT recipients showed reduced CMV infection and/or disease in patients given brincidofovir prophylaxis with 200 mg per week dose started at the time of stem cell engraftment. The most common side effect was diarrhea that became notable in patients given 200 mg or higher weekly doses. Due to the dose-limiting toxicity noted at 200 mg twice weekly, the protocol was amended to 100 mg twice weekly dose for phase III trial. In the phase III trial with amended protocol conducted at 27 centers, 230 evaluable CMV (+) patients undergoing HSCT were randomized to receive oral brincidofovir 100 mg twice weekly versus placebo [240]. It is important to note that randomization was stratified according to the presence or absence of GVHD and CMV viremia. Anti-CMV prophylaxis commenced after stem cell engraftment for a duration of 9–11 weeks and until 13th week post-transplant. CMV DNA PCR was performed weekly, and in patients with presence of CMV breakthrough viremia, drug was discontinued and switched to standard preemptive anti-CMV therapy. The primary end point was presence of CMV disease or viremia (>200 copies per ml) at the time study drug prophylaxis was discontinued. The incidence of CMV events was 27% points lower in patients in whom brincidofovir was given prophylactically (10% vs. 37% in placebo; $P = 0.002$) [240]. Diarrhea was common adverse event in patients receiving brincidofovir at doses of 200 mg or higher weekly doses and was the dose-limiting adverse event associated with brincidofovir prophylaxis [240]. According to the manufacturer website, brincidofovir has not been associated with kidney or bone marrow toxicity in over 1000 patients. Brincidofovir has received Fast Track designation from the FDA for CMV, adenovirus, and smallpox (http://www.chimerix.com) [241].

Leflunomide

Leflunomide is a disease-modifying antirheumatic drug that has shown effectiveness in various autoimmune disorders [242]. Leflunomide has exhibited in vitro anti-CMV activity and dose-dependent anti-CMV response in humans [242]. In HSCT recipients with MDR CMV infection or end-organ viral disease due to such difficult-to-treat drug-resistant strains, options for effective and sustainable therapy remain severely curtailed. Leflunomide has been exploited for possible salvage therapy in such select cases. Leflunomide adjuvant, salvage therapy in three HSCT recipients with MDR CMV infections assessed anti-CMV efficacy of leflunomide based on virologic response and proposed therapeutic drug monitoring [243].

Leflunomide salvage therapy has also resulted in favorable outcome in two SOT recipients with systemic and local antiviral combination therapy refractory CMV retinitis [244]. A kidney allograft recipient with treatment refractory (UL97 mutation) CMV retinitis involving both eyes responded after oral leflunomide was added. This patient had disease worsening despite intravitreal instillation of ganciclovir and foscarnet in addition to IV foscarnet and oral valganciclovir therapy. Following addition of leflunomide, CMV retinitis became inactive for 22 months. CMV retinitis in a lung transplant patient worsened despite intravitreal foscarnet injections and oral valganciclovir. Retinitis was controlled with the addition of oral leflunomide that allowed discontinuation of intravitreal therapy. In this patient, CMV retinitis remained inactive until his death [244].

Experience with leflunomide for CMV infection in nine patients following lung transplantation three such allograft recipients received leflunomide for secondary CMV prophylaxis [245]. In 67% of 12 patients, demonstrable genetic antiviral mutations were noted that are known to confer drug resistance. Leflunomide therapy in 78% of patients resulted in a decline in the level of CMV viremia. Long-term viral suppression was achieved in 58% of these patients. In one-fourth of patients, leflunomide had to be discontinued due to drug toxicity [245]. Leflunomide experimental therapy is currently reserved for patients with ganciclovir-resistant CMV infection that has failed second- and third-line agents.

Artesunate

Artesunate is an antimalarial agent that also exhibits a wide-ranging in vitro activity against a variety of viruses such as herpesviruses, hepatitis, and HIV [246].

Mechanistically, arsenate antiviral activity is linked with interference in essential steps in the host cell kinase cascades. It was shown that DNA-binding activity of the two virus-induced cellular transcription factors Sp1 and NF-kappa B were markedly reduced in the presence of artesunate. The investigators showed noticeable drug-induced inhibition of cellular signaling kinase phosphoinositide 3-kinase, which is required for activation of factors such as Sp1 and NF-kappa B in CMV-infected fibroblasts [247]. Artesunate inhibits CMV replication in human fibroblasts and astrocytes by these mechanisms including strains susceptible or resistant to ganciclovir. Artesunate exhibits anti-CMV activity similar to ganciclovir in astrocytoma and fibroblast cell lines [248].

Limited clinical experience includes a study involving six HSCT patients; preemptive artesunate treatment for CMV infection showed a rapid decline in viral load (0.8–2.1 logs) in two patients a week after therapy commenced. In the other four patients, artesunate therapy resulted in a stunted CMV growth slope. In this preliminary observation, lack of adverse events among six HSCT recipients treated over 7–56 days with artesunate therapy was encouraging and indicated further safety feasibility studies, especially exploring alternative options for drug-resistant CMV infection [249].

Response to salvage artesunate therapy for MDR-CMV infection late after HSCT forms the repertoire of experience with this agent that at best are anecdotal and arbitrary [250]. No systematic evaluation of artesunate feasibility for the treatment of CMV infection or of viral end-organ disease precludes this drug to be recommended for routine use.

Others

The monoclonal antibody MSL-109 when added to traditional anti-CMV therapy did not result in a significant advantage. Further development of cyclic cidofovir and lobucavir has been placed on hold by their respective manufacturers. Adefovir is a nucleotide analogue that possesses anti-CMV activity; however, presently it is only approved for the treatment of HBV infection. Other compounds with anti-CMV activity include BAY 38-4766 and GW1263W94; these are in early stages of development [251].

It is well recognized that infections due to drug-resistant CMV pose a serious management challenge, especially in patients undergoing allogeneic stem cell or visceral allograft transplantation. Response to salvage combination of antiviral drugs including ganciclovir, foscarnet, and cidofovir may only result in a transient response in some patients, and experimental treatment with leflunomide and artesunate appears to provide no clear additional benefit [252]. In order to trounce this daunting obstacle that non-treatment responsive CMV infection presents; one alternative appoach is based on adaptive cellular immunotherapy to achieve sustainable target-specific immune restoration in patients undergoing livesaving transplantation procedures. This is discussed briefly in the later text.

Antiviral Resistance

In recent years, a remarkable progress has been made in deciphering viral genomics. The diversity of CMV virus is much higher among other viruses belonging to *Herpesviridae* group; an individual may be infected with >20,000 single nucleotide polymorphisms, thereby CMV can rapidly evolve after exposure to and under influence of an antiviral drug. It is thought that selection of preexisting viral variant(s) rather than development of a new mutant strain confers drug nonsusceptibility, especially after a prolonged exposure to a drug [253].

Resistance to ganciclovir is linked with the presence of mutations in viral protein kinase, UL97. Such viral mutants prevent intracellular conversion of ganciclovir-monophosphate at a varying degree. Therefore, care must be taken in interpretation of viral genotype analysis, as UL97 mutations do not uniformly disrupt the antiviral effect of ganciclovir on CMV DNA synthesis. In some instances, higher ganciclovir drug concentration may overcome CMV strains exhibiting certain types of UL97 mutations [254].

The active antiviral forms of ganciclovir, foscarnet, and cidofovir share the common molecular viral target, UL54, the viral DNA polymerase. Therefore, CMV-encoding UL54 mutations have the potential to confer phenotypic resistance for all three drugs. It is important to note that cross-resistance between foscarnet and ganciclovir is not common, as mutations in UL54 conferring foscarnet resistance is in a distinct region of DNA polymerase than that for ganciclovir resistance. Some viral stains do exhibit cross-resistance to second- and third-line anti-CMV agents thereby critically limiting options for effective therapy. De novo emergence for CMV resistance to cidofovir while patients are on cidofovir therapy is seldom seen. Similarly, cross-resistance between cidofovir- and foscarnet-resistant CMV strains is not a common occurrence. It is important to note that CMV strains that exhibit certain DNA polymerase mutations that confer resistance to ganciclovir may also make these viral strains less susceptible or resistant to cidofovir [255]. Since clinical experience with cidofovir for treatment of ganciclovir-resistant CMV infection or disease is limited, probably due to risk of nephrotoxicity, cidofovir is not recommended as a second-line drug for the treatment for such infections. A detailed review of molecular bases of antiviral resistance is provided in Chap. 54.

Ganciclovir-resistant CMV has emerged in patients undergoing solid organ allograft transplants. Infections due to such viral strains are difficult to manage. A series of 15 patients at a single transplant center in whom ganciclovir

resistance was demonstrated in clinical CMV isolates and a review the literature on treatment for such infection showed UL97 and UL54 viral genome mutations were present in 100% and 40% of clinical viral strains, respectively [256]. Most of these infections (73%) occurred within 1 year after transplant surgery. Lowering of valganciclovir dose prior to isolation of ganciclovir-resistant CMV was noted in all such patients, thereby suggesting a possible viral escape during low ganciclovir serum concentration; it is possible that multiplication of less drug-susceptible viral mutants may have taken place under the influence of subtherapeutic drug concentration. High-risk CMV serostatus, and history of valganciclovir dose reduction were prominent hosts' risk factors. After diagnosis of drug-resistant CMV infection, half of the patients developed organ rejection, resulting in allograft loss in 27% and death in 20% of patients. Readmissions were common; requiring three or more hospitalizations for treatment of drug-resistant CMV infection. All patients exhibited a major complication including graft rejection (60%), loss of allograft (20%), and death (40%). It appears that hospital readmission rate was reduced when such infections were first approached with reduced immunosuppression, treatment with foscarnet, intravenous immunoglobulins, and leflunomide [256].

Prolonged exposure to antiviral drugs, especially intermittent drug exposure either due to antiviral dose reduction, noncompliance, acute or chronic enteric malabsorption states such as chronic diarrheal diseases, or intestinal GVHD or allograft rejection, may play a role in promoting the risk for viral drug resistance. Resulting intermittent low-level viral replication in the presence of profound drug-induced (antirejection) immune suppression or lack of CMV immunity following allogeneic HSCT promotes a milieu that emboldens possibility for emergence and repopluation with drug resistant viral mutant strain(s) [257].

Drug resistance should be suspected in patients with increasing CMV viral loads by quantitative blood PCR after 10–14 days of adequately dosed, appropriate systemic antiviral therapy. A viral rebound during the first week of antiviral therapy may be noted in one-third of treatment-naïve patients and should not be construed as an evidence of drug resistance [60]. However, in patients with prior ganciclovir therapy, a rising CMV viral load upon reintroduction of intravenous ganciclovir should alert for the probability of infection with ganciclovir nonsusceptible viral mutant strain; switch to foscarnet should be considered while awaiting CMV UL97 and UL54 genotype mutation analysis. Some centers add foscarnet to ganciclovir with hopes for a better viral control; however, studies have shown that addition of foscarnet along with ganciclovir for treatment of ganciclovir-resistant CMV infection or disease adds no clear benefit [258]. Ganciclovir-based combination therapy for the treatment of known ganciclovir-resistant CMV viral infection is presently not recommended.

The new anti-CMV drugs with a favorable toxicity profile such as high-dose maribavir, brincidofovir, letermovir need to be explored further as potential first-line agents for the treatment of CMV infection or end-organ disease. The role of other disease-modifying agents such as leflunomide and artesunate is presently unknown and need to be studied to devise future optimum anti-CMV combination regimen.

Lowering the point state of immune suppression by modification in immunosuppressive drug regimens, such measures may include: (a) lowering corticosteroid dose and (b) calcineurin inhibitor dose reduction; (c) discontinuation of mycophenolate mofetil for the duration of severe clinical illness; d) interrupting treatment with immunosuppressive biologics; and (e), if feasible, switch calcineurin inhibitor to mTOR inhibitor such as sirolimus or everolimus that have shown to impair CMV replication by regulating hosts' cellular signaling pathways that are exploited by cytomegalovirus-encoded homologous proteins.

Adoptive Immunotherapy

Adoptive transfer of T cell as individualized treatment for cancer was heralded as a major breakthrough in 2003 and regarded as "T cells on the attack" [259]. Sophistication in developing validation animal models have also evolved for the adaptive T cell therapy against opportunistic viral infections such as CMV, adenovirus, and EBV [260–262]. CMV-specific T cells generated ex vivo by various different techniques and the adoptive anti-CMV immunity garnered by such an intervention was shown in a number of reports to favorably influence the risk of CMV viremia and end-organ viral disease in patients undergoing allograft transplantation [263, 264].

One major limitation of current approach for anti-CMV adaptive cellular therapy is that most cells are terminally differentiated effector, CMV-specific $CD8^+$ T cells that despite furnishing much needed immediate effector anti-CMV cellular response; such responses are relatively short-lived. Due to the absence of self-renewing memory T cells, borrowed immune restoration via terminally differentiated effector cell have limited life span [265]. Adaptive T cell therapy that consists of a subset of CMV-specific memory T cell population would yield a long-lasting anti-CMV $CD8^+$ T cell repertoire with highly desirable, on-demand capacity to expand and differentiate in events of viral recrudescence.

A bank of 32 virus-specific T cell lines was created at the Center for Cell and Gene Therapy in Houston, Texas. These cell lines were established from individuals with common HLA polymorphisms who were immune to EBV, CMV, or adenovirus. The investigators reported clinical experience for 18 T cell lines that were used in 50 HSCT recipients with severe, or treatment-refractory, intractable viral illness [266]. The cumulative rate of complete or partial response 6 weeks

after T cell infusion was 74% for the entire group [266]. Adaptive T cell therapy resulted in encouraging response for adenovirus (78%), CMV (74%), and EBV (67%) infections [266]. It was important to note that among patients who exhibited a response, only four patients had evidence of infection recurrence or disease progression. There were no reports of immediate infusion-related toxicity. Two patients developed new-onset GVHD. It was noted that despite immunologic discordance between the T cell lines and transplant recipients in whom such investigational antiviral therapy was given, post-infusion virus-specific T cell frequency increased significantly and coincided with conspicuous decline in viremia and resolution of clinical symptoms [266].

The main limitation of "third-party" derived pathogen-specific T cell lines is that specific patterns of HLA expression within a given population probably have widespread geographic and ethnic variations [25]. Nonetheless, virus-specific T cell adaptive immunotherapy from unrelated donors with common HLA polymorphisms offers an important advantage for rapid delivery of virus-specific CD8 T cells to a patient with incompetent pathogen-specific cellular immune response and an intractable systemic CMV infection after transplantation procedure.

Furthermore, adaptive cellular immunotherapy for viral infections has thus far focused on terminally differentiated cytotoxic T cells. Harnessing other T cell subsets including target-specific memory T cell, γδ T cells, and the keen recognition of the role of NK cells play in pathogen-specific recall against opportunistic viruses like CMV are the directions for future research that may further advance the field in providing a durable, on-demand, targeted immune recovery in the high-risk allograft transplant recipients [25].

Adoptive immunotherapy continues to remain an area of great interest for severely immunosuppressed stem cell transplant patients with difficult to treat CMV infection and for prevention of life-threatening end-organ viral disease. The optimum cell type, and infusion dose, along with limited technical personale expertise, technological proficiency, and the current astronomical cost are among the salient issues that have prevented such interventions to gain popularity in broader clinical scrutiny and research.

CMV Vaccines

Presently there is no licensed CMV vaccine [267]. Despite propitious advancement in development and licensing of new anti-CMV drugs like letermovir, and brincidofovir, the financial burden for prolonged drug therapy for prevention and preemptive antiviral approach should provide encouragement for prioritization and incentive for developing and launching a safe and effective CMV vaccine [268]. A vaccine that effectively reconstitutes a durable anti-CMV immune response following transplantation has the potential to transform the existing practice paradigm in transplant medicine.

Potential vaccine candidates such as CMV glycoprotein B showed modest efficacy in preventing CMV infection in young women and adolescents in early stage clinical trial [269]. In a phase-II randomized trial in adults awaiting kidney or liver transplantation, 70 CMV (−) and 70 CMV (+) patients were randomly assigned to receive either three-dose CMV gB vaccine with MF59 adjuvant or placebo. Sixty-seven patients received vaccine, and 73 were randomized to placebo arms. The CMV gB Ab titers were significantly increased in both CMV (−) and CMV (+) vaccine recipients. In patients in whom CMV viremia was demonstrated after transplantation, gB Ab titers correlated inversely with duration of viremia ($p = 0.002$). In CMV-seronegative patients with CMV-seropositive allografts, duration of viremia and duration of ganciclovir therapy were also significantly less among novel vaccine recipients prior to transplant surgery [270]. Vaccines containing CMV gB appears encouraging when boosted with a potent adjuvant and needs further immunogenicity and safety assessment in patients undergoing visceral allograft transplantation.

So far, only one CMV vaccine has been evaluated in a randomized, placebo-controlled phase II study. ASP0113 is a bivalent product containing two plasmids that encode CMV gB and the most abundant constituent of the viral matrix or tegument, phosphoprotein 65 [271]. In an open-label, phase II trial between 2013 and 2014 undertaken at three centers in Japan [272], the safety and tolerability of this combination -immunogen vaccine were assessed in patients undergoing HSCT for hematologic disorders. Nine of ten patients between ages 22 and 61 years were enrolled. Five (5 mg) doses of recombinant vaccine were given before and after transplantation in six patients. No serious adverse events were attributed to the experimental vaccine. CMV antigenemia was observed in seven patients. None of the patients developed CMV end-organ disease. Adverse events associated with recombinant CMV vaccine were fever and injection site skin reaction; hyperuricemia was noted in one individual. Although there was no significant difference in rate of initiation of anti-CMV therapy, rates of CMV viremia were lower, and time-to-first episode of viremia was longer in patients given this investigational vaccine. These findings facilitated the ongoing placebo-controlled phase III trial that is expected to enroll 500 subjects [271].

In patients undergoing visceral allograft transplants, prevention of graft-transmitted CMV infection is of high priority. Recently, two randomized controlled trials, one with active immunization of recipients prior to undergoing transplant surgery and another using monoclonal anti-CMV antibodies for passive immunization at the time of transplantation, showed reduced incidence of CMV viremia during post-transplant period [273]. Further studies and immunization strategies that completely or significantly interrupt CMV transmission from organ donor graft to seronegative recipient are needed.

Dendritic cell vaccines were shown to enhance tumor-specific cytotoxic T cell polyfunctionality. Dendritic cell vaccine has also been shown to garner potent ex vivo antiviral response against the influenza virus and resulted in significant protection against experimental influenza infection in immunosuppressed animals [274, 275]. An interesting anti-CMV vaccine construct with CMV pp65 RNA-loaded dendritic cells was evaluated on polyfunctional CMV pp65-specific cytotoxic T cells. In a pilot trial, 17 patients with newly diagnosed glioblastoma multiforme were randomized to receive CMV pp65-specific T cells with CMV-DC vaccination or saline. Patients who received dendritic cell vaccination plus specific T cells regimen experienced a significant increase in the overall frequencies of polyfunctional (IFNγ+, TNFα+, and CCL3+) cytotoxic T cell that were specific against cytomegalovirus [276]. Generation of polyfunctional T cell responses after recombinant DC vaccine given with target specific T cells is an emerging field. A lot needs to be done before this potential approach is considered for clinical use.

Some of the predictable issues for exploring the potential for new vaccines including the DC vaccine platform with or without specific T cell construct may include the following: (a) production applications need to be fine-tuned, (b) thorough assessment of clinical safety in the short-term and the long term, (c) durability and specificity of such an adaptive immune response, (d) strength of recall following viral exposure (D+/R−), re-exposure (D+/R+) or in the event of viral recrudescence of a remotely acquired infection (D−/R+), (e) influence on de novo or existing GVHD or solid organ allograft rejection, (f) viral disease modification or potential worsening in scenarios where hosts' inflammatory response perpetuates clinical illness/disease, (g) infection-free survival, and (h) patients' overall well-being all need to be taken into keen consideration.

Summary

CMV is a serious infection, which, if remain unchecked, will result in serious illness in patients undergoing transplantation. Recently, a major stride forward in recognizing at-risk subpopulation among solid organ and stem cell allograft transplant recipients has underscored selective allocation of resources where they are most needed. Highly sensitive PCR-based, viral DNA screening tools are now widely used to identify early CMV viremia and better risk-assessment for end-organ viral disease. Awareness regarding drug resistance in clinical practice appears to have now caught up with the development of new antiviral drugs with novel mechanisms of action and are entering advanced clinical validation stages. Understanding the viral immunopathogenesis involved in various end-organ CMV disease including viral pneumonitis has vastly improved treatment outcomes for what used to be a dreaded illness with high fatality rates. Future refinement in adaptive immunotherapy, research in CMV vaccine development with novel vaccine delivery platforms, and multifacted vaccine constructs have the potential to favorably change the current role cytomegalovirus plays in transplant medicine.

Taxonomy, Structure, and Genome

Epstein-Barr virus (EBV), or human herpesvirus-4, is a member of the herpes virus family. EBV is the only human member of the gamma-1 herpes virus subfamily and the prototype of the *Lymphocryptovirus* genus. The latter designation refers to the virus's ability to establish infection in lympho-

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_38

cytes. Structurally, EBV is similar to other herpesviruses. EBV's double-stranded DNA genome is wrapped around a toroid-shaped protein core and enclosed in a nucleocapsid composed of 162 capsomeres. The nucleocapsid is surrounded by a protein tegument, which is housed in a glycoprotein envelope [2].

The genome is 184 kilobase pairs in length and contains both internal and terminal repeat sequences. The repeat sequences divide the genome into short and long unique sequence domains. Most of the nearly 100 open reading frames are found within the unique sequences, though the exact number and identity of all EBV-encoded genes are not yet known [2, 3]. Most EBV genes encode viral proteins important for lytic replication, including enzymes that function in viral DNA replication and viral structural components and noncoding RNAs.

Viral Life Cycle

EBV and all other herpesviruses have both a lytic and a latent phase. In the lytic cycle, the EBV-encoded DNA polymerase replicates the viral episome, and progeny virions are produced. In the latent cycle, a cellular polymerase replicates the viral genome, which persists as a nuclear episome for the lifetime of the host B cell. While lytic phase genes tend to be conserved among *Herpesviridae*, proteins important for the establishment and maintenance of latent infection vary greatly.

Lytic Infection

EBV lytic replication is necessary for the production of infectious virions and for the establishment of persistent latent infection in the B cell. However, once latency is established, lytic replication is not needed for the maintenance of this persistent infection. Thus, EBV latent infection cannot be eliminated by lytic replication inhibitors, such as acyclovir or ganciclovir [4]. Reactivation of lytic replication does occur from latent EBV-infected cells, and the virus is shed more or less continuously into the saliva, which serves as the major source of transmission from one host to the next [5].

The physiologic signals that reactivate EBV lytic replication are not yet well defined. In vitro, lytic infection can be triggered by phorbol esters and n-butyrate or by cross-linking of surface immunoglobulin [6–8]. In vivo, viral replication may occur in Waldeyer's ring memory B cells undergoing differentiation into antibody-secreting plasma cells, as well as in the associated epithelium [5]. Two immediate early EBV transcription factors, BZLF1 and BRLF1, orchestrate the transition from latent to lytic growth. BZLF1, which is related to the cellular activating protein 1 (AP-1) family of transcription factors, is sufficient to activate the lytic replication cycle [9, 10]. In response to BZLF1 and BRLF1, approximately 80 EBV lytic genes are expressed. RNA sequencing has detected transcription of additional EBV genes [11] and demonstrated that EBV transcripts comprise 7% of all mapped reads from the B cell during reactivation. Early antigens (E) include multiple enzymes important for EBV DNA replication, including the viral thymidine kinase, DNA polymerase, ribonucleotide reductase, and alkaline exonuclease. Most virion structural components are produced during the late phase, including the viral capsid antigens (VCA). During the late phase, linear double-stranded DNA genomes are packaged into icosahedral protein nucleocapsids, which are then encased in a lipid envelope laden with viral glycoproteins. These virions can then be transmitted from one cell to another or to a new human host.

Latent Infection

Following resolution of acute primary EBV infection, between 1 and 50 per million B cells remain EBV-infected [12–14]. EBV spends much of its life cycle thereafter in the B-cell compartment, partially hidden in a state of viral latency. While latently infected B cells do not produce progeny viruses, the EBV genome is not entirely quiescent. A limited subset of gene products that promote viral genome propagation and infected cell survival are expressed. This strategy allows EBV to evade immune detection while maintaining persistent infection for the lifetime of the host.

There are four principal patterns of EBV latency. Upon initial B-cell infection, EBV initiates the Latency III growth program, in which all nine latency viral proteins and several noncoding RNAs are expressed. These include three latent membrane proteins (LMPs), six Epstein-Barr nuclear antigens (EBNA), two small non-polyadenylated EBV-encoded RNAs (EBERs), and the BamA genome fragment region-encoded BART transcripts (Table 38.1). Latency III cells morphologically resemble antigen-stimulated B lymphocytes [15]. Latency III proteins comprise over 4000 amino acids and thus provide numerous epitopes for T-cell detection. Furthermore, EBV latency proteins activate NF-kB and interferon pathways, which in turn upregulate numerous T-cell and natural-killer (NK)-cell ligands. The robust immune response to Latency III cells is likely responsible for many of the symptoms of acute infectious mononucleosis (AIM). CD8+ T cells and NK cells responding to Latency III cells comprise the atypical lymphocytes seen in the peripheral blood during AIM [16–19]. Fortunately, most Latency III cells are eliminated by immune surveillance. However, if left unchecked by the host immune system, Latency III B cells are oncogenic. In vitro, EBV uses the Latency III program to efficiently convert resting B cells into immortalized lymphoblastoid cell lines (LCL). Likewise, in the setting of immune suppression such as following hematopoietic stem cell or solid-organ transplant, Latency III cells can give

Table 38.1 EBV genome expression programs and associated characteristics

EBV program	EBV gene products expressed	Cell type	Immunogenicity	EBV-associated malignancy
Latency 0	RNA: EBERs	Resting peripheral blood memory B cell	None	–
Latency I	EBNAs: 1 RNAs: EBERs, BARTs	Dividing peripheral blood memory cell	Low	Burkitt lymphoma
Latency II	EBNA: 1 LMPs: 1, 2A, 2B RNAs: EBERs, BARTs	Germinal center B cell	Moderate	Hodgkin lymphoma, NK- and T-cell lymphoma, DLBCL of elderly, nasopharyngeal carcinoma
Latency III	EBNAs: 1, 2, 3A, 3B, 3C, LP LMPs: 1, 2A, 2B RNAs: EBERs, BARTs, BHRF1	Naïve B cell	High	PTLD, HIV-associated lymphoma, DLBCL of elderly
Lytic	>80 lytic gene products	Plasma cell, Waldeyer's ring epithelial cell	High	–

rise to posttransplant lymphoproliferative disorders (see below). Latency III expression is nearly always present in EBV-associated central nervous system (CNS) lymphomas of patients with human immunodeficiency virus (HIV) infection. Perhaps due to immune senescence of aging, the Latency III pattern is again found in a subset of EBV-associated diffuse large B-cell lymphoma (DLBCL) of the elderly [20].

To establish persistent host infection, EBV must reach the memory B-cell compartment, the site of long-term EBV residence. EBV uses its Latency II program to accomplish this [21, 22]. In Latency II, the viral genome expresses only EBNA1, LMP1, LMP2A, EBER, and BART RNAs. In a ligand-independent fashion, LMP1 and LMP2A mimic signals from CD40 and B-cell immunoglobulin receptors, respectively. LMP2A promotes germinal center (GC) formation, and transgenic LMP2A expression in mice causes spontaneous germinal center formation in the gut-associated lymphoid tissue [21]. Interestingly, LMP2A expression rescues germinal center formation in B-cell receptor (BCR)-deficient mice, and conditional LMP2A expression in germinal center B cells resulted in preferential selection of low-affinity antibody-producing B cells and a lupus-like illness [23]. Meanwhile, EBNA1 tethers the EBV episome to host chromosomes and ensures that the EBV genome is maintained in dividing B cells [22]. Expression of only these three EBV-encoded proteins limits the immunogenicity of Latency II cells.

Upon transition to the peripheral blood memory B-cell compartment, EBV enters the Latency 0 program, in which EBV gene products are not expressed [22]. This EBV B-cell reservoir appears to be a long-lived IgD-, CD27+ resting memory cell [12, 24, 25]. Cell surface phenotype and expression profile analysis suggest that these cells have transited through the germinal center [22], and 90% of these quiescent B cells are in the G0 cell cycle stage at any given time [26, 27]. However, they do divide approximately once per month, at which point EBV switches to the Latency I program. In Latency I, only EBNA1 and the EBER and BART RNAs are expressed. An EBNA1 glycine-alanine repeat domain limits EBNA1 biosynthesis and proteasomal turnover and, thereby, limits presentation of EBNA1 peptide epitopes by the HLA (human leukocyte antigen) class I antigen presentation pathway [28].

Oncogenesis

EBV efficiently converts B lymphocytes into immortalized LCL in cell culture. Recombinant EBV genetic studies have demonstrated that only six EBV protein-encoding genes and several microRNAs (miRNA) are crucial for B-cell transformation: the oncogene LMP1 and the nuclear antigens EBNA1, EBNA2, EBNA-LP, EBNA3A, and EBNA3C. LMP1 is an integral membrane protein that constitutively signals from two C-terminal cytoplasmic tail domains in a ligand-independent fashion [29–31]. LMP1 mimics the immune receptor CD40, and the LMP1 signaling domains can substitute for the CD40 signaling domains in mouse B cells [32]. Forced LMP1 expression causes loss of contact inhibition and anchorage-independent growth in soft agar [33]. Similarly, multiple transgenic mouse models have highlighted an important role for LMP1 in B-cell growth and survival. LMP1 expression produces an activated B-cell phenotype and drives B-cell growth [34]. LMP1 expression, under the control of an immunoglobulin heavy-chain promoter and enhancer, produces lymphoma at a threefold higher incidence than in LMP1-negative control littermates [35]. When LMP1 is inducibly expressed in mouse B cells, T cells efficiently recognize and eliminate the newly LMP1+ cells [36]. Strikingly, in the absence of CD8+ T-cell surveillance, LMP1 drives rapid and fatal lymphoproliferation and lymphomagenesis [36].

Although not required for EBV-mediated B-cell transformation, LMP2A nonetheless plays an important role in vivo. LMP2A also constitutively signals in the absence of ligand and further promotes B-cell development and survival [21, 37]. LMP2A provides an important B-cell survival signal, in particular for B cells that have not successfully rearranged their BCRs. LMP2A expression rescues such BCR-negative,

"crippled" GC B cells that would otherwise undergo apoptosis [38]. The LMP2A N-terminal cytoplasmic tail contains multiple signaling domains, including an immunoreceptor tyrosine-based activation motif homologous to the ones present in the BCR Igα and Igβ signaling chains. LMP2A thereby acts as a BCR surrogate, albeit signaling at lower levels than an activated BCR. At the same time, LMP2A competes with the BCR for recruitment of tyrosine kinases and thereby maintains B-cell latency by preventing antigen stimulation-mediated lytic cycle activation [39].

LMP2A, together with LMP1, may rescue GC B cells that would ordinarily be slated for apoptosis. Such LMP1- and LMP2-mediated rescue of pre-apoptotic cells may play an important pathogenic role in classical Hodgkin disease malignant transformation. Indeed, LMP1 and LMP2A are highly expressed in EBV+ Reed-Sternberg (RS) cells, the malignant B cell of classical Hodgkin lymphoma (HL). RS cells are dependent on constitutive NF-κB pathway activation. Interestingly, the tumor suppressor and NF-κB negative regulator A20/TNFAIP3 is frequently inactivated by somatic mutations in the 50% of HL cases that lack EBV, but is only rarely mutated in LMP1+ RS cells [40]. This observation suggests that EBV LMP1 and NF-κB pathway activating somatic mutations serve redundant functions in HL pathogenesis. Likewise, LMP1 and LMP2A cooperatively promote epithelial tumor development in murine carcinogenesis models [41], and they are frequently co-expressed in nasopharyngeal carcinoma tumor cells in vivo.

The nuclear antigens EBNA2, EBNA3A, and EBNA3C further promote B-cell growth. EBNA2 is an acidic transcriptional transactivator that upregulates expression of both EBV and cell genes, including *LMP1* and *MYC* [42, 43]. EBNA2 associates with DNA, in part through association with RBP-J kappa, a cellular transcription factor that is a downstream component of the cellular Notch pathway [44–46]. LCL chromatin immunoprecipitation-sequencing (ChIP-Seq) analysis suggests that EBNA2 predominantly binds to non-promoter sequences and may frequently regulate gene transcription through long-range DNA interactions [46]. EBNA3A and EBNA3C are both critical for EBV-mediated B-cell transformation, perhaps by jointly repressing expression of the tumor suppressors p16 (INK4A) and p14 (ARF). When EBNA3A or EBNA3C are functionally inactivated, p16 and p14 expression increases, and LCL growth ceases [47]. Reminiscent of adenovirus E1A and human papillomavirus E6/7, EBNA3C also blocks p53-dependent apoptosis and enhances proteasomal turnover of the pRb and p27KIP1 tumor suppressors [48, 49]. EBNA2, EBNA3A, EBNA3C, and EBNA-LP combine with LMP1-activated NF-kB transcription factors to form EBV super-enhancers that target 187 host genes. EBV super-enhancer targets include c-Myc and the anti-apoptosis proteins BCL2 and cFLIP [50].

EBV encodes two Bcl-2 family proteins, BHRF1 and BALF1 [10]. Both are highly, but transiently, expressed upon B-cell infection and are important for EBV-mediated B-cell transformation. BHRF1/BALF1 may function by inhibiting apoptosis of newly EBV-infected cells undergoing the transition into latency [51]. Interestingly, once latency has been established, both EBV Bcl-2 proteins are dispensable for maintenance of latency and for viral reactivation, perhaps since LMP1 highly upregulates cellular Bcl-2 family pro-survival proteins.

EBV also encodes 44 mature miRNAs, more than any other human virus studied thus far [52]. Recent studies have implicated EBV-encoded miRNAs in B-cell transformation. A cluster of miRNAs located near the BHRF1 open reading frame (and therefore called BHRF1 miRNAs) are highly expressed in Latency III and in a range of B-cell tumors [53]. All three BHRF1 miRNAs are important for EBV-mediated B-cell transformation in vitro, and genetic disruption of all miRNAs impairs transformation by 20-fold [54]. The BHRF1 miRNAs may reduce levels of the tumor suppressors PTEN and p27 through incompletely understood mechanisms [55].

Host Immune Response

EBV has coevolved with the human species and its antecedents over millions of years [56, 57]. Over this time period, the virus developed a complex relationship with the human immune system that permits its persistence in the memory B-cell compartment for the lifetime of the host. The host immune response to EBV is robust and equally complex; infected B cells are under constant surveillance by circulating immune cells.

Innate Immunity

Little is known about the innate immune response to primary infection with EBV, though several lines of evidence suggest that innate immunity limits early lytic infection [58]. In AIM, there is an expansion of NK cells, and NK-cell peripheral blood count is inversely proportional to EBV viral loads [59–61]. In vitro, NK cells inhibit EBV-infected B-cell growth [62]. An EBV miRNA, miR-BART2, reduces micB expression, an NK-cell activating ligand [63]. In vivo, patients with X-linked lymphoproliferative disease (XLP) have a specific immune defect that may lead to a fatal inflammatory illness, characterized by marked expansions of EBV-infected B cells and reactive T cells following primary EBV infection [64]. Though still incompletely characterized, XLP may in part arise from inadequate initial NK-cell control of EBV-infected B cells [65–67]. Individuals with immunodeficiencies preferentially affecting NK-cell function, such as CD16 mutations, are also prone to EBV-driven lymphoproliferative disorders [68, 69].

CD8+ T-cell Immunity

The importance of T-cell surveillance against EBV growth-transforming infection is supported by the high frequency with which T-cell-immunodeficient transplant recipients develop PTLD and by the fact that adoptive transfer of polyclonal EBV-specific T cells has proven successful in the treatment of this disease [70].

A large expansion of oligoclonal EBV-specific CD8+ T cells has been observed in patients with infectious mononucleosis at the time of symptom onset [17]. Similar expansions have not been observed in persons with primary asymptomatic infection [71, 72]. In some persons with infectious mononucleosis, the expanded T-cell population may account for up to 50% of the total peripheral blood CD8+ T-cell population [14, 17, 60]. The dominant CD8 T-cell responses are against the lytic immediate early and early antigens. The response to latent antigens is approximately tenfold less in number, and it accounts for 0.1–5% of the total CD8+ T-cell population [14, 17]. In most persistently infected individuals, the strongest response is directed against the Latency III EBNA3 antigens [19] though there is some variability depending on HLA background [14, 17]. As infection progresses, EBV downregulates both lytic and latent antigen expression. Subsequently, antigen stimulation decreases, and the bulk of CD8+ T cells reactive to these antigens undergoes apoptosis. In long-term asymptomatic carriers, MHC (major histocompatibility complex) class I tetramer analyses have shown that 0.2–2% of CD8+ T cells are specific for lytic antigens, versus 0.05–1% for latent antigens [14, 17]. In the carrier state, the majority of T cells have a resting phenotype, as compared to the activated phenotype seen in early primary infection.

In addition to progressive downregulation of antigen expression, EBV employs several strategies to evade CD8+ T-cell detection. As examples, the EBV lytic protein BNLF2A binds to the transporter associated with antigen processing (TAP) and thereby inhibits MHC class I antigen processing [73, 74]. Lytic proteins BGLF5 and BILF1 also function to reduce cell surface HLA I levels by, respectively, reducing new HLA antigen expression and impairing export of new MHC I complexes [75–77]. EBV miRNAs also inhibit TAP expression and downregulate the expression of cytokines that aid in EBV-specific CD8+ T-cell antigen recognition [78, 79]. Latent antigens LMP1 and EBNA1 have also devised strategies to decrease the efficacy by which they are presented on HLA class I molecules [80–82]. Notably, as EBV infection progresses from the acute to the persistent state, the EBV-specific T-cell repertoire becomes less skewed toward early lytic antigens and also encompasses late lytic antigens [83]. This phenomenon suggests that the aforementioned MHC class I immune evasion strategies may have evolved to allow viral replication in the acute phase and to facilitate the establishment of persistent EBV infection [83].

CD4+ T-cell Immunity

The CD4+ T-cell expansion in acute EBV infection appears to be at least tenfold less than that of CD8+ T cells [14, 17, 60]. The hierarchy of immunodominant epitopes is less well studied in the CD4+ than in the CD8+ T-cell population, though the available data suggests CD4+ T-cell responses are more often directed at latent antigens. Among CD4+ T-cell responses directed at lytic antigens, there is a more uniform distribution across the immediate early, early, and late lytic antigens [17, 84]. In contrast to the CD8+ T-cell response, the EBV-specific CD4+ T-cell response is lower in magnitude, and the role of CD4+ T cells is less well defined. However, CD4+ T-cell responses are likely important, as evidenced by the high frequency of EBV-associated lymphomas that arise with waning CD4+ T-cell count in patients with HIV. In vitro, EBV-specific CD4+ T-cell clones exert cytotoxic function and prevent the proliferation of newly EBV-infected B cells [84, 85]. Virus-specific CD4+ T cells may also be necessary for the persistence of adoptively transferred CD8+ T cells in immunotherapy products used for the treatment of PTLD [86].

Several EBV proteins interfere with MHC II antigen presentation and subsequent CD4+ T-cell activation. As examples, BZLF1, an immediate-early lytic protein, downregulates CD74 expression, a chaperone for MHC II dimers [87], and may also reduce surface class II expression by downregulating the class II transactivator, CIITA [88]. BZLF2 also subverts CD4+ T-cell activation by obstructing MHC II and T-cell receptor interactions [89]. The EBV lytic protein BCRF1 encodes an interleukin-10 (IL-10) homolog, which blocks many interferon-gamma-mediated functions, such as upregulated expression of MHC II and other costimulatory molecules needed for CD4+ T-cell activation. Unlike the human IL-10 homolog, viral IL-10 has a reduced ability to stimulate T cells [90].

Humoral Immunity

The humoral response to acute infection is characterized by polyclonal B-cell activation and marked immunoglobulin response to both lytic and latent viral antigens [91]. Antibodies to glycoprotein 350 (gp350), one of the major outer envelope glycoproteins, have been shown to have neutralizing effects [92–94]; generation of antibodies to gp350 is impaired during acute infectious mononucleosis [95]. These features support gp350's use in vaccine strategies. The pattern of antibody development to viral antigens and heterophile antibodies have long been used to diagnose EBV infection and are further reviewed below.

Epidemiology

EBV is ubiquitous and infects over 90% of the world's population [1]. A large portion of the population will acquire infection during youth. Higher rates of acquisition in early childhood are seen in developing nations, where over three quarters of children acquire EBV infection by age 6 [96]. By contrast, in developed nations, EBV infection is detected in less than half of school-aged children [96, 97]. Prevalence increases with age, and by late adulthood, 89–100% of the population harbors latent EBV infection [97–103]. These numbers suggest that a substantial number of pediatric and young adult transplant recipients will be seronegative for EBV at the time of transplantation and thus susceptible to primary infection as well as PTLD. Humans are the only natural host for EBV infection. The major vehicles for transmission to the non-transplant host are saliva and oropharyngeal secretions. Most infected individuals will shed virus in saliva near continuously over their lifetimes, and this appears to be the major reservoir for transmission from one individual to another [5]. Thus, contact with an acutely infected individual is not necessary for EBV spread. However, the degree of contact does play a role. Casual household contact appears to be largely insufficient for transmission [60, 104]. More intimate contact including kissing, mouth-to-mouth transfer of food, or transmission via saliva-contaminated toys, cups, or other fomites as occurs in daycare settings is likely required [105]. In a single study undertaken in the daycare setting, the rate of EBV seroconversion was 9% per month; the likelihood of acquiring infection was proportional to the duration of time spent in daycare [106]. This may have important implications for the pediatric EBV-seronegative transplant host as the likelihood of acquiring primary EBV infection in certain settings is not small.

Several reports of EBV shedding in genital secretions exist [107–110], and the risk of EBV seropositivity increases proportionally with number of sexual partners [111], suggesting that the virus may also be sexually transmitted. However, definitive evidence is lacking. Rare cases of primary EBV infection being transmitted via blood transfusion have also been reported [112]. Leukoreduction significantly reduces the number of B cells in packed red blood cells [113] but may not completely eliminate B cells from packed red blood cell products [114, 115], making blood transfusion a biologically plausible but unlikely source of transmission. One of the major sources of transmission in the transplant recipient is the transplanted organ. Higher rates of PTLD are reported in organ transplants in which a large reservoir of lymphoid cells are transplanted with the organ, such as with intestinal transplantation [116]. However, it is unclear whether this increased prevalence is due to the transfer of an increased number of allogeneic EBV-infected B cells, the higher degree of immunosuppression that often accompanies such transplantation, or the interplay of these two factors.

There are two major EBV strains, type 1 (or A) and type 2 (or B) [117]. An important difference between the two strains is their differential growth-transforming capacity. Type 1 EBV has greater growth-transforming efficiency than the type 2 strain [118, 119]. Type 1 is the more prevalent strain, although there is some suggestion that type 2 EBV may preferentially infect immunocompromised hosts [120]. To date, studies that have addressed whether PTLD is associated with type 1 or 2 have predominantly detected type 1 EBV in PTLD tumor tissue [121, 122].

EBV Diagnostics

An overview of the serologic and virologic assays used to diagnose EBV infection is presented below. As humoral immunity may be impaired in the transplant population, serologic testing may be less reliable in these hosts. Transfusion of blood or immunoglobulin may also result in false-positive serologic testing in the population [123].

Heterophile Antibody Testing

Heterophile antibodies are a group of antibodies, primarily of the IgM class [124], that are produced in acute EBV infection. The precise nature of the antigen, termed the Paul-Bunnel antigen, is not known, but it is believed to be an infection-induced cell membrane glycoconjugate [124]. Heterophile antibodies have the ability to agglutinate sheep and horse erythrocytes and are adsorbed by cattle erythrocytes. The most common clinical heterophile antibody test is the mono-spot assay, which tests for the presence of antibodies in sera that agglutinate purified bovine antigen bound to latex particles. The reported sensitivity of the test ranges from 81% to 95% and the specificity from 94% to 100% in the setting of symptoms of AIM [125, 126]. Heterophile antibodies are positive in 75% of patients during the first week of symptoms and in 90–95% of patients during weeks 2–5 and then decline rapidly thereafter; in some, heterophile antibodies may persist for years [126–128]. The sensitivity of the heterophile assay appears to be reduced in young children [129, 130]. Although the specificity of the test is high, false-positive heterophile antibody testing has been reported in patients with leukemia, lymphoma, systemic lupus erythematosus, viral hepatitis, and acute HIV infection [127, 131–134].

Virus-Specific Antibodies

The humoral response to EBV is composed of a vast number of antibodies to both lytic and latent cycle antigens. Three of these antibodies are routinely used for diagnostic purposes and can distinguish acute from prior infection. Antibodies expressed during lytic viral infection develop during acute infection; antibodies expressed during latent infection develop thereafter.

Antibodies to Lytic Cycle Antigens

The VCA consists of several viral proteins that comprise EBV's capsomers. VCA IgM is a marker of recent EBV infection. It is typically present at the time of AIM symptom onset and then disappears within a few weeks. VCA IgG is frequently detected at the time of presentation or shortly thereafter, peaks, and then declines to a steady state. As VCA IgG persists for life and the assay is relatively sensitive, testing for VCA IgG alone is an appropriate pretransplant screening test for the detection of prior EBV infection.

The early antigen (EA) complex is expressed early in EBV's lytic life cycle. There are two patterns of anti-EA antibodies, diffuse (D) and restricted (R). These designations refer to the pattern of immunofluorescence (IF) observed when these antibodies were first detected [135]. The EA-D IgG arises at the onset of symptoms and typically decreases 3–4 weeks after illness. However, in some the antibody may persist for years. EA-D antibodies have also been detected in 10–20% of the healthy population [136]. Thus, although EA-D IgG arises early in acute EBV infection, it is not a clear indicator of primary EBV infection. The EA-R IgG is detected in only a small subset of patient with AIM and may correlate with severe disease [135].

Antibodies to Latent Cycle Antigens

Anti-EBNA antibody arises 1–3 months following acute infection and persists for life. EBNA1 is the primary antigen targeted by anti-EBNA antibody. Approximately 5% of those infected with EBV will not develop the anti-EBNA antibody [137].

Traditionally, the above EBV-specific antibodies have been detected by indirect IF assays. Though IF assays are more specific, they are technically demanding, and most clinical laboratories are now using enzyme-linked immunosorbent assays (ELISA) in their place. Avidity assays had been used to help distinguish acute primary infection versus prior infection in the past, but their accuracy is uncertain [138].

Viral Load Testing

EBV DNA viral loads are routinely monitored by quantitative polymerase chain reaction (PCR) in patients at risk for the development of PTLD. Presently, there is no FDA-approved assay for the quantitation of EBV DNA. Each assay is developed and validated by each individual laboratory and subject to its standards. Use of the World Health Organization (WHO) International Standard for EBV viral loading testing can help mitigate some of the variability among laboratories [139, 140]. However, specimen handling, DNA extraction methods, primers, probes, and gene targets may all vary between laboratories. Consequently, the upper and lower limits of quantitation, linear range, precision, accuracy, and reported units may also differ. These differences preclude comparison of test results and cutoff values between laboratories. Interpreting viral load results, thus, requires knowledge of the performance characteristics of the specific assay used.

The type of specimen assayed will also affect results. Most commercial laboratories perform viral load testing on either whole blood or plasma. Whole blood-based assays detect intracellular DNA as well as cell-free DNA, which may include both DNA released during lytic viral replication and from dying tumor cells. By contrast, plasma-based assays measure only cell-free DNA. Consistent with the fact that whole blood-based assays detect both intracellular and cell-free DNA, viral loads from whole blood tend to be higher than those from plasma [141–145]. While whole blood-based assays may be more sensitive for the detection of EBV DNA, the significance of viremia depends upon the clinical setting.

EBV DNA is typically not detectable in the plasma of healthy individuals but may be detectable in whole blood at low levels as approximately 0.0001% of circulating leukocytes are estimated to harbor latent EBV infection [141, 143, 146]. In asymptomatic primary infection or AIM, viral loads in plasma may be undetectable or quickly decline after the onset of symptoms [141, 143]. By contrast, virus is frequently detected in whole blood in patients with infectious mononucleosis, and viral loads may remain elevated up to 180 days [141, 143]. It should be stressed that serologies are the preferred diagnostic for acute primary EBV infection and that viral load assay is not licensed for the diagnosis of AIM. However in the immunocompromised host, serologies may be unreliable and a whole blood-based PCR assay may be a useful alternative assay.

The optimal specimen type for PTLD screening has not been determined, though several studies have addressed this issue [141–143, 147–150]. While viremia may be more frequently detected from whole blood, it may not be the test of choice. In a prospective trial by Tsai et al., the sensitivity of both whole blood- and plasma-based assays for the detection of PTLD was similar. However, the plasma-based assay had greater specificity and positive predictive value for diagnosing PTLD. Higher false-positive rates were found with the whole blood assay [142]. Of note, false-negative test results have been reported for patients with CNS PTLD with both whole blood- and plasma-based assays [151, 152]. Some researchers advocate that testing both plasma and whole blood viral loads concurrently may have the greatest predictive value [150]. Finally, because of the lack of standardization of EBV viral load testing, following viral load treads in patients over time using a single assay from a single laboratory may have greater value than attempting to interpret a specific result at a single time point.

Posttransplant Lymphoproliferative Disease

EBV-seronegative solid-organ transplantation (SOT) or hematopoietic stem cell transplantation (HSCT) recipients are at high risk from primary EBV infection. As in the immunocompetent host, primary infection may be asymptomatic or may present with features of AIM, such as fever, pharyngitis and lymphadenopathy, or other systemic symptoms. More severe complications of primary EBV infection include hepatitis, aseptic meningitis, encephalitis, and more rarely cerebellar ataxia and transverse myelitis. Review of the literature at this point in time does not suggest that these complications are more frequent in transplant recipients. The most serious and common clinical manifestation of EBV infection following transplantation is PTLD (Fig. 38.1).

PTLD refers to any abnormal proliferation of lymphocytes that occurs following HSCT or SOT. The spectrum of disease ranges from a benign and self-limited expansion of lymphocytes to fulminant, fatal lymphoma. The majority of PTLD is of B-cell origin, though T-cell disease also occurs.

Incidence

Estimated incidences of PTLD vary among institutions, with the type of transplantation and with the degree of immunosuppression. The true incidence of PTLD is difficult to ascertain, as the disorder itself is heterogenous and approaches to diagnosis differ between institutions. A review of 100,000 adult SOT recipients in the United States found PTLD to be the most common posttransplantation malignancy in kidney and liver transplant recipients with rates of 1.6% and 2.4%, respectively [153]. PTLD was the third most common malignancy in heart transplantation recipients with a frequency of 2.2%. The highest rates for PTLD were reported in lung transplantation recipients at 5.7%, though the incidence of lung cancers still exceeded that of PTLD in this population. Equally comprehensive data is not available in the pediatric SOT recipient population; however, reported PTLD rates are often substantially higher in this population, ranging from 1% to 19% depending on the type of organ transplanted [154–160].

The frequency of PTLD in the allogeneic HSCT population at large is approximately 1% [161], though this varies

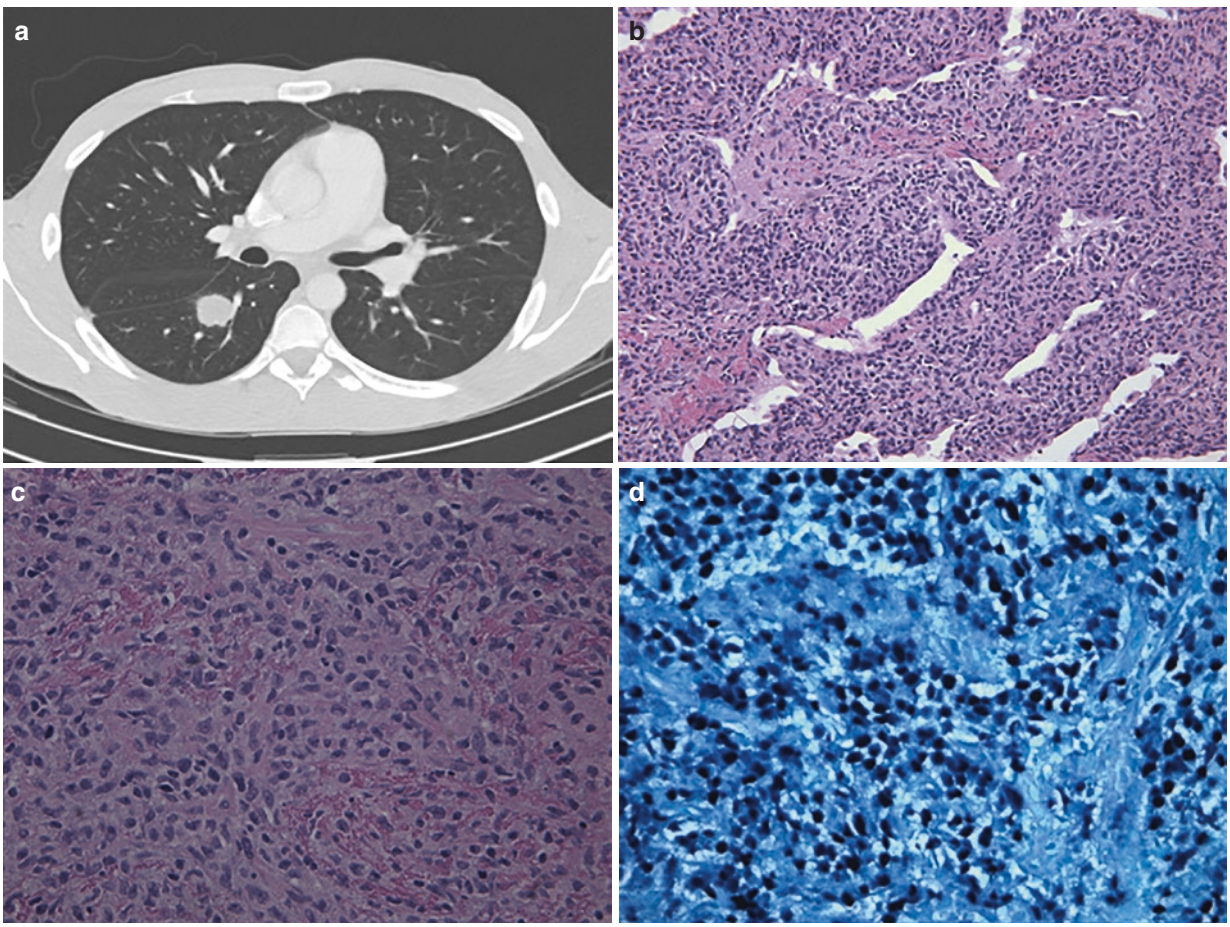

Fig. 38.1 Posttransplant lymphoproliferative disease: (**a**) CT scan of a right lower lobe lung nodule in HSCT recipient. (**b**) The nodule is composed of a sheet-like infiltrate of a relatively monotonous population of lymphocytes. (**c**) Higher-power image of medium to large lymphoid cells with marked nuclear atypia, consistent with DLBCL. (**d**) In situ hybridization for EBER, the dark blue nuclear stain, is positive confirming the presence of EBV in the tumor tissue. (*Photos courtesy of Leona Doyle*)

with the type of transplant and conditioning regimen. Higher rates have been reported in the setting of allograft T-cell depletion by in vitro selection or by in vivo treatment with T-cell-depleting antibody preparations [162, 163]. Within the allogeneic stem cell transplantation populations, the umbilical cord blood transplantation (UCBT) population appears to be at particularly high risk, with reported rates as high as 21% [164–166]. This may not be unexpected, as the majority of UCBT recipients are EBV-seropositive and the transplanted immune system is by nature EBV-naïve. At present, there is not sufficient data to suggest that PTLD rates are higher in pediatric allogeneic HSCT recipients compared with adults. The incidence of PTLD among recipients of autologous HSCT is extremely low.

The majority of PTLD is associated with EBV [167]. This association is strengthened in early-onset PTLD (i.e., PTLD occurring within the first year posttransplant) and in pediatric transplant recipients [168, 169]. Early-onset PTLD is associated with EBV and younger age, while late-onset PTLD appears to be associated with both younger (<20 years of age) and older age (>50 years of age) [168]. The diminished EBV association and increased risk in older age groups suggest that the pathogenesis of late-onset PTLD may be distinct from early-onset disease and more akin to lymphomagenesis in the general population. Late-onset PTLD tends to have a worse prognosis than early disease [170].

Pathogenesis

The oncogenic potential of the virus may best be illustrated by its in vitro activity. The growth of EBV-transformed B cells can be inhibited in tissue culture by the addition of autologous T cells from EBV-seropositive hosts [171–173]. In healthy humans with persistent EBV infection, approximately 0.2–3% of circulating CD8+ T cells are devoted to continually controlling EBV infection [14, 17, 174]. Thus, in the setting of T-cell immunodeficiency, control of the virus-infected B cells may be lost. As detailed above, several EBV proteins inhibit apoptosis, which may further contribute to the outgrowth of EBV-infected B cells in PTLD. Early in the process, this outgrowth may be polymorphic, polyclonal, and largely driven by EBV's latent genes. However, as growth persists, the likelihood of acquiring mutations increases, and monomorphic, monoclonal lymphomas may arise.

Most PTLD lesions exhibit a Latency III growth pattern, though more restricted as well as heterogeneous patterns of latency have also been reported [175–178]. As PTLD arises in the setting of T-cell immunodeficiency and can be controlled by the adoptive transfer of EBV-specific T cells, it is clear that inadequate T-cell immunity plays a significant pathogenic role. However, the events that initiate the development of PTLD have not been fully elucidated, and this remains an area of active investigation. In particular, the role of lytic infection in pathogenesis is poorly defined. PTLD has been reported to arise in both cells of donor and recipient origin [175, 179]. In support of an intervening period of lytic replication, PTLD can arise in recipient B cells in hosts who were EBV-seronegative at the time of transplantation and who received organs from EBV-seropositive donors [179]. Further, strain typing demonstrates that EBV-seronegative transplant recipients often acquire EBV from their donor [175].

Risk Factors

Risk factors for the development of PTLD mirror its pathogenesis and may be broadly categorized into three groups: (1) agents that disrupt T-cell immunity, such as antithymocyte globulin (ATG), OKT3, or calcineurin inhibitors; (2) interventions that either donate or leave behind a reservoir of EBV-infected B cells, such as receipt of an organ from an EBV-seropositive donor or receipt of nonmyeloablative transplantation; and (3) lack of underlying EBV-specific immunity, as is frequently seen in the pediatric SOT recipients or with receipt of UCBT.

The most clearly defined risk factor for the development of PTLD in SOT recipients is EBV seronegativity at the time of transplantation [154, 159, 168, 180]; the highest risk is conferred in EBV-seronegative recipients who receive organs from EBV-seropositive donors [159]. Multiple studies also describe young age as a risk factor for the development of PTLD in SOT recipients [168, 181–183], though this association often weakens in multivariate analyses, suggesting that young age may be a reflection of EBV seronegativity [168]. Intense T-cell immunosuppression is also a commonly reported risk factor for PTLD [184–189], and for all organs, risk seems to be greatest during the first 12 months following transplantation when immunosuppression is at its peak [189]. Though there is little evidence to implicate one induction or maintenance immunosuppressive drug or regimen over another, an increased risk of PTLD with a predilection for CNS disease in EBV-seronegative SOT recipients was reported in Phase III trials of belatacept, a T-cell costimulatory blocker, suggesting that this drug carries particular risk in the EBV-seronegative population [190–192].

In a survey of 235 transplant centers, which included over 18,000 HSCT recipients worldwide, risk factors for the development of PTLD in the first year following transplant included (1) unrelated or HLA-mismatched donors, (2) in vitro T-cell depletion, and (3) the use of ATG or CD3 monoclonal antibodies for the treatment of graft rejection and/or graft versus host disease (GVHD) [161]. Subsequent studies found nonmyeloablative conditioning regimens, especially those containing ATG, to confer risk [163, 193]. Each of these risk factors is consistent with the central role T cells play in controlling the proliferation of latent EBV-infected B cells. To further illustrate this point, methods of

T-cell depletion that selectively target T-cell or T- and NK-cell populations impart greater risk than those that deplete both T and B cells, such as anti-CD52 monoclonal antibodies (e.g., alemtuzumab) [161, 193, 194]. The importance of maintaining balanced T- and B-cell populations has also been found in the UCBT population, where rates of PTLD are as low as 2% in those who receive myeloablative conditioning regimens [165, 195] but rise to as high as 21% in those who receive nonmyeloablative conditioning regimens and ATG [165].

Clinical Presentation

The clinical manifestations of PTLD are protean. Thus, maintaining a high index of clinical suspicion and knowledge of predisposing factors are critical to making the diagnosis. Patients may be asymptomatic or may present with systemic signs that range from fever to frank systemic inflammatory response syndrome. Mononucleosis-type syndromes are not infrequently reported. Symptoms associated with the site or sites of disease may also be present.

As with lymphoma, PTLD may present in lymph nodes or in the lymphoid tissue of other organs. In SOTs, PTLD has a propensity to arise in the transplanted organ [179, 196]; therefore, graft dysfunction should raise suspicion for PTLD. The incidence of localization to the allograft diminishes with time and is significantly less likely beyond the first year after transplantation [197]. The gastrointestinal tract is another common site of involvement, though virtually any organ can be involved [197]. Compared to lymphomas within the general populations, PTLD seems to have a greater propensity to involve the CNS [198].

The majority of PTLD arises in the first year posttransplantation [189] and has been reported to occur as early as 15 days following transplantation. PTLD occurring in the first year following transplantation is termed early PTLD. PTLD occurring thereafter is termed late PTLD. Greater than 90% of early PTLD is associated with EBV, whereas only about half of late PTLD is associated with EBV [199], indicating that a subset of late PTLD may be a distinct disorder.

Pretransplant Screening and Posttransplant Surveillance

Prior to transplantation, both donor and recipient should be screened by serologic testing for EBV infection to assess risk status. Following transplantation, peripheral blood viral load monitoring is commonly used to monitor for elevated levels of EBV DNA. The intent of monitoring is to identify patients who are at higher risk for developing PTLD and afford enough time to intervene by adjusting immunosuppressive regimens and/or by preemptively treating to avert progression to PTLD. Approaches to surveillance differ among transplant centers and society guidelines [200–207].

Conflicting data exist on what constitutes a significantly elevated viral load and to what extent the height of elevation correlates with risk for PTLD [208–212]. Patients with PTLD tend to have higher EBV viral loads than those without [144]. However, many patients with detectable viremia will not progress to PTLD [213, 214]. Sustained high-level viremia without progression to PTLD is particularly prominent in the pediatric population [215–217]. Which populations require routine monitoring is also a matter of debate. Some transplantation centers will monitor all transplant recipients, while others will limit routine monitoring to high-risk groups (e.g., UCBT recipients, in vitro T-cell depletion).

The frequency with which viral loads should be monitored is also unclear and may depend on the risk status of the patient and the type of transplant received. As an example, a renal transplant work group recommended that high-risk renal transplant recipients be monitored once during the first week after transplant, monthly for 3–6 months, and then every 3 months for the first year. Monitoring should then be reinstituted if T-cell immunosuppression for acute rejection is needed [218]. By contrast, another renal transplant work group found that there is insufficient data to suggest that patient outcomes differ with routine monitoring and recommended that testing be individualized [205]. Recommendations from a leukemia working group were for weekly monitoring for a minimum of 3 months in high-risk HSCT recipients [200]. The 2013 American Society of Transplantation guidelines and the 2017 National Cancer Care Network guidelines make no definitive recommendation on whom to monitor and with what frequency [206, 207].

Until standardized approaches are developed through prospective trials, many of the above questions may remain unanswered. Importantly, preemptive viral load testing alone is not 100% effective at predicting disease. In order to augment the positive predictive value of viral load testing, various adjunct assays have been investigated, including measuring specific peripheral blood B- and T-cell subsets, interferon-gamma release to EBV antigens, and cytokine expression levels [219–230], though none are routinely employed in the clinical setting. As PTLD is likely a consequence of impaired cellular immunity, most adjunct assays focus on measuring T-cell number, function, or phenotype. Several studies have used MHC I tetramers for the detection of EBV-specific CD8+ cells in conjunction with viral load monitoring in both SOT and HSCT recipients [231–235]. Though most studies are limited by small sample sizes, many have found that expansion of EBV-specific T cells may indicate appropriate immune control

and predict a lack of progression to PTLD despite elevated EBV viral load [231, 232]. Conversely, lack of expansion of EBV-specific T cells in response to elevated viral load correlates with the development of PTLD [234, 235]. A major disadvantage with MHC class I tetramer monitoring is that the reagent is HLA-specific. Therefore, it is only applicable to patients with common HLA alleles. At present, this diagnostic is not available outside the research setting.

Prevention of EBV-Associated Disease

Several studies have addressed the use of antiviral medications for the prevention of PTLD. Available antiviral medications target lytic cycle replication. It is plausible that lytic cycle replication contributes to the pathogenesis of PTLD; though as described above, the disorder is largely a result of latent gene effects on B-cell growth and survival. The greatest role for antivirals may, therefore, be in the prevention of primary infection (i.e., transmission from an EBV-infected organ or from another infected person) in EBV-seronegative transplant recipients and possibly the mitigation of severe AIM in immunocompromised individuals.

EBV encodes its own DNA polymerase, which replicates viral DNA as linear concatemers. The EBV DNA polymerase is only expressed during lytic replication. In latently infected cells, the host cell DNA polymerase replicates the EBV episome. Thus, available antiviral agents, such as acyclovir, ganciclovir, and foscarnet, each block EBV lytic but not latent replication. Acyclovir and ganciclovir are guanine nucleoside analogues that are converted into nucleotides by the EBV-encoded protein thymidine kinase [236]. The monophosphorylated form is then incorporated into viral DNA and terminates viral DNA chain synthesis.

Acyclovir is the most well-studied drug for the prevention of PTLD. The results of these studies have been mixed [237–243]. Notably, in most cases, the study populations included both EBV-seronegative and EBV-seropositive patients. The effect of acyclovir on prevention of primary infection in the seronegative population may have been obscured. Further, 800 mg of oral acyclovir was used in most of these studies, and the peak serum concentration of this dosage may not be consistently greater than the half maximal inhibitory concentration (IC50) for EBV replication [236, 244]. Valacyclovir, the esterified form of acyclovir, has greater bioavailability, and its peak serum concentration with the commonly used 1000 mg dose exceeds EBV's IC50 [236]. Valacyclovir's use has nonetheless not yet been as rigorously studied for the prevention of PTLD in the transplant population.

Ganciclovir may be more effective than acyclovir in treating or preventing EBV lytic infection. Both peak serum concentrations of the oral form of ganciclovir and the esterified form, valganciclovir, exceed the IC50 of the virus by 4- to 20-fold [236, 245]. Two studies have evaluated the use of ganciclovir or valganciclovir in high-risk EBV-seronegative pediatric SOT recipients. The first found a significant reduction in the incidence of PTLD in high-risk patients treated with 100 days of IV ganciclovir, when compared to historic controls. However, this finding may have been confounded by concurrent intense viral load monitoring with a reduction of immunosuppression for viremia in the treatment group [240]. A small prospective cohort study found that primary EBV infection was significantly decreased in patients who received ganciclovir or valganciclovir compared to those who received no prophylaxis (45% versus 100%, $p < 0.0001$) [246].

Results from some of these trials were included in a meta-analysis of 31 studies, largely observational in nature; no significant difference in rate of EBV-associated PTLD in SOT recipients was observed among those who received prophylaxis (acyclovir, valacyclovir, ganciclovir, valganciclovir) compared with those who did not receive prophylaxis [247]. Overall, use of antiviral prophylaxis remains a controversial area, and as ganciclovir and its derivatives are not without toxicity, further research is needed.

Preemptive Therapy

EBV viral load monitoring has become routine in many transplant centers. However, how to best manage subclinical EBV viremia detected by routine screening remains a major quandary. Present approaches include reduction in immunosuppression and/or treatment with anti-CD20 monoclonal antibodies, such as rituximab. Numerous studies have evaluated the role of rituximab in preemptive treatment, where rituximab is given for EBV reactivation or primary infection with a goal of destroying infected B cells before clinical PTLD can develop. This strategy may be particularly effective in HSCT recipients [217, 248, 249], although not every patient with EBV viremia will progress to PTLD. Thus, this strategy comes at the cost of additional humoral immune deficits in an already immunocompromised population. Adoptive transfer of EBV-specific T cells has also been shown to be effective prophylaxis [250–253], but its use has historically been limited by the technical difficulty of generating an individualized product for each transplant recipient. Each of these management strategies is further detailed below.

Diagnosis

The accurate diagnosis of PTLD requires tissue biopsy. When safe and clinically feasible, excisional biopsy is preferred over needle core biopsy or fine needle aspiration. Elevated or rising EBV viral load within the peripheral blood

or sterile fluid, such as cerebrospinal fluid, raises the likelihood of disease, but it is not diagnostic. Likewise, radiographic evidence of PET (positron emission tomography)-avid lesions increases the likelihood of disease, but again is not diagnostic of PTLD. As with lymphomas in the non-transplant population, CT (computed tomography)/PET imaging should be used to stage disease at diagnosis and may be used to assess for interval change with treatment. Of note, CNS PTLD is less likely to present with an elevated peripheral blood viral load [151, 152]. Tissue biopsy remains the gold standard for diagnosis of CNS PTLD. However, diagnosis may be inferred from the presence of malignant lymphocytes in the cerebrospinal fluid if biopsy cannot be performed [237].

In situ hybridization for EBERs is the gold standard for confirming the presence of EBV in tumor tissue. EBER1 and EBER2 are noncoding RNAs that are expressed at roughly one million transcripts per latently infected cell making them readily amenable hybridization targets [254]. Immunohistochemical detection of EBNA1, EBNA2, LMP1, LMP2, and BZLF1 can also be used to confirm the presence of EBV in tumor tissue, as well as to distinguish EBV latency patterns. However, these assays are typically less sensitive and are also prone to cross reaction with human proteins [240, 254]. Further, it is not typically necessary to distinguish the latency pattern when diagnosing PTLD.

Pathology

The pathologic diagnosis of PTLD is based on the WHO classification [255]. There are four major categories: (1) early lesions, (2) polymorphic PTLD, (3) monomorphic PTLD, and (4) classical Hodgkin lymphoma-like PTLD (see Table 38.2). Early lesions typically arise in the first year following transplantation. A variety of B-cell types can become malignant in early lesions, though the underlying tissue architecture tends to be preserved in this type of PTLD. There are two subtypes of early lesions, plasmacytic hyperplasia and infectious mononucleosis-type PTLD, though some morphological overlap occurs between the two. Both the abnormal B cells and the latent EBV strain tend to be oligoclonal or polyclonal, and chromosomal karyotypes are typically normal in early lesions [204, 255]. By contrast, in polymorphic PTLD, the underlying tissue architecture is effaced by an expansion of B cells in various stages of differentiation. Additionally, there may be a higher degree of nuclear atypia, mitosis, and necrosis [204]. Both B cells and EBV tend to be clonal in polymorphic PTLD, and chromosomal karyotypes are commonly abnormal [146, 204].

Table 38.2 WHO classification of PTLD

Early lesions
Plasmacytic hyperplasia
Infectious mononucleosis-like PTLD
Polymorphic PTLD
Monomorphic PTLD
B-cell neoplasms
Diffuse large B-cell lymphoma
Burkitt lymphoma

Classical Hodgkin lymphoma-type PTLD

Monomorphic PTLD is the most commonly detected form of PTLD and refers to a heterogenous group of monoclonal malignancies of B- or T-cell origin. The most common form of monomorphic PTLD is DLBCL [255]. Monomorphic PTLD may also take the form of Burkitt lymphoma. As in the sporadic form of Burkitt lymphoma, proliferation rates are high and *MYC* mutations are common. Rarely, monomorphic PTLD manifests as a plasma cell neoplasm. Like their counterparts in the non-transplant population, monoclonal immunoglobulins may be found in the serum or urine in patients with this form of PTLD [204].

Up to 15% of PTLD may be of T-cell origin. The association with EBV is weaker, with only 30% of T-cell PTLD harboring the EBV genome [256]. NK-cell disease is even less common than T-cell disease, but the majority of these lesions are EBV positive [257]. In the majority of cases of monomorphic T-cell PTLD, both the malignant cell and EBV are clonal. Classical Hodgkin lymphoma-type PTLD is a rare form of PTLD and tends to occur in the late posttransplant course, though is often EBV positive [258]. Notably, while PTLD appears morphologically similar to many lymphomas arising in the non-transplant population, the gene expression profiles of both polymorphic and monoclonal PTLD appear more similar to one another than to B-cell lymphomas arising in the non-transplant population [259].

Management

There are several strategies for treatment of PTLD, ranging from reduction of immune suppression, local therapy with surgery or radiation, EBV-directed antiviral therapy, rituximab with or without cytotoxic chemotherapy, and adoptive T-cell immunotherapy. A general principle of treatment of PTLD is to start with the best tolerated therapies and proceed to more toxic therapies only if initial management attempts prove inadequate. However, with highly aggressive disease, rapid disease progression and clinical decline may limit attempts at conservative treatment strategies.

Reduction of Immune Suppression

The mainstay of initial treatment for PTLD is reduction of immunosuppression (RI). The goal of RI is to restore the host immune response to EBV infection and, thereby, regain control of Latency III B-cell outgrowth. Thus, RI is a more effective strategy in SOT recipients or in HSCT recipients later in their transplant course once some level of immune reconstitution has been achieved. In addition, RI is typically more effective in polymorphic PTLD than in monomorphic PTLD. As RI can potentially increase the risk of graft rejection in SOT recipients or graft-versus-host disease in HSCT recipients, the risks and benefits must be weighed carefully on a patient-by-patient basis. For SOT recipients, graft function must be monitored closely with RI, especially in recipients of critical organs such as the heart, liver, and lung, where rejection can be fatal.

Although response to RI will vary depending on the immunosuppressive regimen, type of transplant, and pathologic subtype of PTLD, data suggest that lowering immunosuppression as in initial management step can lead to a salutary effect on PTLD, and in some cases it is sufficient for resolution of disease [260, 261]. In one of the largest study to date, 162 SOT recipients with PTLD were analyzed for response to RI [262]. Sixty-seven patients were treated with RI alone, and an additional 30 were treated with complete surgical resection of a localized PTLD lesion followed by adjuvant RI. Of the 67 patients receiving RI monotherapy, the vast majority had monomorphic PTLD, predominately DLBCL-like. RI resulted in an overall response rate (RR) of 45% and complete response rate (CR) of 37%. Of the 67 total patients treated with RI, 60% required further systemic therapy. However, the relapse rate among complete responders was only 17%. Additionally, 32% of treated patients experienced acute rejection, some leading to loss of allograft. Risk factors for lack of response to RI alone included advanced age, presence of B symptoms, hepatitis C coinfection, elevated lactate dehydrogenase, and liver and bone marrow involvement. Conversely, the Southwest and Eastern Cooperative Oncology Groups published results of a protocol starting with a 50% RI for 2 weeks followed by an additional 50% RI if no response, which resulted in only a single partial response among 16 patients [263].

In sum, RI alone is a reasonable initial strategy for patients with PTLD who are not early in their transplant course. Risk factors, such as markers of poor performance status or aggressive disease, have been identified for situations where RI alone may not be effective, but these are not universally accepted.

Local Therapies

In rare cases, focal PTLD lesions may be amenable to either surgical resection or radiotherapy with a curative goal. Local treatments are often followed by adjuvant RI.

Antiviral Therapy

Available antiviral drugs target viral lytic cycle replication and are not appropriate monotherapy for PTLD. However, lytic replication can be induced by histone deacetylation inhibitors (HDACi) such as arginine butyrate [8]. Using HDACi to induce lytic replication followed by treatment with high-dose ganciclovir is a novel PTLD treatment strategy. Notably, unlike acyclovir, phosphorylated ganciclovir also inhibits the cellular DNA polymerase and induces cell death which may also contribute to its effect on PTLD [264, 265]. In a Phase I/II trial of 15 patients with EBV-associated lymphoproliferative disorders refractory to at least 1 prior systemic regimen, 10 patients had a response to arginine butyrate and standard doses of ganciclovir, with 4 complete responses (CR) and 6 partial responses (PR) [266]. Of the six transplant recipients (three HSCT, three SOT), two achieved a CR and three achieved a PR. Adverse effects included tumor lysis syndrome and reversible CNS depression. Although encouraging, there are limited follow-up data; arginine butyrate is poorly tolerated, and the combination remains an uncommon treatment strategy.

Rituximab and Cytotoxic Chemotherapy

The monoclonal antibody rituximab targets CD20, a nearly pan-B-cell marker that is retained on most PTLD B cells. Rituximab given in both a preemptive and initial treatment manner has become a mainstay of the treatment of CD20-positive PTLD in both HSCT and SOT recipients.

For clinical PTLD as opposed to asymptomatic viremia, initial therapy with rituximab either after or with RI (if possible) is a common and frequently effective treatment strategy. This has been addressed in multiple studies and can be curative in a proportion of patients, with most studies falling in the 20–40% CR and 20–70% objective response rate (ORR) range [267–269]. For example, in a study of 11 SOT recipients with CD20-positive PTLD, a regimen of 4 weekly doses of rituximab repeated every 6 months for 2 years led to a 64% ORR with 54% CR rate [270]. A prospective study of 43 SOT recipients treated with single-agent rituximab demonstrated an ORR of 44% and CR in 28% with an OS of 67% at 1 year [271]. Rituximab-related toxicity was minimal, and primary adverse effects include infusional reactions, prolonged immunosuppression due to B-cell suppression, and neutropenia.

Chemotherapy remains an option for patients with a suitable performance status when other therapies have failed or for non-CD20 or non-EBV types of PTLD. Cytotoxic chemotherapy is best studied in patients with CD20- and EBV-positive PTLD, usually of the DLBCL type. Although highly effective, chemotherapy in the transplant population can be markedly toxic and occasionally fatal. As such, numerous studies have examined up-front versus delayed chemotherapy, most commonly with rituximab plus CHOP (cyclophos-

phamide, doxorubicin, vincristine, prednisone). A study of sequential therapy with 4 weekly doses of rituximab followed by 4 cycles of CHOP-21 in 74 SOT recipients with CD20-positive PTLD led to an ORR of 90% with 68% CRs [272]. There was, however, a CHOP-associated mortality of 11%. Significant neutropenia and infections developed in 68% and 41% of patients, respectively. Overall CHOP-related mortality was lower in the patients treated with rituximab initially when compared to those who started CHOP earlier due to progression on rituximab, suggesting that sequential rather than concurrent therapy may lead to improved tolerability of CHOP. A smaller study of 11 SOT recipients with CD20-positive PTLD examined giving CHOP after failure of rituximab and RI alone [273]. Ten patients received CHOP, with an ORR of 70% and CR of 50%, most of which were durable. There was one possible CHOP-associated death, and two of the ten patients did not tolerate CHOP and had to be changed to less toxic therapy. Another study of 26 patients with late PTLD of both B- and T-cell types demonstrated a 50% CR and 15% PR rate, with a 5-year PFS of 43% [274].

Overall, rituximab monotherapy can be curative in some patients with CD20-positive neoplasms and is a reasonable initial option with low concomitant toxicity. Many patients who fail rituximab monotherapy can be salvaged with subsequent CHOP. Additionally, patients who receive sequential rather than concurrent R-CHOP may tolerate the CHOP portion better. For patients with unusual subtypes of PTLD such as Burkitt lymphoma, HL, or T-cell lymphomas, RI and, if needed, standard chemotherapy regimens are the standard of care. For example, patients not responding to RI with HL should in general receive ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine), patients with T-cell lymphomas CHOP, and patients with Burkitt lymphoma a Burkitt-type regimen if it can be tolerated or CHOP if it cannot [275].

Adoptive T-Cell Immunotherapy

Adoptive T-cell immunotherapy is an effective treatment option for select patients with EBV-driven PTLD when available. The principle of adoptive immunotherapy is to restore immunity by transferring T cells from an allogeneic donor to a recipient with PTLD. This was first attempted with unmanipulated donor T cells, which can be rapidly available in the HSCT population, if the donor is willing and available. Treatment with donor lymphocyte infusion (DLI) has efficacy rates of up to 70% for the treatment of PTLD, but at the substantial risk of severe or even fatal GVHD [276, 277], likely due to the fact that alloreactive T cells are often tenfold higher in number than viral reactive T cells in unmanipulated grafts [278].

Another option is EBV-specific T-cell transfer, which dramatically reduces the risk of GVHD. Polyclonal EBV-specific T-cell lines comprised of both CD8+ and CD4+ T cells can be expanded ex vivo from donor cells and infused into patients with PTLD. These cell lines can be either obtained directly from the original allograft donor, which is time-consuming and may not be an option for patients with rapidly progressive disease or unavailable donor, or obtained rapidly from previously banked ("off-the-shelf"), closely HLA-matched virus-specific T cells. A seminal study of 33 patients with refractory EBV-PTLD demonstrated high response rates to closely matched EBV-cytotoxic lymphocytes (CTL), with ongoing responses of 52% at 6 months, including 14 CRs [279]. Patients who had closer HLA matches and higher numbers of infused CTLs had better response rates. At a minimum of 5-year follow-up of the CR patients, 12 were still living, 1 died of relapsed disease, and 1 died of unrelated infection [280]. All patients with PR or no response received alternative PTLD therapy. A more recent study examined 49 HSCT recipients with EBV-PTLD who were either treatment naïve or had received only rituximab [281]. Patients were given either DLI or EBV-specific CTLs. The combined partial and complete response rate for DLI was 73% and for EBV-specific CTLs was 68%. Seventeen percent of DLI recipients developed reversible acute GVHD. Patients with multiorgan involvement of lymphoma were less likely to respond, as were patients with CTLs that did not expand in vivo.

Avoidance of toxicities associated with cytotoxic chemotherapy is one of the major advantages of EBV-specific adoptive T-cell immunotherapy. The chief limitation is availability of donor T cells, either because the initial graft donor is not available (cord blood, cadaveric solid organ, or unwilling/unavailable donor), because the time needed for ex vivo expansion of T-cell lines is too long, or because of the limited availability of preformed T-cell products. Thus, adoptive immunotherapy at this point is generally limited to recipients with living and available donors or to those in transplant centers with access to protocol-based T-cell grafts. Such cells are in practicality only available for HSCT recipients at this point, although there are some techniques for obtaining autologous EBV-specific T cells in SOT recipients with some short-term anti-EBV efficacy. The role of newer agents, including antibody drug conjugates or chimeric antigen receptor (CAR) T cells against antigens like CD19, in the treatment of PTLD remains to be determined.

EBV Vaccine Development

An EBV vaccine was originally proposed nearly 40 years ago by Epstein and Achong [282]. However, the EBV vaccine remains an elusive goal. A US National Institutes of Health (NIH) meeting noted challenges of EBV vaccine development but strongly endorsed ongoing vaccine efforts [283]. While prevention of infection would be the ultimate

endpoint, the biology of EBV may complicate this goal. For instance, in a murine model of the EBV-related gammaherpesvirus 68 infection, a single target cell infected by single viral particle was sufficient to establish persistent host infection [284]. Furthermore, an EBV vaccine would face a high regulatory hurdle – since EBV does not generally cause severe disease, an approvable EBV vaccine could only have minimal side effects. Additionally since EBV is an oncogenic virus, live-virus vaccines would raise safety concerns. Nonetheless, an EBV vaccine that protects against the complications of EBV infection, even without preventing lifelong EBV infection, could still have a substantial public health impact. The NIH study group recommended that an EBV vaccine should have two major goals: to prevent infectious mononucleosis and to prevent EBV-associated cancers [283]. Both of these goals may be attainable without achieving sterilizing immunity that prevents EBV infection. As an example, the attenuated varicella zoster virus (VZV) Oka strain vaccine has greatly reduced the burden of VZV-associated disease without necessarily preventing infection.

Even prevention of AIM alone would have a tremendous public health and economic impact. The major goal would be to limit the extent of lytic virus replication and the growth of latently infected B cells following primary EBV oropharyngeal transmission [7]. Encouragingly, asymptomatic primary EBV infection protects against subsequent AIM, and a vaccine may be able to capture this benefit. A vaccine-primed immune system might be able to better control primary EBV infection. For instance, elevated primary infection EBV viral loads correlate with AIM severity [101], and AIM is associated with a 3.4-fold increased risk for the development of EBV+ HL [285]. An EBV vaccine that reduces viral loads might also reduce the incidence of IM and HL. Likewise, reduction of EBV viral load may lessen the likelihood of PTLD development.

The major EBV envelope glycoprotein gp350 is the principal target of most EBV vaccines in development. EBV initiates B-cell infection via gp350 binding to CD21, the B-cell receptor for complement component C3d [286, 287]. Additional interactions between the EBV glycoprotein gp42 and the co-receptor HLA class II further promote viral entry [288]. EBV also infects CD21-negative cell types such as oropharyngeal epithelial cells, mesenchymal cells, and T cells, suggesting that additional unidentified receptor(s) must exist. Nonetheless, gp350 is an attractive target, since it is the most abundant glycoprotein on the surface of EBV and EBV-infected cells and is the dominant target of neutralizing antibody responses [92, 283, 289].

A recombinant VZV vaccine vector was developed to deliver gp350 nearly 25 years ago [290]. However, the first randomized, placebo-controlled, multicenter, double-blind trial of a gp350-based vaccine to prevent AIM was not reported until some 20 years later [291]. The recombinant gp350 and alum/monophosphoryl lipid adjuvant vaccine induced anti-gp350 antibodies in 98.7% of subjects for at least 18 months after administration of the third vaccine dose. The vaccine also reduced the proportion of symptomatic primary EBV infection over an 18-month observation period, from 10% in the control group to 2% in the vaccine group. Not surprisingly, the vaccine did not protect against asymptomatic EBV infection. An EBV-antibody-seropositive study participant developed an oligoarthritis syndrome, raising potential safety concerns. In a small Phase I trial in children with chronic kidney disease awaiting transplantation, vaccination with recombinant gp350 plus alum induced IgG responses in all 13 evaluable patients [292]. However, neutralizing antibodies were only detectable in four vaccine recipients, and anti-gp350 antibody levels rapidly diminished following completion of the vaccine cycles. More recently, the use of self-assembling nanoparticles to display gp350 domains elicited potent neutralizing antibody responses in mice and nonhuman primate models [293].

The gp350 vaccination can also stimulate cell-mediated immunity, a property that was important for prevention of EBV-associated lymphomas in an animal model [294]. Since many EBV-derived HLA class I epitopes are generated during primary infection, a second vaccine approach has been to stimulate a CD8+ T-cell response to EBV antigens. Indeed, in a small single-blind, randomized, placebo-controlled, single-center trial, an EBNA3 CD8+ T-cell peptide-based vaccine was administered to 9 HLA B*0801-positive individuals. Four individuals received a placebo vaccine. In follow-up, none of the four EBNA3 vaccine recipients experienced symptomatic AIM with primary EBV infection [295]. While exciting and potentially applicable to the prevention and/or treatment of EBV-associated malignancies, this approach is complicated by the diversity of HLA molecules across different human populations. Consequently, a CD8+ T-cell peptide-based vaccine would need to incorporate multiple appropriate EBV epitopes. This goal might be achievable with the use of recombinant polyepitope protein constructs that encode multiple distinct CTL peptide targets in tandem. Vaccines might also combine a gp350-based component with CD8+ T-cell antigens to further limit virus replication and spread [296].

Vaccines to treat EBV-associated malignancies are also being developed. Nasopharyngeal carcinoma (NPC) may be a particularly attractive candidate, as EBV epitopes are detected in most undifferentiated NPC cases. Furthermore, in NPC-endemic regions of Southern China, HLA alleles such as HLA-A11, A24, and B40 are common, potentially simplifying the cocktail of epitopes that may be needed [297]. In one promising approach, an adenoviral vector-based vaccine has been developed that delivers EBNA1, LMP1, and LMP2 epitopes suitable for these HLA alleles. In a preclinical study of patients with recurrent and metastatic

NPC, the vaccine stimulated EBV-specific T-cell development in 72% of patients [297]. T cells were expanded ex vivo and then adoptively transferred back to the appropriate NPC patient. The median overall survival increased from 220 days, without T-cell transfusion, to 523 days with primed T-cell transfer.

39 Herpes Simplex Viruses 1 and 2, Varicella Zoster Virus, and Human Herpes Viruses 6, 7, and 8 in Transplant Recipients

Raymund R. Razonable

Introduction

Human herpes viruses are a family of eight large double-stranded DNA viruses. They are subdivided into α-herpesviruses, herpes simplex viruses 1 and 2 (HSV-1 & HSV-2) and varicella zoster virus (VZV); β-herpes viruses include cytomegalovirus (CMV), human herpesviruses 6 and 7 (HHV-6 & HHV-7), and γ-herpes viruses are Epstein-Barr virus (EBV) and human herpesvirus 8 (HHV-8). All eight members share the characteristic property of establishing lifelong latency in the host. Latent herpes viruses may reactivate causing opportunistic diseases in individuals with compromised immunity such as transplant recipients. Control of herpes virus infection and its reactivation is a function of cell-mediated immunity. Hence, factors that impair cell-mediated immune responses predispose to a potentially severe illness caused by these herpes viruses.

All human herpesviruses have been implicated in various clinical diseases in solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients. This chapter will review the epidemiology, clinical diseases, diagnosis, prevention, and treatment of six of the eight members of the human herpesvirus family, including HSV-1, HSV-2, VZV, HHV-6A and HHV-6B, HHV-7, and HHV-8 (Table 39.1).

Herpes Simplex Viruses 1 and 2

Epidemiology

HSV-1 and HSV-2 are α-herpesviruses that most commonly cause mucocutaneous ulcers. HSV-1 infection, which manifests clinically as orolabial herpes, is usually acquired during early childhood through adulthood. HSV-1 seroprevalence rates in the United States range from 44% in 12–19-year-old individuals up to 80% among individuals older than 60 years [1]. Seroprevalence rates of HSV-2 infection, which manifests as genital ulcers, increase at the onset of sexual activity, from 1.6% among 14–19-year-old individuals to 26.3% among 40–49-year-old individuals in the United States [2]. After primary infection, HSV-1 and HSV-2 establish latency in nerve root ganglia. Periodic HSV reactivations occur throughout life, and this could be in the form of subclinical shedding or manifested as oral or genital ulcers [3, 4].

Seroprevalence rates of HSV-1 and HSV-2 in transplant recipients mirror that of the general population. Up to 80% of adult HSCT patients are HSV-seropositive [5]. Because most transplant recipients are HSV-seropositive, the majority of symptomatic HSV disease and asymptomatic HSV shedding after SOT and HSCT results from reactivation of latent virus. Compared with immunocompetent persons, transplant recipients shed HSV-1 and HSV-2 more frequently and they may have more severe clinical manifestations [6, 7]. The onset of HSV disease occurs during the first 4 weeks after SOT and HSCT [5, 8–12]. Without antiviral prophylaxis, the rate of HSV reactivation among HSV-seropositive HSCT recipients reaches up to 80% [13]. The risk of HSV disease increases during periods associated with intense immunosuppression, such as with the use of muromonab-CD3 and mycophenolate mofetil [14, 15]. Primary HSV-1 and HSV-2 infections may occur less commonly, when HSV-seronegative transplant recipients are exposed to virus shed in bodily secretions of HSV-seropositive individuals. Donor-derived HSV infection, transmitted through the allograft, has been reported rarely after kidney and liver transplantation [10, 16–18].

Clinical Disease

The most common clinical manifestation of HSV-1 and HSV-2 disease after transplantation, whether this is primary or reactivation infection, is orolabial, genital, or perianal

disease [4, 12]. In the HSCT population, HSV mucocutaneous disease occurs in the orofacial region in 85–90% of cases, while only 10–15% occurs in the anogenital region [13, 19]. Up to 10% of HSCT recipients with orolabial HSV disease may have esophageal involvement [20]. While orolabial disease is classically due to HSV-1 and anogenital disease is due to HSV-2, there may be an overlap since some cases of orolabial disease have been caused by HSV-2, while HSV-1 may also be associated with anogenital disease.

Mucocutaneous herpes infections are typically vesicular and/or ulcerative and are often localized. In severe cases, particularly among highly immunocompromised transplant patients, HSV infection may disseminate to visceral organs and cause hepatitis, encephalitis, and pneumonitis [12]. Fever, leukopenia, and hepatitis are the most common signs and symptoms of disseminated HSV disease [12]. Central nervous system (CNS) involvement may occur in the form of encephalitis and viral meningitis [21]. Ocular involvement may occur in the form of keratitis. Bone marrow suppression and damage to the transplanted stem cell graft have also been reported in association with HSV disease following HSCT.

Diagnosis

The diagnosis of mucocutaneous HSV disease in transplant recipients may be made on clinical grounds alone since the symptoms are often typical, with vesicles and ulcers. Occasionally, the clinical manifestations may be atypical, and other pathogens may be suspected. In HSCT recipient, severe mucositis may be due to a number of causes and often multifactorial in nature; this further complicates the diagnosis of HSV infection based only on clinical presentation. In such cases, laboratory confirmation of HSV infection is needed. Laboratory tests are also useful in the diagnosis of extra-mucocutaneous HSV disease such as CNS disease, fulminant hepatitis, and disseminated disease.

The laboratory methods available for the diagnosis of HSV infection are (1) direct fluorescent antibody (DFA) testing of mucocutaneous lesions, bronchoalveolar lavage, and other clinical samples, (2) histopathology of biopsy specimens, (3) viral culture, and (4) nucleic acid testing (NAT) by PCR. Serology is rarely useful for diagnosing HSV infections after transplantation since HSV seropositivity is common, and generation of HSV antibodies may be delayed due to underlying immunosuppression.

Detection of HSV antigens on scrapings of ulcerative lesions by immunofluorescence assay (IFA) is a useful test for diagnosis of HSV disease. Tzanck smear, which demonstrates viral cytopathic effects, can be performed on scraping obtained from herpetic ulcers, although this is not very specific for HSV. Histopathology with immunocytochemistry for HSV may be used to document tissue-invasive disease such as fulminant hepatitis [22]. Culture of the vesicular fluid is very specific for diagnosis of HSV disease, although this is now replaced by molecular HSV NAT by PCR assay as the diagnostic test of choice, especially for cerebrospinal fluid (CSF) [23].

HSV NAT provides high sensitivity, high specificity, and rapid turn-around time compared to culture and other

diagnostic modalities [23]. The molecular assay can be optimized to distinguish HSV-1 from HSV-2 [24]. NAT is especially useful for identifying HSV in blood or other sterile fluids, as viral cultures have poor sensitivity in detecting HSV in these samples. If disseminated disease is suspected in transplant patients, detection of HSV NAT in the blood confirms the clinical suspicion [25]. Quantification of HSV viral load in a clinical sample such as CSF or blood may be used to assess infection severity and guide efficacy of antiviral therapies.

Prevention

HSV reactivation occurs most commonly during the first month after transplantation. Routine surveillance using viral culture or NAT to detect HSV is not recommended. Instead, it is standard clinical practice for transplant recipients to receive antiviral prophylaxis such as acyclovir during the first 4–6 weeks after undergoing SOT [5, 12]. The duration may be prolonged in certain situations such as HSCT, especially if being treated for GVHD, treatment of acute rejection, or recurrent infections [5]. In a placebo-controlled study in HSV-seropositive HSCT recipients, acyclovir abrogated HSV reactivation, while culture-proven HSV lesions were observed in seven of ten placebo-treated patients [26]. Oral acyclovir is preferred, but the intravenous formulation may be needed in HSCT patients with severe mucositis. Valacyclovir, famciclovir, ganciclovir, and valganciclovir are alternative agents. Many SOT recipients receive valganciclovir prophylaxis for CMV prevention after transplantation. Since valganciclovir (or ganciclovir) is also effective against HSV, no additional HSV prevention (such as acyclovir) is necessary in these patients.

Treatment

Antiviral therapy shortens the duration of HSV shedding and disease, facilitates healing, and prevents HSV dissemination to visceral sites. In addition to antiviral therapy, cautious reduction in immunosuppression should be considered, especially those with severe and life-threatening HSV diseases [12].

Limited or mild mucocutaneous HSV disease can be treated with oral acyclovir, valacyclovir, or famciclovir for a minimum of 5–7 days and until complete healing of the lesions. Mucocutaneous HSV disease can also be treated with intravenous acyclovir, especially in HSCT patients with severe mucositis. Intravenous acyclovir at a higher dose (5–10 mg/kg every 8 h) should be considered for disseminated, cerebral, visceral, or extensive mucocutaneous HSV disease. A minimum of 14 days of treatment is recommended for severe disease, and others have extended the duration to as long as 21 days in cases of pneumonia and encephalitis. Some have used HSV NAT to guide the duration of treatment of HSV meningoencephalitis [27].

Acyclovir-resistant HSV may occur in less than 5% of immunocompromised patients. The most common mechanism of resistance is a genetic mutation that results in diminished or absent activity thymidine kinase, an enzyme that is essential for the activation of acyclovir, valacyclovir, and famciclovir. The drug of choice for treatment of acyclovir-resistant HSV is foscarnet and cidofovir as the alternative agent. There is significant toxicity associated with the use of these drugs, most commonly nephrotoxicity. Topical formulations of cidofovir and imiquimod may be used for localized mucocutaneous disease [12].

Varicella Zoster Virus

Epidemiology and Clinical Disease

VZV is a highly infectious α-herpesvirus that causes varicella commonly known as chickenpox. Infection is acquired through direct contact with a skin lesion or airborne spread from respiratory droplets. Varicella is manifested by fever, constitutional symptoms, and vesicular, pruritic, widely disseminated rash. The distinctive feature of varicella is the concurrent appearance of papules, vesicles, and crusted lesions that typically spares the palms and soles. Varicella is generally a self-limited illness lasting 7–10 days in the immunocompetent patients, although it may infrequently lead to viral hepatitis, pneumonitis, encephalitis; retinal necrosis, and purpura fulminans are uncommon albeit, serious complication often noted in severely immunosuppressed individuals [28].

After primary infection, VZV establishes latency in cranial nerve and dorsal root ganglia. Reactivation of VZV later in life is manifested as zoster (shingles), which is characterized by grouped vesicular exanthem in 1–3 dermatomal distribution [29]. Some patients, especially those who are immunocompromised such as transplant patients, may develop disseminated zoster that mimics primary varicella infection. Others may have visceral involvement [29], with fulminant hepatitis as one of the severe forms of visceral zoster [30]. Zoster lesions may be secondarily infected with bacteria and, in the long term, may be associated with debilitating postherpetic neuralgia [29].

Since over 90% of adult transplant recipients are VZV-seropositive from prior primary varicella infection, the vast majority of VZV infection after transplantation presents as zoster. Reactivation VZV, which is manifested most commonly as single or multiple dermatomal zoster, occurs in approximately 8–11% of SOT recipients [29] and 10–68%

among patients undergoing HSCT [5]. The peak incidence of herpes zoster occurs during the first 12–14 months after SOT [29] or 3–12 months after HSCT with a median of 5 months after transplantation [5]. Risk factors after SOT are older age, use of mycophenolate mofetil, and recipients of heart and lung transplants [31–33]. Older age, severe immunosuppression, a myeloablative regimen, severe lymphopenia, receipt of cord blood transplant, and chronic GVHD are associated with increased risk of VZV after HSCT [5]. While the majority of herpes zoster remains localized to one or few adjacent dermatomes, severely immunocompromised transplant patients may have poly-dermatomal distribution or may have disseminated disease with visceral involvement [29], including fulminant VZV hepatitis [34]. Some cases of VZV disease may manifest without the classic herpes skin lesions and present only with severe pain such as abdominal pain in patients with VZV gastritis and hepatitis.

Since the majority of patients are VZV-immune prior to transplantation due to prior infection or immunization, primary varicella is rarely seen after transplantation. Chickenpox may still occur in non-vaccinated VZV-seronegative transplant recipients. The clinical manifestation of varicella in these patients is typical, with fever and a generalized pruritic vesicular rash. The illness may be very severe and devastating, sometimes with encephalitis, hepatitis, pneumonia, and other visceral involvement [29]. VZV-seronegative transplant candidates should therefore be vaccinated prior to transplantation.

Diagnosis

The diagnosis of varicella and zoster is made based on clinical grounds due to their classic presentations. However, transplant patients may present atypically (such as disseminated disease without skin rash) or may have disseminated herpes that can mimic other disease states. In these cases, laboratory testing for VZV is essential to establish the diagnosis.

Rapid diagnostic assays for VZV diagnosis are NAT by PCR and direct fluorescent assay (DFA) [5, 35]. DFA is performed on scraping taken from the base of the skin lesion. A PCR test to detect and amplify VZV DNA is currently the most sensitive test, and this may be used to detect VZV in the vesicle fluid, peripheral blood, CSF, and tissues [36]. VZV NAT in the blood is used to diagnose visceral zoster in the absence of skin manifestations. Most VZV NAT assays are qualitative, although many offer quantification [35, 36]. Quantitative VZV NAT may be used to assess the severity of disease such as higher viral load, which often reflects more severe disease, and to guide management strategies, for example, a persistently high viral load may require longer duration of treatment and a concern for drug-resistant viral strain.

Viral culture is a less sensitive assay with slower turnaround time [29]. Serologic testing is rarely helpful in the diagnosis of varicella and zoster due to high rates of seropositivity, and transplant patients have delayed ability to mount antibody response [29].

Prevention

Vaccination is the most effective method for the prevention of varicella in transplant recipients, but it should be given prior to transplantation. Since the varicella vaccine contains a live-attenuated virus, it is contraindicated after transplantation. Varicella vaccine should be given to VZV-susceptible transplant candidates at least 2–4 weeks prior to SOT [29] or >4 weeks prior to conditioning regimen for HSCT [5]. Giving the live-attenuated virus vaccine within a short-time period prior to immunosuppression may risk for clinical illness due to the vaccine strain. The role of recombinant zoster vaccine for VZV prevention in transplant recipients is under investigation.

VZV-seronegative transplant recipients should avoid exposure to individuals with varicella or zoster or those who recently received live virus vaccine. VZV-seronegative transplant recipients who have significant exposure to varicella and zoster are at high risk of developing severe primary infection and should receive postexposure prophylaxis using immunoglobulin within 10 days of exposure. Antiviral prophylaxis with oral acyclovir or valacyclovir may also be used for 3–21 days as an adjunct to VZV immunoglobulin prophylaxis or as the primary method for prevention in patients unable to receive VZV immunoglobulin [5, 29]. If used, antiviral prophylaxis should be given as soon as possible, and within 10 days of significant exposure. VZV-seronegative transplant recipients with significant exposure to varicella or herpes zoster could be considered contagious, and thus, airborne precautions should be instituted 7 days after and up to 21 days exposure or for 28 days after exposure for patients who received passive immunization against VZV.

Because of the high risk of zoster, antiviral prophylaxis is recommended for VZV-seropositive allogeneic HSCT recipients [5]. This can be in the form of oral acyclovir (800 mg PO twice daily) or valacyclovir (500 mg orally once or twice daily) for at least 1 year after allogeneic HSCT or longer for patients with severe immunosuppression and chronic GVHD [5]. Antiviral prophylaxis for autologous HSCT and SOT recipients is not currently recommended.

Treatment

Antiviral treatment for varicella and zoster halts disease progression, prevents visceral dissemination, reduces the

duration of viral replication, and reduces postherpetic pain syndrome. Transplant patients who develop primary varicella infection should be treated as soon as possible with intravenous high-dose acyclovir, 10 mg/kg given every 8 h; the dose requires adjustment in patients with declining renal function. Reduction in immunosuppression should be considered, as these patients are at risk of developing severe and potentially fatal disease. The role of immunoglobulins as adjunct to antiviral therapy is debated [29]. Alternative drugs are valacyclovir and famciclovir. Intravenous therapy is indicated for severe disease, but this can be tapered to oral treatment once there is sufficient control of the infection [5, 29].

Localized or nonsevere forms of herpes zoster may be treated with oral famciclovir and valacyclovir. Treatment should be given for at least 7 days but should be continued until 2 days after the lesions have crusted. Localized disease involving vital organs such as herpes zoster ophthalmicus involving the trigeminal ganglion and herpes zoster oticus also known as Ramsay Hunt syndrome should be treated with intravenous acyclovir. Disseminated or organ invasive herpes zoster should be treated with intravenous acyclovir [5, 29].

Human Herpes Viruses 6A and 6B

Epidemiology

HHV-6A and HHV-6B are two distinct lymphotropic β-herpesviruses that infect the majority of humans [37, 38]. By age 5, the majority of humans are HHV-6 seropositive [38]. In immunocompetent individuals, primary HHV-6 infection is often asymptomatic, or it could be manifested clinically as a febrile illness associated with an exanthem, diarrhea, respiratory symptoms, or seizures [37–40]. The classic presentation of primary HHV-6 infection is roseola infantum also known as sixth disease or exanthem subitum. A disease in young children characterized by high fever that lasts for 3–5 days followed by erythematous blanching maculopapular rash that starts at the neck and trunk spreading to the extremities [39]. HHV-6B accounts for the majority of documented primary HHV-6 infections [38]. In contrast, the epidemiology of HHV-6A infection is less defined [41], although it is more neurotrophic and thus has been implicated in neurologic disorders.

After primary infection, HHV-6 establishes lifelong latency in hosts' mononuclear cells [39], and frequently reactivates later in life, especially in patients with severe adaptive immune dysfunction. HHV-6 is unique among human herpes viruses because of its ability to integrate into the human chromosome known as chromosomally integrated HHV-6 (CIHHV-6) [42–45]. Chromosomal integration by HHV-6A and HHV-6B occurs in 1% of individuals [42–45], and the integrated viral genome is passed to offspring in a Mendelian manner [42].

HHV-6 infection after SOT and HSCT occurs either as primary or as secondary infection due to reactivation of endogenous latent virus or reinfection from donor-transmitted HHV-6 virus [37, 46]. Since HHV-6 seroprevalence is over 90% in adults, most HHV-6 infections are believed to be due to reactivation or reinfection [37, 46]. For the minority of HHV-6 seronegative transplant recipients, primary HHV-6 infection may occur in the following manner: acquired from the donor allograft, blood and blood product transfusions, or natural transmission from close contacts [47, 48]. Pediatric transplant recipients, especially those younger than 2 years of age, are likely HHV-6 seronegative and at risk of primary infection [48].

The incidence of HHV-6 infections has been reported in 10–60% of SOT [37, 46] and approximately 50% of HSCT recipients [49]. The majority is due to HHV-6B and detected during the first 2–4 weeks after transplantation [37, 46]; in contrast, only 2–3% of HHV-6 infections after HSCT are due to HHV-6A. The vast majority of HHV-6 infections are transient subclinical reactivations with clinical consequences [37, 46]. In contrast, clinical disease directly due to HHV-6 occurs in <1% of transplant recipients [50, 51]. HHV-6B accounts for most cases of clinical disease [37, 46]; only a few cases have been associated with HHV-6A [47].

Clinical Disease

HHV-6 disease after transplantation is most commonly manifested as a febrile illness accompanied by bone marrow suppression [52]. HHV-6 encephalitis is one of the most severe clinical manifestations, often in the form of limbic encephalitis [53, 54]. Encephalitis is particularly seen in HSCT recipients, although it has been reported in SOT recipients [55, 56]. Clinical manifestations include confusion, depressed sensorium, seizures, disorientation, and short-term memory loss. HHV-6 is also known to infect hematopoietic progenitor cells, and may delay engraftment, especially of platelets, after HSCT [57]. HHV-6 has also been associated with fever and rash [58], hepatitis [47], gastritis and enteritis [59], colitis [60], pneumonitis [55], pancytopenia, hemophagocytosis syndrome, and disseminated infection [61].

HHV-6 has several indirect effects in SOT recipients, possibly as a result of its immunomodulatory effects [37, 46]. These indirect effects of HHV-6 infection include the increased risk of CMV disease after kidney and liver transplantation [62, 63], higher risk of fungal and other opportunistic infections [64], allograft rejection and dysfunction

[65], early fibrosis due to hepatitis C virus recurrence after liver transplantation [66], and a higher mortality rate after transplantation [67, 68].

The impact of CIHHV-6 in transplant recipients is not well defined. Because of the very high levels of HHV-6 DNA in the blood, patients with CIHHV-6 have been mistaken to have active infection and given unnecessary treatment. The clinical impact of CIHHV-6 was recently investigated in a cohort of liver and other transplant recipients and was found to be associated with a significantly higher risk of bacterial infections and allograft rejection [42–45].

Diagnosis

HHV-6 NAT by PCR is the most commonly used test for the diagnosis of HHV-6 infection after transplantation [37, 46, 69]. HHV-6 PCR is most commonly performed on blood samples [52, 70], although it has been used to detect HHV-6 DNA in CSF and BAL fluid [71, 72]. HHV-6 DNA is demonstrated in the CSF of patients with HHV-6 encephalitis, often accompanied by non-specific CSF findings. Only half of the patients may have CSF pleiocytosis and elevated protein. MRI of the brain is sensitive in demonstrating multiple non-enhancing low attenuation signals in the temporal lobe and the limbic system. Active HHV-6 infection is often indicated by high viral load compared to the low DNA level in some cases of latent infection. Quantitative HHV-6 PCR test is therefore preferred, as viral load is also used to differentiate severe from mild HHV-6 infection, assess antiviral treatment responses, and guide duration of treatment [37, 69].

In the interpretation of HHV-6 PCR assay results, it is critically important to consider the potential detection of CIHHV-6 [42–45]. In a consensus statement, detection of 5.5 logs of HHV-6 in the blood should raise suspicion for chromosomally integrated virus, and this can be confirmed by persistently elevated viral load over time and, if needed, cytogenetic analysis, hair follicle analysis, and testing of siblings and relatives [42–45].

Histopathology with or without immunohistochemistry is preferred for the diagnosis of tissue-invasive HHV-6 disease, such as hepatitis and pneumonitis [37]. The other tests for the diagnosis of HHV-6 are serology, viral culture, and antigenemia [37]. However, these are rarely used in clinical practice since they are not widely available.

Prevention

Ganciclovir, foscarnet, and cidofovir are active against HHV-6. There have been few observational studies to indicate that ganciclovir may reduce the incidence of HHV-6 infection in SOT [70] and HSCT recipients [73]. However, HHV-6 reactivation is common after HSCT and SOT, and clinical disease occurs very rarely [69]. Hence, antiviral prophylaxis and preemptive therapy are not recommended after SOT [37] and HSCT [49]. There is no clinical benefit in preventing HHV-6, since the majority is subclinical, self-limited, and transient [37].

Treatment

For established HHV-6 disease in SOT and HSCT, antiviral therapy with foscarnet and/or ganciclovir is recommended, and cidofovir is considered as alternative agent [37]. The doses recommended follow the guidelines for the treatment of CMV disease [37]. Antiviral treatment is especially indicated in the setting of HHV-6 encephalitis and other tissue-invasive diseases, and it should also be considered for other clinical syndromes attributable to HHV-6 [37]. In addition to antiviral therapies, SOT recipients with HHV-6 disease should have cautious reduction in their pharmacologic immunosuppression [37]. Antiviral treatment is generally guided by serial monitoring of HHV-6 viral load, and it is recommended to continue therapy until the virus is cleared from the blood or other sites of infection. It is recommended to rule out the existence of CIHHV-6 in the interpretation of HHV-6 PCR results [42–45].

Human Herpes Virus 7

Epidemiology

HHV-7 is a β-herpesvirus that infects humans during the first 5 years of life [74]. Primary HHV-7 infection occurs at a slightly later age compared to HHV-6 [75], and it presents most commonly as an asymptomatic infection or as a benign self-limited illness characterized most commonly by fever and seizures [76]. Upper respiratory symptoms, vomiting, diarrhea, seizures, encephalitis, or a Roseola-like illness have been reported in association with HHV-7 infection [74, 76].

Detection of HHV-7 DNA in blood samples of patients is common during the early period after transplantation. It has been reported in up to 40% of transplant recipients. Almost all of these are transient, low level, and not associated with any clinical manifestations [37]. Since over 95% of individuals are HHV-7 seropositive, the detection of HHV-7 DNA in transplant recipients is likely a reflection of viral reactivation [37]. HHV-7 reactivation occurs mostly during the first 2–4 weeks after transplantation [37, 77]. Reinfection with donor-transmitted virus may also occur, while primary HHV-7 infection is rare [37].

Clinical Disease

Clinical disease due to HHV-7 is rare after transplantation [37]. The true incidence of clinical disease is not known but likely less than 1% of patients [37, 78]. There have only been a few sporadic cases of HHV-7 disease reported. Fever, thrombocytopenia, and acute myelitis have been described as potentially caused by HHV-7 [52, 78, 79]. Most commonly, HHV-7 is detected in the blood of patients with CMV disease [52]. HHV-7 has been implicated to have indirect effects such as predisposition for CMV disease [63, 80] and acute rejection [81].

Diagnosis

There are no tests recommended for surveillance of HHV-7 in SOT recipients [37]. In patients with clinical suspicion for HHV-7 infection, nucleic acid testing, serology, culture, and histopathology are the tests for diagnosis [37]. The most commonly used test is HHV-7 NAT by PCR [37, 52, 82]. However, clinical correlation between HHV-7 load and clinical disease has not been established [52]. To document tissue-invasive HHV-7 disease, including encephalitis, histopathology is required. Demonstration of HHV-7 proteins is preferred over DNA detection in order to confirm the diagnosis of HHV-7 disease. A less invasive strategy to diagnose HHV-7 encephalitis would be to demonstrate HHV-7 nucleic acid in the CSF, although this should be interpreted with caution since latent virus may be amplified from reactive lymphocytes and other leukocytes present in the CSF.

Prevention and Treatment

Since HHV-7 is not a well-established common cause of clinical disease after transplantation, there is no recommendation for its prevention after HSCT [49] and SOT [37, 69]. For the rare occurrence of proven HHV-7 disease, treatment may be initiated with foscarnet or cidofovir [37]. Ganciclovir is not active against HHV-7. Data suggest that HHV-7 is resistant to ganciclovir in vitro and may not be inhibited with achievable concentrations of ganciclovir [70, 83, 84]. Antiviral treatment should be complemented by a reduction in the degree of pharmacologic immunosuppression [37].

Human Herpes Virus 8

Epidemiology

HHV-8 is a γ-herpesvirus that causes Kaposi's sarcoma [85]; hence, it is also known as Kaposi's sarcoma-associated herpes virus. Unlike other ubiquitous members of the human herpesvirus family, HHV-8 is a geographically restricted virus [86]. HHV-8 seropositivity is highest in Africa (up to 50%) [87] and the Mediterranean (up to 35%) [88] and intermediate in South America (up to 16%) [89] and Asia (up to 24%) [90]. Seroprevalence rates in North America and Northern Europe are comparatively lower [86].

Primary HHV-8 infection occurs commonly in children [91]. Transmission occurs during close contact, likely through transfer of body secretions such as saliva and genital secretions [92–94]. Primary HHV-8 infection is associated with mild non-specific symptoms of fever and rash [91], and it has also been associated with diarrhea, fatigue, and lymphadenopathy [95].

HHV-8 infection in transplant recipients may occur either as primary infection in HHV-8 seronegative patients who receive allograft from HHV-8 seropositive donors [96–101] or as secondary reactivation of latent virus [102]. Overall, KS and other HHV-8 disease are generally rare in HSCT [49] and SOT recipients, although the rates vary depending on the geographic area [86]. The reported incidences of KS in SOT recipients vary from as low as 0.5% among transplant recipients from North America, Asia, and Northern Europe to as high as 28% among HHV-8 seropositive transplant recipients from the Middle East [103–106]. In Saudi Arabia, KS was the most common malignancy in kidney recipients, representing 87.5% of all tumors in these patients [104]. The median time to the onset of KS is 30 months after transplantation, although it may occur as early as 3 months to as late as 124 months after transplantation [107].

Risk factors for HHV-8-associated disease, specifically KS, include older age, male gender, and residence or exposures in HHV-8 endemic area [37, 86]. Certain populations in areas of low endemicity may be at higher risk such as the men who have sex with men [37, 86]. Both pretransplant HHV-8 seronegativity and seropositivity have been associated with KS, suggesting that both primary HHV-8 infection and reactivation, respectively, can result in clinical disease [37, 86]. Because control of HHV-8 infection is mediated by T cells, the intensity of pharmacologic immunosuppression and the use of antilymphocyte agents have been suggested to play a role in HHV-8 pathogenesis after transplantation [108].

Clinical Disease

The most common clinical manifestation of HHV-8 infection is KS, a multicentric neoplasm of lymphatic endothelium-derived cells, which manifests as multifocal progressive mucocutaneous lesions with dissemination to visceral organs [109–112]. More than 95% of transplant patients with KS present with a skin lesion characterized by

reddish-bluish or purplish discoloration, mainly in extremities. In 25% of cases, KS has visceral involvement and may involve the lymph node, lungs, gastrointestinal tract, and liver. The other malignancies associated with HHV-8 are body cavity lymphoma also known as primary effusion lymphoma (PEL) and Castleman's disease [96, 107, 113]. PEL is a form of non-Hodgkin lymphoma characterized by involvement of serosal surfaces such as the peritoneum, pericardium, and pleura. Castleman's disease is an angiofollicular lymphoproliferative disease characterized by high fever, night sweats, and other constitutional manifestations related to overexpression of IL-6. The prognosis of Castleman's disease and PEL is generally poorer compared to KS [86]. HHV-8 has also been reported as a cause of nonmalignant illnesses presenting with fever, hemophagocytosis, myelosuppression, and multiorgan failure in transplant recipients [88, 100, 114, 115].

Diagnosis

Histopathology is required for diagnosis of KS, Castleman's disease, and PEL [37, 86]. Demonstrating HHV-8 in the tissues can be done through immunohistochemistry using monoclonal antibodies against the virus [111].

Active HHV-8 infection may be indicated by seroconversion or IgM response [100, 116, 117]. However, serology has limited utility in immunocompromised transplant recipients [100, 116, 117]. Active HHV-8 infection can be diagnosed using NAT to quantitate HHV-8 load in clinical samples [37, 86]. Studies conducted using these PCR assays have demonstrated their potential clinical utility in the surveillance, diagnosis, and management of HHV-8 infection and malignant disease [37, 86]. HHV-8 quantification has been utilized for infection and disease risk surveillance [108, 117, 118] and has been used to monitor patients with KS and assess their response to therapy [108, 117, 118].

Prevention and Treatment

Treatment of HHV-8 and its associated malignant disease would potentially include (1) reduction in immunosuppression, (2) surgical debulking, (3) cytotoxic chemotherapy, and (4) antiviral therapies [37, 86]. The cornerstone and first-line therapy for KS and other malignant HHV-8-associated diseases is the cautious reduction or cessation of immunosuppression [37, 86, 119]. Reduction in immunosuppression has resulted in complete remission in 25–30% of patients with isolated cutaneous KS [86]. Another emerging strategy is to switch the immunosuppressive regimens from calcineurin inhibitors like cyclosporine to mTOR inhibitor such as sirolimus or rapamycin [96, 97, 101, 120, 121]. Sirolimus has antiproliferative properties that may be useful in the treatment of KS and other angiogenic proliferation diseases. Several studies have demonstrated that conversion to sirolimus has led to regression of KS lesions in some patients [96, 97, 101, 120, 121].

Patients whose lesions do no not regress despite reduction in immunosuppression may require surgical excision, radiation therapy, or cytotoxic chemotherapy. The standard treatment of Castleman's disease is surgical resection, which is highly curative if this is unicentric and localized [122]. The benefits of ganciclovir, foscarnet, and cidofovir therapy in transplant recipients with established KS or other manifestations of HHV-8 infection are not well defined [107].

Respiratory Viral Infections in Transplant Recipients

40

Catherine Liu, Dora Y. Ho, and Michael Boeckh

Introduction

Respiratory viral infections (RVIs) are common causes of illness in humans. While such infections tend to be mild and self-limiting in healthy individuals, severe or even life-threatening disease can be seen in immunocompromised hosts, as well as the very young and the elderly. In particular, RVIs are frequently associated with significant morbidity following hematopoietic stem cell transplantation (HSCT) or solid organ transplantation (SOT). A number of RNA and DNA viruses can cause respiratory tract infections. This chapter focuses on the epidemiology, clinical manifestations, diagnosis, treatment and prevention of respiratory syncytial virus (RSV), parainfluenza viruses (PIVs), human metapneumovirus (HMPV), influenza viruses, human coronaviruses (HCoV), and human rhinoviruses (HRV).

The respiratory viruses are associated with a wide range of clinical syndromes in the general population, including the common cold, pharyngitis, tracheobronchitis, laryngotracheobronchitis (croup), bronchiolitis, and pneumonia. For transplant recipients, disease spectrum similarly spans from asymptomatic or mild infections to life-threatening lower respiratory tract involvement, although severe complications tend to be more frequent. The severity and outcome of infection largely depend on the type of virus as well as host factors, including the type of transplantation and the degree of immunosuppression at the time of infection. Coinfections with other pulmonary pathogens including bacteria or fungi, e.g., *Aspergillus* species, *Pneumocystis jiroveci*, or other viruses like CMV or more than one respiratory viruses, are also common and can further complicate treatment and lead to poorer outcomes [1–3]. For HSCT recipients, most RVIs occur in 1–10% of the patients during the first 100 days post-transplantation [1, 4, 5], with cumulative incidence varying from a few percent (e.g., HMPV, influenza, RSV, PIVs) to 11–22% such as HCoV and HRV [5]. Infections with RSV, influenza, HMPV, PIVs, and adenovirus have a higher risk of progression from upper respiratory tract infection (URTI) to lower respiratory tract infection (LRTI) and tend to cause the most serious disease, with mortality rate of up to 40–60% among those with LRTI [6–9]; HRV and HCoV infections tend to be mild, but severe LRTI from these viruses can rarely occur [10]. Risk factors for disease progression to LRTI include pre-engraftment status, allogeneic transplant, myeloablative conditioning, graft-versus host disease, and lymphopenia [1, 2, 6, 11–15].

SOT recipients can also suffer from severe disease and complications from RVI. Risk factors for disease progression are not as well defined, but those with lung and heart-lung transplant are particularly vulnerable. Cumulative rates of RVIs in lung transplant recipients range from 8% to 21% in retrospective studies of 5–7 years [16, 17], and a high incidence of progression to LRTI up to 26% has been reported [18]. In contrast, the incidence of RVIs among heart, liver, and kidney transplant recipients is similar to that of the general population, although complications are more frequent [19].

In addition to direct effects from viral infection, RVIs may promote immunologically mediated lung injury in HSCT or lung transplant recipients, potentially leading to acute allograft rejection in the case of lung transplant recipients and/or the development of bronchiolitis obliterans syndrome (BOS), which is characterized by progressive circumferential fibrosis of the small terminal airways histopathologically, resulting in fixed airflow obstruction [20, 21]. BOS is the major limiting factor for long-term survival after lung transplantation [22–28]. The reported incidence of BOS associated with RVIs ranges from 6% to 42% [17, 23], while

the incidence of acute rejection associated with RVIs varies from 16% to as high as 82% [25, 28–30]. For HSCT, BOS is often observed in the setting of chronic graft-versus-host disease, but it has also been associated with RVIs [31–34]. Among the respiratory viruses, RSV, PIV, HMPV, and influenza have all been associated with BOS [30, 35, 36], and mortality associated with these viruses can be up to 20% in lung transplant patients [37]. For heart, liver, or kidney transplantation, no relationship between RVI and rejection has been noted [19].

Paramyxoviruses

RSV, PIVs, and HMPV are members of the *Paramyxoviridae* family. The epidemiology, clinical manifestations, and treatment of each of these viruses are discussed separately.

Respiratory Syncytial Virus (RSV)

Epidemiology and Clinical Manifestations

RSV has two subtypes, A and B, with the former typically causing more severe disease. While both subtypes can simultaneously circulate during outbreaks, a few distinct genotypes of each subtype can predominate within a community. The dominant strains can also shift yearly. This shifting of viral strains, along with the waning protective immunity from natural infection, might account for frequent re-infections throughout life [38].

RSV usually causes mild and self-limited URTI in healthy older children and nonelderly adults, but certain patient populations are at risk for developing severe RSV infection, including premature or very young infants, elderly patients with comorbidities, or immunocompromised hosts [39–41]. RSV has been associated with apnea in young or preterm infants [42] and can cause severe LRTI in children including bronchiolitis, pneumonia, and acute respiratory failure [42]. Among adults infected with RSV, more than 80% are symptomatic, and lower respiratory tract signs and symptoms can occur in a quarter of the patients [43]. Signs of URTI include cough, rhinorrhea, and conjunctivitis, and compared to influenza, RSV is more frequently associated with nasal congestion, ear and sinus involvement, productive cough, and longer duration of illness [43].

RSV Infection in Transplantation

For transplant patients, RSV is a leading cause of viral respiratory tract infections [44, 45]. Among HSCT recipients, the incidence may be as high as 10% during winter months [6]. URTI precedes pneumonia in 80–90% of patients, and approximately 30–40% of patients with URTI progress to pneumonia after a median of 7 days [46]. Attributable mortality among HSCT patients ranges from 7% to 83% [47, 48], with more recent studies showing mortality rates of about 20–35% [49–54]. Risk factors for the development of LRTI include allogeneic transplant, mismatched or unrelated transplant, presence of graft versus host disease, myeloablative regimens, advanced age, prolonged lymphopenia, relapse of malignancy, and lack of engraftment [1, 6, 8, 9, 12, 13, 15, 55, 56].

For SOT recipients, RSV-associated mortality rate is significantly lower than that experienced in HSCT [57] although mortality rates among lung transplant patients of up to 20% have been reported [17, 37]. While there have been some reports of favorable outcomes in lung transplant recipients even in the absence of specific antiviral treatment [58], other studies suggest that up to 33% of RSV-infected patients develop long-term pulmonary dysfunction [23, 24, 37] and up to 60% have worsening of BOS stage [58].

Treatment of RSV

Available Agents for RSV Treatment

Treatment modalities for RSV are limited to ribavirin with or without the addition of immunomodulatory agents and/or corticosteroids. Currently, the only Food and Drug Administration (FDA)-approved therapy for RSV is aerosolized ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboximide), which was licensed in 1986 for the treatment of RSV LRTI in hospitalized high-risk infants and young children [59]. Ribavirin is a synthetic nucleoside analog with a broad spectrum of activities against many RNA and DNA viruses in vitro and in vivo. It competitively inhibits inosine monophosphate dehydrogenase and can be incorporated into the viral genome, leading to lethal mutagenesis [60]. The drug also has immunomodulatory properties that might contribute to its efficacy in vivo [61, 62].

The standard regimen of aerosolized ribavirin consists of a daily dose of 6 g delivered at a concentration of 20 mg/ml of sterile water for 18 h/day. Due to potential teratogenicity, the drug is usually administered to patients within a scavenging tent and preferably in a negative pressure room to prevent environmental contamination. After administration, the room needs to be cleaned to minimize secondary exposure to health care workers and visitors [48]. Women of childbearing potential should not care for or visit patients receiving aerosolized ribavirin. For ease of administration and improved compliance, the drug is often delivered with an intermittent dosing schedule at 2 g administered for 2–3 h every 8 h [63, 64]. In a randomized trial of 50 subjects, patients receiving intermittent vs continuous dosing had a lower incidence of progression from URTI to LRTI [65]. The reported duration of treatment is variable in the literature; the 4th European Conference on Infections in Leukaemia (ECIL-4) guidelines recommend a duration of 7–10 days [66].

Side effects of aerosolized ribavirin treatment include cough, dyspnea, bronchospasm, rash, nausea, headache, and conjunctival irritation. Patients can also experience claustrophobia and deterioration of pulmonary function. Ribavirin can also be administered intravenously or orally, with major side effects including hemolytic anemia, leukopenia, and hyperbilirubinemia [47].

Intravenous RSV-specific immunoglobulin (RSV-IVIG and palivizumab [PVZ]) were licensed initially for prevention of serious complications from RSV infection in high-risk children (refer to section "Immunoprophylaxis") [67], but they have also been employed for RSV treatment [68–72]. Intravenous immunoglobulin (IVIG) is also frequently used for the treatment of RSV and other severe viral infections in transplant recipients. The efficacy of these agents for prophylaxis or treatment among transplant patients has not been evaluated in randomized controlled trials although in an observational study of HSCT patients with RSV LRTI, multivariate analysis did not find any effect of antibody-based therapies on treatment outcomes [73].

Treatment of RSV in HSCT

The evaluation of any treatment modalities for RSV, or any other respiratory viruses, has been limited by the fact that most published studies are small observational studies which lack standardized definitions of URTI and LRTI, use different dosages and duration of therapy, and are subject to selection and publication bias. Among dozens of reports on the treatment of RSV in HSCT patients, there have only been two small randomized clinical trials. One study of aerosolized ribavirin was discontinued due to slow accrual, after enrollment of 14 patients in 5 years [69]. The other trial enrolled 50 patients and found that an intermittent dosing schedule of aerosolized ribavirin for treatment of RSV URTI was more effective than a continuous dosing schedule for prevention of progression to LRTI [64].

Two pooled analyses of published studies between 1980 and 2010 suggest that treatment of RSV URTI and LRTI with aerosolized ribavirin and IVIG reduces the risk of progression to LRTI in individuals with URTI and reduces mortality [47, 48]. When compared to no treatment, aerosolized ribavirin decreased the rate of progression to LRTI and mortality with the greatest impact observed when aerosolized ribavirin was given in combination with an immunomodulator. Specifically, when comparing aerosolized ribavirin treatment alone with no treatment, progression to LRTI was decreased from 47% to 25% and the mortality rate was reduced from 89% to 50% [47]. The addition of immunomodulators such as PVZ, IVIG, and/or RSV-IVIG to ribavirin compared to no treatment decreased progression to LTRI from 45% to 12% and mortality rate from 77% to 24%. There are paucity of reports on the use of intravenous or oral ribavirin, but the combined data suggest a benefit compared to no treatment. It is important to recognize that neither of these systematic reviews represented formal meta-analyses; there was no adjustment for confounders, and thus, results should be interpreted with caution. The only trial to date that evaluated PVZ as monotherapy for the treatment of RSV infection in HSCT recipients showed no benefit in prevention of progression to LRTI or mortality [74].

Overall, these analyses show a trend toward improved outcomes with regard to progression to LRTI and mortality among HSCT recipients treated with a combination of aerosolized ribavirin and immunomodulators than those treated with aerosolized ribavirin alone or with intravenous/oral ribavirin, or those given no treatment. However, the use of aerosolized ribavirin is cumbersome and very costly with the price increase in 2015 to $30,000 per day [75]. In addition, the aerosolized form of ribavirin is not available in all countries, and the intravenous form is not commercially available in the United States. The experience with oral ribavirin in HSCT is limited and warrants further evaluation, but some studies suggest that it may be a safe and effective alternative to aerosolized ribavirin for the treatment of RSV [51, 76–78]. In a retrospective study of 124 HSCT recipients with RSV infection, there was no difference in rates of progression to LRTI and mortality among patients receiving oral compared to aerosolized ribavirin [51]. The optimal dose of oral ribavirin for treatment of RSV is unclear and quite variable in the literature [79]. Commonly described dosing strategies include a fixed dose of 600–800 mg two or three times a day or a loading dose of 10 mg/kg followed by 20 mg/kg/day divided into three doses, adjusted for renal failure [51, 77, 79].

Treatment of RSV in SOT

Similar to the HSCT population, the mainstay of treatment for paramyxoviral infections in SOT populations has been aerosolized ribavirin [37, 80]. In an observational study, a combination of aerosolized ribavirin, IVIG, and corticosteroids was found to be safe and effective in preserving lung function in lung transplant recipients after RSV or PIV infections 29. Few studies have examined the role of oral ribavirin. Pelaez et al. [81] reported treatment of five lung transplant patients with RSV infection using oral ribavirin in combination with methylprednisolone and found this regimen well tolerated and effective with mean forced expiratory volume in 1 s (FEV1) returning to baseline with treatment. In a prospective observational study, oral ribavirin treatment in 38 patients with RSV, PIV, or HMPV infection was associated with earlier recovery of graft function and prevention of BOS as compared to 29 patients with only supportive care including corticosteroids [82]. In one study that evaluated lung transplant patients who received either aerosolized or oral ribavirin for RSV infection, no significant differences in 6-month outcomes were noted between the two groups,

but variations in their adjunctive therapies, e.g., use of corticosteroids, IVIG, and/or montelukast, might have altered the patients' clinical response [83]. Intravenous ribavirin was also found to be a safe and cost-effective treatment among 18 patients with RSV after lung transplantation [84].

Overall, these studies support the use of ribavirin in treating RSV infection among SOT recipients although it is important to recognize that the evidence is limited to small, uncontrolled studies. There are significant variabilities among these studies regarding the dose and duration of treatment as well as the use of immunomodulating agents such as corticosteroids, IVIG, or PVZ as adjunctive measures.

More recently, a new agent presatovir (GS-5806), an orally bioavailable antiviral agent that inhibits fusion of RSV with host cell membranes, is being developed for treatment of RSV infection. Phase II clinical trials studying HSCT and lung transplant recipients were completed, and the data on lung transplant recipients has been published [85]. In this Phase 2b randomized controlled trial that enrolled a total of 61 lung transplant patients with RSV, presatovir was apparently well tolerated, but its use did not result in improved viral or clinical or outcomes.

Parainfluenza Viruses (PIVs)

Epidemiology and Clinical Manifestations

There are four distinct serotypes of PIVs, namely, PIV-1 to -4. These viruses can circulate throughout the year in most communities, although PIV-3, the dominant serotype affecting transplant populations, seems to have the highest prevalence during spring and summer seasons [38]. PIVs cause a spectrum of respiratory tract infections similar to RSV, but most are URTIs and result in fewer hospitalizations. PIV-1 and, to a lesser extent, PIV-2 are the principal causative agents of croup or laryngotracheobronchitis, primarily in children between the ages of 6 and 48 months. PIV-3 is most frequently associated with pneumonia and bronchiolitis; neonates, immunocompromised, and the elderly are at particular risk for severe disease. PIV-4 is infrequently detected and is thought to cause mostly asymptomatic or mild infections.

PIV Infection in Transplantation

Symptomatic PIV infection affects about 3–7% of HSCT recipients [2, 64, 86, 87] and approximately 3–5% of lung transplant recipients [28, 88]. LRTI can develop in up to 50% of PIV-infected HSCT patients, with associated mortality rate ranging from 12% to 57% [2, 8, 64, 86, 87, 89, 90]. Two large retrospective studies have evaluated PIV infections in HSCT and found that most patients (70–87%) presented with URTI, but 13–24% subsequently progressed to LRTI [2, 64]. Among those with LRTI, overall mortality at 30 days was 17–35% [2, 64]. Independent risk factors for progression to LRTI included receipt of corticosteroids at the time of URTI diagnosis, neutropenia, an APACHE II score >15, and respiratory coinfections. Independent predictors of death included relapsed or refractory underlying cancer, APACHE II score >15, and high-dose corticosteroid use considered in patients given cumulative dose of prednisolone >600 mg within 4 weeks of PIV diagnosis [2, 14]. Whether steroids are still important if adjusted for lymphopenia requires further study. While RSV infections are always symptomatic, asymptomatic shedding is present in about 1/3 of PIV-infected HSCT patients [91]. In a surveillance study of lung transplant recipients, asymptomatic PIV infection was present in 70% of patients [28].

PIV LRTI has also been associated with a significantly increased risk of severe airflow decline after HSCT when compared to RSV 31. For lung transplant patients, PIV has been associated with acute rejection and BOS [18, 28, 88, 92, 93].

Treatment of PIV

A number of studies reported treatment of PIV with ribavirin (see section "Treatment of RSV"), but most are limited to case reports or small series. For HSCT, both aerosolized [2, 86, 87, 94, 95] and oral ribavirin [96, 97] have been employed, although some patients received intravenous ribavirin when they did not respond to aerosolized or oral treatment [86, 98]. In a series that included 55 patients with PIV-3 LRTI, 31 were treated with aerosolized ribavirin with or without IVIG in a nonrandomized fashion. Such therapy did not appear to alter mortality from PIV-3 pneumonia or decrease the duration of viral shedding [2]. A more recent retrospective study evaluated 173 HSCT recipients with PIV infection [90]. Forty-one patients with LRTI were treated with aerosolized ribavirin with or without IVIG, but 100-day mortality of this group was similar to those with LRTI not treated with ribavirin. Overall, there is no convincing evidence that ribavirin is effective for treatment of PIV upper or lower tract disease in HCT recipients. Effective prophylaxis and treatment for PIV in HSCT population are desperately needed.

Successful treatment of PIV LRTI has been reported in heart transplant recipients with aerosolized ribavirin or with intravenous ribavirin plus methylprednisolone [99, 100] as well as in a kidney transplant recipients with aerosolized ribavirin and IVIG [101] although none of these studies included controls.

DAS181 is a novel sialidase fusion protein with activities against multiple strains of influenza and PIVs. It has been used for PIV treatment in a small number of HSCT and lung transplant recipients. The drug was found effective in most of these cases and was well tolerated [102–106]. A phase II, randomized, double-blind, placebo-controlled study to

examine the effects of DAS181 in immunocompromised hosts with LRTI by PIV has been completed, but no results have been published to date.

Human Metapneumovirus (HMPV)

Epidemiology and Clinical Manifestations

HMPV was first described in 2001 among Dutch children with bronchitis [107], although serological studies indicate that it has been a cause of human infection since 1958 [108]. There are two subgroups of HMPV, A and B, and each with two clades, A1, A2, B1, and B2. All four subtypes co-circulate, while a single subtype tends to dominate each year [109]. HMPV has a worldwide distribution; it circulates in late winter to early spring in temperate climates and in late spring to summer in tropical regions [108].

HMPV may contribute to 12–20% of all previously virus-negative LRTI [110]. When compared to RSV, infection with HMPV tends to occur in slightly older children and cause milder symptoms, but severe disease can occur among small children, elderly, and those with immunosuppression or chronic medical conditions [111]. Clinical manifestations range from mild URTIs to severe pneumonia. Elderly patients are much more likely to experience dyspnea and wheezing than young adults, and hoarseness is a more common complaint when compared to other paramyxoviruses [112]. Among hospitalized patients and recipients of HSCT, wheezing is prominent and noted in up to 80–90% of patients [113, 114].

HMPV Infection in Transplantation

For patients with hematologic malignancies or HSCT, HMPV is responsible for approximately 3–14% of RVIs [114–117]. A systematic review of HMPV infections among HSCT recipients and hematologic malignancy patients found that despite lack of directed antiviral therapy, overall mortality rates are low (6%) unless patients progress to LRTI (27%) [118]. Approximately one-third of patients with HMPV URTI develop LRTI [119].

In lung transplant recipients, HMPV is responsible for 14–30% of RVIs with a similar morbidity when compared to other community-acquired respiratory viruses [3, 35, 36, 120]. Acute HPMV infection has been associated with allograft rejection [36]. In a study [120] of 89 lung transplant patients who presented with RVIs, HMPV and RSV were equally prevalent and had similar clinical manifestations, although severe bronchospasm was less common with HMPV. A significant number of patients with either HMPV or RSV infection developed graft dysfunction (63% and 72%, respectively), but onset or progression of BOS occurred only in patients with RSV (38%) at 6 months and in none with HMPV. Another study of 60 lung transplant patients also showed that HMPV infection increased the risk of acute graft rejection without associated chronic rejection or BOS [3, 120].

Treatment of HMPV

Treatment for HMPV is largely supportive, as there is currently no antiviral therapy licensed for this virus. Ribavirin is active against HMPV in vitro and in animal models [121, 122]. In clinical settings, there have been scattered reports in the literature describing HMPV cases treated successfully using aerosolized, oral, or intravenous ribavirin given with or without IVIG [3, 120, 123–126]. However, these studies did not include any untreated control groups, and the efficacy of these regimens cannot be determined. Some have suggested that ribavirin with IVIG may be considered as a treatment option for patients with severe disease [125], but this approach is not routinely used.

Several new approaches for treatment of HMPV are in development, including monoclonal antibodies against the fusion protein [127, 128] or synthetic peptides with antiviral activities [129]. Their efficacies against HMPV have been demonstrated in vitro and in animal models, but studies in human have not been reported.

Diagnosis of Paramyxoviruses

Radiographic Evaluation

LRTI by respiratory viruses produces a spectrum of imaging findings; with the most common high-resolution chest computed tomography (HRCT) scan, observations include small, poorly defined centrilobular nodules or tree-in-bud opacities, ground-glass opacities, bronchial wall thickening, and airspace consolidations, which may be difficult to differentiate from other causes of pulmonary consolidation [130–137]. There is considerable overlap in the imaging appearance of viral, bacterial, mycobacterial, and fungal respiratory tract infections in transplant population. The findings such as tree-in-bud opacities, bronchial wall thickening, and peribronchiolar consolidation may suggest a viral etiology [138]. HRCT findings between immunocompetent and immunocompromised patients are relatively similar [139], but infection with co-pathogens is common among transplant recipients, thus complicating interpretation of radiographic findings. Correlation with patient immune status, recent treatment, and exposure history, as well as epidemiologic factors, are essential to help narrow the list of possible etiologies both infectious and noninfectious and to guide diagnostic testing and appropriate therapy [130].

Laboratory Diagnosis of Paramyxoviruses

Laboratory diagnosis of respiratory viruses is usually made by analysis of respiratory secretions. Samples can

be obtained as a nasal wash, nasopharyngeal or throat swab, bronchoalveolar lavage, or, for those incubated, tracheal aspirate. Detection of the virus in the respiratory samples can be performed by cell culture, antigen testing, and PCR.

Viral isolation by cell culture used to be the gold standard for diagnosis but has largely been replaced by molecular studies. Reverse transcriptase (RT)–PCR is now routinely used for respiratory viral diagnosis for the detection of RNA viruses in respiratory secretions [140] and has higher sensitivity than either viral culture or antigen detection assays, particularly in immunocompromised patients [91, 140]. Compared with culture, the sensitivity and specificity of RT-PCR techniques can reach 100% and 95–98%, respectively [141–143]. PCR-based tests for respiratory viral detection are often designed as part of a multiplex PCR assay that can allow detection of multiple respiratory pathogens simultaneously [144], and rapid point-of-care tests are being developed as well [145, 146].

Transmission and Prevention of Paramyxovirus Infection

The modes of transmission of PIVs and HMPV are not as well studied as RSV, but these respiratory viruses are mostly transmitted by direct person-to-person contact, through exposure to nasopharyngeal secretions from infected individuals such as respiratory droplets or by self-inoculation after touching contaminated surfaces has also been described [147, 148]. Outbreaks of RSV, PIVs, or HMPV have been reported in outpatient clinics, in long-term care facilities, and in hospitals, including hematology and HSCT units [94, 149–153]. To prevent transmission of respiratory viruses in health care setting, policies and procedures regarding patients with respiratory viruses should be formulated; in particular, compliance with proper hand hygiene and contact precautions are of paramount importance. Other infection control measures include isolating infected patients in private room, cohorting patients, and/or limiting transport of patients from their rooms. During a nosocomial outbreak, personnel caring for infected patients should be restricted from caring for uninfected high-risk patients if possible [154–156].

Immunoprophylaxis

PVZ is a RSV-specific humanized monoclonal antibody directed against the F glycoprotein of RSV and is FDA approved for immunoprophylaxis against RSV in high-risk children. Data for its use in immunocompromised adult patients are limited [48, 68], with only one uncontrolled study in the literature reporting the use of PVZ as immunoprophylaxis during an RSV outbreak in an adult HSCT unit [150]. RSV-IVIG prophylaxis has also been studied in high-risk adult HSCT recipients; an increase in antibody titers against RSV was demonstrated, but the study was underpowered to evaluate its efficacy [157]. There are several monoclonal antibodies against RSV under development.

Vaccines

Despite the major clinical importance of paramyxoviruses, there is currently no vaccine approved for these viruses in humans. Using various strategies for vaccine development, those tested in animal models include live-attenuated virus vaccines including chimeric and recombinant variety, inactivated virus vaccines, and subunit vaccines. A number of them are currently in phase I–II clinical trials [158–161].

Other Strategies

In a retrospective study of 37 HSCT patients with pretransplant RSV URTI, 34 patients had their transplant delayed or conditioning aborted [162]. Overall, RSV pneumonia occurred in 1 of 34 patients for whom HSCT was delayed, compared with two of three patients for whom there was no delay. This study suggested that for HSCT candidates with pretransplant RSV URTI, a delay of HSCT might reduce the risk of developing RSV pneumonia. Thus, the strategy of delaying transplantation to prevent progression of a viral URTI to LRTI is recommended unless precluded by progression of underlying malignancy. There are limited data for other respiratory viruses [66, 147] although some proposed guidance is available (Table 40.1) [163].

Orthomyxovirus: Influenza

Influenza belongs to the family *Orthomyxoviridae* with three types, influenza A, influenza, B, and influenza C virus. Influenza A viruses are further classified into subtypes based on their hemagglutinins (HA) and neuraminidases (NA). One of the unique features of influenza virus is the frequency by which antigenic variation occurs which is the reason that influenza continues to be a cause of major epidemics. Annual variation of the influenza virus is due to relatively minor antigenic changes within the HA and/or NA and is known as antigenic drift. Major changes in HA or NA through genetic reassortment or a major mutation are known as antigenic shift and occur once every 10–30 years. This results in an entirely novel strain to which the population has no immunity, leading to an unhindered global spread; the last pandemic occurred in 2009 with the emergence of a novel strain of influenza A/H1N1.

Table 40.1 Recommendations for respiratory viral infections prior to hematopoietic stem cell transplantation

Virus	Recommendation for URTI	Recommendation for LRTI
RSV	Delay transplant if possible If not possible to delay, consider oral ribavirin	Delay transplant; consider ribavirin if delay is not feasible (anecdotal data)
Influenza virus	Delay transplant if possible and treat If not possible to delay, treat	Delay transplant and treat
Parainfluenza virus	Delay transplant if possible If not possible to delay, supportive care	Delay transplant; consider ribavirin if delay is not feasible (anecdotal data)
Metapneumovirus	Delay transplant if possible	Delay transplant; no data on ribavirin
Rhinovirus	No delay needed for URTI	Delay transplant for allogeneic transplant if feasible
Coronavirus	No data	No data
Bocavirus	No data	No data

Epidemiology

Influenza is a significant cause of morbidity and mortality in transplant patients. In recipients of solid organ transplantation, up to 42% of URTIs and 48% of LRTIs may be due to influenza infection and the annual between 1% and 4% [164]. During the 2009 H1N1 pandemic, mortality rates ranged from 0 to 8% in most case series [4] although one study reported a mortality rate of 21% among lung transplant recipients [165]. Of the organ transplants, lung transplant recipients appear to be at the highest risk; in one study, the incidence of influenza was 10–15 times higher in recipients of lung transplantation compared with recipients of other solid organs such as kidney or liver [166].

The incidence of influenza among HSCT ranges between 1% and 4% with 7–44% of such patients may develop LRTI. Death rates associated with influenza in HSCT recipients are higher than in SOT. Among patients with LRTI, mortality rates ranged from 15% to 28% and case fatality rates during the 2009 H1N1 pandemic ranged from 0 to 38% [4]. The main risk factor for disease progression to LRTI was lymphopenia; allogeneic HSCT, infection during early post-transplant period, presence of graft-versus-host disease, myeloablative preparatory regimen, and delayed initiation of antiviral therapy were other risk factors [1, 11, 12, 167]. Of interest, concomitant corticosteroid use has not been associated with an increased risk for progression to LRTI, a need for mechanical ventilation, or infection associated death; however, patients given systemic higher doses (≥1 mg/kg) of corticosteroids may be predisposed to prolonged viral shedding [11, 168]. The potential role of corticosteroids in influencing risk of progression to LRTI and mortality of influenza and other respiratory viral infections is summarized in Table 40.2 [163].

Clinical Manifestations

Clinical manifestations of influenza are similar to those in immunocompetent patients. In a multicenter cohort study of 242 organ transplant patients during the 2009 H1N1 pandemic, the most common presenting symptoms were cough (91%), fever (85%), myalgias (51%), gastrointestinal symptoms (44%), rhinorrhea (43%), and sore throat (43%) [169]. In a multicenter cohort study of 286 HSCT recipients during the 2009 H1N1 pandemic, the most common presenting symptoms were cough (85%), fever (81%), rhinorrhea (49%), myalgias (29%), and sore throat (23%) [170]. However, atypical presentations may occur in those with significant immunosuppression, which may include fever as the only presenting symptom or afebrile patient with rhinorrhea alone. It is speculated that corticosteroid use and blunting of the cytokine response associated with

acute influenza infection in these patients may contribute to the reduction or absence of systemic symptoms in selected patients.

The primary complication of influenza infection in transplant patients is progression from URTI to LRTI which can lead to acute lung injury and death. Morbidity and mortality appear to be greatest among HSCT and lung transplant recipients. While diffuse or peribronchial ground-glass opacity is the typical radiographic appearance in patients with LRTI, centrilobular nodules and frank lower lobe consolidation can also be observed [171]. Coinfection with other viral, bacterial, or fungal pathogens may occur and was reported in 29% of patients in a multicenter study of SOT recipients with pandemic influenza A/H1N1 [172]. Compared to those with viral co-pathogens, patients with bacterial or fungal coinfections had worse outcomes [11, 172]. Although uncommon, influenza can also a cause a variety of extrapulmonary complications including myocarditis, myositis, encephalopathy, renal failure, severe diarrhea, and pneumomediastinum [166, 173, 174]. Virus-associated hemophagocytic syndrome has been reported as a severe complication of pandemic H1N1 leading to multiorgan failure [175]. As discussed previously, several studies suggest an association between RVIs including influenza and allograft rejection/BOS in the case of lung transplants, while others have not; a prospective study is needed to better characterize the impact of these infections on long-term sequelae [19, 44, 172, 176].

In healthy adults, seasonal influenza virus shedding ranges from 5 to 7 days and may extend beyond 1 week in hospitalized patients [177, 178] and even longer in transplant recipients. The median duration of viral shedding among allogeneic HSCT recipients was between 11 and 12 days compared to 1 week among recipients of autologous transplants [11, 179]. Prolonged viral shedding beyond 2 weeks and, in some cases, for months has been described in HSCT recipient. Risk factors for prolonged viral shedding include the use of corticosteroids at dosages ≥1 mg/kg per day and use of bone marrow and cord blood versus peripheral blood stem cell.

Diagnosis

There are several methods available for detection of influenza including rapid antigen, direct immunofluorescence antibody (DFA), viral culture, and PCR. As for other respiratory viruses, molecular tests have largely replaced these other testing modalities. In a study evaluating test characteristics of four different diagnostic assays during the 2009 H1N1 pandemic, PCR was found to have the greatest sensitivity and specificity. Given their improved sensitivity and specificity over other methods, PCR or other nucleic acid-based detection assays are preferred for the diagnosis of influenza infection in this susceptible patient population. Multiplex PCRs have the added advantage of identifying other causes of respiratory viral infections as well.

Treatment

Currently, there are two major classes of antiviral agents with activity against influenza: adamantanes which block the viral M2 protein ion channel, thereby preventing fusion of the virus with host cell membranes, and neuraminidase inhibitors which prevent the release of progeny virus from infected cells. While the adamantanes, amantadine, and rimantadine are only active against influenza A, the neuraminidase inhibitors oseltamivir and zanamivir are active against both influenza A and B viruses, although reduced effectiveness of oseltamivir has occasionally been reported for influenza B virus [180]. The development of resistance to the adamantanes among influenza A virus has substantially limited their utility in clinical practice. Although 2008–2009 seasonal H1N1 remained susceptible to the adamantanes, resistance emerged among seasonal H3N2 in 2003 and was widespread among 2009 pandemic H1N1 viruses. Oseltamivir resistance first emerged in 2007 among seasonal H1N1 viruses and was described during the 2009 H1N1 pandemic [181]. Oseltamivir resistance is primarily conferred by the H275Y mutation which does not result in cross-resistance to zanamivir. PCR testing is available for the detection of the H275Y mutation. In 2010, the S247 N mutation was detected in strains of 2009 pandemic H1N1 collected in Asia and was found to confer low to moderate oseltamivir and zanamivir resistance [182]. Otherwise, there has been very little zanamivir resistance reported to date, and thus, it is recommended for the treatment of oseltamivir-resistant influenza infection.

Because resistance patterns evolve over time, clinicians should become familiar with local patterns of influenza circulation in their communities throughout each influenza season and refer to the Centers for Disease Control and Prevention (CDC) influenza website (http://www.cdc.gov/flu) [183] for updated information regarding antiviral resistance and recommendations regarding antiviral use. In addition, antiviral resistance appears to occur more commonly among severely immunocompromised patients likely due to prolonged viral shedding [184, 185]. During the 2009 H1N1 pandemic, the majority of patients with oseltamivir-resistant virus reported to the CDC were HSCT recipients or patients who had a hematologic malignancy receiving chemo- or immunosuppressive therapy [186].

There have been no randomized clinical trials of antiviral therapy for influenza in transplant patients. All randomized trials have included healthy adult outpatients who were treated within 48 h after symptom onset and, in aggregate, demonstrate a reduction in duration of symptoms by ~1 day

and time to return to normal activity [180]. Although further study is needed regarding the role of antiviral therapy >48 h of symptom onset, the 2009 IDSA guidelines for management of seasonal influenza suggest that antiviral therapy initiated >48 h after symptom onset may be beneficial in hospitalized patients based on a prospective cohort study [167, 180, 187]. Observational studies suggest that early antiviral therapy of HSCT recipients with influenza URTI is effective in preventing progression to LRTI [8, 11, 168, 179, 188]. Among SOT recipients, a multicenter study found that early antiviral therapy was associated with a lower incidence of hospitalization and likelihood of ICU admission as compared to delayed (>48 h after symptom onset) therapy [169]. Although antiviral therapy may have its greatest value when initiated early, it is felt that symptomatic transplant patients may benefit even beyond 48 h if they have evidence of viral replication, and in general, treatment of all symptomatic transplant patients is recommended regardless of the duration of symptoms [189–191].

The optimal dose and duration of antiviral therapy in transplant patients has not been established. Oseltamivir has been studied at doses of 75 mg or 150 mg twice daily in immunocompetent patients with seasonal influenza; there was no significant advantage of the higher dose although a slightly higher rate of adverse effects was observed [192, 193]. However, due to concerns over higher viral loads, prolonged viral shedding, and uncertain drug absorption particularly in those patients undergoing chemotherapy or with gastrointestinal graft-versus-host disease, some experts suggest using the higher dose in transplant patients particularly if absorption is uncertain, in those patients with severe LRTI or who are critically ill [189–191]. Based on clinical studies in healthy adults, the recommended duration of treatment of influenza in immunocompetent patients is 5 days [180]. However, transplant patients may need longer durations of therapy due to prolonged viral shedding. Some experts recommend treating all SOT recipients until viral replication has ceased; authors recommend checking PCR once a week and treat until negative [190, 191]. Others have suggested a 10-day course for HSCT recipients and extending treatment in those patients with pneumonia, ongoing symptoms, or viral shedding [189]. Resistance testing should be considered in those patients with persistent viral shedding or who progress despite antiviral therapy.

While most literature in transplant recipients has focused on oseltamivir, inhaled zanamivir appears to be a reasonable alternative. IV zanamivir is currently available for compassionate use, and there is limited published experience among transplant recipients where it has been used with some benefit among patients with oseltamivir-resistant influenza or severe disease [194].

Peramivir, a parenteral neuraminidase inhibitor, was FDA approved in 2014 for the treatment of uncomplicated influenza infection in adults who have been ill for ≤2 days. There are limited data regarding the use of peramivir in transplant recipients. Of note, the H275Y mutation which confers oseltamivir resistance also confers cross-resistance to peramivir.

There are currently no data that indicates a clear clinical benefit of combination antiviral therapy over single drug therapy. A randomized, double-blind, multicenter phase 2 trial found that combination antiviral therapy with oseltamivir, amantadine and ribavirin reduced day 3 viral shedding compared to oseltamivir monotherapy, but there was no difference in clinical outcomes including resolution of symptoms or fever or time to recovery after illness [195].

Table 40.3 summarizes antiviral options for treatment of influenza.

Table 40.3 Antiviral options for the treatment of influenza

Antiviral agent	Dose	Parenteral formulation?	Side effects	Remarks
Oseltamivir	75 mg PO twice daily	Yes, investigational	Gastrointestinal: nausea, vomiting, diarrhea Neurologic: confusion, delirium, depressed consciousness (mostly reported among Japanese adolescents and adults)	Some experts recommend higher doses (150 mg PO BID) in transplant patients who are critically ill with LRTI
Zanamivir	2 puffs (10 mg) inhaled twice daily	Yes, investigational	Bronchospasm, cough, headache, dizziness, sinusitis, nausea, diarrhea	Little cross-resistance with oseltamivir
Peramivir	600 mg IV once daily	Yes (only available as parenteral formulation)	Gastrointestinal: nausea, vomiting, diarrhea Neutropenia	Cross-resistance with oseltamivir exists.
Amantadine	100 mg PO twice daily	No	Neurologic: insomnia, lethargy, inability to concentrate, dizziness Gastrointestinal: nausea	No longer routinely recommended due to high incidence of resistant influenza unless circulating strain known to be susceptible
Rimantadine	100 mg PO twice daily	No	Gastrointestinal Neurologic (less common than amantadine): lightheadedness, insomnia, inability to concentrate, nervousness	No longer routinely recommended due to high incidence of resistant influenza unless circulating strain known to be susceptible

Prevention

Annual influenza vaccination is a key component of infection prevention among HSCT and SOT recipients. There are several types of influenza vaccines: standard-dose inactivated influenza vaccines (IIV), available either as a trivalent or quadrivalent injection, high-dose IIV (available as a trivalent injection), live attenuated influenza vaccine (LAIV), intradermal IIV, and recombinant egg-free IIV. All vaccines are modified annually based on the anticipated circulating strains during the upcoming influenza season. The LAIV is contraindicated in immunocompromised patients and should not be used in transplant recipients. The intradermal IIV has not been evaluated in transplant recipients.

For HSCT recipients, influenza vaccination is recommended ≥6 months post-transplant and beginning 4 months following transplant if there is a community influenza outbreak [196]. If the vaccine is administered earlier than 6 months after HSCT, a second dose should be considered. The timing of vaccine administration appears to predict response with one study demonstrating that influenza immunization at least 6 months after HCT was 80% effective in preventing influenza [197]. The high-dose trivalent IIV is FDA approved for individuals ≥65 years of age and was found in a multicenter randomized clinical trial to induce higher antibody responses and improved protection against influenza compared to standard dose IIV [198]. In a phase I trial, HSCT recipients randomized to receive high-dose trivalent IIV had evidence of greater immunogenicity when compared to those receiving standard-dose trivalent IIV [199]. There was a higher frequency of injection site reactions, but most were mild. There are ongoing studies to further evaluate the role of high-dose IIV in HSCT.

For SOT recipients, influenza vaccination is recommended 3–6 months after transplant [164]. The immunogenicity of influenza vaccine following SOT is variable depending on the type of transplant, time from transplant, and immunosuppressive regimens. Among SOT recipients, overall responses based on seroprotection or seroconversion have ranged from 15% to 93% with greater responses observed several years after kidney transplant and lower responses seen in lung transplant [164]. Although there is a theoretical concern that influenza immunization may be associated with early allograft rejection or allosensitization of patients after transplant, this has not been observed in clinical trials [200]. In a randomized, double-blind trial of 172 SOT recipients, high-dose influenza vaccine demonstrated significantly better immunogenicity than the standard-dose vaccine [201]; no increased risk of rejection was reported although the study was not powered to address this outcome.

Immunization of health care workers and household contacts of transplant recipients is a critical component of influenza prevention and is strongly recommended in published guidelines [147, 164]. A systematic review suggests that vaccination of healthcare workers reduces influenza-like illness and all-cause mortality in the elderly [202]. Due to the theoretical risk of transmission of LAIV, the CDC recommends that IIV not be used for household members and health care workers who have close contact with severely immunosuppressed patients such as recipient of hematopoietic stem cell allograft transplantation during those periods in which the patient requires care in a protective environment. Those persons who receive LAIV should avoid providing care for and contact with such patients for 7 days after vaccination.

Although influenza vaccination is the primary tool for influenza prevention, antiviral chemoprophylaxis may be considered as a prevention strategy in selected situations. The 2009 IDSA Guidelines for Management of Seasonal Influenza recommends consideration of antiviral chemoprophylaxis in high-risk patients during the 2 weeks after vaccination before an adequate immune response develops if influenza is circulating in the community [180]. It should also be considered among transplant recipients following exposure within the previous 48 h to an individual with influenza, particularly among those for whom the vaccine is contraindicated, unavailable, or expected to have low effectiveness such as patients with severe immune suppression. The choice of chemoprophylactic agent depends on the susceptibility pattern of the circulating influenza strain.

Human Coronaviruses (HCoV) and Human Rhinoviruses (HRV)

Epidemiology

HRVs and HCoVs are also common causes of RVIs in human, classified into the *Picornaviridiae* family (genus *Enterovirus*) and the *Coronaviriae* family, respectively. Approximately 100 serotypes of HRV have been identified. In comparison, HCoV-229E and HCoV-OC43 were the only two known HCoVs for >40 years. In 2004, a new HCoV was identified as the causative agent of the outbreak of Severe Acute Respiratory Syndrome (SARS) and was named SARS-CoV. Subsequently, two other new HCoVs, NL63 and HKU1, were discovered in 2004 and 2005, respectively. In the latter part of 2012, another novel CoV was identified as the cause of severe respiratory illness in two adults from the Middle East [203] and was termed Middle East respiratory syndrome coronavirus (MERS-CoV). Similar to SARS-CoV, this virus can also cause severe, life-threatening disease. The ability of these emerging HCoVs to cause major outbreaks can be a potential threat to global public health and economy [204].

HCoV and HRV in Transplantation

In immunocompetent hosts, HRVs and HCoVs usually cause URTIs, but HCoVs can also cause croup, wheezing, as well as pneumonia, which can be severe with significant mortality, as in the case of SARS. The significance of HRV and HCoV in transplant populations has not been well established. According to a prospective study of HSCT recipients [5], infection with these viruses appears common in the first 100 days after allogeneic transplant, with day 100 cumulative incidence estimated as 22% for HRV and 11% for HCoV. HRV infection was associated with URTI signs and symptoms, but HCoV infection was asymptomatic. More than half of the infected patients had prolonged viral shedding for more than 3 weeks, and about 13% shed virus for more than 3 months [5]; only a few patients developed LRTI in that study. Fatal pneumonia associated with HRV and HCoV have been reported among HSCT recipients [205–207]. Recent studies suggested that HRV and HCoV LRTI with viral detection in the BAL are associated with mortality rates similar to those seen with RSV, PIV, or influenza viruses [10, 208].

For SOT, HRV and HCoV are frequently isolated among lung transplant patients [23, 25, 28], but a majority of these patients can be asymptomatic, according to a prospective surveillance study [28]. As discussed previously, RVI can increase the risk for developing acute rejection and/or BOS even with asymptomatic infections [23, 25, 28], but whether HRV or HCoV infection confer the same level of risk as compared to the paramyxoviruses or influenza cannot be delineated from these studies.

Currently, there are no specific agents licensed for the treatment of HRV and HCoV, but antiviral therapy for enteroviruses is under intense research.

Conclusions and Future Directions

Respiratory viral infections are common and associated with significant morbidity and mortality among patients undergoing hematopoietic stem cells and solid organ transplantation. The optimal management of these infections is limited by insufficient randomized treatment data as well as a limited new and novel antiviral drugs being investigated for potential clinical use. Large, preferably multicenter prospective, randomized trials are essential to (1) assess preferred therapy for life-threatening infections such as RSV, (2) define the role of combination antivirals for influenza virus infections, and (3) determine the use of adjunctive immunomodulatory therapy and/or corticosteroids in the management of these infections among the highly susceptible transplant population. The evaluation of novel long-lasting potent monoclonal antibodies for prevention may be warranted.

Hepatitis A, B, and C

41

Jonathan Merola, Alexander Z. Jow, and Samuel H. Sigal

Introduction

Inflammation in the liver secondary to viral infection defines viral hepatitis. Infections may manifest with acute pathology but may also take on a more indolent, chronic form. The five most common hepatitis viral infections are unrelated and classified as hepatitis A, B, C, D, and E. The former three viruses are commonly considered and managed in transplant population and are the focus of this chapter. Hepatitis A is an RNA virus acquired enterally that often manifests as an acute, self-limited illness. It can be prevented with vaccination and is treated supportively. Hepatitis B is a DNA virus that directly integrates into the host genome following infection by blood or sexual transmission. In addition to an initial acute infection, it may result in an indolent, chronic inflammatory disease following an initial acute infection occurring by blood or sexual transmission. While preventable by vaccination, hepatitis B may be treated with direct antiviral therapy but confers a significant risk of developing hepatocellular carcinoma despite complete response to treatment. Hepatitis C, also acquired through blood-borne transmission, is an RNA virus that often results in a chronic, subclinical inflammation. Chronic infection may at times lead to cirrhosis, and new direct antiviral therapies have recently become available with high rates of cure. While the hepatotropic nature of these viruses unites these pathogens, prevention, treatment, and post-treatment surveillance vary widely between them and are described in this chapter.

Hepatitis A

Hepatitis A virus (HAV) is an enteric picornavirus that harbors a single-stranded 7.5 kilobase RNA genome of positive-strand polarity. The genomic sequence encodes for multiple proteins that are processed to give rise to several viral proteins including VP-1, VP-2, and VP-3. Predominantly transmitted by the fecal-oral route, HAV is often acquired from contaminated food and water sources or close contact with infected individuals. Infection is most common in developing regions, with an annual 1.5 million cases reported worldwide, although reported cases likely underestimate the true incidence of global HAV infection [1].

In immunocompetent individuals, HAV typically causes a self-limited illness characterized by fever, anorexia, right upper quadrant abdominal pain, and jaundice that follows a 4-week viral incubation period [2]. The severity of acute illness is closely related to age, as symptomatic infection is more common in older adults while acute infection in children is typically asymptomatic [3]. Laboratory findings typically demonstrate the presence of anti-HAV IgM in patients' serum and detection of virus in stool prior to the onset of clinical illness, whereas elevation in serum hepatic transaminases appears to coincide with the development of clinical symptoms. In patients with recent HAV exposure, a single-antigen vaccine or immune globulin can be given within 2 weeks for prevention of symptomatic hepatitis [4]. Supportive care is the mainstay of treatment in most cases [5]. In patients with severe acute hepatitis A associated liver injury, early treatment with N-acetylcysteine has been shown to provide benefit and potential for recovery [6].

A subset of patients (1–12%) experience relapsing HAV cholestatic hepatitis. This is characterized by jaundice and cholestasis, 1–3 months after resolution of the initial

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_41

symptoms of acute hepatitis A infection [2]. In such cases, treatment is predominantly supportive, as the infection commonly spontaneously resolves within 6 months, although the use of oral corticosteroids may be considered in patients with severe cholestasis [7]. Additionally, treatment with ursodeoxycholic acid has been demonstrated to improve biochemical indices in cases of relapsing hepatitis [8].

In rare cases (~0.2%), HAV infection can lead to acute liver failure (ALF), particularly in elderly patients or those with chronic liver disease [9]. Mortality rates in such cases approaches 40–50%, leaving emergency liver transplantation as the only lifesaving measure for a considerable number of patients with HAV ALF [10]. Severe HAV infection is responsible for a small proportion (3%) of cases of fulminant acute hepatic failure requiring liver transplantation [11].

Transplant recipients on immunosuppressive medications are particularly susceptible to acute HAV infection [12]. Cases of intractable recurrent HAV infection requiring re-transplantation after initial liver transplantation procedure have been reported [13, 14]. All patients undergoing transplant evaluation should be screened for hepatitis A IgG and vaccinated if not immune. Two doses of the Hepatitis A vaccine, given 6 months apart, successfully induced seroconversion in 95% of patients with compensated liver disease [15]. The development of liver failure is closely associated with a lack of response to the HAV vaccine [16]. Due to pre-transplant screening and vaccination for susceptible individuals, post-transplant acute hepatitis A infection is rare. If there is suspicion for an acute infection, the patient should be tested for serum IgM antibodies [17].

Reinfection of allografts after liver transplantation in patients with fulminant hepatic failure associated with HAV hepatitis is rare. Recurrent hepatitis A infection presents as acute graft dysfunction and may be misinterpreted as an episode of allograft. Routine measurements of anti-HAV IgM and viral RNA in peripheral blood during the early post-transplant period in HAV-associated liver transplant recipients may differentiate reinfection from an episode of acute cellular rejection [14]. Detection of genomic HAV RNA by RT-PCR in serum and stool at the time of graft dysfunction is diagnostic of recurrent HAV infection [13].

Hepatitis A vaccination is less effective in patients after transplantation. In a retrospective review of children following liver transplantation, vaccine antibody responses developed in only 7 of 18 individuals (39%), and only 25% developed an antibody response after undergoing heart transplantation [18]. In addition, a significant proportion of patients with detectable protective antibodies before liver transplantation can lose immunity following transplantation: 18% and 29%, first and second year after undergoing transplantation, respectively [12]. In liver and kidney transplant recipients with satisfactory seroconversion rate after complete immunization, there is a rapid decline in antibody levels compared with controls; 59% of liver and 26% of renal transplant seroconverters showed titers above the cutoff level considered protective against HAV infection [19]. Based on the above observations, it is recommended that patients with chronic liver disease undergo vaccination early in the course of their disease and that patients on immunosuppressive antirejection therapy be re-immunized [19, 20].

Hepatitis B

Hepatitis B virus (HBV) is a DNA virus that integrates into the host genome and replicates by reverse transcription [21]. HBV infection is a major cause of hepatic cirrhosis and liver-related mortality evidenced by the roughly 250 million people chronically infected worldwide. HBV is attributable to over half of all hepatocellular cancers [22, 23]. In the United States, HBV represents the second most common viral infection after hepatitis C virus leading to liver transplantation. The proportion of liver transplants for HBV have been decreasing in the United States from 4% in 1994 to about 2% in 2009, primarily due to advances in treatment for infection and HBV-related liver disease [24, 25].

HBV is often acquired through intravenous drug use and sexual transmission in Western countries, while transmission in high-prevalence areas is often through perinatal transmission [26]. In the United States, vaccination is routinely performed in infancy. Screening is recommended in persons from high prevalence areas and those with high-risk exposures [27]. Testing includes serologic tests for Hepatitis B surface antigen as well as surface and core antibodies. The presence of core antigen or the presence of core antibody in the absence of surface antibody indicates HBV exposure, while the co-presence of core and surface antibodies occurs in those immune following vaccination.

Chronic HBV infection occurs in less than 5% of adults but in over 95% of infected infants [28, 29]. Such infections are often subclinical until advanced cirrhosis develops. An annual rate of 0.5–1% of hepatocellular carcinoma is estimated for non-cirrhotic HBV patients and 2–3% among those with cirrhosis [30].

Early results of liver transplantation in patients with chronic HBV infection showed recurrence rates of greater than 80% and 5-year survival rates of 40–60% [31]. Subsequently, HBV infection was initially viewed to be a contraindication to liver transplant. Liver transplantation in HBsAg-positive patients remained controversial until 1993 when studies demonstrated that long-term passive immunoprophylaxis with hepatitis B immune globulin (HBIG) could be used to prevent graft reinfection and reduce the rate of recurrence from 75% to about 36%,

thus improving patient survival [32]. The absence of HBV DNA in serum prior to transplantation was also found to be an independent predictor of lower risk of HBV recurrence after transplantation [32]. With the use of long-term HBIG prophylaxis, survival significantly improved from 53% in the period of 1987–1991, to 69% between 1992 and 1996, to 76% in the period of 1997–2002 [33]. The main limitations to long-term HBIG prophylaxis is its limited supply and its cost of up to $100,000 in the first year and $40,000–50,000 each year thereafter. The combination of HBIG and lamivudine achieves significantly lower HBV recurrence rates in comparison with HBIG or lamivudine monoprophylaxis, more potent nucleos(t)ide analogues may lead to substantial reduction in HBIG dosage or even eliminate the need for HBIG after the initial postoperative period [34, 35].

Nucleos(t)ide analogues (NUCs) inhibit viral replication by targeting the HBV reverse transcriptase in competitively incorporating into the viral DNA and preventing transcriptional elongation and are capable of altering the natural history of HBV pre-transplant and enabling most patients to safely undergo transplantation with outcomes similar, if not better, than those achieved for other liver transplant indications [36, 37]. Currently available drugs for the treatment of chronic HBV infection target HBV DNA polymerase and include the nucleoside antagonists lamivudine (LAM), entecavir (ETV), and telbivudine (TBV) and the nucleotide antagonists adefovir (ADV) and tenofovir (TDF). These antiviral medications have been shown to delay disease progression and even reverse hepatic decompensation, as well as reverse histologic changes such as hepatic inflammation and fibrosis [38, 39]. Until recently, tenofovir disoproxil fumarate and entecavir were used as first-line agents due to resistance profiles [40]. Although not yet studied in the transplant setting, tenofovir is now available as the prodrug tenofovir alafenamide, which is capable of delivery to target cells more efficiently at a lower dose and, as a result, is associated with a more favorable renal and bone safety profile [41].

Antiviral prophylaxis is also an important consideration for prevention of de novo HBV infection in hepatitis B surface antigen (HBsAg)-negative recipients receiving liver transplantation of hepatitis B core antibody (HBcAb)-positive donors. The use of HBcAb (+) grafts is associated with a 25–95% risk of de novo HBV transmission without the use of antiviral agents and immunoprophylaxis, which can lead to severe hepatitis and graft loss [42]. Both lamivudine monotherapy and HBIG + lamivudine have been shown to significantly decrease the risk of de novo infections to about 3%, with viral breakthrough infection frequently related to medication noncompliance. While risk of developing lamivudine resistance with long-term use is likely less in the population because of significantly less or undetectable viral loads, other new and more potent nucleos(t)ide analogues with lower resistance profiles such as tenofovir and entecavir are preferable over lamivudine [43].

Non-liver Transplant Recipients

Kidney Transplant Recipients

Kidney Transplant Recipients

The prevalence of HBV infection in dialyzed patients varies by regions; it is estimated to be between 0% and 10% in industrialized countries and 2–20% in the developing regions of the world [44]. Over the last 20 years, the prevalence of HBV infection has declined dramatically due to improved screening, hygiene, and preventative measures such as vaccination. Prior to the advent of effective antiviral agents, patients with chronic HBV infection were excluded from kidney and other organ transplantation due to the risk of severe viral recurrence and progression of disease. Fornairon et al. reported in a large cohort study of 151 HBsAg-positive renal transplant recipients a high rate of persistent viral replication (50%) and reactivation (30%) [45]. Histologic deterioration was observed in 85.3% of 101 patients who underwent serial liver biopsies, and liver disease was the leading cause of death. Among renal transplant recipients, reactivation was reported in patients with prior exposure and clearance of HBV infection [46]; with the widespread availability of new-generation antiviral drugs, it is important to note that renal transplantation can be safely performed in patients with chronic HBV kidney transplant recipient infection and end-stage kidney disease in need of long-term renal replacement therapy.

The impact on positive HbsAg on mortality and survival in renal transplant recipients has been controversial. Earlier studies failed to show a difference in 5-year survival between HBsAg-positive and HBsAg-negative patients [47, 48, 49]. However, subsequent studies of larger populations with longer follow-up indicated worse graft and patient survival [50, 51, 52]. A meta-analysis including 6050 patients performed by Fabrizi et al. found that HBsAg was an independent risk factor for death after transplantation [51]. However, the study included recipients transplanted between 1972 and 1999, prior to the widespread use of effective antiviral agents. In a more recent analysis of 1346 HBsAg-positive renal transplant recipients in the period between 2001 and 2007 in the United States, patient and graft survivals in HBsAg-positive recipients were comparable to HBV-negative recipients, even though HBsAg-positive recipients were at increased kidney transplant recipient risk of developing liver disease [53].

The rates of HCC were higher in renal transplant recipients prior to the use of antiviral therapy, likely secondary

to antirejection drug-induced immunosuppression [50, 54]. The utilization of antiviral therapy has changed the clinical course of liver disease after transplantation, presumably by reducing the risk for development of HCC; however, further larger prospective trials are needed to investigate the long-term outcomes of transplant recipients receiving antiviral therapy. It is recommended that transplant recipients with HBV and/or HCV infection to kidney transplant recipients receive early screening for HCC with abdominal ultrasound every 3 months for patients with cirrhosis and every 6–12 months for those without evidence of cirrhosis [55].

The current recommendation is that all HBsAg-positive patients who are candidates for solid organ transplantation be treated with nucleos(t)ide analogues. While immunosuppressive therapy lasts, patients should receive preemptive therapy regardless of HBV DNA levels. Anti-HBc-positive HBsAg-negative patients with undetectable HBV DNA may also be at risk for reactivation and should be followed up closely with HBV DNA and serum ALT testing every 3 months and treated with antiviral therapy if reactivation occurs. The most experience has been with lamivudine, the first nucleos(t)ide agent approved in 1998. Studies have shown that HBsAg-positive renal transplant recipients treated with lamivudine have similar 10-year survival rates as HBsAg-negative patients (85% vs. 88%) [56, 57]. However, the high rate of developing drug resistance and subsequent breakthrough viral reactivation is a concern with the use of lamivudine. Althoug lamivudine improves short-term (50 month) reactivation-free survival, it is nor effective in preventing HBV reactivation or improving long-term survival after transplantation suggested that although the use of lamivudine improved reactivation-free survival in the short term (first 50 months), it was not effective in the prevention of HBV reactivation or improvement in long-term survival after transplantation [58]. Newer agents such as entecavir and tenofovir are preferable to lamivudine because of lower risk of development of post-exposure viral kidney transplant recipient mutation resulting in de novo drug resistance [59, 60].

Heart Transplant Recipients

Similar to renal transplantation, chronic HBV can often progress aggressively after heart transplantation.

In early studies among cardiac transplant recipients, chronic HBV after transplantation was seen frequently. Reports in 1980s had attributed this to iatrogenic acquisition of HBV infection during the post-transplant endomyocardial biopsies; sporadic standards for infection prevention and equipment contamination were regarded as a potential source for such infections [61]. In a study, 56% of patients with de novo HBV infection after heart transplantation developed severe fibrosis or cirrhosis within a mean duration of 7.4 years [62] . Long-term follow-up of HBsAg-positive patients also showed significantly reduced survival when compared with HBV non-infected controls, often as a result of liver-related deaths (32% vs. 62%, respectively) [62]. As with the experience in the recipients of renal transplants, long-term antiviral therapy has been shown to be well-tolerated and efficacious, preventing progression of liver disease and potential for hepatic decompensation [63]. Observational studies have also shown that HBsAg-positive donor hearts can be safely transplanted into HBsAb-positive recipients; however, HBsAg-positive donors should only be considered for high-risk situations [64].

Bone-Marrow Transplant Recipients

The risk of HBV reactivation is most significant among patients undergoing allogenic bone marrow transplantation and can often have serious, life-threatening consequences. Due to severity of hosts' immune dysregulation following myeloablative allogeneic HSCT preparatory conditioning regimens, reactivation of hepatitis B viral infection in HBsAg-positive patients is near-universal [65]. HBV reverse seroconversion in patients with serologic evidence of past HBV infection (HBsAg negative, HBcAb positive) has also been frequently reported [66, 67]. Because of fatal consequences of reverse seroconversion and viral reactivation, all potential bone marrow recipients are tested for HBV biomarkers and receive antiviral prophylaxis if there is evidence of past HBV infection. Reactivation often develops during late HSCT period, between 1 and 3 years after undergoing transplantation, so long-term, if not lifelong, antiviral treatment is often recommended [68, 69, 70].

Pre-transplant Evaluation

All patients undergoing a transplant evaluation should be evaluated for exposure and/or active infection with hepatitis B with HBsAg, HBsAb, and HBcAb. Level of viremia with HBV DNA viral load should be assessed in all patients. Occasionally, patients will have occult HBV infection (OBI), in which low viral replication is present without detection of HBsAg. The prevalence of OBI depends on both the sensitivity of testing available as well as the prevalence of HBV infection in the population. In low HBV prevalence countries such as the United States, OBI has been reported in 0.1–2.4% of HBsAg-negative, HBcAb-positive blood donors, with or without the evidence of HBsAb positivity. In the regions with high HBV endemicity, the risk of OBI may be as high as 15% [71, 72, 73]. The clinical significance of OBI is controversial, with some case reports describing HBV reactivation in allogeneic HSCT and solid organ transplant recipients with OBI receiving post-transplant immunosuppression [74, 75]. Other studies have found that OBIs have not been associated with increased risk of acute rejection or development of de novo hepatitis B virus infection [76]. There is, however,

significant evidence that OBI is a risk factor for HCC development [77].

For patients without evidence of previous exposure, vaccination should be provided prior to transplantation due to suboptimum vaccine response noted after undergoing allogeneic transplantation. In prior nonresponders to hepatitis B virus vaccine, revaccination with a double dose may be more effective [78]. In hemodialysis patients, who have impaired response to hepatitis B vaccines, double dose revaccination and repeated booster doses are often necessary to achieve prolonged seroconversion [79]. There is also evidence that combined HAV/HBV vaccination may enhance vaccination response to HBV [80].

Hepatitis C

Hepatitis C virus (HCV) is a small 30–60-nm-diameter, enveloped, positive-sense, single-stranded RNA virus belonging to *Flaviviridae* family [81]. It possesses a 9.6 kb genome that encodes ten proteins as well as two glycoproteins, E1 and E2, which possess two hypervariable regions that are prone to extensive mutation and antigenic variability [82]. Six major HCV genotypes have been identified, differing in their nucleotide sequence by approximately 30% [83]. The major genotypes differ in geographic location and therapeutic options. Genotype 1a is most prevalent in the United States and Northern Europe [83].

There are approximately 160 million human carriers of HCV worldwide and over 4 million or 1.6% of the population in the United States [84, 85]. The highest prevalence of 15% is reported from Egypt's Nile Delta, whereas prevalence in Europe, the Americas, Southeast Asia, and Africa ranges from 1% to 5% [84]. HCV is predominantly transmitted through percutaneous exposure to infected blood and less commonly via unprotected sexual intercourse and vertical transmission [86, 87]. Populations at highest risk include intravenous drug users, tattoo recipients, and health care workers. Prior to 1992, recipients of blood and blood products and patients who underwent solid organ transplantation were at increased risk for HCV infection, due to less sensitive HCV screening assays [88].

HCV has historically carried a significant disease burden in industrialized countries as the leading cause for liver failure and the most frequent indication for liver transplantation [89]. The approval of direct antiviral agents in 2011 has dramatically altered the treatment landscape in providing a near-complete virologic response rate in most cases [90]. This stands in contrast to traditional treatment strategies based on pegylated interferon and ribavirin, which achieved virologic response rates of <50% in patients with HCV genotypes 1 and 4 infection and up to 80% in HCV genotypes 2 and 3 infection [90]. Direct-acting antivirals may also now be used safely in patients with advanced liver disease, who can be treated prior to undergoing liver transplantation, substantially reducing the risk for HCV recurrence during post-transplant period. HCV eradication in cirrhotic patients leads to improvements in MELD score and portal hypertension, albeit, such viral eradication may heighten the risk of progression of hepatocellular carcinoma. Patients with HCV infection who have received a liver transplant may also now be safely treated with the new effective direct anti-HCV drugs, although the choice of regimen should be tailored to minimize interactions with immunosuppressive medications. New areas of controversy have been ushered in by the use of direct antiviral agents, as the ability to utilize of HCV-positive organs and treat patients effectively following transplantation had led to careful consideration regarding timing of treatment that can on one hand hinder disease progression but may also limit access to HCV-positive organ grafts. Direct-acting antivirals can be utilized to eradicate HCV infection in non-liver transplant patients; however, despite effective anti-HCV therapy, the accompanying risks of cirrhosis and hepatocellular carcinoma remain.

Hepatitis C-Mediated Liver Disease

Acute Hepatitis C

The majority of acute HCV infections are asymptomatic and subclinical. Symptomatic HCV infection manifests with nonspecific flu-like symptoms, including fatigue, nausea, abdominal pain, loss of appetite, mild fever, and pruritus [91]. HCV RNA may be detected in the serum within 1–3 weeks following the initial exposure to the virus [92]. Viral detection is followed by a rise in bilirubin as well as an increase in serum transaminase levels frequently to values of more than ten times the upper limit of normal, indicating active hepatocellular injury [92]. HCV-induced fulminant hepatic failure (FHF) is uncommon, with occurrence in 10% of patients presenting with acute HCV infection [93]. Coinfection with hepatitis B virus is an important risk factor for developing HCV-induced FHF and carries a survival rate of 20–30% [93, 94].

Chronic Hepatitis C

Disease progression and risk of development of cirrhosis is variable in patients with HCV infection. End-stage liver cirrhosis develops in 4–24% of patients with chronic HCV infection within 20 years [95–97]. Host, viral, and external interactions influence the time frame between initial HCV infection and the development of cirrhosis. The progression of HCV-induced fibrosis is closely related to the age at the time of initial infection; older individuals appear to progress to cirrhosis at a much more rapid rate compared with those in whom the infection is acquired at a younger age [98].

Factors known to promote hepatic inflammation augment disease progression in HCV-infected patients. Increased hepatic iron promotes increased inflammation in the liver and fibrosis in patients with chronic HCV infection [99, 100]. Ongoing steatohepatitis is associated with more rapid progression in liver fibrosis and may increase the risk for HCC by nearly threefold [101]. Excessive alcohol consumption is an independent risk factor for the development of cirrhosis [98]. Alcohol intake of >50 g daily has been shown to markedly increase the progression of liver fibrosis [102]. Viral factors such as infection with HCV genotype 3 result in greater progression of liver disease and risk of death [103, 104].

HCV coinfection with HBV significantly enhances risk of death compared to patients with chronic HCV infection alone [105]. The frequency of hepatic failure appears to be eightfold higher among the 35 million people coinfected with HBV and HCV [93]. Nearly 30% of HIV-infected patients are coinfected with HCV in the United States [106]. Coinfection in this population is associated with greater risk of cirrhosis-related complications compared to HCV infection without HIV [106].

Complications associated with hepatic decompensation include ascites, variceal bleeding, and severe bacterial infections. The annual rate of these severe complications is approximately 2–9% among cirrhotic patients [107]. Following the first episode of hepatic decompensation, a 1-year mortality rate ranges between 15% and 20%; furthermore, a 10-year patient survival rate declines below 50% [108].

In patients with chronic HCV infection, hepatocellular carcinoma typically develops in the context of liver cirrhosis with an annual risk ranging between 2% and 4% [109]. Surveillance is not recommended for all HCV-infected patients, but it is recommended for all HCV-infected patients with cirrhosis [110]. Overall, hepatitis C virus is responsible for 25% of hepatocellular carcinomas worldwide [111].

Treatment of Hepatitis C in the Liver Transplant Setting

Effective antiviral treatment prevents the progression of liver disease at all stages and leads to improvement in hepatic histopathology and degree of fibrosis [112, 113]. Among cirrhotic patients who achieve a sustained virologic response, 64% of such patients demonstrate regression in hepatic cirrhosis [113]. Treatment with a sustained virologic response (SVR) in cirrhotic patients is associated with improvement in portal hypertension, prevention of varices, and hepatic decompensation. It is important to emphasize that SVR following interferon-based therapy was associated with a 10–20% rate of hepatocellular carcinoma [114].

Until the approval of direct antiviral, interferon-free therapy (DAA) in 2011, treatment of HCV infection in both the pre- and post-transplant periods was highly problematic due to low efficacy and high treatment-related toxicity [90]. Cirrhotic patients were often ineligible to receive pegylated-interferon and ribavirin-based regimen due to risk of further decompensation, development of bacterial sepsis, or the occurrence of potentially life-threatening myelosuppression evident by leukopenia and/or thrombocytopenia. Ribavirin-induced anemia posed a significant challenge in cirrhotic patients with preexisting spur cell hemolytic anemia and those with gastrointestinal bleeding. Psychiatric comorbidities may be intensified due to interferon-associated neuropsychiatric adverse events, particularly depression [115]. In the post-transplant setting, HCV recurrence after interferon-based therapy was associated with high morbidity, especially hematologic toxicity that may be accentuated in patients with renal insufficiency and concurrent treatment with antirejection drugs or anti-GVHD therapy; SVR rate ranged from 8% to 50%.

With the advent of DAA, the treatment of hepatitis C virus infection in the transplant setting was immediately transformed. In cirrhotic patients, effective therapy is associated with improvement in liver function as evidenced by a decline in MELD score as well as diminished in hepatic portal venous pressures and esophageal varices [116, 117]. With the population of HCV-positive patients diminishing due to successful antiviral treatment prior to liver transplantation, and the availability of effective post-transplant treatment (see below), the burden and clinical significance of post-transplant HCV recurrence have greatly diminished.

Timing of Direct-Acting Antiviral Therapy

Controversy exists as to the optimum timing and most clinical benefit of DAA during pre-transplant period. In contrast to patients with decompensated hepatitis B cirrhosis, in whom up to 60% demonstrate a dramatic clinical and biochemical response to effective anti-HBV therapy, patients treated for HCV cirrhosis frequently improve biochemically with decrease in MELD and CTP scores but may not exhibit clinical improvement [118]. Although pre-transplant treatment improves MELD score and diminishes the risk of death and need for transplantation, it may also render a patient with more advanced cirrhosis with a poor quality of life and nonprogressive liver disease with diminished priority for liver transplant. Opting for post-transplant treatment also enables access to HCV-positive allografts. Recently, this approach has been taken one step further with transplantation of HCV-positive allografts into HCV-negative recipients followed by DAA therapy given after transplantation [119]. As a result, there is currently a debate as to the optimal timing of DAA therapy. Although recent analyses have found pre-transplant treatment to be more cost-effective, both options are now commonly a focal point of patient-physician decision-making. Finally, DAA therapy has recently been reported to be possibly associated with the increased risk of aggressive and early recurrence

of hepatocellular carcinoma. Protective anti-HCV endogenous interferon release, critical for maintaining effective tumor surveillance by hindering tumor proliferation and angiogenesis, may be downregulated following DAA therapy [120]. These observations have led some clinicians to monitor cirrhotic patients closely during and after treatment for malignancy and consider deferral of therapy in patients with active and recently treated hepatocellular cancer.

Direct-Acting Antiviral Therapy in the Pre-transplant Setting

Essentially all patients with advanced liver disease can be safely treated for HCV with a high degree of expectation and probability for achieving a durable SVR. Treatment of hepatitis C prior to liver transplantation is associated with rare post-transplant HCV recurrence, especially for those who are HCV RNA negative for at least 1 month prior to undergoing transplantation [121]. Fatty liver disease is common among HCV-positive patients, and progression of fibrosis in patients achieving an SVR may progress due to nonalcoholic steatohepatitis [122]. Moreover, the risk for hepatocellular carcinoma persists, particularly in patients with HCV genotype 3 [123].

Treatment options are based on the HCV genotype and involve combinations of agents directed at two or three specific viral targets, including the RNA polymerase, protease, and NS5a. Due to rapidly expanding options, the American Association for the Study of Liver Diseases (AASLD) maintains a web-based consensus statement that permits frequent updates [124]. As a result, specific therapies will not be discussed. As a general guideline, however, the patient with advanced cirrhosis who is commonly treatment experienced requires a longer duration of therapy and occasionally with the concomitant use of ribavirin to achieve comparable treatment results to those with less advanced disease. In addition, the use of protease inhibitors is usually avoided due to the risk of drug-induced hepatotoxicity with the potential for rapid and progressive liver failure leading to death.

Direct-Acting Antiviral Therapy in the Post-transplant Setting

The treatment options for post-transplant hepatitis C virus are, for the most part, similar to those applied during the pretransplant period with a minor difference in effectiveness despite the concomitant use of immunosuppression; the reader is referred to the AASLD guidelines that are regularly updated [124] Special considerations for patients after allograft transplantation include drug-drug interactions with tacrolimus and cyclosporine with several of the regimens requiring calcineurin inhibitor (CNI) dose adjustment or altogether CNI avoidance, with a possible need for prolonged therapy and/or concomitant use of ribavirin. Patients may also need an increased immunosuppressant dose after HCV virologic clearance and its potential adverse effect on hosts' antiviral immune surveillance.

Recurrent Hepatitis C After Liver Transplantation

Hepatitis C infection following transplantation is nearly universal for those with active viremia prior to transplantation [125]. Until recently, recurrent hepatitis C infection was a major cause of graft failure and risk of death. Recurrent HCV infection is associated with a more rapid rate of progression of liver fibrosis compared to immunocompetent patients, and up to 30% of patients develop cirrhosis within 5 years compared with cirrhosis that took 20–30 years to develop in the immunocompetent population [126]. Recurrence of HCV-related cirrhosis was until recently the main cause of allograft dysfunction or graft loss and significantly curtailed patient survival as compared to non-HCV controls undergoing liver transplantation [127, 128] In addition, approximately 5–10% of patients developed a severe form of recurrent HCV known as fibrosing cholestatic hepatitis, characterized by very high HCV RNA levels, cholestatic laboratory patterns with bilirubin levels >6 mg/dL, and alkaline phosphatase >5-fold normal values; ballooning hepatocytes, sinusoidal fibrosis, cholestasis, and a low level of tissue inflammation despite bile duct proliferation on liver biopsy were prominent histologic features of FCH in this setting [129, 130]. High viral load, older recipient age, non-Caucasian race, female gender, insulin resistance and diabetes mellitus, high-dose corticosteroid treatment for acute cellular graft rejection, donor age greater than 55 years, and HIV coinfection were significant risk factors for more severe HCV recurrence following liver transplantation.

Hepatitis C and Non-liver Transplantation

Kidney Transplantation

Hepatitis C and End-Stage Kidney Disease

Chronic hepatitis C is common in the kidney transplant population, with the prevalence of HCV seropositivity ranging from 7% to 40% in developed countries [131–133]. Several factors account for this high prevalence. Firstly, HCV is a possible factor in the development of the renal disease. Chronic HCV infection may induce a mixed cryoglobulinemia and a systemic vasculitis, leading to glomerulonephritis and renal failure [134–136]. Chronic HCV infection is also associated with a high rate of insulin resistance and type 2 diabetes mellitus [137]. In addition, de novo acquisition of hepatitis C among patients on hemodialysis occurs with high frequency. In patients receiving routine hemodialysis,

HCV seroprevalence (8–10%) and acquisition rate (1–3% annually) was higher compared to patients on peritoneal dialysis (3–5% and <1% annually, respectively) [138–140]. Nosocomial HCV transmission has been described in several reports and can be averted by strict adherence to standard HCV precautions [141, 142]. Mortality rates are higher in dialysis patients with HCV infection as compared to uninfected individuals [143]. While there is a higher incidence of liver disease in HCV-infected patients, cardiovascular causes are the most frequent cause of death, and the presence of diabetes mellitus and the duration of dialysis are the two factors associated most closely with mortality [144].

Hepatitis C and Kidney Transplantation

HCV-positive renal transplant recipients have better survival than matched HCV-positive patients awaiting transplant [145]. Although the presence of HCV infection is not a contraindication to kidney transplantation, a complete evaluation of the infection and its impact on liver function and presence of portal hypertension should be noted [146]. The natural progression of chronic hepatitis C in the kidney transplant patient and impact of accelerated liver fibrosis during the post-transplant periods were concerns historically, although are much less so now with the availability of effective post-transplant DAA therapy.

Evaluation of the Kidney Transplant Patient

Given the high incidence and a significant effect of HCV infection on survival in ESRD patients, screening is routinely recommended for patients undergoing routine hemodialysis [131]. Although traditional ELISA are a useful screening tool for the presence of HCV infection, it is important to note that HCV viremia in anti-HCV Ab-negative HD patients may occur and ranges between 1% and 15% [147, 148]. While it has been suggested that immunologic alterations in this population may account for negative anti-HCV antibodies, newly available commercial third-generation assays have been demonstrated to be more effective and sensitive as HCV PCR in detecting infection in this patient population [149, 150]. Additionally, in the HCV population, the presence of normal liver enzymes is more common among uremic patients compared to non-uremic patients, and normal aminotransferase levels do not exclude the presence of significant hepatic pathology [151]. Historically, staging of fibrosis with liver biopsy of elasticity was recommended in all HCV-positive patients undergoing pre-transplant screening, as aminotransferase levels are not reliable in determining HCV disease activity [152]. However, noninvasive elastography is now widely used during pre-transplant evaluation.

Natural History of Hepatitis C in the Kidney Transplant Patient

The natural history of the kidney transplant patient with chronic hepatitis C is highly variable. It has been reported that HCV-postive renal transplant recipients matched with individuals without renal failure have a significantly lower annual rate of fibrosis progression in the transplanted group (0.05–0.18) compared to patients without renal failure (0.13–0.26) observed on 37-month follow-up liver biopsy [153]. HCV infection after renal transplantation in most patients did not adversely affect liver histology in the extended follow-up. In fact, liver fibrosis might regress after transplantation in some patients, especially in those with an initial mild fibrosis score [154]. While the presence of cirrhosis on pre-transplant liver biopsy has been reported to be associated with a 26% 10-year survival, renal transplantation may still be considered in this population [153]. Acquisition of acute hepatitis C infection at the time of kidney transplantation or during the post-transplantation period, however, is characterized by a rapid progression of hepatic fibrosis, development of cholestatic syndrome, and high mortality rate [155].

Renal transplantation among HCV-infected individuals undergoing renal transplantation have decreased mortality and cardiovascular events and improved qualitiy of life compared to those maintained on long-term renal replacement therapy [145, 156]. Overall survival is improved following kidney transplantation for the HCV-infected individual; however, long-term patient and graft survivals are reduced in HCV-infected patients compared with uninfected transplanted controls, with a reported relative risk of 1.6 12 years after undergoing transplantation [157, 158]. Additionally, increased burden due to liver disease, new-onset diabetes mellitus, post-transplant glomerulonephritis, and sepsis was observed notably more frequently among HCV-positive patients [158, 159].

Successful treatment of HCV in patients with end-stage renal disease is associated with a lower incidence of HCV-related post-transplant glomerulonephritis [160]. Due to the potential for interferon treatment-induced acute allograft rejection, post-transplant HCV treatment was previously regarded as a contraindication. The strong efficacy of DAA now renders all HCV patients potential treatment candidates after kidney transplantation.

Source of Allograft

The use of HCV-positive donors in HCV-positive recipients is commonly employed to mitigate the shortage of organs in the face of increasing waitlist times. The prevalence of post-transplant liver disease and graft and patient survival in the HCV-positive population was similar after an aver-

age of 26–30-month follow-up regardless of donor HCV status [161]. A subsequent large retrospective study demonstrated that longer-term survival was favorable among HCV-negative donors, and in HCV-positive donor kidney transplant, survival improved compared with such patients who remained on hemodialysis [162]. Due to effectiveness of post-transplant treatment, a clinical trial of transplantation of HCV-positive allografts into HCV-negative recipients is currently underway [163].

Heart and Lung Transplantation

Among heart transplant recipients, the presence of HCV ranges from 7% to 18% [164, 165]. In a retrospective study of 96 patients with and without pre-existing HCV infection, no difference in mortality rates was observed, although liver-related deaths were more common among HCV infected patients (39%) compared with those without HCV infection (2%) [166]. Several subsequent studies with follow-up periods of 5 years have found a significantly higher mortality in HCV-seropositive individuals [167, 168].

Unlike liver and kidney allograft transplants, which are known viral reservoirs, the reported rate of HCV transmission from HCV-seropositive donor heart transplants has been lower, ranging between 25% and up to 82% [169, 170]. Although satisfactory outcomes of allocating HCV-positive hearts to elderly recipients have been reported, recent studies have reported an increased mortality in recipients of HCV-infected donor hearts [171].

Heart transplantation recipients should be carefully evaluated for antiviral treatment. Interferon may exacerbate heart failure or arrhythmias, and ribavirin-induced anemia may precipitate coronary ischemia and should be used with caution in such patients. Direct-acting antiviral treatments with improved side effect profiles have demonstrated successful eradication of HCV and may therefore become more widely utilized in this population [172].

The prevalence of HCV-seropositive lung transplant recipients in the period 2000–2007 was 1–2% [173]. Rapidly progressive hepatic fibrosis largely accounts for the high mortality rate following lung transplantation [174]. Most centers defer lung transplantation in HCV-seropositive patients. However, a survey report published in 2011 indicated that 19 centers that considered HCV-seropositive patients for lung transplantation had a 5-year post-transplant survival rate of 51% compared with 49% observed in HCV-Ab-negative recipients [173]. Although the study was encouraging, it had many important limitations as it did not distinguish the virologic status of HCV-seropositive lung transplant recipients by the level of HCV viremia and pre-transplant liver histopathology in HCV-seropositive candidates. Based on data from a few single-center reports with small numbers, guidelines from the American Society for Transplant Physicians and International Society for Heart and Lung Transplantation indicate that "Hepatitis C with biopsy-proven histologic evidence of liver disease" is a contraindication for lung transplantation [173–175]. Finally, combined liver/heart transplantation for patients with decompensated cirrhosis has been proposed [176].

Hepatitis C in Bone Marrow Transplantation

Hepatitis C is an important pathogen in patients undergoing HSCT. Recent epidemiologic and molecular observations have linked HCV to the development of mostly non-Hodgkin B-cell lymphomas following allogenic stem cell transplantation. Studies from Italy and Japan, where HCV prevalence in the general population ranges between 2% and 10%, demonstrated an increased risk for B-cell lymphoma (odds ratio from 2 to 4) in individuals with chronic HCV infection [177, 178, 179]. Although the precise molecular basis for HCV-induced B-cell proliferation remains to be determined, possible mechanisms include chronic antigen stimulation of B-cell subpopulation through B-cell surface receptors and complex cell immortalization and proliferation via a variety of pathways currently under investigation [180, 181, 182]. Antiviral therapy for the treatment of chronic HCV infection in patients with potential HCV-related B-cell neoplastic processes is without effect.

The prevalence of HCV infection was nearly 6% in HSCT recipients [183]. HCV infection poses unique challenges in this population during early and late post-transplant period. In the early transplant period, HCV infection has been associated with a higher risk for veno-occlusive disease and acute graft-versus-host disease involving the liver [184, 185]. Patients after HSCT may have five- to tenfold increase in the serum alanine aminotransferase level; distinguishing between acute hepatic GVHD vs. acute viral or drug-induced hepatitis becomes difficult [184]. In the late transplant period, patients with chronic HCV infection may have a higher rate of liver-related mortality. Eleven to twenty-four percent of long-term HSCT survivors (20 years) may develop cirrhosis of the liver [186, 187]. In one series, HCV genotype 3 was determined to be a risk factor for the development of cirrhosis, and the median time to cirrhosis in 96 HCV-seropositive allogeneic HSCT recipients was 18 years as compared with 40 years in 158 HCV-infected controls who did not receive transplants [187].

Because of the increased risk of complications, determination of the stage of HCV disease prior to stem cell transplantation is essential. Presence of severe hepatic fibrosis and cirrhosis increases the risk for fatal sinusoidal obstruction syndrome (SOS) following certain myeloablative preparatory regimens, and in such patients, highly immunosuppressive conditioning regimens are contraindicated. While the presence of hepatitis C infection is not

an absolute contraindication to undergo allogeneic HSCT, patients should be selected based on the potential risk for complications during the post-transplant period. Liver biopsy may be considered in certain high-risk individuals before transplantation. There is limited literature describing the optimal approach to treatment of hepatitis C following blood and bone marrow stem cell transplantation. However, because of higher risk of earlier cirrhosis, it is recommended to repeat histological liver evaluation in all patients to evaluate the degree of fibrosis and grade of necrosis and inflammation. Interferon and ribavirin treatment in patients with hematologic malignancies posed a serious challenge due to the increased risk of drug toxicity [184]. Nearly 30% of patients cannot be treated because of contraindications [188]. In patients who can tolerate therapy, 20–40% may demonstrate a sustained virological response after bone marrow transplantation with combination treatment, reducing the risk for severe HCV-related complications [186, 187]. While direct-acting antivirals have prospects for improving treatment efficacy in this population, they have not to date been rigorously evaluated in the setting of allogeneic blood and bone marrow transplantation.

Enterovirus Infection in Immunocompromised Hosts

42

Joanna M. D. Schaenman, Dora Y. Ho, Lindsey R. Baden, and Amar Safdar

Introduction

Enteroviruses are single-stranded RNA viruses with a small genome that, as their name suggests, are typically spread by the fecal-oral route and replicate in the gastrointestinal (GI) tract. Most enteroviral infections are asymptomatic, but may spread to secondary sites outside of the GI tract. Such infections may present as mild upper respiratory tract illness; epidemic hand, foot, and mouth disease; or more serious diseases such as myocarditis, meningitis, and acute flaccid paralysis [1]. It is not unexpected that enteroviral infections lead to potentially more serious illness in the immunocompromised host.

Virology

The *Picornaviridae* family includes clinically significant genera like *Rhinovirus*, *Hepatovirus* (hepatitis A virus), and *Enterovirus*; viruses belonging to *Picornaviridae* are common cause of viral infection in humans [2]. Poliovirus, the best-studied member of the *Enterovirus* genus, was one of the first viruses to be completely sequenced, allowing for mapping of viral proteins and a better understanding of the viral replication process [3]. The non-enveloped enterovirus virion is small and consists of an icosahedral capsid of approximately 300 angstroms in diameter enclosing a positive strand of RNA of 7.4 kilobases [4]. The viral RNA codes for a 250 kD polyprotein which is then cleaved into P1, P2, and P3 proteins [5]. Protein P1 is processed by viral proteases into capsid proteins VP1, VP2, VP3, and VP4, while proteins P2 and P3 undergo subsequent processing to generate the viral RNA polymerase (protein 3D), viral protease (protein 3C), and other proteins necessary for viral replication [6, 7]. Like other RNA viruses, the high mutation rate during genome replication coupled with short replication times and a large number of daughter viruses per infected cell can give rise to heterogeneous viral populations in the course of a single infection [8].

The lack of a lipid envelope makes these viruses resistant to alcohol; *Enteroviridae* are stable at a wide range of pH [9]. They are vulnerable to drying, ultraviolet radiation, extreme heat, as well as sodium hypochlorite and glutaraldehyde [10].

Nomenclature

The nomenclature of the subgenera can be confusing, as it has changed over time based on enhanced genome sequencing data. The traditional classification divided the *Enteroviridae* into four main groups. Poliovirus (PV), the causative agent of poliomyelitis, was the first subgenera to be identified [11]. Subsequently coxsackievirus was isolated in 1948 from the stool of children in Coxsackie, New York, with evidence of myelitis or meningitis and no evidence of

poliovirus [12]. Initial classification was based on the results in a newborn mouse model of neurologic disease, as injection of what came to be known as the group A coxsackieviruses (CVA) associated with milder disease with flaccid limb paralysis. Group B coxsackieviruses (CVB) caused spastic paralysis and widespread tissue destruction. The so-called echoviruses (enteric cytopathic human orphan viruses) were initially isolated from the stool of asymptomatic individuals and were initially thought to cause no discernable clinical disease [13]. Over 60 human serotypes were described that were distinguished by cross-reactivity of serum from clinical isolates and were given sequential notations, for example, CVA9 or CVB1. The newer enteroviruses (EV) were assigned numbers, for example, EV71 [3]. Some gaps in the numbering exist due to changes in classification because some serotypes were subsequently found to be identical to other viral subtype [14]. Limitations of this classification system include (1) difficulty in culturing some enteroviruses, (2) limited availability of antisera for serotyping, and (3) serotyping procedures which are technically challenging [15].

An alternate method for enterovirus typing based on molecular genetic techniques has been developed which relies on sequencing of the P1 region that encodes the capsid proteins. The current viral taxonomy divides the enteroviruses into groups A through D based on sequence homologies. There are data that suggest a stronger association with clinical syndromes when this typing method is used as compared with the previous classification [16]. The assignment of the classical subtypes and new genetic subtypes is shown in Table 42.1. Many members of species human enterovirus A and human enterovirus B have now been sequenced [2, 17].

An interesting insight from the mass sequencing of the enteroviruses has been the discovery of the frequent recombination events between genetic material outside of the capsid protein-encoding region [18]. Recombination typically occurs within species, and interestingly, sequence similarity between strains has been found to mirror previously described antigenic cross-reactivity [17].

Although there remains much overlap in clinical syndromes among the species classifications, in general human enterovirus A (HEV-A) has been associated with hand, foot, and mouth disease and CNS infections; human enterovirus B (HEV-B) with pleurodynia, myocarditis, meningitis, and encephalitis; human enterovirus C (HEV-C) with poliomyelitis, meningitis, and hemorrhagic conjunctivitis; and human enterovirus D (HEV-D) with respiratory tract infection [14, 16].

Enterovirus 71 (EV71) in the HEV-A species is also notable for its appearance in several epidemics in Asia, causing an especially large and severe outbreak in Sarawak, Malaysia, which was associated with high mortality [19]. Other countries in Asian such as Taiwan, Singapore, Malaysia, and Japan had reported similar infections [20]. Hand, foot, and mouth disease and herpangina are common illnesses due to this virus; EV71-related encephalitis and acute flaccid paralysis are a concerning complication noted with the emergence of this virus, mostly described in outbreaks in Asia [21]. Some studies have suggested that virologic differences may exist between strains isolated from patients with herpangina compared with neurotropic strains causing encephalitis [22].

Table 42.1 Classification of the enteroviruses [14]

Current taxonomy	Traditional taxonomy
HEV-A	CAV2–8, CAV10, CAV12, CAV14, CAV16; EV71, EV76, EV89, EV90, EV91
HEV-B	CAV9; CBV1–6; E1–7, E9, E11–21, E24–27, E29–33; EV69, EV73–75, EV77–78, EV79–88, EV100–101
HEV-C	CAV1, CAV11, CAV13, CAV17, CAV19–22, CAV24, PV1–3
HEV-D	EV68, EV70

Adapted from the CDC report on enterovirus surveillance Khetsuriani et al. [14]
HEV-A human enterovirus A, *HEV-B* human enterovirus B, *HEV-C* human enterovirus C, *HEV-D* human enterovirus D, *CAV* coxsackie A virus, *EV* enterovirus, *CBV* coxsackie B virus, *E* echovirus

Pathogenesis

The reservoirs for human enterovirus infection are humans; nonhuman primates may be experimentally infected with human enteroviruses; they are not the source of virus in naturally occurring infection [13]. The standard model for pathogenesis is that of the poliovirus, where the process begins with the initial infection of host cells in the oropharynx and/or intestinal mucosa. From there, the virus can gain access to the cervical and mesenteric lymph nodes resulting in transient viremia (Fig. 42.1) [11]. Although fecal-oral transmission is the most common, infection via the respiratory route may also occur. At this point infection may be asymptomatic or may cause nonspecific symptoms such as fever, malaise, and sore throat. One study showed that the presence of intestinal bacteria may promote replication of enteroviruses in the gut as mice treated with antibiotics had a 50% decrease in mortality compared with untreated mice, and the reintroduction of bacteria in this model enhanced poliovirus disease [23]. Central nervous system (CNS) access may be gained either directly from the blood or by axonal transport.

Enteroviruses gain entry into epithelial and lymphoid cells via binding to specific cell surface receptors, which varies by subtype. Poliovirus binds to the poliovirus receptor (CD155), a cell surface molecule whose physiologic function is still uncertain [24]. The coxsackievirus A group utilizes intercellular adhesion molecule 1 (ICAM-1 or CD54)

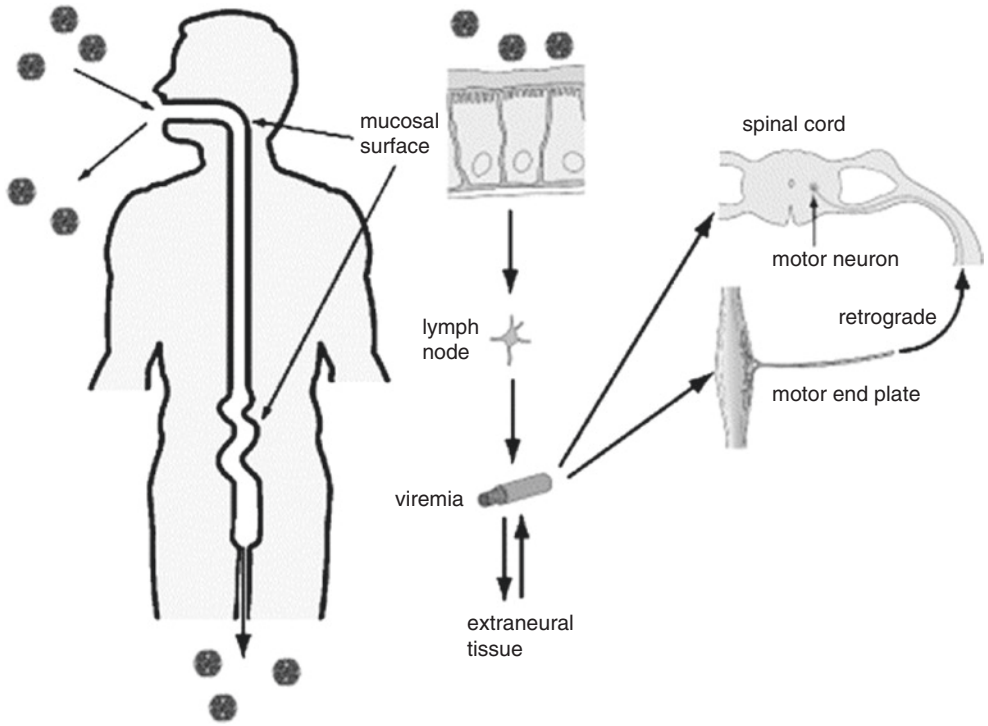

Fig. 42.1 Hypothetical scheme of poliovirus pathogenesis based on experimental findings in humans, monkeys, chimpanzees, and transgenic mice. Ingested virus initially replicates in the oropharyngeal and intestinal mucosa. Virus replication at these sites reaches the blood through the lymph nodes, resulting in a primary viremia. Invasion of virus into the central nervous system may occur either directly from the blood or by retrograde axonal transport when the virus enters the neuromuscular junction. It is believed that invasion of the brain or spinal cord must be preceded by viral multiplication in extraneural tissues, which leads to a sustained viremia. These extraneural tissues may include the skeletal muscle and brown fat. Virus is spread most frequently by the fecal-oral route. Shedding of virus from the nasopharynx may lead to transmission of infection by the respiratory route, which occurs in developed countries with high standards of sanitation [11]. (Reprinted from Virology, Vol. 344/Issue 1, Racaniello VR, One hundred years of poliovirus pathogenesis, pages 344:9–16, © 2006, https://www.sciencedirect.com/science/article/pii/S0042682205005830, with permission from Elsevier)

that functions as an integrin receptor to gain entry into host cells; rhinovirus also uses ICAM-1 for this purpose [25]. The coxsackievirus B group can bind to either decay-accelerating factor (DAF or CD55) or coxsackievirus-adenovirus receptor (CAR), another immunoglobulin superfamily member, with the latter thought to be the dominant receptor [26]. Many of the enterovirus and host receptor protein crystal structures are now known [27]. For some of these cell surface receptors, it has been postulated that the level of expression in the host may determine susceptibility to viral infection. For example, children have high levels of CAR expression in the heart and may exhibit a heightened susceptibility to myocarditis [28]. Other host factors that may play a role in susceptibility to enteroviral diseases such as poliomyelitis and myocarditis include malnutrition, pregnancy, and exhaustion from strenuous exercise [1, 28].

For specific disease entities, the details of pathogenesis vary by the organ type involved. For poliomyelitis, when the virus enters the CNS either via blood or via axonal transport, the replication in motor neurons within the spinal cord, brainstem, or motor cortex leads to cellular damage and muscle paralysis [11].

CNS disease due to EV71 reflects viruses' high propensity for neurotropism, with the brainstem being the major target of infection [29]. Axonal pathway spread similar to poliovirus has been suggested. In a study among children in Taiwan with this infection, there was correlation with the levels of cytokines IL-6 and interferon-gamma in the CNS with more severe cases of brainstem encephalitis presenting with autonomic system dysregulation and pulmonary edema [30].

In myocarditis, the pathogenesis of disease includes both direct cellular damage from the viral infection and secondary damage due to the elicit hosts' immune response. Coxsackievirus proteases can inhibit cell protein synthesis machinery by protease cleavage of eukaryotic initiation factor, and these proteases can also cleave dystrophin, affecting the integrity of the sarcolemma membrane [28]. The antiviral immune response can be beneficial in limiting the extent of viral replication but can also lead to increased cellular destruction and clinical disease [31]. Cellular damage is irreparable in organs such as the heart and brain with terminally differentiated cells. Persistence of enterovirus RNA in the heart after acute infection has also been associated with worsened clinical outcome in patients with enteroviral myocarditis [32].

Immune Response

The response to enterovirus infection involves both innate and adaptive immunity. One important experimental model has been transgenic mice expressing CD155, the poliovirus receptor. The use of this model has demonstrated the importance of type I interferons as mice deficient in the interferon-alpha receptor demonstrate viral replication in many tissues that are not normal targets of poliovirus such as the liver and spleen [33]. Not surprisingly, the Toll-like receptors (TLR) have also been shown to be important in the control of viral infection as TLR7 detects viral single-stranded RNA and TLR3 viral double-stranded RNA, which is an intermediate in the replication pathway. In a mouse model of poliovirus infection, knockout mice lacking TLR3 had much higher viral loads in nonneural tissues and high mortality [34]. The importance of TLR3 has also been shown in a myocarditis model of coxsackie B virus infection [35]. In addition, both NK cells and macrophages have been thought to play an important role in the control of infection [36].

It has been observed that both humoral and cellular immunity are important for the control of infection for all species of enteroviruses [37]. The crucial role of neutralizing antibodies for the control of viral infection is highlighted by the observation that patients with agammaglobulinemia are very vulnerable to chronic enterovirus infections [38]. This is further supported by the strong antibody response generated by poliovirus vaccination, which is also seen in mouse models of infection [37]. B cells, however, may also play a role in viral dissemination as mice deficient in B cells have lower viral titers on day 1 postinfection compared with normal mice [39]. It has also been postulated that the virus gains access to these immune cells by binding to cell surface proteins at tight junctions between epithelial cells, allowing for virus tagged along the migratory immune cells to sites of injury or inflammation. This may represent a mechanism for spread throughout the body as well as evading neutralizing antibody response [40].

Early studies in mice demonstrated the importance of T cells in the control of enterovirus replication as longer virus persistence was seen in athymic nude mice in the myocarditis model [41]. Similarly, in a mouse model of poliomyelitis, administration of antithymocyte globulin led to longer persistence of virus in the CNS with associated increased rates of CNS disease and death [42]. The effect of inflammatory cells such as T cells is important for clearance of infection but may cause additional cell-mediated injury and necrosis [28]. This CD8+ T-cell role, however, appears to be independent of perforin in the mouse model as perforin knockout mice were able to clear infection at similar rates to wild type but had less myocarditis and subsequent fibrosis [43]. CD4+ T cells are also thought to play a role in inflammation as transfer of naïve cells exacerbated myocarditis in a mouse model, while transfer of CD4 + CD25+ Tregs protected mice from early mortality with decreased viral load and inflammation [44].

The role of autoimmunity has also been posited in myocarditis, either through molecular mimicry where sequence similarities between viral and host antigens lead to autoimmunity, through the release of autoantigenic host cell proteins released from dying cells, or possibly via nonspecific upregulation of the immune system with increased CD40 expression and TLR stimulation creating a permissive atmosphere for autoimmunity to develop leading to cardiomyopathy [45]. A large volume of literature also exists exploring the likely connection between enterovirus infection of the pancreas and the development of type 1 diabetes [46]. Both the genetic predisposition of the host and the age at which one is exposed to enterovirus infection, with delayed exposure now common in the developed world due to improving standards of hygiene over the past 50 years, may play a role in the propensity to develop diabetes after infection.

Epidemiology

In the USA, enterovirus infections are tracked by the National Enterovirus Surveillance System as well as the National Respiratory and Enteric Virus Surveillance System, two laboratory surveillance systems that rely on voluntary reporting. The peak of enterovirus activity in temperate climates is in the summer and fall, with 70% of reported detections in the 2006–2008 period occurring between July and October [47]. The five most common serotypes in that period were CVA9, CVB1, E6, E9, and E18 and accounted for over 50% of total serotyped detection. In over 1600 cases reported, the mean age was 9 years and median age 2 years [47]. These findings regarding the time of onset, age range, and serotypes are similar to previous trends described in the USA [14]. Enterovirus is endemic worldwide; epidemics can also occur, observed in underdeveloped regions with suboptimum hygiene [46]. Viral spread has also been reported from recreational water exposure [48].

The epidemiology of poliovirus charts an incredible chronicle of public health response to infection, with a groundbreaking vaccination campaign launched in response to a surge of cases in the 1940s and 1950s in the USA [49] resulting in eradication of this public menace in the USA in 1979. A greater than 99% reduction in the incidence of new polio cases worldwide as of the year 2000 through the use of oral poliovirus vaccine (OPV) and inactivated poliovirus vaccine (IVP) was encouraging [50]. However, over the past decade, the struggles continue in preventing the remaining 1% of polio cases due to under-immunization in developing regions such as Africa, where vulnerable population remains susceptible to the reimportations of wild-type poliovirus in

previously polio-free regions [50, 51]. As of 2013, there are three remaining countries where endemic wild-type poliovirus continues to exist; these include Pakistan, Afghanistan, and Nigeria [52].

In addition to naturally occurring poliovirus disease, the use of OPV, a live-attenuated virus, has led to circulation of vaccine-strain viruses, and in some instances, vaccine-derived polioviruses have acquired neurovirulence resulting in clinical disease even in immunocompetent hosts [53, 54]. Due to this concern, IPV has been exclusively used in the USA since the year 2000 [55]. Worldwide, new outbreaks of vaccine-derived poliovirus continue to occur with new outbreaks since 2009 in Afghanistan, Ethiopia, and India [56].

Clinical Syndromes

Poliovirus

Although poliovirus is best known for causing paralytic poliomyelitis, like other enteroviruses, it manifests a range of clinical entities ranging from asymptomatic illness to mild gastrointestinal disease to severe paralysis and death [49]. Nearly 5% of patients who do develop symptoms after exposure most experience "minor illness" or "abortive poliomyelitis" with fever, malaise, headache, sore throat, and GI complaints without neurologic findings [13]. Poliovirus can also cause an aseptic meningitis, known as "nonparalytic poliomyelitis."

Paralytic poliomyelitis can present initially similar to the aforementioned minor clinical illness; resolution of these nonspecific symptoms may be followed by meningitis with recurrence of fever, malaise, meningismus, and muscle pain followed by motor weakness and paralysis [13]. The so-called provocation poliomyelitis can be seen when an intramuscular injection is given after poliovirus exposure and paralysis begins or is most severe in the extremity where the injection occurred [49]. Patients can experience severity of illness ranging from weakness of a single muscle to complete quadriplegia, with an asymmetric distribution of flaccid paralysis, and rarely paralysis of muscles innervated by cranial nerves possibly leading to airway obstruction. The differential diagnosis would include other enteroviral infection including EV71 as well as West Nile virus. Guillain-Barré is more symmetrical in presentation and is associated with loss of sensation, which is very rarely described in poliomyelitis. Paralytic poliomyelitis leads to permanent weakness in two-thirds of patients [57].

Vaccine-derived poliovirus can also cause disease, especially in population with poor immune coverage. OPV recipients without previous poliovirus immunity can shed vaccine virus in their feces for 1–6 weeks and in the oropharynx for 1–3 weeks.

There are several different clinical scenarios that can occur with OPV vaccine strains. Rarely, OPV vaccinees can develop vaccine-associated paralytic poliomyelitis; frequency of this dreaded complication is estimated at one to two cases per million OPV immunizations [58]. Family members or other individuals in close contact with vaccinees are also exposed to the altered vaccine strain with disease-causing potential and at risk of such, albeit, exceedingly rare complications [58]. Finally, these reverted vaccine strains can enter the community; immunocompromised transplant recipients may rarely encounter these infections via casual person-to-person contact resulting in clinical disease and an unwitting reservoir for such infections due to prolonged periods of viral shedding [56].

Non-poliovirus

Most non-poliovirus enterovirus infections are asymptomatic; over 90% of patients are either asymptomatic or exhibit mild symptoms such as nonspecific fever or upper respiratory infection symptoms [13]. In every infection, there is an approximate 3- to 5-day incubation period during which viral shedding occurs without clinical symptoms.

Aseptic meningitis is one of the most common clinically diagnosed manifestations of enteroviruses, often seen with the HEV-B species such as CVB and echoviruses [14]. In review of cases with aseptic meningitis in whom CSF PCR testing was routinely performed, enteroviruses were identified in 20–40% of such cases reported from Sweden, Finland, Greece, and the USA [59–62]. Many patients initially presented with fever and upper respiratory infection-like symptoms, which temporarily abate followed by the appearance of headache and reappearance of fever.

Encephalitis or meningoencephalitis may be the primary clinical presentation of infection due to enteroviruses. Clinical presentation includes depressed or altered state of consciousness, presence of focal neurologic signs, and new-onset seizures [13]. In fact, enteroviruses make up a substantial portion of known causes of such illnesses; in a case series using PCR for viral diagnosis, enteroviruses were second in frequency to herpes simplex virus in patients with central nervous system viral infections [59]. EV71 can cause a severe form of brainstem encephalitis presenting with symptoms such as truncal ataxia, myoclonus, intention tremor, and altered mental status [29]. For enterovirus CNS infections in children, deaths are often due to pulmonary edema, which is hypothesized to have resulted from neurogenic sympathetic overactivation. Patients undergoing transplantation with severe immune dysregulation are considered at additional risk for enteroviral encephalitis or meningoencephalitis.

A syndrome of flaccid paralysis can also be seen secondary to the non-poliovirus enteroviruses that are often difficult to differentiate from poliovirus infection as well as other viral CNS infections due to flaviviruses and rabies [19]. Flaccid paralysis is described in patients with HEV-B, EV68, and EV71 infections [14, 29].

One of the best-known enterovirus manifestations is viral exanthem including hand, foot, and mouth disease (HFMD). In the USA, HEV-A species is the prominent cause of HFMD and CAV16 the most common serotype isolated with such infections [63]. Children are most commonly affected. The presentation includes mild fever with skin rash on palms and soles along with shallow ulcers in the oral cavity. The rash is classically vesicular-papular and can also involve the buttocks; less commonly it may be seen with a maculopapular rash on palms and soles with or without oral ulcers [64]. Herpangina is another relatively benign manifestation of enterovirus and presents with fever and painful ulcers over the tonsillar pillars [64]. HFMD and herpangina are caused by the HEV-A species including EV71 as well as the HEV-B species [14, 19]. It is unclear if such infections are more severe in transplant recipients.

Acute hemorrhagic conjunctivitis is another syndrome caused by enteroviruses that is highly contagious resulting in often large epidemics around the world, mostly in individuals residing in tropics and subtropical regions [65]. This syndrome is clinically indistinguishable from adenovirus-associated conjunctivitis and is typically caused by HEV-C, typically CAV24 [14]. To our understanding, transplant patients do not have high susceptibility for acute enteroviral hemorrhagic conjunctivitis compared with the general population.

Myositis can also be seen with enterovirus infection and most commonly manifests as pleurodynia, a syndrome characterized by fever and sharp, spasmodic chest or upper abdomen pain [66]. Although it is a benign disease, patients may experience severe anxiety due to splinting and resultant difficulty in breathing. It was originally reported as "acute rheumatism spread by contagion" in Norway; more recent epidemics are reported in Asia [66]. It is commonly associated with HEV-B species CVB1, whereas EV71 is associated with myositis [14, 19].

Myocarditis due to enteroviruses is a major cause of acute and chronic heart disease; its exact incidence in the general population is unknown; however, autopsies in children have reported a frequency of 2% [67], with an estimated range between 6% and 29% among children dying with idiopathic cardiomyopathy thought to be viral in origin [68]. Among the known causes of myocarditis, enteroviruses, notably CVB3 of HEV-B species, accounted for 50% of all cases [31, 69]. Other important viruses associated with myocarditis include adenovirus and cytomegalovirus infections and may be of concern in transplant recipients with severe adaptive T-cell dysfunction [70]. Presentation of viral myocarditis, which often involves myopericarditis, is sharp anterior chest pain, accompanied with cardiac arrhythmias, and dyspnea and acute pulmonary edema have been described and so are cases of unexplained sudden cardiac arrest [68]. In addition to causing acute-onset heart failure, enteroviral infections have also been implicated in playing a role in patients with chronic cardiomyopathy. PCR studies in autopsy cases and explanted hearts demonstrated persistence of enterovirus RNA and protein in such myocardial tissue [71].

Infections in Immunocompromised Hosts

The classic enterovirus disease associated with impaired immunity is chronic meningoencephalitis, a persistent CNS infection due to enteroviral infections. Patients with B-cell immunodeficiencies such as X-linked agammaglobulinemia are susceptible, and such infections are often fatal [38]. Patients typically present with symptoms of encephalitis, weakness, lethargy, depressed consciousness, ataxia, and seizures. Additional manifestations of clinical viral infection with a diffuse skin rash or acute viral hepatitis may also be present in some individuals. This syndrome is often due to echoviruses in HEV-B species, also seen in neonates [38]. Maintenance therapy with intravenous immunoglobulin (IVIG) has shown to reduce the risk for this complication in such patients [72]. This syndrome has also been described secondary to vaccine-derived poliovirus in patients with hypogammaglobulinemia or those with common variable immunodeficiency (CVID) syndrome; in one report viral persistence for 22 years despite treatment attempts underscores patients' vulnerability with profound defects in mounting a sustained and robust humoral antiviral response [73, 74].

There are many case reports of vaccine-derived poliomyelitis secondary to vaccination with OPV in patients with CVID and other causes of hypo- or agammaglobulinemia prior to the switch to IPV [75]. This disease has also been described in immunocompromised children who did not receive vaccine but reside in communities where OPV is in use. For example, a fatal case of meningoencephalitis was seen in Japan in an infant with hypogammaglobulinemia who had not been vaccinated; cultures grew a revertant neurovirulent strain of attenuated OPV [76]. Case reports as well as the fact that, even without causing clinical disease, OPV viral strains can replicate for years in patients with severe immune deficiency should alert caregivers for the transplant patients for this potential complication in these highly susceptible populations [56].

Although common in the community, the literature on enteroviral infections in immunocompromised hosts is relatively sparse with a limited number of case reports described

in patients undergoing hematopoietic stem cell transplant (HSCT) or antineoplastic chemotherapy [77]. PCR-based studies of stool and oropharyngeal samples in recipients of T-cell-depleted HSCT in the UK revealed a 10% incidence of enteroviral infection, unrelated donor graft being the prominent risk factor for such infections [78]. Most infections in these patients were symptomatic; upper respiratory tract illness was common, although persistent pneumonia with CVB and CMV and protracted weakness, fatigue, and myalgia were observed in one patient each. A study in children receiving chemotherapy revealed a high incidence of enteroviral infection. Over 50% of children undergoing treatment for acute leukemia developed a symptomatic infection detected by PCR testing. It was not surprising that incidence and seasonal variation reflected those of the surrounding community [79]. These infections often lead to severe clinical disease, and 15% died from complications of such infections including encephalitis and myocarditis.

Typical enteroviral infections such as hand, foot, and mouth disease have also been reported in immunocompromised hosts, with case reports of patients with lymphopenia experiencing prolonged periods of new crops of rash appearing over a duration of several weeks [80]. There was an additional report of disseminated enterovirus infection resulting in conjunctivitis, nephritis, and persistent diarrhea in a patient with lymphopenia following alemtuzumab therapy [81]. Some investigators have hypothesized that increasing use of B-cell-depleting agents such as anti-CD20, rituximab, and anti-CD52, alemtuzumab, may lead to higher rates of enterovirus infections [82]. Finally, a fatal case of disseminated enterovirus infection was reported in autologous HSCT recipient with an extensive prior history of antineoplastic therapy for Hodgkin's disease; the virus was demonstrated to have involved the heart, lung, liver, and spleen in this patient [83].

Similar to non-immunosuppressed patients, enteroviral CNS infection in the immunocompromised patients includes encephalitis and myelitis. Two children following HSCT in Austria presented with fever, lethargy, and seizures, diagnosis of enterovirus infection was made, and both patients made full recovery [84]. Whereas a patient with heavily treated relapsed lymphoma and known stable chronic enterovirus meningitis underwent HSCT, 40 days after transplantation, a rapidly progressive enterovirus encephalitis was fatal [82]. Several cases of enterovirus meningoencephalitis in patients given rituximab have been described including those undergoing combination chemotherapy such as R-CHOP for non-Hodgkin's B-cell lymphoma [85]. Enterovirus 71 encephalitis has been observed to result in more severe disease in patients with primary immunodeficiency and those with agammaglobulinemia. Similarly, cancer patients with treatment-induced leukopenia and those undergoing treatment with rituximab have also demonstrated a high disease severity due to enterovirus 71 infection. In immunosuppressed patients, diagnostic workup should include PCR analysis of CSF and skin lesions, when present [77, 86]. A report from Italy described severe myelitis in a patient receiving interferon therapy for chronic HBV hepatitis; this patient presented with lower limb paraplegia, and diagnosis was confirmed by PCR on CSF sample [87].

Pneumonia and other respiratory tract infections due to enterovirus are well described in immunocompromised hosts. A case series from Spain in patients undergoing treatment and HSCT for hematologic malignancies showed 33% had enterovirus respiratory tract infections detected by immunofluorescence and viral culture [88]. Among these patients presence of lymphopenia was noted as an important risk factor for enterovirus infection compared with a comparable cohort of patients diagnosed with rhinovirus lower respiratory tract disease [88]. The mortality rate approached 30%, especially in patients with concurrent and/or superimposed infections due to bacteria, *Aspergillus* spp., or CMV. Others have reported 75% mortality in enteroviral lung infection among HSCT recipients, even in the absence of concurrent infection due to other pathogen(s) [89]. Fatal cases of enteroviral pneumonia have also been described in pediatric recipients of hematopoietic stem cell allografts [82]. Enteroviral respiratory infections have been described after lung transplantation; enterovirus was detected in respiratory secretions from symptomatic and asymptomatic lung transplant recipients in PCR screening studies for potential viral pathogens [90, 91].

Gastroenteritis in patients undergoing allograft hematopoietic stem cell transplantation showed approximately 10% of cases were due to enterovirus infection [92]. Another interesting study in HSCT recipients identified an increased frequency of enterovirus isolation in the recipients of unrelated donor grafts; such patients also tested positive for other intestinal pathogens [93].

Hemophagocytic syndrome secondary to enterovirus infection has also been described in children with malignancy. In a study from Greece, 5% of patients admitted to a hospital with enterovirus infection had evidence of infection-associated hemophagocytic syndrome; diagnosis was confirmed by PCR in bone marrow biopsy samples along with immune staining illustrating the presence of enteroviruses and exclusion of other potential pathogens [94].

Viral myocarditis is not well described in immunocompromised hosts, although it has a strong correlation with transplant-induced immune suppression and clinical presentation such as idiopathic cardiomyopathy. A study from Germany in heart transplant recipients reported 60%, of mostly young donors, had PCR presence of enteroviral nucleic acid in the heart tissue; not unexpected that CVB was the prominent viral strain identified [95]. This observation

suggests a significant risk for graft-transmitted viral infection in patients undergoing heart transplantation, especially from a young donor. In fact, there have been suggestions that enterovirus or adenovirus infection of the transplanted cardiac graft in children attributed toward the subsequent risk for allograft loss [96].

Given the increased morbidity and mortality associated with enteroviral infections among the immunocompromised host, high prevalence of asymptomatic or mild clinical illness in the general population including household contacts of patients undergoing allograft hematopoietic stem cell or solid organ transplantation remains a cause for concern. Such patients should be instructed to take precautions regarding contact with any individual with a viral illness including diarrheal illness, especially in infants, children, and young adults. Table 42.2 shows some clinical syndromes caused by enteroviruses.

Table 42.2 Clinical syndromes caused by enteroviruses [14, 72, 94]

Clinical syndrome	Predominant enterovirus species (serotype(s))
Hand, foot, and mouth disease	HEV-A (CAV16, EV71), HEV-B (CVB5)
Herpangina	HEV-A (EV71), HEV-B (CVB3, CVB5, E30)
Gastroenteritis	HEV-B (E6, E7, E13)
Respiratory infections	HEV-A (EV71), HEV-B (E30), HEV-D (EV68)
Myositis/pleurodynia	HEV-B (CVB1)
Myocarditis	HEV-A (CAV16), HEV-B (CVB3, CVB5)
Acute hemorrhagic conjunctivitis	HEV-C (CAV24)
Aseptic meningitis	HEV-A (EV71), HEV-B (CVB5, E9, E30)
Encephalitis	HEV-A (EV71), HEV-B (CVB5, E9, E30)
Chronic meningoencephalitis	HEV-B (E3, E11, E24)
Myelitis/flaccid paralysis	HEV-A (EV71), HEV-B (CVB5, E7, E9)
Poliomyelitis	HEV-C (PV1, PV2, PV3)
Vaccine-derived poliovirus disease	OPV
Hemophagocytic syndrome	HEV-B (CVB3)
Systemic infection	HEV-B (CVB3, CVB5)

Adapted from the CDC report on enterovirus surveillance Khetsuriani et al. [14] plus other selected references [72, 94].
HEV-A human enterovirus A, *HEV-B* human enterovirus B, *HEV-C* human enterovirus C, *HEV-D* human enterovirus D, *CAV* coxsackie A virus, *EV* enterovirus, *CBV* coxsackie B virus, *E* echovirus, *OPV* oral poliovirus vaccine
The most common etiologies of each clinical syndrome are listed based primarily on US epidemiologic studies; the indicated species are not meant to be a complete list of possible enteroviral causes of each syndrome. Serotypes are listed alphabetically/numerically, not in the order of frequency

Diagnosis

As can be appreciated from the diverse clinical syndromes associated with enteroviruses that often present with a significant overlap in various disease manifestations, the key approach tends to be a presumption for such infections. For CNS disease including poliomyelitis, examination of the CSF includes pleocytosis, classically described as with a neutrophil predominance early in infection followed by prominent lymphocytes during the post-acute phase of infection. CSF proteins may be modestly elevated as seen with other cases of viral meningitis [49]. Enteroviral meningitis in children recently challenged the dogma of late appearance of lymphocytes in the course of such infections [97].

Cell culture is the traditional method for diagnosis. Enteroviruses grow ex vivo in a variety of commercially available cell lines. The observation of cytopathic effects, followed by evaluation of serotype either by testing with antisera or using commercially available monoclonal antibodies for florescent staining, is used for species and subtype confirmation [98]. Tissue samples, pericardial fluid, CSF, blood, and feces can be used for laboratory cell culture analysis.

RT-PCR which targets the conserved 5′ noncoding region of the enterovirus genome is a newer technique that allows for quicker and more sensitive test results compared with culture-based identification methods [98]. PCR assay on CSF samples now plays an important role in the accurate diagnosis of enteroviral meningitis in children presenting with nonspecific febrile illness [99]. CSF, throat swabs, stool, urine, serum, and endomyocardial biopsy material are suitable samples for PCR analysis. Newer methodologies aimed at EV71 utilize real-time RT-PCR allowing for a more rapid and accurate diagnosis of both enteroviral infection and diagnosis of specific EV71 viral strain [100]. Serology testing of the blood using neutralization type-specific immunoassays is often used for outbreak investigations and prevalence analysis of enteroviral infections [13].

In patients with CNS disease, MRI examination is now considered as the gold standard for evaluation of patients with flaccid paralysis due to enterovirus; characteristic lesions in the anterior horns of the spinal cord are considered highly suggestive for such infections [101]. A series of patients with enterovirus 71 encephalitis revealed hyperintensity in the posterior portion of the brainstem on T2-weighted and FLAIR images; however, less typical lesions including leptomeningeal enhancement have also been observed in other patients with EV71 encephalitis [102].

Prevention

Prevention against poliovirus infection and disease has a long history [1] and continues to be part of the CDC's Advisory Committee on Immunization Practices "Recommended

Immunization Schedule for Persons Aged 0 Through 18 Years." New developments in vaccines have spurred the rising frequency of reported enterovirus outbreaks, especially EV71, in many parts of Asia, leading to increasing calls for a public health vaccination approach [21, 103]. A multicenter, randomized trial conducted in China including more than 10,000 children demonstrated vaccine safety and efficacy of 90% in the prevention of hand, foot, and mouth disease and 80% efficacy in the prevention of EV71-associated herpangina and neurological complications [104]. Other EV71 vaccine trials have shown improved immunogenicity with higher vaccine doses that may persist for up to 12 months after vaccination [105].

Treatment

There is hope for significant future progress in the treatment of severe enteroviral disease although specific antiviral drug treatment is still not available. In the early days of poliomyelitis, strict bed rest was found to reduce the extension of paralysis [49]. For bulbar involvement, the "iron lung" was the supportive treatment of choice. In the modern era, patients presenting with hypoxia and inability to control secretions may require endotracheal intubation for airway protection. Once progression of paralysis has ceased, physical therapy can begin [49].

IVIG is considered as the mainstay of treatment for both enteroviral myocarditis and encephalitis. A Cochrane review of IVIG therapy for viral myocarditis illustrated favorable response with IVIG therapy in both adult and pediatric population; this treatment approach is also recommended for patients with suspected enteroviral disease [106]. In a randomized controlled trial, IVIG daily dose of 1 g per kg body weight given for 2 consecutive days was regarded as beneficial [107].

For CNS disease, a formal review of IVIG effectiveness has not been performed. Several case reports in patients with severe meningoencephalitis due to HEV-B and EV71 in children with hematologic and other neoplastic diseases had a favorable response to IVIG therapy [77, 108]. A more recent randomized controlled trial from India in children with severe enteroviral encephalitis, myocarditis, or both, showed a reduced mortality in patients given IVIG; mortality was 4% in the treatment group compared with 23% in patients in whom IVIG was not given [109]. In this study, daily IVIG dose was 400 mg per kg body weight given for 5 consecutive days. A study from Taiwan among children with severe EV71 brainstem encephalitis showed that plasma levels of interferon-gamma, IL-6, IL-8, IL-10, and IL-13 were significantly reduced after IVIG administration, which may reflect a potential mechanism for IVIG-mediated modification in enteroviral CNS disease via modulation of hosts' immune inflammatory response [110]. This is underscored by the observation that in patients with hypogammaglobulinemia and persistent vaccine-derived poliovirus infection, IVIG therapy has not been shown to successfully eradicate chronic enteroviral infection [74].

In cases of chronic meningoencephalitis, treatment with IVIG and intraventricular immunoglobulin administration via reservoir devices have resulted in favorable response [38]. However, this treatment is not universally successful, and patients have died with this disease despite salvage intraventricular immunoglobulin and ribavirin treatment in the setting of X-linked agammaglobulinemia [72].

Milrinone, a cyclic nucleotide phosphodiesterase typically used for heart failure, has also been used for treatment of severe EV71 infection presenting with severe encephalitis and pulmonary edema. The antiviral or disease-ameliorative mechanism for this drug in life-threatening enteroviral infection remains unknown [111].

Pleconaril is an antiviral compound which is thought to work by inhibiting the uncoating of the viral capsid in all enteroviruses, preventing the virus from undergoing RNA replication; it has antiviral activity against both enteroviruses and rhinoviruses [112]. The initial use of pleconaril on compassionate release for treatment of severe enteroviral infections was encouraging, yielding a favorable clinical response up to 80% [113]. Other case series also suggested efficacy in the treatment of viral myocarditis as well as systemic enteroviral infection in immunocompromised hosts [112]. However, as phase 1 and 2 studies in previously healthy adults and children with enteroviral encephalitis showed only marginal improvement in symptom duration compared with patients given placebo, this compound did not receive FDA licensing, and production was abandoned in 2003. Interest in pleconaril has rekindled after Schering-Plough acquired the compound from ViroPharma. A phase 2 clinical trial of pleconaril nasal spray for the treatment of rhinovirus cold symptoms and asthma exacerbations is now completed; results are pending [114]. Another trial of pleconaril for treatment of enteroviral sepsis syndrome in infants sponsored by NIAID is listed as "ongoing, but not recruiting participants" [115].

There are other capsid targeting antiviral compounds under development including pirodavir (BTA-798) and V-073 that are being targeted for human respiratory viruses and poliovirus, respectively [114]. One concern, however, with any single-drug approach is the ability of RNA viruses to develop mutations, increasing the chances for development of de novo drug resistance. With this in mind, for-profit and research laboratories are investigating compounds that target a variety of antiviral targets such as protease, helicase, and RNA polymerase [114].

Another therapeutic approach under development is RNA interference. This approach appears promising against a

range of enteroviruses including poliovirus, coxsackievirus, and EV71 in in vitro models as well as in a murine model of myocarditis [116]. These and other new drugs under investigation are expected to provide much-needed treatment option for immunocompromised patients undergoing transplantation with severe, potentially life-threatening enteroviral infections.

Summary

As for all community-onset infections that are transmitted via casual person-to-person contact, enteroviral infections pose a risk to transplant recipients. The risk is further enhanced by the ease of infection transmission from an unsuspected, asymptomatic individual or those with clinically subtle disease, and infection may be transmitted by saliva, respiratory secretions, and fecal contamination. As most enteroviral infections are difficult to clinically differentiate from other viral illnesses, and present with a wide range of clinical presentations, a low threshold of suspicion should be maintained, especially during the summer and fall months when these viruses have high seasonal presence in most communities. Humoral immune defects and lymphopenia are known risk factors for potentially life-threatening systemic enteroviral disease including viral pneumonitis and encephalitis in recipients of allogeneic HSCT [89, 117]. OPV should never be given to transplant recipients. Furthermore, these patients are at risk for vaccine-derived disease for close contacts in countries where OPV vaccination is prevalent [58]. IVIG is important for prevention of serious enteroviral infections in individuals with hypogammaglobulinemia. IVIG therapy has been successful in some patients with serious lung, heart, and CNS acute enteroviral disease [72]. The future developments in (1) novel antiviral therapies, (2) advances in rapid and accurate diagnostic tests, and (3) better understanding of host susceptibility for such infections and proclivity for various end-organ diseases remain an encouraging prospect, especially in the care for highly susceptible transplant population.

Parvovirus B19

43

Morgan Hakki and Lynne Strasfeld

Introduction

The family *Parvoviridae* encompasses two subfamilies, *Parvovirinae* and *Densovirinae* [1]. The *Parvovirinae* are further divided into five genera, of which parvovirus B19 (B19) is a member of the genus *Erythrovirus* [1]. Three distinct phylogenetic clusters (genotypes 1–3) of B19 are recognized based on 13–14% sequence divergence at the nucleotide level, with B19 representing the prototype of genotype 1 [2–5]. However, sequence variability does not account for the various clinical manifestations of B19 infection, as the clinical spectrum of illness caused by the three genotypes tends to overlap [6].

B19 was discovered in 1975 during screening of blood for the hepatitis B virus [7], and the first reports linking B19 infection to human disease appeared in 1981 with the description of cases of aplastic crisis in patients with sickle cell disease [8, 9]. The first published report of B19 infection after transplantation, in 1986, described persistent anemia in a renal transplant recipient [10]. Since then, B19 infection has come to be a recognized infectious complication of solid organ (SOT) and hematopoietic cell transplantation (HCT). While typically a benign, self-limited infection in immunocompetent hosts, B19 can have serious sequelae in SOT and HCT recipients.

The B19 Genome and Proteins

B19 is a relatively small (18–25 nm) unenveloped virus [1]. The genome consists of plus- or minus-sense single-stranded linear DNA of 5.6 kilobases (kb) characterized by an internal unique region flanked by inverted terminal hairpin repeats. It is thought that DNA replication initiates at the terminal hairpins, with the hairpin formed by the 3′ repeat serving as a primer for DNA synthesis [11]. A series of linear duplex monomeric and dimeric intermediate forms leads to a template for DNA synthesis, and the resulting plus- and minus-sense single-stranded DNA is packaged in the virion with equal frequency [1].

Five proteins are translated from nine mRNA forms transcribed from a single promoter, p6 [12, 13].

The 77 kilodalton (kD) nonstructural protein (NS1) is encoded by the single nonspliced transcript located near the 5′ end of the genome [14–16]. NS1 is a polyfunctional protein that is required for B19 replication [17]. NS1 regulates activity of the p6 promoter [18, 19], and sequence analysis has shown that NS1 contains motifs for nucleoside triphosphate (NTP) binding and hydrolysis [20] associated with helicase activity, suggesting a role of NS1 in B19 DNA replication. NS1 induces caspase-dependent apoptosis [21, 22] and regulates the activity of the E2F family of transcription factors to promote cell cycle arrest in G1 and G2 phases [23–25].

Two proteins, the 83 kD VP1 and the 58 kD VP2, make up the B19 capsid. Because the sequences of VP1 and VP2 are collinear, VP2 is identical to the carboxy-terminus of VP1, while the amino-terminal 227 amino acids of VP1 are unique (VP1u) [13]. VP2 is the major capsid protein, comprising 95% of the capsid [15]. VP2 functions in viral entry by binding directly to blood group P antigen (globoside), the cellular receptor of B19 virus [26]. VP1 is the minor capsid protein, accounting for the remaining 5% of the capsid protein content [15]. The main neutralizing epitopes of B19 are in VP1u, which is located on the outside of the capsid [27–29]. VP1u also contains a conserved phospholipase A2-like motif (HDXXY), and mutation of this motif attenuates the infectivity of B19, indicative of a role for VP1 phospholipase activity in the B19 life cycle [30, 31].

Two other smaller nonstructural proteins, 7.5 kD and 11 kD, have been detected during B19V infection [32, 33]. The 11 kDa protein has been shown to have a role in

virion production and trafficking in infected cells and induces apoptosis by activation of caspase-10 in primary erythroid progenitor cells (EPCs) [34, 35]. The role of the 7.5 kDa protein during B19 infection, if any, is unknown.

Infection and Pathogenesis

Humans are the only known host for B19 infection, and the consequent lack of animal models, coupled with the difficulty in culturing B19 in vitro, has posed obstacles to studies of B19 infection and pathogenesis. Culture systems utilizing bone marrow cells [36], megakaryoblastoid cells [24, 37], erythroid leukemia cells [38], and ex vivo expanded EPCs [22, 39, 40] have been developed, but each system is marked by limitations inherent to in vitro models. As a result, fundamental aspects of the virus-host interaction remain poorly understood, and more research is needed in this area.

During acute infection, viremia is typically detectable by 5–6 days post-infection, peaks at 6–12 days post-infection, and clears by days 15–20 [41]. However, using more sensitive modern diagnostic techniques such as polymerase chain reaction (PCR), it is now known that many immunocompetent persons exhibit low-level persistent viremia for months after initial detection [42].

The primary sites of B19 replication are erythroid progenitor cells (EPCs) found in bone marrow and peripheral blood, due in part to the limited expression of P antigen [26]. While P antigen expression is necessary for B19 infection [26, 43], it does not appear to be sufficient, as some cell lines are resistant to transduction by a B19 vector despite P antigen expression [44]. Thus, it is possible that a co-receptor(s), such as beta-integrins [45], may contribute to viral entry. P antigen is also expressed on other tissues, including placental villous trophoblast cells during the first and second trimesters of pregnancy [46], potentially accounting for B19 transmission during pregnancy.

Viral entry by endocytosis is followed by release of the viral capsid into the perinuclear cytoplasm, nuclear transport, and release of genomic DNA [1, 26]. The mechanisms governing the latter two processes are not precisely defined. Unlike *Parvoviridae* such as adeno-associated virus, B19 is autonomous in that it can replicate in the absence of a helper virus. However, since B19 does not encode a DNA polymerase, genome replication is dependent on host cell proteins, and efficient replication requires the infected cell to pass through S phase of the cell cycle [1].

Ultimately, induction of host cell apoptosis, particularly of primary EPCs and megakaryoblastoid cell lines, results in the severe disease manifestations (hydrops, aplastic crisis) of B19 infection [21, 22, 34, 47, 48].

Immunology

The development of IgM antibodies directed against conformational and linear epitopes of VP1 and VP2 occurs 7–10 days post-infection and correlates with virus clearance [41, 49, 50]. Symptoms of fifth disease, such as rash and arthralgias, as well as post-infectious polyarthropathies in adults with acute B19 infection, develop during this phase of illness, consistent with a role for immune complex deposition in the pathogenesis of these disease manifestations [41]. An IgG response, directed primarily against conformational epitopes of VP1 and VP2, develops soon thereafter and confers lifelong protection from reinfection [51–56]. The successful use of immune globulin to control viremia and the association of persistent B19 infection with a deficient antibody response support the role of antibodies in providing immunity to B19 [57–60]. Additionally, VP1 and VP2 can elicit neutralizing antibodies when administered together as a recombinant vaccine [61]. Antibodies directed against epitopes present on NS1 have been found and may be useful as a tool to diagnose recent (<6 weeks) infection [62–65].

B19-specific CD4+ and CD8+ T-cell responses have been detected against VP1, VP2, and NS1 [66–71], although the role that CD4+ and CD8+ responses play in B19 protective immunity or in the pathogenesis of post-infectious syndromes is not clear.

Epidemiology

The seroprevalence of B19 increases with age, and by adulthood approximately 70–90% of persons are seropositive [52, 72]. The annual seroconversion rate among women of childbearing age has been estimated to be 1.5% [73]. The primary mechanism of B19 transmission is incompletely understood. The finding of viral DNA in respiratory specimens during viremia indicates that community-acquired B19 infection may result from transmission of virus excreted in the nasopharynx and upper airway [41, 74, 75]. Whether transmission occurs by close contact, droplet, aerosol, or fomites is not clear. B19, like most parvoviruses, is relatively stable in the environment, suggesting that contaminated surfaces may contribute to transmission [76]. While secondary attack rates ranging from 20% to 50% during school outbreaks and at home [74, 75, 77] indicate efficient transmission, the precise probability of transmission via various routes (i.e., droplet, aerosol, fomite) has not been conclusively established.

Transmission via whole blood or blood products, such as factor VIII and factor IX concentrates, is a well-documented but rare event [78, 79]. The prevalence of B19 DNA varies from 0.003% to 1.07% in blood donor samples, the variability likely due to differences in the sensitivity of the assay being used as well as the population and seasonality [78,

80–83]. Screening of whole blood components intended for individual patient transfusions is not currently routinely performed in the United States [42]. However, plasma derivatives have been screened for B19 by PCR since 2002 [84].

Transmission of B19 from donor to recipient via solid organ transplant has been suspected on occasion due to factors such as time of onset of infection after transplant and the finding of B19 in non-transplanted donor tissue [85, 86]. However, these findings must be interpreted with caution, and B19 transmission in this manner has not been definitively proven by documenting the genetic relatedness of a B19 strain present in the donor and recipient.

Clinical Presentation

Manifestations in the Non-transplant Host

There are five well-established clinical syndromes associated with B19 infection that are largely dependent on host age and immune status (Table 43.1). Most seropositive, immunocompetent individuals do not recall specific symptoms of infection. Roughly 25% of infections will be entirely asymptomatic, 50% will have nonspecific flu-like symptoms, and the remaining 25% will present with more classic symptoms, including arthralgias and rash [87, 88]. B19 infection is self-limited in nonpregnant immunocompetent individuals, with severe or complicated disease a rare exception [89].

B19 infection in immunocompetent children manifests most commonly as erythema infectiosum, frequently referred to as "fifth disease" [90]. The illness is typified by a nonspecific viral prodrome, followed 2–5 days later by a characteristic erythematous malar rash ("slapped cheek rash") with circumoral pallor. The facial rash is often followed by a lacey rash involving the trunk and extremities. The characteristic rash is reported more often in children, whereas arthralgias and myalgia are seen more commonly in immunocompetent adults, particularly in women [88, 91, 92]. A nondestructive polyarthropathy, often symmetric and most frequently involving the small joints of the hands, wrists, knees, and feet, may occur. Both the rash and joint symptoms typically occur soon after B19 antibody response is detectable, suggesting these phenomena are immunologically mediated. In pregnancy, complications of infection include nonimmune hydrops fetalis, intrauterine fetal death, or miscarriage [93]. Transient aplastic crisis (TAC), characterized by severe anemia and a dramatic decrease or even absence of measurable reticulocytes, may occur with B19 infection in patients with chronic hemolytic disorders (e.g., sickle cell anemia) [8].

Patient population	Clinical presentation
Immunocompetent hosts	
Children	Erythema infectiosum ("fifth disease")
Pregnant women	Hydrops fetalis
Adults (women > men)	Polyarthropathy syndrome
Patients with red cell disorders	Transient aplastic crisis
Immunocompromised hosts	Pure red cell aplasia Other less common manifestations: rash, leukopenia, thrombocytopenia, hepatitis, myocarditis, pneumonitis, encephalitis Allograft dysfunction

Clinical Manifestations in the Transplant Recipient

The classic presentation of B19 infection in transplant recipients and other immunosuppressed hosts (HIV with advanced immunodeficiency, congenital immunodeficiencies, etc.) is chronic infection with pure red cell aplasia. Although most reported cases of B19-associated pure red cell aplasia have occurred within the first year posttransplant [85, 94–97], when immunosuppression is maximal, there are numerous reports of late-onset disease as well [98, 99]. B19 DNA was demonstrated in serum in 23% of 48 kidney transplant recipients presenting with anemia compared with 5% of the controls [95]. In a prospective single-center study of kidney transplant recipients with erythropoietin-resistant anemia over a 3-month period, three of eight (38%) patients screened had B19 infection [99]. Therefore, testing for B19 should be strongly considered in transplant recipients with otherwise unexplained anemia.

The largest published review to date of B19 infection after SOT or HCT summarized 98 cases, of which 7 were seen at the Mayo Clinic over a 16-year period and the remainder found by review of the medical literature [96]. In this study, the median time to diagnosis posttransplant was 7 weeks (range, 1 week to 96 months). Not surprising given the tropism of B19 for EPCs, anemia was present in the vast majority (99%). However, other cell lines were often affected as well, with leukopenia occurring in 38% and thrombocytopenia in 21%. Fever and flu-like symptoms occurred in 26%, and, perhaps due to impaired immune responses, rash (13%) and arthralgia (6%) were less common. Proven or suspected accompanying organ-invasive disease occurred in 11%, including myocarditis, pneumonitis, hepatitis, and glomerulonephritis. Allograft loss or dysfunction was observed at the time of B19 infection in 10%. Death attributable to B19 disease occurred in three patients, all a result of cardiogenic shock related to myocarditis.

While anemia is the hallmark of B19 infection, other manifestations have been described in transplant recipients.

Myocarditis is perhaps the most common, and the cardiotropism of B19 has been demonstrated in transplant as well as in immunocompetent patient populations [96, 100–103]. Hepatitis [96, 104], encephalitis [97], pneumonia [94, 96], rash [105], hemophagocytic lymphohistiocytosis with thrombotic microangiopathy [98], and multi-organ system failure [106] have also been reported.

There is evidence to suggest that B19 may play a role in chronic allograft injury. Numerous studies have reported on the association of allograft dysfunction with B19 infection, documented by detecting the presence of the viral genome in graft tissue [85, 100, 107]. In a study of 69 kidney transplant recipients with allograft dysfunction, B19 DNA was found in nearly two-thirds (35/57) of baseline biopsies, and intrarenal persistence of B19 DNA was a risk factor for the development of acute rejection [107]. B19 DNA was detected on endomyocardial biopsy in 35 of 99 consecutive pediatric cardiac transplant recipients, on 14% of 700 biopsies performed [100]. In this series, B19 was the most common viral genome amplified, more common than cytomegalovirus, Epstein-Barr virus, adenovirus, and enterovirus. While the presence of B19 DNA in the myocardium was not associated with cellular rejection, patients with chronic infection had significantly increased risk for early development of advanced transplant coronary artery disease (TCAD), the leading long-term cause of death in pediatric heart transplant recipients. It has been speculated that because virus is detected in endothelial cells of the vasculature [108], rather than in cardiomyocytes, that B19 may be involved in the endothelial cell dysfunction associated with TCAD.

Incidence of B19 Infection After SOT and HCT

The incidence of posttransplant B19 infection ranges widely in the literature and is generally poorly characterized. The variability is due in part to screening parameters (symptomatic vs. universal screening, serial vs. episodic screening), along with heterogeneity of host immune status and diagnostic test performance characteristics.

In a retrospective study of 137 SOT and 75 HCT recipients, the incidence of infection was 1.4% (3/212), with only 1 patient (<1%), a liver transplant recipient, presenting with clinically overt disease as manifested by anemia [109]. On molecular surveillance throughout the first year posttransplant in a mixed group with 47 transplant recipients (32 SOT and 15 allogeneic HCT recipients), none were found to be positive for B19 by PCR testing of serum [96]. Thus, serial screening for B19 by PCR in all-comers posttransplant is low yield. Risk factors for B19 infection and disease after transplant are not well described.

Diagnostics

Diagnosis of B19 infection typically rests on detection of viral DNA in clinical samples coupled with histopathologic assessment of bone marrow if cytopenias are present and/or serologic testing for B19-specific IgM and IgG. B19 is not easily cultured in vitro, and therefore culture-based methods are not routinely used to diagnose B19 infection. Classification of B19 disease entails diagnosis of infection, along with anemia and/or organ-specific findings.

The diagnostic test of choice depends on host immune status. In immunocompetent individuals, serology is the preferred methodology, with detection of B19-specific IgM consistent with acute or recent infection and IgG with previous infection. In a large study of B19 infection in transplant recipients, however, 29% had negative IgM at disease onset [96].

Given that serology is often unreliable in the immunosuppressed host [59], PCR testing to detect B19 DNA, or nucleic acid amplification testing (NAAT), is the recommended diagnostic approach. PCR testing is routinely performed on serum, plasma, and bone marrow [96, 110], with reports describing B19 DNA detection in various other body fluids [94, 106, 111, 112] and tissue specimens [94, 103, 107]. PCR-based B19 assays can provide a quantitative assessment of viral load in addition to a simple qualitative result. Although there is some evidence that higher viral loads are more likely to be associated with symptomatic infection in transplant recipients [113], it has yet to be determined what the clinically significant level of B19 DNA is. Given the lack of specificity for active or acute disease, PCR-based testing requires careful clinical interpretation. The value of following PCR to monitor response to treatment is unclear, noting that viremia can persist for months despite appropriate clinical response [114].

Bone marrow examination may reveal giant, multinucleated erythroblasts and pronormoblasts, with near-complete absence of late normoblasts [115]. Confirmation of B19 is provided by PCR testing for B19 DNA and in situ hybridization or immunohistochemical staining for B19.

Treatment

There are no antiviral drugs available for the treatment of B19 infection. As infection is chiefly self-limited in immunocompetent individuals, care is supportive. The cornerstone of therapy for symptomatic B19 infection in transplant recipients and other immunosuppressed hosts is intravenous immunoglobulin, based largely on the observation that specific antibodies neutralize the activity of virus in vitro [116]. Since the first description of the use of immune globulin for treatment of B19-associated red cell aplasia [58], there have

been numerous reports on the application of such therapy in transplant recipients and other immunocompromised hosts [96, 99, 117–119]. Moreover, the observation that B19 disease is not seen in cohorts of HCT recipients who are receiving prophylactic immune globulin for other reasons is supportive of the utility of this therapy [120].

The optimal dosing regimen and duration of therapy with immune globulin are not well established. Based largely on expert opinion and accepted standard practice, 400 mg/kg/day of intravenous immune globulin for 5 days is the usual approach [99, 110]. Following treatment with immune globulin, relapse of infection, defined by the reappearance of signs and symptoms of infection after completion of treatment, was observed in 27.6% of SOT and 9.5% of HCT recipients in one study [96]. Interestingly, the rate of relapse did not differ significantly among patients according to the total dose of immune globulin (when stratified by >2 g/kg or <2 g/kg) [96]. Relapses can be treated with a second course of immune globulin [110]. However, it should be noted that immune globulin therapy was associated with nephrotoxicity in 11.6% of SOT recipients [96], and therefore this intervention should be undertaken with care, balancing the risk of treatment with the potential benefit to be derived.

While immune globulin is the accepted approach to B19 disease in transplant recipients, there are reports of patients who have cleared infection solely with reduction in immunosuppression [96]. Therefore, reduction of immunosuppression, as an adjunct to immune globulin therapy, should be considered at the time of diagnosis. The key role of host immune response in clearing infection is perhaps best exemplified by reports of HIV-positive patients with B19-associated chronic red cell aplasia who have had resolution of anemia following initiation of antiretroviral therapy alone [121–123].

Prevention

Vaccine Development

The ability of the capsid proteins VP1 and VP2 to elicit protective antibody responses during natural infection makes them natural proteins to include in vaccine development. A phase I study evaluated a recombinant B19 vaccine consisting of ~25% VP1 and ~75% VP2 conjugated to a surfactant-stabilized emulsion conjugate (MF59C.1) given to B19-seronegative adults at 0, 1, and 6 months [61]. Subjects received either 2.5 or 25 μg of vaccine, and all subjects in both groups developed virus-neutralizing antibodies that persisted for at least 6 months after the third dose, although titers were higher in the 25 μg group. A third trial comparing the safety and immunogenicity of three doses of a 25 μg dose of B19 recombinant capsid to 2.5 and 25 μg doses of the recombinant capsid plus MF59C.1 and saline placebo was then performed in healthy adults [124]. The study was halted before any subject could receive the third scheduled dose due to the occurrence of three unexplained cutaneous events. After two doses, neutralizing antibodies developed in 11.1%, 37.5%, and 42.9% of persons who received 2.5 μg + adjuvant, 25 μg + adjuvant, and 25 μg without adjuvant, respectively. Ultimately, it was decided by the Safety Monitoring Committee and the Food and Drug Administration that the potential benefits of the vaccine to those affected most severely by B19 infection would outweigh the adverse events encountered in the study, and therefore the study could be resumed [124]. By the time this decision was reached, re-enrollment of a new group of volunteers and preparation of new batches of vaccine and adjuvant were required [124]. Thus, efforts to develop and test a safe and effective B19 vaccine continue.

Hospital Infection Control

B19 is most commonly transmitted by the respiratory route, through close person-to-person contact, fomites, and respiratory secretions or saliva [41]. Contagion coincides with viremia, and so immunocompetent individuals are infectious before, but typically not after, the onset of B19-associated rash or arthritis. B19-viremic patients with TAC or red cell aplasia represent a potential risk for transmission in the healthcare setting, with reports of nosocomial transmission and infection among hospital staff associated with contact with TAC patients [125–127]. To prevent healthcare-associated infection, droplet and standard precautions should be implemented for patients with TAC and for immunosuppressed hosts with chronic infection [128].

Conclusions

B19 infection remains a relatively rare but potentially serious infection following SOT or HCT. Suspicion for B19 infection should be heightened in transplant recipients presenting with unexplained anemia, particularly red cell aplasia, with or without other cytopenias. Diagnosis depends primarily on detection of B19 DNA by PCR in serum and/or tissue, or the finding of characteristic bone marrow changes by histopathology, in the appropriate clinical setting. Treatment is largely supportive, although intravenous immune globulin may be beneficial in severe cases. Continued effort may lead to the development of a safe and effective vaccine for populations at risk for severe sequelae of B19 infection.

SOT	Solid organ transplantation
TLR	Toll-like receptor
WNE	West Nile encephalitis
WNF	West Nile fever
WNND	West Nile virus neuroinvasive disease
WNV	West Nile virus

Introduction

West Nile virus (WNV) is an emerging pathogen endemic in Africa and Europe. Recent events demonstrate the speed with which a vector-borne pathogen, such as WNV, can disseminate when introduced into a susceptible, pathogen-naïve population, where competent reservoir and vectors are present. Since the arrival of WNV to the North American continent in 1999, it is estimated that 2–4 million people have been infected in the USA alone [1, 2]. It has special relevance to the immunocompromised host populations because of the possibility of WNV transmission through organ transplantation and the increased risk of neuroinvasive disease in immunocompromised patients. Here we present epidemiology, clinical manifestations, as well as avenues for diagnosis, treatment, and prevention of this viral pathogen, with emphasis on transplant recipients.

Virus and Reservoir

WNV is a member of genus *Flavivirus* in the family *Flaviviridae*. The genus *Flavivirus* has >70 members and includes other important human pathogens such as dengue, yellow fever, Zika, St. Louis encephalitis, and Japanese encephalitis viruses. WNV is an enveloped, single-stranded, positive-sense RNA virus, of about 11 kilobase genome size. The single open reading frame is translated into a polyprotein, which is further cleaved into ten proteins by cellular and viral proteases. The three structural proteins include a capsid protein (C), an envelope protein (E), and a transmembrane protein (prM). The seven nonstructural proteins, i.e., NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5, form the viral replication machinery and also modulate the host immune response [3, 4]. Natural transmission of WNV is mosquito-borne with the principal vectors being *Culex* spp., although at least 43 other mosquito species, including *Aedes* and *Anopheles*, have been found to harbor the virus [5–8]. Susceptible birds, especially corvids such as crows and jays, are principal vertebrate reservoirs, and humans appear to be incidental host. Many animal species, including humans, horses, squirrels, and even alligators, can become infected with WNV and present with clinical disease, but they do not develop sufficiently prolonged or high-level viremia to play

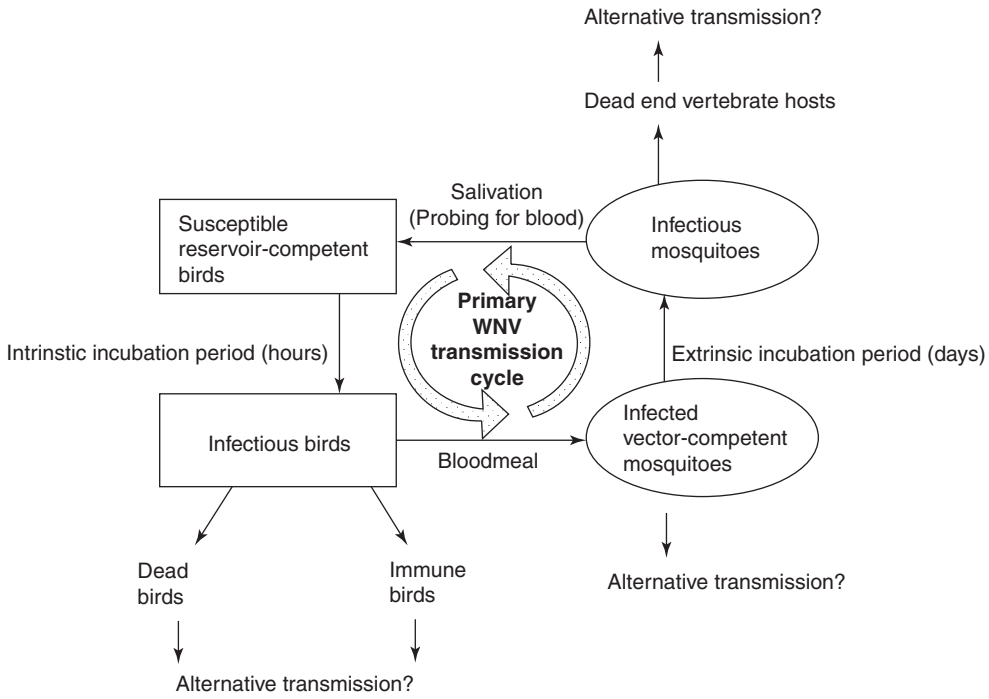

Fig. 44.1 The primary West Nile virus transmission cycle involves certain reservoir-competent birds that transmit virus to feeding mosquitoes during a brief period of elevated viremia that follows infection. Viremia is rapidly neutralized by development of antibodies. A portion of vector-competent mosquitoes that survive the extrinsic incubation period may transmit to susceptible birds to keep the cycle going. Alternative modes of transmission may exist at multiple points along the cycle. (Reprinted from Komar [7], © 2003; with permission from Elsevier)

a significant role in WNV amplification and transmission [7, 9–11] (Fig. 44.1).

Although WNV has a single serotype, it exhibits considerable genetic variation and a large variety of strains have been described worldwide. Based on their genetic differences, they are classified into at least eight lineages [12]. The two major lineages, 1 and 2, are responsible for outbreaks in humans and equines. Dramatic differences in the virulence and neuroinvasion properties have been observed between lineage 1 and lineage 2 strains [13]. Lineage 1 strains have been responsible for most human outbreaks since the 1950s. However, since the beginning of this century, lineage 2 strains have emerged to cause recent outbreaks in various European countries, including Greece (2013) and Italy (2014) [14, 15].

Epidemiology

WNV was first isolated in 1937 from a febrile patient in Uganda [6]. Prior to 1996, there were several documented epidemics in the Old World, but most cases were asymptomatic or mild, and severe neurological manifestations were rare. Since the mid-1990s, there was an increased frequency and scale of outbreaks in humans and horses, including large outbreaks in Romania (1996), Volgograd region of Russia (1999), Northeastern USA (1999), and Israel (2000) [6, 8, 16–19]. There was also worsened disease severity in humans, including neurological complications and death [20]. WNV entered the USA in August 1999 and was identified in an unusual cluster of cases of meningoencephalitis in New York City. Concurrent to these clinical cases were extensive mortality in crows as well as deaths of several exotic birds at a zoological park was noted in the same area. The initial epidemiologic and environmental investigations suggested an arboviral etiology [17], and sequence analyses of viral isolates from dead birds, mosquitoes, and two fatal human cases identified WNV as the causative agent [21, 22]. This outbreak represented the first time WNV was detected in the Western Hemisphere [17]. The WNV strain from the 1999 New York outbreak showed a close phylogenetic relationship to an isolate obtained from a goose in Israel in 1998 [21, 22]. Although the specifics of how WNV was introduced in the USA was not known, it is conceivable that infected mosquitoes or birds could have been carried to New York City on an incoming flight or ship [20]. Alternatively, a viremic person might have been the carrier.

Since the initial 1999 outbreak in New York, the virus has spread, like a slow wave, across the continental USA from East to West, likely representing movement between the mosquito and the presumed avian reservoir (Table 44.1) [20]. By 2006, WNV has spread to all 48 states of the US continent. A marked increase in the total number of cases was observed between 2002 and 2003 and was likely due to the request of Center for Disease Control and Prevention (CDC) to include West Nile Fever (WNF) cases as reportable to ArboNET (the national surveillance system for arboviral diseases in the USA) and wider availability of testing for suspected cases. From 1999 to December of 2017, more than 48,000 cases have been reported in the USA, including 22,999 cases of neuroinvasive disease and 2,163 deaths [23]. However, most WNV infections are

Table 44.1 1999–2017 West Nile virus human infections in the United States [23]

Year	Neuroinvasive cases	Non-neuroinvasive cases	Total cases	Total deaths

[a]CDC requested WNV cases be reported to ArboNET in 2003, resulting in a change of case definition
Data adapted from CDC website https://www.cdc.gov/westnile/statsmaps/cummapsdata.html

asymptomatic and therefore, not reported. It is estimated that 2–4 million people in the USA have been infected by this virus, resulting in 0.4–1 million cases of viral illness [1]. Since its peak incidence of 1.02 cases/100,000 US population in 2003, the annual incidence rate up to 2011 was in a continued decline, with an incidence of 0.4/100,000 in 2004–2007, 0.2/100,000 in 2008, and down to 0.13/100,000 in 2009 [24]. However, after a period of low-level activities from 2008 to 2011, a resurgence of WNV cases was noted in 2012, with a total of 5,674 human cases reported to the CDC, including 2,873 cases of neuroinvasive disease and 286 deaths. The fluctuation of WNV activities might be attributed to a number of factors including variation in population of vectors and susceptible vertebrate host, immunity or the lack of avian amplifying host, human behavior such as the use of insect repellents and protective clothing, community-level interventions, reporting practices, and environmental factors, such as warming temperature and rainfall [1, 25]. Importantly, the 2012 resurgence of WNV cases suggests that the USA can expect periodic epidemics of WNV infection and highlights the importance of continued research and preparedness for future outbreaks [26].

In the USA, about 85% of human infections occur in the late summer, peaking around August and September. This reflects the seasonal activity of its major vector *Culex* mosquitoes as well as the virus' amplification in the late spring and early summer in its avian hosts. In fact, the magnitude of birds dying from WNV in early summer often predicts the severity of subsequent human or equine disease in the area [7]. In warmer areas, transmission might be year-round. During an epidemic, the seroconversion rate in a human population is estimated at about 3–4% [19, 27].

Other than natural transmission through mosquito bites, WNV infections in human have also been acquired through transfusion of blood products [28, 29], breast-feeding [30], transplacental transmission [31], occupational exposure in laboratory workers [32], as well as infected solid organ allograft transplantation (SOT; see below). In 2002, 23 patients were confirmed to have acquired WNV infection through transfusion of blood products in the USA [33]. These cases led to the development and implementation of nucleic acid amplification testing (NAAT) of pooled or individual samples of blood products. Since then, transmission of WNV by transfusion has largely been prevented [34]. WNV transmission through tissue transplantation, e.g., cornea, is also theoretically possible as demonstrated in animal experiments [35, 36], although no human cases via this mechanism have been reported, thus far.

Pathogenesis and Immune Response

Much of our current knowledge on WNV pathogenesis and its host immune response has stemmed from experiments in animals [37]. After a mosquito bite, WNV first infects keratinocytes and Langerhans cells, which then migrate to regional lymph nodes [38]. Replication in these cells results in primary viremia and seeding of other visceral organs, such as the kidney and spleen. A second round of replication then ensues. The level of viremia appears to correlate with subsequent risk for central nervous system (CNS) disease, although the mechanisms by which WNV enters the CNS remain unclear. Several mechanisms have been proposed, including infection or passive transport through the endothelium or choroid plexus epithelial cells, infection of olfactory neurons and spread to the olfactory bulb, transport by infected immune cells trafficking to the CNS, as well as direct axonal retrograde transport from infected peripheral neurons [37–39]. A number of host proteins or cytokines, e.g., TNF-α, Drak2, ICAM-1, MIF, and MMP-9, have been implicated in altering blood-brain barrier permeability during WNV infection [3, 40] and might facilitate WNV entry into the CNS. However, the disruption of the blood-brain barrier may not be the primary mechanism of WNV invasion into the CNS. Instead, it is possibly a multistep process employing different mechanisms as the infection progresses [41].

Since most WNV human infections are asymptomatic and only about 1 in 150 develops CNS disease, it is thought that subclinical infection presumably reflects peripheral clearance of the virus by the immune response before neuroinvasion or before neuronal damage occurs. The innate immune

system appears to be important for viral clearance [42]. For instance, type I interferons (IFNs) IFN-α and IFN-β inhibit WNV replication in vitro; IFN-α/β receptor-deficient mice infected with WNV showed uncontrolled viral replication, rapid dissemination to the CNS, as well as increased mortality [43]. Type II IFN (IFN-γ) can also prevent viral dissemination to the CNS; mice deficient in IFN-γ or its receptor had higher peripheral viral burden, earlier viral entry into CNS, and higher lethality [44].

The complement system also protects against WNV infection and limits viral infection by stimulating the adaptive immune response (reviewed in [45]). Complement activation augments antibody-mediated neutralization of viruses, including WNV [46]. Mice deficient in complement C3 or complement receptor 1 and 2 showed increased mortality after lethal WNV challenge [46]. Deficiencies in C1q, C4, factor B, or factor D also led to increased mortality in WNV-infected mice [47]. These observations suggest that many components of the complement activation pathways seem to orchestrate protection against WNV [47, 48]. The RIG-I-like receptors, Toll-like receptors especially TLR3 and TLR7, and Nod-like receptors have been implicated in modulating the innate immune response against WNV infection as well [49, 50]. γδ T cells and NK cells are also crucial components of the host innate immune system. However, while animal studies have demonstrated protective effects of γδ T cells against WNV infection, the role of NK cells remains controversial, with reports suggesting active suppression of the virus to no effect on viral replication at all [51]. Overall, the innate immune response plays a crucial role in orchestrating various arms of the immune system, including the humoral and cell-mediated immunities to control WNV replication and to limit the virus-induced pathology [37, 50].

For the adaptive immune response, WNV appears to be more susceptible to antibody-mediated than cell-mediated immunity [52, 53]. The humoral immune response plays a key role in the pathogenesis of WNV infection [54]. B-cell-deficient mice uniformly died after WNV infection but were protected by passive transfer of immune sera [51, 55]. In particular, induction of a specific, neutralizing IgM response early in the course of WNV infection is crucial in limiting viremia and dissemination into the CNS, as well as protecting against lethal infection [38, 56]. T cells are also essential [57] as the absence of functional CD4 or CD8 T cells results in the failure of clearing WNV from the CNS [51]. In rodent models, CD4 T cells provide help for antibody responses and sustain WNV-specific CD8 T-cell responses in the CNS, which then enable viral clearance [58, 59]. Regulatory T cells may also play a modulatory role during acute WNV infection. In one study, symptomatic patients were found to have fewer regulatory T cells than asymptomatic patients, suggesting that regulatory T-cell responses might exert a protective effect by dampening the WNV immune response and inflammation [60].

Chemokines have important roles in the host response to WNV infection. Early neutrophil recruitment to the infection site was associated with CXCR2, and leukocyte movement from the blood to brain was affected by CXCR 4, CXCR 3, CXCL10, and CCR5 [61]. In particular, individuals genetically deficient in CCR5 have increased risk of symptomatic disease once infected [62, 63]. Another human gene, OAS1 (2′-5′-oligoadenylate synthetase 1b), has also been implicated in playing a role in the susceptibility to WNV infection [64]. OAS1 is a member of the type I IFN-regulated OAS gene family involved in viral RNA degradation. A single nucleotide polymorphism in OAS1 was found associated with increased risk for WNV encephalitis and paralysis in human [65]. SNPs in IRF3 and MX1 have been identified as susceptibility loci to WNV infection as well [65].

While an intact immune system is essential for the control of WNV infection, the inflammatory response to infection may play a role in disease pathology. WNV infection can cause neuronal death directly by inducing apoptosis and the process appears to be caspase-3 dependent [66]. Pro-inflammatory markers IL-1β, IL-6, IL-8, and TNF-α also play a role in mediating neuronal death in response to WNV infection in vitro [67]. Both neurons and microglial cells are potential sources of such pro-inflammatory cytokines [68].

Collectively, in vitro and in vivo studies have demonstrated the importance of innate, humoral, and cellular immunity in controlling WNV infection, but the inflammatory response may contribute to the pathogenesis of the disease.

Clinical Syndromes

Incubation period from the initial exposure to WNV and onset of clinical illness is between 2 and 14 days. Among those infected, about 80% are asymptomatic [27, 69], while 20–30% develops a mild infection called WNF. WNF in most cases is self-limiting, but some cases might be severe. During the 2002 Illinois outbreak [70], 38% of patients with WNF required hospitalization, although there might be a bias toward diagnosing and reporting WNF in persons with more severe illness [70].

Common symptoms of WNF include fever, malaise, lymphadenopathy, periocular pain, gastrointestinal symptoms such as nausea, vomiting, and abdominal pain; myalgia, and headache. A maculopapular rash, when present is more frequently seen in younger patients [71]. While some symptoms, such as fever, typically resolve in a 1 week or so, others can persist for weeks. In a case series studying the symptoms and outcome of 98 patients with WNF in Illinois, 63% of respondents continued to have symptoms 30 days

after the onset of illness, and 96% had fatigue for a median of 36 days [72]. Non-neurologic manifestations of WNV infection include myocarditis, myositis, orchitis, and pancreatitis [73–76], but these complications are rare. In contrast, retinopathy associated with WNV has been noted in about one fourth of patients with a history of WNV infection and is more frequently observed among those with severe neurological complications [77].

For the general population, the risk for developing WNV neuroinvasive disease (WNND) was estimated to be less than 1% [27]. Clinical syndromes of WNND include meningitis, encephalitis, and acute flaccid paralysis (AFP). Risk factors for the development of WNND have been examined after several outbreaks [19, 78–80], and advanced age was noted as a major risk factor [70]. Other independent risk factors associated with developing WNND include male sex, hypertension, diabetes mellitus, immunosuppressing conditions, and cardiovascular disease [81, 82].

Similar to other forms of viral encephalitis, symptoms of WNV encephalitis (WNE) are non-specific, but most patients have fever (70–100%), headache (50–100%), and altered mental status (50–100%) [24]. Vomiting (30–75%), diarrhea (15–35%), and rash (5–50%) are also seen, but a prominent finding of WNE is muscle weakness with flaccid paralysis and hyporeflexia, in up to 30–50% patients. Other neurologic findings include cranial neuropathies, e.g., peripheral seventh nerve palsy, optic neuritis, and ataxia. Movement disorders including postural or kinetic tremor, myoclonus, and Parkinsonian features such as rigidity or postural instability are also common [24, 83]. Seizures, increased intracranial pressure and cerebral edema are infrequent events [83]. An example of clinical characteristics in patients with WNV meningitis and encephalitis during the 2002 Illinois outbreak is illustrated in Table 44.2 [70]. Among those with severe illness due to WNV, the overall case-fatality rates range from 3% to 15% and are highest among the elderly [84].

AFP occurs in 5–15% of patients with clinically apparent neuroinvasive disease and can present as a poliomyelitis or Guillain-Barré-like syndrome [20, 85]. The Guillain-Barré form is rare and likely results from a peripheral demyelinating polyneuropathy [86]. Saad et al. reviewed 56 cases of AFP from the literature and summarized the clinical characteristics of these patients [87]. Notably, the spectrum of clinical presentations ranged from single extremity paralysis to flaccid quadriplegia with cranial nerve involvement. Respiratory failure and bladder dysfunction were also common, observed in 54% and 22% of patients, respectively [87]. AFP was found more common in younger patients, but elderly patients had a higher mortality with an overall mortality up to 22%, and the survivors were left with persistent neurologic impairment [87, 88].

After symptomatic WNV infection, more than half of the patients experience persistent symptoms for more than 6 months [89]. While patients with WNND can be left with persistent cognitive or physical deficits, even those with mild WNF may have long-lasting subjective or somatic complaints [90], including tremor, abnormalities in motor skills, and executive functions [91]. For instance, Klee et al. studied the recovery of New York City residents infected during the 1999 WNV outbreak and reported that

only 37% achieved a full recovery by 1 year [92]. Another study followed 56 cases of WNV, including 48 patients with meningitis or encephalitis, which occurred in Tennessee 2002. One year later, 12 of 22 (55%) persons still reported lack of complete recovery, with symptoms including fatigue, weakness, difficulty ambulating, and memory problems [93]. More recently, Weather et al. reported an observational study [94] which studied the long-term neurological outcomes of WNV-infected patients. Neurological examinations were conducted 1–2 and 8–11 years following acute WNV infection. Depending on the severity of their initial illness, e.g., WNF vs. WNE, 27–86% of patients had abnormal neurological exam at the first assessment at 1–2 years postinfection. Among those available for the second assessment at 8–11 years postinfection, many had persistent neurological deficits, and some were noted to have developed new neurological complications.

Other than physical symptoms, a significant proportion of patients may experience neuropsychiatric disturbances, with about one-thirds of patients reported new-onset depression in a study [95]. During the 1999 WNV outbreak in New York City, 38% of patients reported depression 1 year after the onset of infection. Similarly, a study conducted after a WNV outbreak in Louisiana reported that 23% of patient still had depression and anxiety at 1-year follow-up [96]. Thus, physicians should be aware of the neuropsychiatric consequences of WNV in patients.

The possibility of persistent WNV infection has been suggested. Several investigators have reported the persistence of WNV viral RNA for months or years in animal models as well as in human [20, 97–99]. In particular, WNV RNA was demonstrated in urine samples from convalescent patients up to >6 years after the initial infection, suggestive of a persistent renal infection [99]. The same group of researchers also linked WNV infection to the development of chronic kidney disease [100]. The association between WNV and chronic kidney disease remains inconclusive, but whether WNV can establish any significant chronic infections in human warrants further investigation.

In conclusion, other than acute morbidity and mortality, WNV infection can lead to significant long-term physical, cognitive, and functional sequelae, as reviewed systemically by Patel et al. [101]. An understanding of these complications and their risk factors can allow early diagnosis, preventive measures, and improved patient care.

Laboratory and Imaging Findings

For patients with WNV infection, total leukocyte counts in peripheral blood are mostly normal or elevated, but lymphocytopenia and anemia can also occur [17, 102]. Hyponatremia can be seen, especially in patients with encephalitis. Studies of cerebrospinal fluid (CSF) in general show pleocytosis with lymphocytic dominance generally <500 cells/μL, but a predominance of neutrophils has also been reported [103]. Protein levels are usually elevated (<150 mg/dL), while glucose levels remain normal.

The MR imaging findings of WNV encephalitis are nonspecific and share similarities with many other inflammatory and infectious processes, including those of St. Louis encephalitis and Japanese encephalitis. Patients with WNND can have normal neuroimaging studies, but abnormalities, when present, are primarily seen in areas of the basal ganglia, thalamus, cerebellum, and brainstem [104]. Some patients may also have involvement of the mesial temporal structures. For patients with extremity weakness, abnormalities can be seen in the gray matter of the spinal cord, more pronounced in the ventral horns, as well as the conus medullaris and the cauda equina. Abnormalities seen by MRI might be progressive, transient and/or migratory, and the transient nature of the imaging abnormalities might explain the negative studies in some patients [105]. Overall, although imaging results of WNV are non-specific, certain MRI findings, such as deep gray matter or mesial temporal lobe involvement, should prompt inclusion of WNV on the differential diagnosis, especially if the clinical picture, epidemiologic factors, and mosquito exposures are taken into account.

WNV Infection in Transplant Recipients

For transplant recipients, the most likely mode of transmission is still through mosquito bites, the natural route of WNV transmission. However, transmissions through blood transfusion and organ transplantation have also been well documented. In a review of 23 past reports of transfusion-transmitted infections in SOT [106], six reports described WNV transmission through blood transfusion, resulting in infection of nine organ recipients. All nine patients developed severe neurological complications, and two subsequently died. While most of these cases involved transfusion of infectious blood products into organ recipients, rarely, the organ donor was the one to receive the infectious unit just prior to transplantation resulting in graft-transmitted WNV infection the recipient [107].

Graft Transmitted WNV Infection

Transmission through SOT was first described in 2002 [107]. Fever and mental status changes developed in four organ recipients from a common donor. Subsequent investigation identified WNV infection in the organ donor and in all four organ recipients. Three recipients developed enceph-

alitis with one death and one developed a febrile illness. The organ donor was thought to have required WNV through blood transfusion. In 2005, three cases of WNV infection were reported among four patients who received organs from a single donor. Two recipients developed WNE. The donor's infection was likely mosquito-borne [108]. In 2008, a patient developed WNE shortly after heart transplantation, and the donor was thought to be infected through blood transfusion [109].

In 2009, a patient developed fever and neurological symptoms approximately 2 weeks after undergoing liver allograft transplant surgery. CSF showed pleocytosis. The patient was treated empirically with intravenous immunoglobulin (IVIG) for possible WNV encephalitis, with prompt clinical improvement. Both CSF and serum of the recipient were positive for WNV IgM. The organ was procured from a 53-year-old man who died from brainstem herniation secondary to an intracranial hemorrhage during a hypertensive crisis. His blood was negative for WNV IgM but positive by NAAT. The route of WNV transmission to the donor was unclear, but presumably he may have acquired mosquito-borne WNV shortly before death, as he had not received blood transfusion [110]. There are two other clusters of WNV transmission in the USA that occurred in 2009 and 2010, and both resulted in encephalitis in one of the two kidney recipients, but the details of these cases were not reported (Table 44.3) [111].

The first case of WNV transmission through organ transplant in Europe was reported in 2010 [112]. The donor died from cerebral hemorrhage, and her liver was harvested and transplanted into a 25-year-old woman. As the local public health authority in the Emilia Romagna region, Italy, mandated NAAT for WNV in blood and organ donations from all subjects in WNV risk areas, the donor's blood sample was tested the day after the harvest and was found positive. On the third postoperative day, the recipient was tested positive for WNV by NAAT, before the development of any clinical evidence of WNV infection. Her immunosuppressive therapy was promptly reduced to a minimum, and she was treated with WNV hyperimmune plasma and gamma globulin. Her posttransplant course was complicated by two episodes of rejection, but she did not develop any clinical WNV disease.

Despite the mandate by the Italian National Transplant Network to perform NAAT within 72 h of donation on all donors living in the WNV endemic areas, four cases of WNV transmission from a single multi-organ donor was reported in August 2011 [113]. The donor's death was not related to a transmissible disease, and the donor's blood sample were tested negative by NAAT within 72 h of organ procurement. However, about 10 days after transplant, the two recipients of kidneys from this donor developed fever and symptoms of encephalitis. The liver and heart recipients remained in good health, while the lung recipient developed neurological symptoms, which was ascribed to immunosuppressive therapy toxicity. WNV transmission was confirmed in the recipients of kidney, liver, and lung, whereas, liver and lung recipients did not develop clinical WNV disease. Repeat testing of the donor materials confirmed a negative test result by NAAT, however, serological tests showed the presence of IgM and IgG. The donor likely had very low level of viremia, which was insufficient for detection by the NAAT technique.

The most recent known cluster of WNV transmission through organ transplantation occurred in the fall of 2011 and was reviewed by Winston et al. [114]. A patient with a recent kidney transplant from a deceased donor was diagnosed with WNV encephalitis, which led to an urgent investigation by the local Department of Public Health and CDC [115]. Three other organ recipients from the same donor were identified. The donor was a 56-year-old man with a history of cerebral palsy, developmental cognitive delay, blindness, and seizures [35, 114] and had outdoor exposure in a region of with known WNV activity. He presented to the emergency room of a local hospital with acute onset of fever, muscle weakness, and an altered mental status and was sent home on an antibiotic for a possible urinary tract infection. Three days later, he was found unresponsive at home and in cardiopulmonary arrest. After resuscitation and intubation, he was brought to another local hospital by paramedics and was admitted to the intensive care unit. However, he remained unresponsive and an electroencephalogram showed no cortical activity consistent with brain death. His death was initially attributed to culture negative sepsis, but his serum was subsequently found positive for WNV IgM. WNV RNA was detected in samples from his spleen/lymph node, skin, and fat associated with the tibia bone, as well as some of the muscle, tendon, and bone marrow specimens, but not in serum [35]. All four organ recipients had WNV RNA in serum and CSF. Three developed WNE, while the liver recipient had no neurological symptoms. The recipients were treated with various modalities, including IVIG, fresh frozen plasma containing WNV IgG, IFN, ribavirin, and/or reduced immunosuppression, with two deaths resulted.

Characteristics of WNV Infection in Transplant Recipients

Reports of WNND in transplant recipients including SOT or hematopoietic stem cell transplant (HSCT) suggest that prodrome and symptoms were similar to those reported in the immunocompetent patients, including fever, weakness, gastrointestinal complaints, and altered mental status. Laboratory findings, e.g., CSF profile, as well as imaging findings on MRI were also similar [116, 117], although the

[a]Pre-transplant serum of the lung recipient was positive for WNV IgG, but sera posttransplant were negative

CSF WBC counts in transplant patients with WNE are minimally elevated as compared to immunocompetent patients (mean CSF WBC counts were 86 cells/mm^3 versus 227 cells/mm^3, respectively) [114]. Due to their immunocompromised status, transplant recipients might have longer incubation periods and prolonged phase of viremia [112]. The incubation period for WNV is generally thought to range from 2 to 14 days, but for the patients that acquired WNV through SOT, symptoms began 5–37 days after the transplantation, with a median of 13 days [114]. Studying 23 patients that acquired WNV through blood transfusion, Pealer et al. also reported a median incubation time of 13.5 days for transplant recipients versus 8 days for those without any immunosuppressing conditions [33]. The duration of viremia can last for about 4 weeks, as compared to approximately ≤2 weeks of viremia in immunocompetent hosts [112]. The development of antibody might also be delayed [116]. For instance, the liver recipient reported by Morelli et al. [112] developed a WNV IgM antibody response by day 26 posttransplant but did not develop IgG seroconversion to WNV for more than 4 months after transplantation. In comparison, IgM and IgG seroconversion was noted within the first 1–2 weeks in normal hosts [118].

A seroprevalence study previously reported that asymptomatic WNV infection is as common among immunocompromised SOT patients as in non-immunocompromised controls and the incidence of WNND is low in the SOT population, comparable to the <1% estimated rate in the general population [119]. However, most studies support an increased risk of neuroinvasive disease and suggest a higher mortality among immunocompromised patients. During the epidemic in Israel in 2000, immunocompromised patients were noted to have a mortality rate at 31%, as compared to 13% among those not immunocompromised [120]. A case series of 11 transplant patients with mosquito-borne WNV reported a mortality rate of 18% [116]. For the 2002 outbreak in Toronto, Canada, the risk of WNND in a transplant patient infected with WNV was estimated at 40% as compared to 1% in the general population [121]. These reports studied naturally transmitted WNV infection in transplant patients, in whom infection occurred months to years after transplantation. SOT patients that acquired WNV through donor-organ transmission might have even higher rates of morbidity and mortality, as the level of immunosuppression is likely higher during the immediately posttransplant period. Of the 26 transplant recipients exposed to WNV through SOT (Table 44.3), infection was confirmed in 22 patients and 14 (64%) developed WNV encephalitis, resulting in high morbidity and mortality. The high level of immunosuppression routinely given in posttransplant period may also alter the "expected" clinical and laboratory findings. For instance, Winslow et al. noted that although 70% of patients that acquired WNV through SOT eventually developed encephalitis, only 33% had neurological symptoms at the initial presentation [114]. For the case series of naturally acquired WNV encephalitis in transplant patients reported by Klenishcmidr-DeMasters [116], pleocytosis was present in all cases and ranged between 5 and 540 cells/mm^3 with a mean cell count of 89 ± 152 cells/mm^3. In contrast, among the 14 patients with organ graft-transmitted WNE, CSF data were available for nine patients, and three did not have any pleocytosis (Table 44.3). For HSCT recipients, morbidity and mortality are likely increased as well. Among seven such patients reported in the literature, five died shortly after presentation [122].

In summary, the diagnosis of WNV infection in transplant recipients requires a high index of clinical suspicions, when the patient presents with unexplained fever, with or without neurological manifestations, and, in particular, when there is known WNV activity in the region. Furthermore, the possibility of donor- or transfusion-derived WNV infection must be considered during the early posttransplant period.

Diagnosis

Laboratory diagnosis of WNV is typically made by detecting the presence of either antibodies specifically IgM against the virus or the viral nucleic acid in blood or CSF. The dynamics of viremia and IgM and IgG seroconversion during the early stages of WNV infection have been described (Fig. 44.2) [118]. WNV-specific IgM antibodies are usually detectable 3–8 days after disease onset [123]. WNV IgM in serum or CSF is routinely detected by IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA). The test is available commercially but can also be obtained with the state or county public health departments. A lateral-flow rapid IgM strip assay, which has a 98.8% sensitivity and a 95.3% specificity as compared to two commercially available MAC-ELISA tests and two public health-developed WNV IgM tests, was also approved [124]. Since IgM does not cross the blood-brain barrier, its presence in CSF is indicative of CNS involvement. However, the finding of IgM in serum must be interpreted with caution, as IgM can persist for months or even >1 year [118, 125]. In those cases, correlation with clinical picture and exposure history would be crucial. IgG can also be detected by ELISA, but the presence of IgG alone may represent past infection only and is difficult to use in isolation to diagnosis acute infection. Past exposure to or vaccination against other flaviviruses can lead to false-positive serological results due to cross-reactivity. Thus, a careful assessment of the patient's prior travel, exposure, and vaccination history is important. Definitive serological diagnosis would require the use of different flaviviral antigens or a comparison of neutralization activity against related flaviviruses. Confirmation of WNV infection can be obtained using the

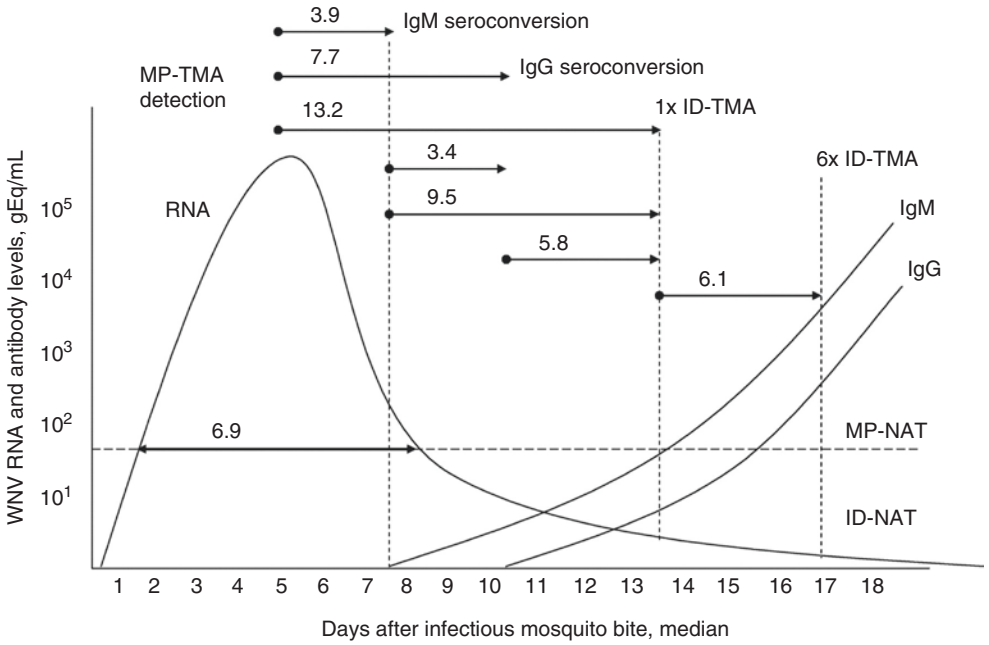

Fig. 44.2 Dynamics of West Nile virus (WNV) RNA and WNV-specific antibody positivity and negativity. Please refer to [118] for details. A total of 245 donors with WNV viremia were followed up weekly for 4 weeks and then monthly for up to 6 additional months or until seroconversion. Plasma samples were tested for WNV RNA by transcription-mediated amplification (TMA) and for WNV-specific IgM and IgG antibodies. The top three intervals represent window periods that start with the index donation (i.e., the donation that tested positive for WNV in minipools of 16 donor specimens [MP] by TMA [MP-TMA]). Although positive results of MP-TMA can occur anytime during the 6.9-day window period when results of MP nucleic acid amplification testing (NAT) are positive, for illustrative purposes, the first three window periods are depicted as beginning at the midpoint of this window period. The median time from RNA detection to IgM seroconversion was 3.9 days; to IgG seroconversion, 7.7 days; to RNA negativity by single-replicate (1x-ID) TMA, 13.2 days; and to RNA negativity by 6-replicate (6x-ID) TMA, 6.1 additional days after results of 1x ID-TMA are negative. (Reproduced from Busch et al. [118], © 2008, with modification of figure legend, by permission of Oxford University Press)

plaque reduction neutralization test (PRNT), which is more specific for WNV. A rising titer by PRNT can also be used to confirm an acute WNV infection, when the presence of IgM alone cannot provide any certainty of the diagnosis. However, this test usually takes several days to perform and is not routinely used to confirm all WNV cases.

NAAT can be used to detect WNV in CSF, tissues, or other body fluids. Although NAAT has high specificity, due to the transient nature of viremia lasting only 2–15 days [118], sensitivity is relatively low. However, NAAT may aid in diagnosis among immunocompromised patients, with whom viremia can be prolonged and antibody response to infections may be delayed or inadequate. Isolation of the virus by culture techniques or detection of viral antigen can also be performed, but these methods are less sensitive than NAAT and are not routinely employed for diagnostic purpose. Furthermore, isolation of the virus by culture requires a Biosafety Level 3 laboratory and is limited to facilities with this capability. It is important to note that transplant patients may be seronegative, especially early in the course of infection. Therefore, both serologic assays and NAAT should be considered in transplant recipients with the clinical suspicion of WNV infection [126].

Treatment

Treatment of WNV is mostly supportive, and there is no specific accepted antiviral therapy. However, several modalities of treatment have been tested or employed in animal studies and human cases [127].

IVIG

IVIG is a preparation of human IgG obtained from pooled plasma from thousands of healthy blood donors and contains antibodies directed against a broad spectrum of microbes. However, the activity against any specific pathogen depends on the prior exposure of the donors to the microbes in their environment as well as immunity obtained through vaccination. Different lots of IVIG from different areas or countries can have substantial variability in WNV neutralizing capacity [128], but overall, preparations from areas endemic for WNV show higher titers to WNV. Plasma obtained from blood donors with anti-WNV antibodies can be further pooled to develop preparations with greater potency than those from regular donors [129]. Besides the neutralizing

activities against WNV, the non-specific anti-inflammatory and immunomodulating properties of IVIG may also play an important role in its protective effects against WNV infection [130].

The successful use of IVIG to treat WNV infection was first reported in 2001, when a woman with chronic lymphocytic leukemia became comatose from WNE and recovered with IVIG treatment [131]. Successful outcome associated with IVIG treatment for WNE has also been reported in organ transplant recipients, including those of lung [132], kidney [133], and liver [110] transplantation. In all these cases, the patients had severe neuroinvasive disease from WNV but recovered fully after prompt administration of IVIG. IVIG has also been used to treat AFP caused by WNV successfully [134]. However, there might be a reporting bias and cases of failure have been noted [135].

A phase I/II randomized, placebo-controlled trial that evaluated the safety and efficacy of hyperimmune IVIG (Omr-IgG-am) in the treatment of patients with or at high risk for progression to WNV encephalitis was completed in 2007 [ClinicalTrials.gov: NCT00069316]. The timing of IVIG administration appears to be critical, as most patients that responded to IVIG therapy had received treatment early in the course of infection, especially prior to developing neurological symptoms [108, 136]. In 2005, when four patients received organ transplantation from a WNV-infected donor, all four patients received Omr-IgG-am. While the two asymptomatic patients that received Omr-IgG-am as a prophylactic measure remained well, the other two patients received Omr-IgG-am 10 days after the development of neurological symptoms and did not respond [108]. Makhoul et al. also reported a case series of eight patients with WNE treated with high dose of hyperimmune IVIG; those patients who received early treatment showed significant improvement [136]. Together, these cases argue that the timing of IVIG administration may be critical to its efficacy [110].

Animal studies also support early treatment of WNV with IVIG. A number of animal models demonstrated clear protection by IVIG when the animals are treated during the viremic phase, before or shortly after inoculation with WNV [52, 137]. After infection by flaviviruses, invasion of the CNS may occur in a few days. Using a murine model, Roehrig et al. showed that the window for successful application of prophylactic antibody to prevent flaviviral encephalitis closes at about 4–6 days postinfection concomitant with viral invasion of the brain [138]. In fact, when most patients present, they are no longer viremic [139, 140] and, therefore, may not respond to IVIG treatment. Other than the timing of starting IVIG, the route of administration may be important as well [135]. IgG enters the blood-brain barrier at only low level and might explain the relative ineffectiveness of IVIG treatment when CNS involvement is already evident. Intraventricular or intrathecal administration can deliver higher levels of immunoglobulins into the CNS. This approach has been used successfully in a few cases of enterovirus encephalitis in children with hypogammaglobulinemia [141] although this approach has not been reported for treatment of *Flavivirus*-associated CNS disease. However, if CNS infection might have an immunopathological component, then administration of IVIG, especially via intraventricular or intrathecal route, could potentially exacerbate the clinical disease [142]. There is also a theoretical concern for "antibody-dependent enhancement" of infection, during which subneutralizing concentrations of antibodies bound to *Flavivirus* can enhance infection by facilitating uptake into Fc-receptor-bearing cells [143].

Humanized monoclonal antibodies against WNV were developed [127]. A humanized monoclonal antibody against WNV E protein (MGAWN1) was found to be safe and generally well-tolerated in healthy human subjects in a phase I clinical trial [144]. A phase II study to evaluate the safety and efficacy of MGAWN1 in patients with WNV infection was initiated in 2009, however the clinical trial was terminated due to inability to enroll study subjects [ClinicalTrials.gov: NCT000927953].

Interferon Therapy

IFN play important role in defense against viral infections. IFN-α was studied in several clinical trials against flaviviral disease. A small pilot study showed efficacy of IFN-α-2b against meningoencephalitis due to St. Louis encephalitis virus [145], but a larger randomized double-blind placebo-controlled trial of IFN-α-2a for Japanese encephalitis did not show an improved outcome [146]. For WNV, only case reports exist, and experiences of both success [147, 148] and failure [149]. Kalil et al. [147] reported two patients with WNE who showed significant improvement of neurological function with IFN-α treatment. Lewis and Amsden [148] also described successful treatment of an 83-year-old man with WNE, even though IFN was given 3 weeks after the onset of clinical disease. In contrast, Chan-Tack and Forrest [149] reported failure of IFN-α-2b in the treatment of a 72-year-old man with WNE and AFP. As pointed out by the authors, the failure of treatment in this case may be due to the patient's advanced age, severity of CNS disease, and delay in starting treatment, 17 days after the onset of symptoms. Similar to IVIG, failure of IFN in treatment of WNV CNS disease may also be under-reported due to potential for publication basis.

There are concerns that IFN therapy may induce an immunoreactive state and promote the risk of graft rejection in patients following solid organ allograft transplantation [150]. For instance, long-term use of IFN-α-2b has been associated with an increased risk of acute rejection in renal transplant recipients [151]. In contrast, four renal transplant recipients

with WNE in a single cohort received short courses of IFN given between 4 and 17 days; none of these patients had demonstrated significant deterioration in renal graft function [116].

Ribavirin

Ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboximide) is a synthetic nucleoside analog with in vitro and in vivo activities against a number of DNA and RNA viruses. It competitively inhibits inosine monophosphate dehydrogenase and can be incorporated into the viral genome, leading to lethal mutagenesis [152]. It also has immunomodulatory properties that may contribute to its efficacy against viral infections [153, 154].

Ribavirin has inhibitory activity again WNV in cell culture, but only at high drug concentrations (EC50 of 60–100 μM) [127, 155]. To approximate the in vitro EC50, high ribavirin doses would need to be given intravenously, increasing the risk for drug toxicity [156]. Animal studies showed little effect of ribavirin on CNS viral infections; in fact, ribavirin treatment increased mortality in a hamsters with experimental WNV infection [157]. During the 2000 WNF outbreak in Israel, the use of enteral ribavirin was associated with increased mortality, although this was likely due to the fact that oral ribavirin was offered to the sicker patients and later in the course of illness [78]. Its lack of efficacy in treating CNS infections appears to be attributed to its low lipid solubility, resulting in ineffective drug passage through the blood brain barrier [155].

Other Strategies

RNA interference-based intervention were shown to protect mice against lethal encephalitis from WNV and Japanese encephalitis [158], but the experience with this strategy is limited to in vitro and animal models. Antisense technology has also been used to protect mice against WNV infection [159]. A phase I/II randomized-blinded study in human was initiated in 2004 to evaluate the safety and efficacy of an antisense compound, AVI-4020 targeting WNV [ClinicalTrials.gov: NCT00091845]. However, the study was terminated due to limited pool of eligible WNV patients.

In recent years, high-throughput screens with small molecule libraries have been used to identify potential therapeutic compounds against various pathogens. Several groups have identified small molecules that have anti-WNV activities in vitro, but there are only scant reports using these compounds in animal models [127].

As pointed out by Diamond [127], regardless of the type of treatment used, a major challenge is to effectively administer the drug before extensive and/or irreversible end organ (CNS) damage occurs. Ideally, the anti-WNV agent should be able to cross the blood-brain barrier, as intracranial drug administration might not be feasible in severely ill patients following allograft transplantation.

Prevention

For natural WNV infection through mosquitoes, preventive strategies, such as avoiding outside activities at dawn and dusk when it is prime mosquito feeding time, application of insect-repellents; (e.g., N,N-diethyl-m-toluamide, DEET), and elimination of stagnant waters as breeding sites, may reduce this route of transmission. Screening of blood donors can also help reduce acquisition of WNV through transfusion of blood products [160].

The Organ Procurement and Transplant Network in the USA currently does not require WNV laboratory testing of organ donors. Instead, organ procurement organizations are advised to exclude deceased donors with encephalitis, meningitis, or acute flaccid paralysis of undetermined etiology from regions with reported WNV activity [111]. The impact of this decision was examined in 2004 by Kiberd et al. [160]. It was concluded that since most positive test results would be false positive, annual screening could result in the loss of potentially 452.4 life years. However, this report was based on an assumption of WNV prevalence among donors at 0.024%. In the USA, the prevalence of WNV might be substantially higher in certain counties, especially during the peak seasons of transmission. Furthermore, this report assumed the baseline screening test specificity and sensitivity to be 99.5% and 95%, respectively. Current assays have improved performance, e.g., Procleix WNV assay reportedly has a specificity of >99.9%, although actual test performance might differ among various laboratories.

A 3-year experience of donor screening for WNV by NAAT in Alberta, Canada [161], showed no false-positive results and no solid organs lost due to WNV testing. It was concluded that such WNV screening can be implemented without compromising availability of donors. Of note, there were no confirmed positive donors in this study, and a direct benefit could not be demonstrated either, but screening of donors in highly endemic areas should be considered. Recommendations for identification of potentially WNV-infected SOT donors have been outlined by Singh and Levi (Table 44.4) [162].

As most people infected with WNV remain asymptomatic, prevention of WNV transmission through organ transplantation relies on the exclusion of donors with viremia. However, among the nine clusters of organ-transmitted WNV, screening by NAAT alone would have only identified five donors as acutely infected with WNV (Table 44.3). This certainly underscores the fact that current methodologies for donor screening for WNV are imperfect. Clinicians evaluat-

Table 44.4 Recommendations for identification of potentially WNV-infected SOT donors (Grade III – opinions of respected authorities, descriptive epidemiology)

1. Defer donors with meningitis, encephalitis, or flaccid paralysis of unknown etiology from regions with reported WNV activity
2. Live donor screening:
(a) Consider live donor screening with WNV NAAT as close to time of donation as possible
(b) Liver donors with positive WNV NAAT should be deferred for 120 days
(c) Live donors who report a post-donation febrile illness with headache, eye pain, body aches, generalized weakness, new skin rash, or swollen lymph nodes within 2 weeks of donation during WNV season should be tested with WNV IgM and NAAT
3. Obtain WNV IgM and NAAT for SOT recipients with febrile illnesses if WNV is suspected
4. Deceased donors who are WNV NAAT positive prior to organ harvesting:
(a) Consider transplantation only in emergent, life threatening situations
(b) Counsel patient and family with regard to risks of transplantation of potentially infected organ

Reproduced with permission from Singh and Levi [162], © 2013, with permission from John Wiley and Sons

ing donors for organ transplantation or taking care of transplant recipients need to carry a high index of suspicion for WNV infection when the patient presents with a febrile illness and neurological symptoms, especially during the peak season of transmission in endemic areas.

Vaccines

Currently, several WNV vaccines have been licensed for use in horses, but none is available for human use. Various strategies have been employed to develop WNV vaccines and several human vaccine candidates have entered or completed phase I and/or phase II clinical trials. For example, a live, attenuated chimeric vaccine, ChimeriVax-WN02, was tested in a phase II randomized, double-blind, placebo-controlled trial. This vaccine was produced by insertion of the WNV genes encoding proteins prM and E in a yellow fever vector and was found to be highly immunogenic and generally well-tolerated [163–165]. A DNA vaccine encoding prM and E was also tested in a phase I clinical trial. It was generally well-tolerated and able to elicit T-cell response in healthy human subjects [166]. Other than attenuated chimeric vaccines and DNA vaccines, other approaches include vector-based vaccines, such as canarypox or vesicular stomatitis virus vectors that express prM and E, as well as live-attenuated WNV vaccines [167]. Universal WNV vaccination in the USA is not likely to be cost-effective, given the sporadic nature of WNV infection. However, certain high-risk patients, such as those with immunodeficiency and/or residence in endemic areas, may benefit from a safe and effective WNV vaccine.

Conclusion

WNV remains an important threat to public health, whereas effective treatment and vaccines for this virus are currently not available. While sporadic cases and outbreaks of WNV disease features interplay of multiple factors that are often unpredictable, surveillance systems at national level such as ArboNET; state, and local levels are expected to play a vital role in monitoring WNV disease activity. This in turn heightens public awareness and allows appropriate public health responses to be administered in a timely manner. Physicians need to be aware of the local WNV activities and become familiar with the clinical syndromes of WNV disease, in particular, the lack of easily recognizable signs and symptoms of infection in the immunocompromised patients undergoing transplantation.

List of Abbreviations

AIDS	Acquired immune deficiency syndrome
APMV-1	Avian paramyxovirus 1
ATL	Adult T-cell leukemia
CDC	US Centers for Disease Control and Prevention
cDNA	Complementary DNA
CHIKV	Chikungunya virus
CMV	Cytomegalovirus
CSF	Cerebrospinal fluid
DENV	Dengue virus
DF	Dengue fever
DFA	Direct fluorescent antibody
DHF	Dengue hemorrhagic fever
DNA	Deoxyribonucleic acid
DSS	Dengue shock syndrome
FLAIR	Fluid-attenuated inversion recovery
GVHD	Graft-versus-host disease
HAM	HTLV-associated myelopathy
HBoV	Human bocavirus
HCV	Hepatitis C virus
HEV	Hepatitis E virus
HFRS	Hemorrhagic fever with renal syndrome
HHV-8	Human herpes virus 8
HIV	Human immunodeficiency virus
hMPV	Human metapneumovirus
HPS	Hantavirus pulmonary syndrome
HSCT	Hematopoietic stem cell transplant
HTLV-1	Human T-cell leukemia virus 1
HYSV	Huaiyangshan virus
Ig	Immunoglobulin
IHC	Immunohistochemistry
IV	Intravenous
IVIG	Intravenous immunoglobulin
JEV	Japanese encephalitis virus
LCMV	Lymphocytic choriomeningitis virus
MDMA	3,4-methylenedioxymethamphetamine (ecstasy)
MMLV	Moloney murine leukemia virus
MMR	Measles, mumps, and rubella vaccine
NP	Nasopharyngeal
OPO	Organ procurement organization
OPTN	US Organ Procurement and Transplantation Network
PARV4	Parvovirus 4
PBMC	Peripheral blood mononuclear cell
PCMV	Porcine cytomegalovirus
PCR	Polymerase chain reaction
PEP	Postexposure prophylaxis
PERV	Porcine endogenous retrovirus
PLHV	Porcine lymphotropic herpesvirus
RDA	Representation difference analysis
RNA	Ribonucleic acid
RSV	Respiratory syncytial virus
RT-PCR	Reverse transcription polymerase chain reaction
RVFV	Rift Valley fever virus
SARS	Severe adult respiratory syndrome
SFTSV	Severe fever with thrombocytopenia syndrome virus
SISPA	Sequence-independent single-primer amplification
SME	Subacute measles encephalitis
SOT	Solid organ transplant
TBEV	Tick-borne encephalitis virus
TNF	Tumor necrosis factor
TTV	Torque teno virus
USUV	Usutu virus
WNV	West Nile virus
XMRV	Xenotropic murine leukemia virus-related virus
YFV	Yellow fever virus
ZIKV	Zika virus

Introduction

An emerging infectious disease, as defined by the Institute of Medicine and adopted by the CDC, is an infectious disease whose incidence in the human population has increased in the preceding two decades or threatens to increase in the near future [1, 2]. Viral diseases account for a large proportion of such infections, and the emerging viruses are typically divided into two groups: (1) newly identified viruses and (2) previously recognized viruses with an apparent increase in disease incidence [3, 4]. When applied to the transplant population, this second category can include agents with no recognized pathogenicity in the immunocompetent patient and those that result in atypical, more frequent, or more severe disease presentations in the immunocompromised host [5].

In this chapter, we will begin by discussing viral diagnostics and the rapidly evolving field of viral discovery, which has increased the speed of virus identification but has brought along new challenges for clinicians and researchers. Our focus then shifts to discussing specific emerging and re-emerging viral pathogens in the transplant community (see Tables 45.1 and 45.2). A number of emerging viral pathogens in the transplant population are discussed in detail in other chapters throughout this text (human herpes virus 7, human metapneumovirus, hepatitis E virus (HEV), novel polyomaviruses, and non-SARS coronaviruses) and will not be covered further here. Recent reviews in the literature have also discussed the topics of emerging viral infections in transplant recipients generally [4–10], as well as in solid organ transplant (SOT) [11] and hematopoietic stem cell transplant (HSCT) recipients specifically [12].

Following the discussion of emerging viral pathogens identified in the transplant community, we will briefly discuss global emerging viral pathogens, including flaviviruses, alphaviruses, bunyaviruses, and filoviruses. Given the nature of many of these pathogens, including their endemic ranges or relatively recent identification, few, if any, reports exist on their presentation in transplant recipients. Finally, we discuss the special situation of xenotransplantation and the reporting of suspected emerging viral diseases.

Table 45.1 Rare and emerging viral infections in the transplant population: case series or multiple cases reported [10]

Species	Virus family	Transplant	Clinical manifestations	Comments
HTLV-1	*Retroviridae*	SOT and HSCT; donor-derived infections reported	Adult T-cell leukemia and HTLV-1 associated myelopathy	Associated with lower survival after HSCT from HTLV-1+ donor
Rabies	*Rhabdoviridae*	SOT, ileac artery graft, cornea transplants; all cases donor-derived	Fatal encephalitis; cornea transplants present with pain in eye with graft	Survivors reported: cornea transplant with immediate PEP; liver transplant 20 years after vaccination; two exposed cornea transplants, grafts negative by RT-PCR
LCMV and a novel arenavirus	*Arenaviridae*	SOT; all reported cases donor-derived	Fever, abdominal pain, nausea, vomiting, diarrhea, altered mental status; often peri-incisional rash and tenderness	14 of 17 patients died; ribavirin employed but effect unclear; three cornea transplants unaffected; evidence of LCMV in donor rarely found
Measles	*Paramyxoviridae*	SOT and HSCT	Occasional clinical measles; SME (afebrile, altered mental status, intractable seizures); interstitial pneumonia	SME fatal in 4/6 transplant patients; case series suggest severe measles represents minority of cases in transplant patients
Mumps	*Paramyxoviridae*	SOT and HSCT	Parotitis, orchitis, vestibular neuronitis, and renal allograft involvement (SOT); fatal encephalitis (HSCT)	Three cases in SOT, all renal transplant patients and all survived; single case in HSCT
Dengue	*Flaviviridae*	SOT and HSCT	Dengue fever, severe dengue including hemorrhagic fever and shock; single case of colitis reported	Dengue shock associated with high mortality; rates of severe dengue differ in case series
Orf	*Poxviridae*	SOT; infected from contact with infected sheep	Giant and recurrent skin lesions on hands and forearms	Often misdiagnosed and treated with excision or amputation; case reports document responses to cryotherapy, cidofovir cream, or imiquimod
Bocavirus	*Parvoviridae*	SOT and HSCT	Associated with LRTI in young children; disseminated infection in transplant patients documented	Clinical significance of infection or reactivation in the immunocompromised patient remains unclear; no treatment available
Parvovirus 4	*Parvoviridae*	SOT	Associated with "viral syndrome" or early HIV; detected in renal and lung transplant recipients	Clinical significance in the immunocompromised patient remains unclear, thus far not associated with disease

Reprinted from Waggoner et al. [10], by permission of Oxford University Press

HSCT hematopoietic stem cell transplant, *HTLV-1* human T-cell leukemia virus 1, *IVDU* intravenous drug users, *LCMV* lymphocytic choriomeningitis virus, *LRTI* lower respiratory tract infection, *PEP* postexposure prophylaxis, *SME* subacute measles encephalitis, *SOT* solid organ transplant

Table 45.2 Rare and emerging infections in the transplant population: single cases reported [10]

Species	Virus family	Transplant	Clinical manifestations	Comments
APMV-1	*Paramyxoviridae*	HSCT	Fatal pneumonia; no other pathogens identified	Known pathogen in birds; tested in virotherapy for certain malignancies
Chikungunya	*Togaviridae*	SOT	Fever, headache, abdominal pain; no arthritis or arthralgia; recovered fully	Identified in four corneal grafts during Reunion outbreak, no transplant cases reported
Monkeypox	*Poxviridae*	HSCT	Fever and headache followed by characteristic rash (similar to smallpox)	Clinical course not reported as severe, patient recovered, though full details not reported
Usutu virus	*Flaviviridae*	SOT	Fever and headache; recovered but required prolonged rehabilitation	Viremic prior to developing liver failure and receiving liver transplant
Hantavirus	*Bunyaviridae*	SOT	Fever, headache, arthralgia, oliguric renal failure	Dobrava-Belgrade virus isolated (mild HFRS), no cases of HPS reported

Reprinted from Waggoner et al. [10], by permission of Oxford University Press
APMV-1 avian paramyxovirus 1, *HFRS* hemorrhagic fever with renal syndrome, *HPS* hantavirus pulmonary syndrome, *HSCT* hematopoietic stem cell transplant, *SOT* solid organ transplant

Methods

The body of literature referenced in this chapter is no doubt fraught with bias as it is largely based on case reports and small case series. Our understanding of most of these emerging viral infections, including their incidence, clinical manifestations, diagnosis, and management, in the immunocompromised host is limited, and larger, prospective studies in endemic areas are necessary. With the increasing number of transplants, both SOT and HSCT, performed globally, any description of emerging viral infections in this population will require frequent monitoring and updating. For the purposes of this chapter, we performed searches of the medical literature in PubMed, limited to studies reported in English. Searches were performed through May of 2016, using the name of the virus family, genus, or species of interest matched with the search terms "transplant," "transplant*," and "immunocompromised." We also performed general searches for emerging viruses and transplant recipients to identify case reports of novel or rare pathogens causing disease in transplant recipients. Finally, we included pertinent references from the publications identified during our search. With rare exceptions, we excluded reports involving only patients with HIV or AIDS.

Viral Discovery and Disease Association

Clinical virology laboratories affiliated with transplant centers typically employ a range of techniques for the diagnosis of viral infections from patient samples as well as for the quantitation and resistance testing of certain viruses. These techniques include, but are not limited to, viral culture, serology, antigen detection, direct fluorescent antibody staining (DFA), polymerase chain reaction (PCR) and reverse-transcription PCR (RT-PCR), and sequencing of certain pathogens (particularly HIV). While viral diagnostics are discussed in detail elsewhere in the text, we will briefly discuss these tests in the context of emerging viral infections followed by a discussion of newer technologies employed in viral discovery.

Viral culture provides a semi-unbiased technique for virus identification from patient samples, though this is a labor-intensive process and often requires days to weeks to detect viral growth. Many viral pathogens do not grow well, or do not grow at all, in cell culture, and viral detection is limited by the range of cells on which a given virus will grow and the number of cell lines a given lab can maintain. Even when cytopathic effect develops in a cell monolayer, the virus has to be identified by other means (often DFA or PCR). The majority of the viruses discussed in this chapter are diagnosed by other means, though agents such as lymphocytic choriomeningitis virus (LCMV) and dengue can be grown in culture as well [13, 14].

The other testing modalities routinely offered in a clinical virology lab, or even specialized tests performed at state and national reference laboratories, utilize conserved sequences (in the case of PCR or RT-PCR) or specific antigens or antibodies to detect the causative virus in patient samples. Hence, pathogen detection is limited by the knowledge and judgment of the ordering clinician or the available tests. The increasing use of multiplex testing for clinical syndromes, particularly for respiratory tract infections, will allow for a less biased approach to viral diagnosis but still faces limitations in identifying rare or emerging pathogens [15]. It should be noted that in very rare situations, as in the case of Usutu virus (USUV) discussed below, an unusual or novel pathogen may be detected by testing for known pathogens. In this case, a woman presented with USUV viremia, which gave a low-positive result by WNV PCR and was eventually identified by sequencing [16].

Viral discovery has typically relied on the replication of a new virus in cell culture. Despite the aforementioned limitations of viral culture, this technique remains useful, as indicated by the identification of two novel bunyaviruses, Huaiyangshan virus (HYSV, also known as severe fever with

thrombocytopenia syndrome virus, SFTSV) in China and Heartland virus [17, 18] A number of more rapid molecular methods are now being employed in viral discovery; however, these are typically categorized as sequence-dependent (such as the pan-viral microarray or PCR based on conserved sequences) or sequence-independent techniques [19]. The pan-viral microarray (Virochip) is an array spotted with oligonucleotide sequences representing all known viral pathogens. Novel viruses can also be identified if there is sufficient similarity between sequences in the new virus and those included on the array. Amplicons can be then be recovered from the array, cloned, and sequenced [20]. This technology has been used in the identification of the SARS coronavirus, XMRV, and was also tested as a means to rapidly identify the 2009 pandemic influenza strain (H1N1) [19, 21]. PCR based on conserved sequences is possible but generally has limited applicability in viral diagnostics, as viruses do not contain highly conserved sequences analogous to the 16s ribosomal sequences utilized in bacterial identification [22]. One example of this is the performance of PCR using primer sets that amplify members of a virus family followed by sequencing, as reported in the identification of USUV from patient samples using a pan-flavivirus RT-PCR [16, 23].

The sequence-independent amplification and sequencing of nucleic acids in biological fluids or environmental samples has been termed viral metagenomics [19, 24]. Sequence-independent approaches include subtractive hybridization or representation difference analysis (RDA), sequence-independent single–primer amplification (SISPA), rolling circle amplification, and next-generation sequencing. Subtractive hybridization or representational difference analysis (RDA) uses infected and uninfected samples from an individual patient. Viral nucleic acid is selectively concentrated by repeated rounds of hybridization and purification of the unhybridized, single-stranded nucleic acid molecules, which are then subcloned and sequenced. These techniques have been used in the identification of human herpes virus 8 (HHV-8) and the torque teno viruses (TTV), but they require large amounts of starting material as well as relatively high virus levels [19, 22, 25]. SISPA circumvents the need for large amounts of viral genomic material. This technique, introduced in 1991, and its derivations involve the attachment of a linker/primer to blunt-ended nucleic acid and the subsequent amplification of all nucleic acid present, followed by cDNA library creation and sequencing [26]. SISPA was utilized in the identification of HEV, Norwalk virus, and Parvovirus 4 [22, 27]. Rolling circle amplification involves the use of the PhiX29 polymerase primed with random primers to amplify circular viral genomes or cloned fragments. It was used in the identification of human bocavirus (HBoV) among others [19, 28].

Viral metagenomics has been aided in the last few years by the development of a number of new sequencing platforms. Termed "next-generation sequencing" or "deep-sequencing," such technologies allow for the rapid and parallel generation of one million to over one billion sequences per run. Most of the current technologies rely on the non-specific amplification of DNA or RNA molecules followed by sequencing by synthesis using different technologies to detect base incorporation [22, 24, 29, 30]. Recently, single-molecule sequencing has become available, and this technology continues to develop, resulting in a greater number of reads (i.e., deeper sequencing) and longer read lengths [30]. These technologies are able to detect viral copy numbers near the limit of detection for specific quantitative PCR assays and have been shown to be more sensitive than microarray analysis (2 per 10^6 versus 1 per 10^5 sequences in one study) [31, 32]. Next-generation sequencing has been utilized to identify novel viruses in patient samples (see arenaviruses below) and determine the cause of fevers of unknown origin [32–35]. The potential utility of direct sequencing in the outbreak setting has also been shown following the 2009 influenza pandemic [21].

Deep sequencing, to the extent that it is sensitive and sequence-independent, has a great ability to detect both known and previously unknown (divergent) viruses as well as provide phylogenetic information. What it cannot do, however, is demonstrate causation. For many of these viruses, classical Koch's postulates cannot be applied, and as recently demonstrated in the cases of TTV, GB virus C, and human bocavirus (HBoV), establishing a causative role for many of these agents can be difficult [22, 25, 36]. Mokili and colleagues have instead proposed an approach they call "Metagenomic Koch's Postulates," but whether they are sufficient remains a matter for discussion [22].

At this time (and for the near future), next-generation sequencing remains a tool for research purposes rather than clinical diagnostics. Sequencing reactions take a good deal of time to set up and perform, with run times between 12 h and 14 days [29]. These runs also generate massive amounts of data that must be filtered to remove human and low-complexity sequence prior to analysis using various alignment programs designed to handle the large numbers of short reads [29, 32]. Finally, results must be interpreted carefully, as contaminants from the laboratory and even from commercial reagents, such as Moloney murine leukemia virus (MMLV, from polymerase preparations), are often identified [21, 32]. Confirming the presence of a virus identified with small numbers of sequences can also be difficult. In the study of metagenomics following the 2009 influenza pandemic, one patient from British Columbia was found to have two sequences matching an Ebola Sudan isolate, and during the evaluation of children in Nicaragua with fevers of unknown origin, a child had sequence similar to African swine fever virus [21, 32]. Run-time and data management and analysis will need to be streamlined before such technology will be applicable for relatively routine use in a clinical laboratory.

Emerging and Re-emerging Pathogens

Human T-Cell Leukemia Virus Type 1

Human T-cell leukemia virus type 1 (HTLV-1) infection is endemic in Japan, West Africa, South America, the Middle East, and the Caribbean with seroprevalence ranging approximately from 3% to 30%, while in western countries <1% are infected [37]. Most of the millions who are affected acquired their infections vertically via breast milk, but this retrovirus may also be transmitted by blood transfusion, sharing of needles, and organ transplantation. A number of complications are associated with chronic HTLV-1 infection, most frequently adult T-cell leukemia (ATL) and HTLV-associated myelopathy (HAM), which occur in 5% or fewer of those infected. Immunosuppression administered to transplant recipients who are HTLV-1 carriers may trigger progression to these known complications of the infection (for a brief summary, see Table 45.1) [38–40]. Numerous reports document the devastating clinical impact of ATL and HAM from HTLV-1 infection in solid organ transplant recipients [38, 41, 42]. The majority of these cases are from Spain and Japan, though additional reports in the United States have surfaced in recent years involving donors and recipients with expected epidemiologic risk factors (i.e., residence in endemic regions) [43, 44].

Complications from HTLV-1 can be a result of reactivation disease in HTLV-1/2 seropositive recipients, de novo primary infection, and donor-derived infection in organ transplant recipients. In a nationwide survey in Japan, Yoshizumi et al. identified 82 living donor liver transplant recipients who were HTLV-1 positive prior to transplantation. ATL developed in 5 of these 26 (15.4%) after intervals of 181–1315 days after transplantation. All five died, four due to ATL and one due to rejection after reduction in immunosuppressive therapy. In a compelling case series of donor-derived HTLV-1 infection, liver and two kidney recipients from HTLV-1 seropositive donor were acutely infected with HTLV-1 with rapid dissemination early in the posttransplant period. HTLV-1 provirus was detected by PCR on days 16–23 and increased by 2–3 logs by day 38–45, after which steady state was reached. HTLV-1 antibodies were first detected between 16 and 39 days following transplantation. Alignment of the HTLV-1 5′ LTR of the donor and the three recipients showed 100% sequence identity consistent with a common viral source of infection. Though no cases of early onset or rapid progression of HAM were observed in this series, in another case series, all three HLTV-1-negative recipients of organs from a single HTLV-1-positive donor (two kidney transplants and a liver transplant) developed antibodies to the retrovirus and developed HAM within the 2 years of transplantation. HTLV-1 isolates from these three recipients were homologous to the donor isolate by DNA sequencing [45, 46]. Two case reports also document the occurrence of HAM in a heart transplant recipient and an HSCT recipient who both acquired HTLV-1 through blood transfusions [39, 47].

Despite these case examples, clinical disease due to HTLV-1 occurs infrequently after solid organ transplantation, even in endemic regions with high seroprevalence [38, 41, 42]. Shirai et al. reviewed the courses of nine HTLV-1-positive patients who underwent renal transplantation with basiliximab (anti-CD25) induction together with corticosteroids, mycophenolate mofetil, and cyclosporine or tacrolimus. No patient developed ATL or HAM during follow-up of approximately 5 years, although one patient died of aspiration pneumonia 17 days after transplantation [48]. A previous study also found no cases of ATL in 16 HTLV-1-positive kidney transplant recipients after up to 10 years of observation, at which point patient survival was 81%. Patient and graft survival were not significantly different from HTLV-1 negative patients [49]. Smaller reports from western Japan (10 patients with up to 17 years of follow-up) and Iran (10 patients with up to 6 years of follow-up) presented similar findings [50, 51].

While screening of donors may prevent the transmission of HTLV-1 to recipients, the demand for organs may override this concern, even in highly endemic areas such as certain regions of Japan. In regions with low rates of infection, screening of all donors generates many false positives, resulting in delays in transplantation or the loss of potential organs for donation. Following the three cases of donor-derived HTLV-1 infection in Spain, 2870 potential organ donors and recipients were screened for antibodies to HTLV-1, including 1079 immigrants. Only five patients tested positive (confirmed by Western blot), and all of them were immigrants from South America or Africa [52]. The practice of universal HTLV-1 screening is no longer recommended by the United States Organ Procurement and Transplantation Network (OPTN) [37, 53]. However, targeted screening for HTLV-1/2 seropositivity by organ procurement organizations (OPO) may be encouraged in high-risk living and deceased donors based on local prevalence data [43, 54].

HSCT has been used in the treatment of ATL in HTLV-1-positive patients, but since leukemia is a known complication of HTLV-1 infection, it can be asked if HSCT is safe and effective in such patients. Near relatives are the preferred sources of stem cells for transplantation, but in endemic areas, such individuals are also frequently infected with this retrovirus. The largest study addressing this question involved a retrospective analysis of data from three centers in Japan. In this study, 386 patients with ATL underwent allogeneic HSCT with a 3-year survival rate of 33%. Unfortunately, those who received their transplant from a related HTLV-1-positive donor had a higher risk of disease-associated mortality relative to those whose related donor

was HTLV-1 negative. HSCT recipients in complete remission at the time of transplantation had a higher rate of survival compared to patients not in complete remission (51% versus 26%). These results likely account for the finding that patients who received an HSCT from matched unrelated donors did as well as those from matched related donors (3-year survival, 39% versus 41%) [55]. No proven effective therapy for HAM exists. Some experts suggest antiviral prophylaxis with zidovudine and raltegravir, but antiviral therapy drugs are generally believed to have little effect on HTLV-1 because it is a cell-associated virus and proviral load is predominantly maintained by cell division of infected cells rather than free viral replication. Furthermore, definitive long-term benefits of interferon and corticosteroids have yet to be established [43].

Rabies Virus

Rabies virus is a member of the *Rhabdoviridae* family of RNA viruses and is one of seven species belonging to the genus *Lyssavirus*. All of these viruses except for Lagos bat virus have resulted in fatal human disease, but at this time, only rabies has been reported in the transplant population [56]. Rabies virus is typically acquired in humans through the bite of an infected animal. It is estimated that over 55,000 cases occur annually, worldwide, and most result from the bite of an infected dog [56, 57]. In countries where canine vaccination is routine, bites from insectivorous bats have emerged as the most common source [57]. Rabies infection results in an encephalitis that is nearly universally fatal unless the patient has been vaccinated or receives postexposure prophylaxis (PEP). Limited data suggest that some individuals can survive rabies exposure without intervention, including a single case in the United States and serologic data from humans in the Peruvian Amazon, but these cases appear to be rare [58, 59].

Sixteen cases of rabies have been reported in transplant recipients, and to date, all of these cases have been transmitted through the transplanted tissue or organ (Table 45.1) [60–70]. Houff et al. first reported the transmission of rabies through a corneal graft in 1979 [66]. Since that time, eight other cases of rabies transmission have occurred through corneal transplantation. In seven of these nine cases, the cornea recipients presented with neurological symptoms within 40 days of their surgery and died soon after admission. Symptoms often included significant pain involving the eye that received the transplant [61, 62, 65–67]. In a case from France, reported in 1981, a patient exposed to rabies through corneal transplant survived after receiving PEP on the first postoperative day [70]. A second corneal transplant recipient, documented in a report from India, received partial PEP but then refused further treatment. He developed rabies 9 months after transplant and died shortly thereafter [67].

Three clusters of rabies cases have occurred following solid organ transplantation. The first four cases occurred in Texas in 2004 [63, 64, 69]. Rabies developed following the transplantation of the liver, both kidneys, and an iliac artery graft from an Arkansas man who died after being diagnosed with a subarachnoid hemorrhage. All four patients developed encephalitis within 30 days of transplantation and died between 7 and 23 days later. The diagnosis was confirmed by serology in the three recipients, immunohistochemistry (IHC) staining of pathological samples, and viral isolation in cell culture. During the follow-up investigation, it was determined that the donor had been bitten by a bat shortly before organ donation [69].

The second cluster of cases occurred in Germany in 2005 but was not widely published until 2010 [71–73]. Six patients were potentially exposed to rabies virus following the death of a 26-year-old woman, who died after presenting with altered mental status. She had reportedly consumed cocaine, amphetamines, and MDMA before her admission, developed cerebral edema, and was declared brain dead. During a contact investigation after the report of cases, it was discovered that she had been bitten by a dog on a recent trip to India. PEP was administered to all six transplant recipients (lung, liver, kidney, kidney-pancreas, and both corneas), though not until at least 45 days after transplantation. The recipients of lung, kidney, and kidney-pancreas transplants died of rabies. Antiviral treatment was administered (with ribavirin and interferon) in these three cases as well as in the case of the liver transplant recipient. The lung recipient died on posttransplantation day 49 despite the initiation of deep sedation with ketamine and midazolam. The kidney transplant recipient died on day 52 despite the addition of amantadine but not deep sedation. The kidney-pancreas recipient was also treated with deep sedation starting with midazolam followed by ketamine and phenobarbital. Brain death was declared after 9 weeks and supportive measures discontinued. The liver transplant recipient had been vaccinated against rabies over 20 years before transplantation and never developed disease [71, 72]. Both corneal grafts were explanted, but rabies virus was not detected in either cornea by RT-PCR. It has been suggested that the lack of rabies in these corneal grafts was the result of the limited excision procedure performed such as subcorneal complex excision rather than enucleation and the prolonged storage of the grafts prior to transplant for 5 days [72, 73].

In 2013, another case of transplant-transmitted rabies was identified in the United States. Signs and symptoms of rabies developed in a deceased-donor kidney recipient, a Maryland native, 17 months after transplantation, who ultimately died from rabies 3 weeks after hospitalization. Given lack of epidemiologic risk factors, an exploration of donor transmission was sought. In addition to a clinical presentation consistent with rabies in the organ donor, a raccoon rabies virus variant

more than 99.9% identical across the entire N gene was identified in both the organ donor and the infected recipient. The genetic sequence was also closely associated with a raccoon variant circulating in North Carolina, the donor's state of residence [74]. Three unvaccinated recipients of organs (kidney, liver, and heart) from the same donor were asymptomatic when rabies was diagnosed in the donor. PEP with rabies vaccination and immunoglobulin was initiated in these asymptomatic organ transplant recipients, and protective neutralizing antibodies developed in all three [75].

As mentioned previously, the management of rabies focuses on prevention either with vaccination in high-risk patients or PEP following an animal bite. Three individuals have apparently recovered from rabies (diagnosed by antibody testing) without receiving either intervention. These have all been young women (aged 8, 15, and 17), and two patients received treatment with what is now called the Milwaukee protocol (named after Milwaukee, WI), which includes a prolonged therapeutic coma, antiviral therapy, management of vasospasm, and avoidance of prophylaxis [58, 76, 77]. To date, 30 patients have received the Milwaukee protocol, but only one other patient has survived to hospital discharge [78, 79]. This patient had received partial PEP, however [78]. In two reports (one case report and a case series of eight patients), transplant recipients who received rabies PEP appeared to mount an adequate response (antibody titers of 0.5 IU/mL), though titers were lower than those seen in immunocompetent patients [80–82]. Rodriguez-Romo et al. reported the case of a kidney transplant recipient who received two courses of PEP after being bitten by a rabid dog. Following the first course, adequate antibody titers developed but then declined. A second PEP course was administered along with a reduction in immunosuppression; he maintained an adequate antibody level and remained asymptomatic [81]. Taken together, these data indicate that rabies vaccination can be effective, even after transplantation, and PEP may be safe and effective in transplant recipients.

Lymphocytic Choriomeningitis Virus and the Arenaviridae

Lymphocytic choriomeningitis virus (LCMV) is a member of the Old World complex of *Arenaviridae*, a family of viruses that also contains important hemorrhagic fever pathogens endemic in Africa and South America. LCMV was the first isolated arenavirus, identified in 1933 during an outbreak of St. Louis encephalitis [83]. Infection with LCMV in the immunocompetent host is often mild or asymptomatic. Symptomatic infections present as aseptic meningitis, but the mortality in immunocompetent patients is <1%. In the largest recorded outbreak, 181 cases were documented in the United States associated with pet hamsters. While 46 patients were hospitalized, no one died [83–85].

In contrast to the clinical course of infection in immunocompetent patients, five clusters of cases following LCMV transmission through organ transplantation (including 17 cases and 12 deaths) document the ability of this pathogen to cause severe disease in transplant recipients (Table 45.1) [13, 33, 86–88]. Another cluster of cases involved the transmission of a newly identified arenavirus in Australia (three patients, all of whom died) [33]. As in rabies infections documented in transplant recipients, all of these cases resulted from human-to-human transmission through organ transplantation [13, 33, 86, 87]. At this time, cases acquired following transplant by exposure to rodents and their excreta have not been described. Also, cases have not been described in the HSCT population.

All five reported case clusters of LCMV infection occurred in SOT recipients in the United States (ten kidney, four liver, and three lung transplants). The first set of cases took place in 2003 in Wisconsin (four cases, four deaths), followed by clusters in 2005 in Massachusetts and Rhode Island (four cases, three deaths), 2008 in Massachusetts (two cases, two deaths), 2011 in Arkansas (four cases, two deaths), and 2013 in Iowa [13, 86–88]. Symptoms developed between 2 and 23 days posttransplant and included fever, abdominal pain, nausea, diarrhea, and altered mental status occasionally accompanied by seizures. A number of patients also developed a peri-incisional rash and tenderness. Laboratory findings included increased transaminases and creatinine. Both leucopenia and leukocytosis occurred. CSF findings included elevated protein (often marked), normal to low glucose, and a mild pleocytosis. The diagnosis of LCMV was confirmed in all patients using IHC on tissue samples or RT-PCR on tissue and serum samples. Serology was performed less frequently and was often negative. Bronchopneumonia or diffuse alveolar damage and hepatic inflammation or necrosis were the most common findings at autopsy [13, 86, 87, 89].

Five patients survived LCMV infection following SOT, including four kidney transplant recipients and a single liver recipient. One kidney transplant patient received treatment with ribavirin starting on posttransplant day 26 (2005 cluster) and survived, though a second kidney transplant recipient was treated with ribavirin (2008 cluster, starting 6 weeks posttransplant) and died [13, 86]. Similarly, in the 2013 cluster, all three recipients received ribavirin therapy, and two also received intravenous immunoglobulin starting 6 weeks posttransplant, with survival in the two kidney recipients and death in the liver transplant recipient [88]. The two other survivors (2011 cluster) recovered without antiviral therapy [87]. Ribavirin has been shown to be clinically effective in the early treatment of Lassa fever, a related Old World arenavirus, but data for efficacy in the treatment of LCMV is lacking [90]. Four corneal transplant recipients were also
