potentially exposed to LCMV in these clusters, though none of them developed symptoms or seroconverted (two recipients in 2005 and a single recipient in 2011). The second cornea removed from the 2011 donor was never transplanted. This tissue tested negative for LCMV by IHC and RT-PCR [13, 87].

Contact investigation following these cases revealed exposure to rodents for two of the donors: a pet hamster (2005 donor) and rodent infestation of the home (2011 donor) [13, 87]. No definitive evidence of rodent exposure was discovered for the 2013 donor, although he had spent substantial time outside along the Mississippi River. Three of the donors also had positive LCMV testing: detectable IgM and IgG in archived serum from the day before death (2008 donor), a positive RT-PCR from a single lymph node (2011 donor), and a positive RT-PCR from aortic endothelial cells (2013 donor) [86–88]. Investigation into the 2003 donor revealed no clear exposure history and serology, viral culture, and IHC performed on other tissues collected at the time of donation were all negative [13, 91]. Likewise, all diagnostic testing (including RT-PCR) performed on stored samples from the 2005 donor was negative, and all further testing performed on samples from the 2011 donor was negative (including other lymph nodes) [13, 87]. It has been advised that immunocompromised patients avoid contact with rodents, including pets [92, 93]. While this recommendation seems intuitive, this was not the mode of acquisition in these outbreaks, and it is unclear to what extent this will prevent future LCMV cases in transplant recipients.

An additional cluster of arenavirus cases occurred after the transplantation of the kidneys and liver from a single donor to three recipients in Australia in 2007. Patients developed fever, altered mental status, pulmonary infiltrates, and graft rejection soon after transplant, and they died between 29 and 36 days posttransplant. While their clinical course is not discussed in great detail, it sounds similar to that described for LCMV. The agent was identified by next-generation sequencing (Roche, 454 pyrosequencing) as Dandenong virus following random primer amplification. Sequences were consistent with an arenavirus, though certain segments were closest to LCMV and others more closely resembled Kodoko virus (isolated in African wild mice) [33].

It has been noted that the clinical disease caused by LCMV and this newly identified arenavirus are more similar to the severe illnesses caused by the other Old World arenaviruses, Lassa and Lujo viruses, and the New World arenaviruses such as Junin, Machupo, and Guanarito viruses [91]. Infection with any of these pathogens can result in a viral hemorrhagic fever with varying degrees of encephalopathy [83, 90]. Cases of Lassa, Lujo, and New World arenavirus infections have not been described in immunocompromised patients, however. This absence of reporting may result from the relatively defined areas of endemicity for each virus as well as the limited number of transplants that are performed in those regions. Another possible explanation may stem from the unusual mode of transmission that leads to severe LCMV infection after SOT.

Human Bocavirus and Parvovirus 4

Human bocavirus (HBoV) and Parvovirus 4 (PARV4) are newly identified members of the *Parvoviridae* family of DNA viruses, subfamily *Parvovirnae*. Prior to their discovery, the only parvovirus known to infect humans was parvovirus B19. Both of these agents were identified in 2005, though there is a greater amount of clinical information on HBoV currently than PARV4 [27, 28, 94].

HBoV was initially detected in the nasopharyngeal (NP) aspirates of children with respiratory tract infections. Allander et al. randomly amplified DNA and RNA from these samples, followed by cloning and sequencing. This identified sequences similar to members of the genus *Bocavirus*, named for the type species *bo*vine parvovirus and *ca*nine minute virus. They then showed that 17 pediatric patients (of 540 screened) had HBoV detectable by PCR, and in 14 of these patients, HBoV was the only pathogen detected. All patients had been admitted with respiratory distress and ten had fevers. The virus was also predominantly detected in the winter months (14 of 17) [28].

Since the original study, a number of reports have confirmed the association between HBoV detection and respiratory tract infections, along with the seasonality of detection [95–102]. The establishment of HBoV as a pathogen, however, has been complicated by the high rates of detection of co-pathogens along with HBoV (up to 90%), detection of the virus in asymptomatic patients (43% in one study from Canada), and significant difference in the study design of published reports, including different methods of sample collection (NP swab, NP aspirate, or bronchoalveolar lavage) and the extent to which other pathogens were excluded [36, 97, 100]. It does appear that HBoV causes a subset of respiratory tract infections, particularly among infants and young children (<2 years of age), and the use of quantitative PCR may be a means to identify these patients. A 5.7% prevalence of HBoV has been reported from testing over 1800 NP swabs from healthy children presenting with a respiratory illness over a 3-year period [103]. In a separate study by Allander et al., patients with high HBoV viral loads (>10^4 copies/mL) in NP aspirates were more likely to have an isolated HBoV infection (though 18 of 28 patients still had another pathogen detected) and often had concomitant viremia detectable by PCR [95]. One study also reported an association between high HBoV viral loads in NP aspirates with longer duration of hospitalization in healthy pediatric children presenting with a respiratory illness [103]. The detection of HBoV in

the blood is not necessarily surprising as other parvoviruses (B19 and PARV4) are also detected in this compartment. HBoV DNA has also been detected from stool, though its potential as a gastrointestinal pathogen is unclear [102].

The incidence and clinical manifestations of HBoV infections in the immunocompromised host have not been established (Table 45.1). In 2007, Schenk et al. reported the case of an HSCT recipient with disseminated HBoV infection. The patient was a 4-year-old boy who underwent HSCT and had a complicated hospital course including persistent fevers, which improved but did not completely resolve upon neutrophil engraftment, a lower respiratory tract infection, and diarrhea. HBoV was detected repeatedly from NP aspirates, serum, and stool, though its role in this case is complicated by the co-detection of rhinovirus from an NP aspirate, CMV reactivation, and grade I GVHD of the skin (no mention of path from the GI tract) [104]. In 2011, the same group reported on three more cases of immunocompromised patients (along with the case from 2007) with repeatedly positive tests for HBoV. These patients had virus detectable after weeks of isolation, often during the summer months, which supports the hypothesis that HBoV may establish latency and reactivate in the setting of a coinfection or impaired immunity [105]. Severe diarrhea was also reported in a 9-year-old transplant recipient (both liver and HSCT) associated with detectable HBoV in plasma and stool [106]. Other studies evaluating the role of HBoV as a respiratory pathogen in immunocompromised adults have detected the virus at low levels (or not at all) and have not documented a difference in outcomes between immunocompromised patients and immunocompetent controls [107–109].

Many significant questions remain regarding the significance of HBoV in the transplant population, both pediatric and adult. One seroepidemiologic study out of Japan showed that between 94% and 100% of individuals have been exposed to HBoV by 6 years of age [110]. If this virus establishes latency, most transplant recipients will be at risk to develop reactivation, but whether that results in disease or is simply a marker of severe immune suppression has yet to be determined. The reporting of HBoV will no doubt increase. There are a number of published PCR assays to use for detection, and at least one platform for multiplex respiratory pathogen detection includes HBoV in a panel of 21 agents [36, 111]. There is no specific antiviral treatment for HBoV at this time.

Much less clinical information on PARV4 exists. This virus was originally identified by SISPA from the serum of 1 of 25 patients presenting with an unidentified "viral syndrome" [27]. The virus has since been detected in a high percentage of patients who use IV drugs (30%) and patients with HIV-HCV co-infection (95%) [112, 113]. The clinical significance of these infections is unclear, though PARV4 may be associated with symptomatic early HIV infection [113]. One report also documents two cases of encephalitis of unclear etiology in children (2 and 3 years of age) where PARV4 DNA was detected in the CSF [114]. Studies in transplant recipients have documented PARV4 in 5 of 164 renal transplant recipients and 14 of 104 lung transplant recipients (Table 45.1). No associations with clinical outcome have been identified [112, 115].

Enterovirus D-68

Enterovirus D-68 (EV-D68) belongs to the family *Picornaviridae* and is the causative agent of an outbreak of severe respiratory illness in 2014 that began in the United States and spread to several countries around the world. EV-D68 was first identified in 1962 in four children suffering from pneumonia and bronchiolitis and, prior to 2014, detected in only a small number of patients [116]. The 2014 outbreak began concurrently in Kansas City, MO, and Chicago, IL, where an increase in hospitalizations for severe respiratory illness was noted in pediatric patients. Multiplex PCR assays detected an increase in rhinovirus/enterovirus in nasopharyngeal specimens. Evaluation by the CDC found 19 of 22 specimens from Kansas City and 11 of 14 specimens from Chicago positive for EV-D68. Of these 30 patients, 29 (96.7%) were admitted to the ICU and 6 (20.0%) required mechanical ventilation [117]. By the end of 2014, over 1100 cases of respiratory illness caused by EV-D68 had been *reported* in the United States, predominantly among children. Subsequently, more than 2000 cases of respiratory illness were attributed to EV-D68 in 20 countries worldwide [118, 119].

Though the manifestations of EV-D68 can be severe, EV-D68 more commonly causes an upper respiratory tract infection that does not require hospitalization. Factors that predispose to milder disease are incompletely understood, though several studies report asthma as a risk factor for ICU admission and need for mechanical ventilation [118, 120]. Concurrent with the respiratory outbreak, clusters of children with acute flaccid paralysis and severe neurologic disease were observed in the United States and Europe and attributed to EV-D68 given the temporal relationship of symptoms and detection of the virus in pharyngeal swabs [121]. EV-D68 has since been linked with acute paralytic poliomyelitis, encephalitis, myelitis, encephalomyelitis, or acute transverse myelitis [119]. As no specific vaccine or antiviral for EV-D68 exists, treatment of children with EV-D68 is mainly supportive and focused on symptom relief for fever and respiratory support if needed.

Few studies have evaluated the extent of EV-D68 infection in immunocompromised patients. Eight cases of EV-D68 in hematologic malignancy or HSCT recipients were found in one study, which retrospectively tested for the

presence of the virus in respiratory samples (n = 506) that had tested positive for human rhinovirus (HRV) or negative for all respiratory viruses in a multiplex panel collected over a 3-month period. Thirteen (11.5%) cases originally identified as HRV were subsequently characterized as EV-D68 with a specific PCR assay, highlighting the limited specificity of HRV primers and the potential for inaccurate diagnosis. Furthermore, of the 393 cases initially negative for all respiratory viruses, 8 (2%) were presumptive EV-D68. This has implications for infection control as patients with negative tests results would likely be removed from droplet isolation and theoretically could result in person-to-person transmission particularly among immunocompromised patients. The eight cases of EVD-68 in hematologic malignancy or HSCT recipients (51–1833 days from transplant) developed symptoms ranging from mild upper respiratory tract infection to respiratory failure [122]. Cases were not limited to children, as all were in immunocompromised adults aged 22–69 years old. At this time, cases of EV-D68 in solid organ transplants have yet to be reported in the literature.

Measles, Mumps, and the Paramyxoviridae

The family *Paramyxoviridae* contains a number of significant human pathogens and is divided into two subfamilies, *Paramyxovirinae* and *Pneumovirinae*. The major pathogens within the *Pneumonvirinae*, respiratory syncytial virus (RSV) and human metapneumovirus (hMPV), are discussed in detail elsewhere in this text. *Paramyxovirinae* contains five genera and includes measles (*Morbillivirus*) and mumps (*Rubulavirus*), the emerging pathogens nipah and hendra (*Henipavirus*), as well as the avian pathogen, avian paramyxovirus 1 (APMV-1, also known as Newcastle disease virus; *Avulavirus*). Measles and mumps are not typically considered emerging pathogens. However, the potential to cause severe disease in transplant recipients as well as the recent rise in incidence for both agents brings them into consideration here [123–131]. Nipah, hendra, and APMV-1 will also be discussed briefly.

Measles and mumps are both vaccine preventable illnesses and following the introduction of the MMR vaccine in 1967, there was a marked decrease in the incidence of these diseases in developed countries [125]. However, immunity can wane over time, even after the recommended two dose series in the immunocompetent patient. This decline in humoral immunity has been well documented in the transplant population, and even following repeat vaccination, response rates are suboptimal [132–135]. Repeat MMR vaccination posttransplant appears to be safe, and this topic will be covered in detail in a later chapter [133–135].

Severe disease in transplant recipients has more often been reported as a result of measles infection than mumps. The most significant manifestation of measles in this patient population is subacute measles encephalitis (SME, also reported as immunosuppressive measles encephalitis or measles inclusion body encephalitis), but severe cases of pneumonia and one case of liver transplant rejection possibly resulting from measles have also been reported (Table 45.1) [127, 129, 130, 136–142]. SME was originally documented in patients immunocompromised from chemotherapy or malignancy, and the disease was first reported in a renal transplant recipient in 1979 [127]. It has since been reported in other renal transplant recipients, though not always confirmed by IHC staining or RT-PCR, and a single patient following HSCT [129, 136, 141, 143]. Patients with SME may initially present with an illness compatible with measles, including fever, conjunctivitis, and a rash, though this is not consistent and typically is only recognized as measles in retrospect [127, 136, 139, 141]. Patients typically improve but then re-present with altered mental status and seizures between 2 weeks and 4 months after their initial illness. In a review of the literature, the range was 1–7 months, but this included predominantly nontransplant patients [129, 136, 139, 141]. At the time of admission for seizures, fevers are particularly uncommon, and CT imaging and CSF analysis are often normal. The first imaging changes are seen by MRI with increased signal intensity on FLAIR. The clinical course is one of deteriorating mental status and worsening seizures refractory to anti-epileptic drugs [127, 129, 136, 139]. Four of six transplant cases of SME died. The two survivors were reported in 2006 by Turner et al. Both cases occurred in pediatric renal transplant recipients, 6 and 11 years out from transplant. They both received one dose of IVIG and a course of IV ribavirin. Both of them survived, though both had significant neurological deficits [141]. A single case of SME occurred in a previously healthy boy following MMR vaccination, though during admission, he was found to have a primary immune deficiency [144].

The incidence of severe measles in transplant recipients is unclear as most of the data comes from case reports and reviews of the literature. In an attempt to answer this question, Machado et al. evaluated 156 HSCT recipients during the 1997 outbreak of measles in Sao Paolo. These investigators identified eight cases among 54 patients deemed to be susceptible (based on an IgG $\leq$ 100 mIU/mL), and notably, only one of them had severe disease, manifested as interstitial pneumonia. All eight patients survived [138]. It has been noted that the case definition, requiring a serological response (appearance of IgM or rise in IgG), may be too restrictive for HSCT recipients, resulting in a number of missed cases [145]. A second, short report by Lee et al. documented a fatal case of pneumonia in an HSCT recipient clinically diagnosed with measles during an outbreak in Korea from 2000

to 2001. At their center, they presumptively diagnosed 16 HSCT recipients with measles (methods not specified), with this as the only case of severe disease. The patient who died of pneumonia never developed detectable IgM or IgG [137]. The incidence of measles in SOT and HSCT recipients remains unclear, though given the 222 cases of measles in the United States and tens of thousands of cases in Europe in 2011, it is likely under reported [128, 131].

Five cases of posttransplant mumps infection have been documented, including three renal transplant recipients and two HSCT recipients (Table 45.1) [123, 124, 146–148]. The three renal transplant patients developed parotid gland swelling. Two patients showed involvement of their graft: one in a patient with a failed graft already on dialysis and the second with a previously functioning graft who developed tubulointerstitial nephritis and permanent graft failure. This second patient also developed orchitis and vestibular neuronitis with persistent vertigo after recovery. All three patients survived [123, 146, 147]. Both cases in the HSCT literature document fatal encephalitis in young patients with severe combined immunodeficiency treated with HSCT. The first patient was a 16-month-old infant who developed meningoencephalitis and seizures prior to HSCT and deteriorated rapidly after transplant. Mumps was isolated in culture from urine, blood, and CSF. The infant had been vaccinated for mumps several months prior, and the authors suggest the vaccine strain as the potential cause of infection [124]. The second patient was a 19-year-old who developed subacute encephalomyelitis from a wild-type mumps strain 2 years after HSCT. Infection occurred during an outbreak of mumps in England and Wales in 2004 and 2005 [148].

APMV-1 causes lethal infections in birds and has been tested as a potential agent for virotherapy in certain malignancies [149]. Cases in humans have rarely been documented and typically involve an acute, self-limited conjunctivitis, often in poultry workers. In 2007, Goebel et al. reported a case of pneumonia in a 42-year-old HSCT recipient where APMV-1 was isolated in culture from bronchoalveolar lavage fluid, a lung biopsy, stool, and urine (identity confirmed by sequencing; Table 45.2). The patient died after 24 days, and IHC was consistent with APMV-1 infection. No other pathogens were isolated, though the patient was on broad spectrum antibiotics at the time of bronchoscopy [150].

Nipah and hendra viruses (and the recently identified Cedar virus, which will not be discussed further) comprise the genus *Henipavirus* and were identified in the 1990s as causes of encephalitis [151–153]. Old World fruit bats serve as the natural host for nipah and hendra, but these pathogens are notable among the *Paramyxoviridae* for their ability to infect a wide range of hosts, including pigs, horses, and humans. Hendra has been transmitted from horses to their handlers, and nipah has been transmitted from pigs and bats to humans [152, 154]. Human-to-human spread of nipah has also been documented in recent outbreaks [154–156]. Infection resulting from either virus can result in severe respiratory tract disease, encephalitis, or both. In a series of 92 cases of encephalitis from Bangladesh, 69% of patients also had respiratory difficulty, though this rate was higher than that seen in a series from Malaysia (21%) [157, 158]. Mortality from encephalitis has ranged from 30% to 70% in different series, and residual neurological deficits can persist in survivors [157, 158]. An unusual feature of infection with either of these viruses is the occurrence of relapsing or late-onset encephalitis that has been documented to occur up to 22 months after initial presentation and still carries a high mortality [159]. Treatment remains supportive. In the large series reported to date, which involve nipah virus, there have not been documented cases involving transplant recipients or immunocompromised hosts, though the comorbid illnesses of patients included in these series have not been fully described [157, 158].

Poxviridae

Poxviridae is a family of large DNA viruses that includes four genera (among many) of viruses with the potential to infect humans: *Orthopoxvirus* (including variola), *Molluscipoxvirus* (including molluscum contagiosum virus), *Parapoxvirus*, and *Yatapoxvirus*. Molluscum contagiosum is widely recognized, and in the immunocompromised patient, molluscum contagiosum virus infection can cause an eruption of large and widespread skin lesions. We will not discuss this agent further in this chapter.

Orf virus, a *Parapoxvirus*, is a well-known pathogen in sheep, particularly young lambs, and causes papulovesicular lesions in the mouth and groin of affected animals [160, 161]. Orf lesions, also known as ecthyma contagiosum, also occur in humans. These lesions tend to be solitary and occur on the extremities of individuals who work with infected sheep. In the immunocompetent patient, these lesions are self-limited and tend to heal over 1–2 months [160, 161]. In transplant and immunocompromised patients, however, a number of cases of recurrent and giant orf lesions have been reported (Table 45.1) [160–164]. These lesions can be 5 cm or more in diameter and have been confined to the hand or forearm. All patients reported contact with sheep. Patients have undergone excision with skin grafting or even amputation when these lesions are not diagnosed correctly, but even with such aggressive treatment, lesions tend to recur after a few weeks to months [160, 162–164]. A single patient also developed a new lesion at the skin-graft donor site [164]. While no standard treatment exists, three case-reports document responses in renal transplant patients using cryotherapy, cidofovir cream, or imiquimod (a single case for each treatment) [161, 163, 164]. The patients treated with cryotherapy

and cidofovir required a second course of treatment but again responded well [161, 163].

Cases of human monkeypox, an *Orthopoxvirus*, were first recognized in 1970 during the vaccination campaigns to eradicate smallpox, though earlier cases may have been diagnosed as the clinically similar smallpox [165, 166]. Outbreaks of disease continue in the Democratic Republic of the Congo and neighboring Sudan, and indeed, the incidence appears to be increasing after cessation of routine smallpox vaccination over 30 years ago [165–167]. In 2003, the first cases of monkeypox outside of Africa occurred in the Midwestern United States, with 37 confirmed cases associated with exposure to sick pet prairie dogs that in turn had been infected by rodents imported from West Africa [152, 166, 168]. Though fatal cases of monkeypox in Africa are well described, no fatalities were reported among these 37 patients [167–169]. Nine patients were described as having severe disease, including a single case each of encephalitis and respiratory distress, and five patients were hospitalized. One patient described in the series had received an HSCT, but they were not reported among the cases of severe disease and appear to have recovered fully (Table 45.2) [152, 166, 168].

A novel orthopoxvirus was recently identified to cause a rash illness in a renal transplant recipient who was 26 months posttransplantation. The patient developed a tender, erythematous, and indurated rash with development of vesiculopustular lesions on the right lateral chest wall. Multiple debridements failed to demonstrate the causative agent and were negative for HSV and VZV by IHC straining and acid-fast and fungal organisms by special staining. A dense inflammatory infiltrate composed of lymphocytes, histiocytes, and focal eosinophils extending into the subcutaneous adipose tissue was consistently demonstrated on multiple specimens. Culture on human epithelial type 2 cells and BSC40 cells demonstrated viral cytopathic effects, but could not be further identified with standard evaluation. Viral DNA was then sequenced by next-generation sequencing. De novo assembly of the viral genome and phylogenetic analysis revealed a novel poxvirus most closely related to Yoka poxvirus, which was isolated from mosquitoes in the Central African Republic in 1972 during an ecologic survey. The patient had no travel outside of his community in upper New York state. The epidemiology of this novel pox virus is not known at this time; however this case serves as reminder that immunocompromised patients are prone to novel infectious diseases [170].

Global Emerging Pathogens

SOT and HSCT have become the treatments of choice for a large number of disease processes. Advancements in immune suppression and improvements in the management of opportunistic infections have allowed a growing number of centers worldwide to perform such procedures. According to the Global Observatory on Donation and Transplantation, over 100,000 solid organ transplants were performed in 2013, including 80,000 kidney and 25,000 liver transplants. From 2000 to 2010, the number of countries performing kidney transplant increased from 33 to 84. While the number of kidney transplants performed annually in the United States and Canada stayed relatively stable from 2005 to 2015 (16,485–17,878 and 1049–1265, respectively), the total number performed in the Americas region nearly doubled (from 14,512 to 28,324). Countries that include endemic areas for many emerging infectious diseases are now performing a significant number of transplants (e.g. Brazil and India, which both performed around 5000 kidney transplants in 2010) [171]. In the following sections, we will briefly discuss a number of different emerging viral pathogens. To date, few of these have been documented in transplant recipients. With the marked increase in both SOT and HSCT, this will no doubt change, and we expect a corresponding increase in emerging viral infections in transplant hosts, both from known viruses and those yet to be identified.

Dengue Virus, Zika, and the Flaviviruses

Flaviviruses are single-stranded RNA viruses, and this genus contains a number of important human pathogens, including dengue virus (DENV), Zika virus (ZIKV), yellow fever virus (YFV), Japanese encephalitis virus (JEV), West Nile virus (WNV), St. Louis encephalitis virus, and tick-borne encephalitis virus (TBEV), among others. In this section, we will focus on DENV but also briefly discuss ZIKV, YFV, and case reports of USUV, an emerging avian pathogen in Africa and Europe [172]. Cases or case series of other flaviviruses have not been reported in the transplant literature, which may be partly explained by effective vaccines for both JEV and TBEV.

DENV is the most common vector-borne disease worldwide and has emerged as a significant pathogen in an increasing number of countries over the last 40 years [173]. Four serotypes of DENV exist (DENVs 1–4) and are transmitted by *Aedes aegypti* and *Aedes albopictus* mosquitoes. All have the potential to cause a range of clinical illness, from asymptomatic infection to classical dengue fever (DF) to severe dengue, including dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS). Infection with one serotype (primary infection) results in immunity to that serotype, but infection can occur with any of the remaining serotypes (secondary infection) [173]. Secondary infection has been shown to be a significant risk factor for the development of severe dengue, and this appears to result from both disadvantageous humoral and cellular immune responses (termed

antibody-dependent enhancement and original antigenic sin, respectively) [174, 175]. Other factors are also important, such as the order of infection as well as the specific DENV strain [176, 177].

A number of reports have documented the occurrence of both DF and severe dengue in transplant recipients (Table 45.1) [178–187]. Two case series from Brazil (27 patients) and Singapore (6 cases) present a less severe picture of DENV infection in renal transplant patients [178, 182]. In the study from Brazil, eight patients had been hospitalized and one died of respiratory failure. Only a single patient developed DHF, and this person recovered [178]. The six patients in Singapore were identified on presentation to the hospital. Though all survived, the mean platelet count was 80,000 and 5 patients developed leucopenia. There were no cases of DHF or DSS [182]. All 33 patients in these 2 series had stable graft function.

Severe cases of dengue were reported from India in a series of eight renal transplant patients, who were diagnosed with DENV on admission to the hospital. Five patients developed DHF, and three patients developed DSS. All those in the latter group died [186]. Four other case reports in renal transplant recipients include three cases of DHF and a single, fatal case of DSS [179, 181, 184, 185]. Though these represent a small number of cases, it is notable that four of the patients with severe dengue developed disease within 1 month of transplantation (two during their initial hospitalization), while all of the patients in the series from Brazil and Singapore developed their illness 3 months or more after transplant. Reports also document a single fatal case of DSS occurring in a liver transplant recipient (date of transplant not reported) and a fatal case of severe dengue 4 days after HSCT [180, 183] Most patients were diagnosed using NS1 protein detection or rapid IgM and IgG, and RT-PCR was less commonly performed. The serotypes, when reported, included DENVs 1, 3, and 4 [180, 183–185].

Human-to-human transmission of DENV as a result of organ transplantation has been documented. In one case of DENV transmission from a living donor to liver transplant recipient in India, the donor developed fevers, thrombocytopenia, and transaminitis 2 days after liver donation. Donor blood was positive for DENV NS1 antigen. The recipient developed a similar clinical presentation 5 days after transplantation and was also positive for DENV NS1 antigen. Both recipient and donor were treated with supportive measures and discharged after their full recovery 2–3 weeks after transplantation [188]. A case of donor-derived DENV transmission in HSCT has also been reported. In this report from Germany, the donor similarly developed clinical symptoms of DENV days after donation of peripheral blood stem cells to a recipient with acute myeloblastic leukemia and was only later noted to have returned from a trip to Sri Lanka. DENV NS1 antigen and PCR were positive in the donor. The recipient was subsequently treated with IVIG; however, the recipient ultimately developed cardiopulmonary arrest and died 9 days posttransplant. Blood testing of the recipient also was positive by DENV NS1 antigen and PCR. Sequencing of virus showed genotype 1 infection with sequence similarity to circulating DEV 1 genotype 1 strains in Sri Lanka [189].

Emergence of ZIKV, another mosquito-borne flavivirus, was first reported in 2007 in the Federated States of Micronesia where an outbreak of febrile illness occurred that was characterized by rash, conjunctivitis, and arthralgias. By 2015, ZIKV spread throughout the Pacific Islands, continental South America and into Central America, the Caribbean, and Mexico. ZIKV is linked with outbreaks of Guillain-Barre syndrome and devastating birth defects, most notably fetal microcephaly, from infection during pregnancy. Given the recency of the epidemic, the effects of ZIKV infection in transplant recipients are currently not known. The potential impact of any major viral infection on transplant outcomes can be significant with increased morbidity and mortality in transplant recipients who develop disease [190]. The full influence of ZIKV on transplantation remains to be determined.

YFV is closely related to DENV, exists in sub-Saharan Africa and South America, and is transmitted by the bite of infected *Aedes* species mosquitoes. To date, no cases of YFV have been reported in the transplant literature [191]. The YFV vaccine is effective, but it is live-attenuated and not currently recommended for transplant recipients. In one small study, 19 SOT recipients received the YFV vaccine inadvertently during outbreaks in Brazil. No severe AEs were reported, and the mean posttransplant time at vaccination was over 5 years [192]. Similarly, a patient with AML who started chemotherapy just 7 days after receiving YFV vaccination did not develop AEs despite detection of the 17D attenuated viral strain by RT-PCR in plasma samples for 15 days after vaccination. Interestingly, protective neutralizing antibodies were detected 1 month after the vaccine, indicating that memory B lymphocytes may have been preserved despite ablative bone marrow suppression [193].

Two case reports exist, both from Italy in 2009, of USUV causing encephalitis in immunocompromised patients [16, 23, 172]. The first report was of a woman with diffuse large B-cell lymphoma who presented with fever and a resting tremor. CSF was sent for a pan-flavivirus RT-PCR, and sequencing was consistent with USUV [23]. The second patient had TTP and was admitted with fevers and a headache. She developed fulminant liver failure and received a liver transplant (Table 45.2). Plasma drawn just before transplant gave a weak positive signal in a WNV RT-PCR. Flavivirus RT-PCR was then performed, and sequencing was consistent with USUV [16]. Both patients recovered, though had some residual neurological deficits.

Alphaviruses

The alphaviruses are a genus of single-stranded, positive-sense RNA viruses (within the *Togaviridae* family) that cause either encephalitis such as eastern, western, and Venezuelan equine encephalitis viruses or a systemic febrile illness with a rash and arthritis including Semliki Forest, Sindbis, O'nyong-nyong, Mayaro, Ross River, and Chikungunya viruses. In 2004, Chikungunya virus (CHIKV) re-emerged in Kenya and spread to countries around the Indian Ocean, including Reunion, a French overseas district, and India, resulting in millions of cases [194, 195]. Autochthonous spread was even detected in Italy in 2007 [196]. Symptomatic CHIKV infections result in a severe arthritis, which can persist for months following resolution of the fever and rash [197, 198]. Cases of meningoencephalitis and fatalities have been reported [199, 200]. Two cases of severe CHIKV infections in immunocompromised patients were reported by Kee et al., in 2010, including one patient taking an herbal medicine felt to contain steroids and a liver transplant recipient (Table 45.2). The liver transplant recipient presented with fever, headache, and abdominal complaints. IgM was positive for CHIKV, but IgG and serum RT-PCR remained negative (lumbar puncture was not performed). He recovered fully. Neither patient developed arthritis or arthralgias during the course of their infections [201]. A subsequent case of CHIKV infection in an HIV-infected kidney transplant recipient who had traveled to the Dominican Republic 4 years of transplantation reported an episode of arthritis lasting 2 months, which ultimately self-resolved [202]. In a second study, investigators tested corneal grafts from patients living in La Reunion during the 2005–2006 CHIKV outbreak. Twelve of 69 asymptomatic, potential donors were found to be viremic (3 patients) or IgM positive (11 patients, including 2 patients with viremia), and corneal grafts from 4 of these patients (all 3 viremic patients) had detectable CHIKV RNA on RT-PCR. While no cases of transplant-associated CHIKV transmission have been documented, researchers did show that transmission can occur by the ocular route in mice [203].

Bunyaviridae

Bunyaviridae is a family of segmented RNA viruses that includes a number of emerging pathogens, including Rift Valley fever virus (RVFV), the hantaviruses, Crimean-Congo hemorrhagic fever virus, and two newly identified phleboviruses, HYSV and Heartland virus. Bunyaviruses are vector-borne viruses, except for the hantaviruses, which are transmitted through aerosols from infected rodents. RVFV is an important livestock pathogen in Africa and causes outbreaks of severe human disease, often following periods of heavy rain. Many human infections are asymptomatic or result in a self-limited febrile illness, though cases of encephalitis and hemorrhagic fever are reported. Disease severity tends to be greater during large outbreaks, and mortality rates of up to 30% in symptomatic patients have been seen. Recently, this infection was seen for the first time in countries outside of Africa, causing outbreaks in Saudi Arabia and Yemen [204, 205]. To date, there have not been reported cases within the transplant community.

HYSV and Heartland virus have been described in the last 2 years, and clinical experience remains limited. HYSV is a tick-borne bunyavirus and was identified in patients in China presenting with fevers and thrombocytopenia without an identified cause [17]. A recent publication on the clinical course of 49 inpatients with confirmed HYSV documented a mortality of 16%, which correlated with high viral loads on admission [206]. Heartland virus has been isolated from two patients in Missouri, United States, who were admitted with fevers, diarrhea, and thrombocytopenia. They both improved with supportive care [18]. Both of these viruses were initially isolated in cell culture before being further characterized by electron microscopy and sequencing, and they appear to be closely related members of the genus *Phlebovirus* [17, 18]. Given their recent identification, it is not unexpected that these infections have not been characterized in the transplant population.

The *Hantavirus* genus includes at least 23 related viruses that cause hemorrhagic fever with renal syndrome (HFRS) or hantavirus pulmonary syndrome (HPS). Three cases of hantavirus infection in immunocompromised patients, including a single case in a renal transplant recipient, have been reported (Table 45.2) [207–209]. All of these cases involved Old World hantaviruses that are associated with HFRS including Dobrava-Belgrade virus, one case, and Puumala virus, two cases. The renal transplant recipient, 18 months after transplantation, presented with 5 days of fevers, headache, and arthralgia. He developed oliguric renal failure and required 5 days of dialysis prior to return of normal urine output. He was treated with steroids for acute rejection, but given his presentation, he was also evaluated for other causes. IgM returned positive for Dobrava-Belgrade virus, and the patient made a full recovery [207]. The two cases of Puumala virus infection involved a patient with acute leukemia and one receiving anti-TNF therapy. Both patients did well, though interestingly, the patient with leukemia was felt to be infected through a platelet transfusion [208, 209]. The treatment of hantavirus infections remains largely supportive. There is limited data for the use of ribavirin, which decreased mortality in a study of HFRS in China, reported in 1991 [210]. A trial of ribavirin in HPS was terminated early due to slow patient accrual. This study showed no improvement in the patients given ribavirin, though it was underpowered [211]. No benefit was seen in the use of oral prednisone in HFRS [212].

Filoviridae

Marburg and Ebola viruses are the only members of the *Filoviridae* family and are two of the most virulent human pathogens, causing outbreaks of hemorrhagic fever with mortality rates of up to 90%. Except for the first identified outbreak of Marburg virus in 1967, when it was isolated from patients in Germany and Yugoslavia who had handled infected African green monkeys, these viruses have only caused hemorrhagic fever outbreaks in Africa. The largest Ebola outbreak recorded began in 2013 in West Africa (predominantly Liberia, Sierra Leone, and Guinea) and has resulted in over 28,000 cases and 11,000 deaths to date and include the transmission from individuals infected in West Africa to health-care workers in the United States and Europe [213–215].

The incubation period for these viruses is 3–13 days. Patients then become acutely ill, developing high fevers and other nonspecific complaints such as malaise, nausea, vomiting, and diarrhea. Most patients develop a maculopapular rash, and they often develop hemorrhagic manifestations from multiple mucosal sites. Laboratory abnormalities are not diagnostic but include initial leucopenia, often followed by a leukocytosis, thrombocytopenia, increased transaminases (typically AST more than ALT), and prolonged prothrombin time [213]. Virus is detectable, using RT-PCR, antigen detection, or culture, in the blood and other body fluids at the time of presentation [213, 216, 217]. Care at this time is supportive along with infection control procedures including patient isolation. The majority of patients who die as a result of Marburg or Ebola do so within the first 2 weeks, and convalescent time for survivors is often prolonged [213]. Many long-term complications have been reported in survivors, with rheumatologic and ocular complaints most predominant. 50–75% of survivors report symmetric, polyarthritic arthralgias. Eye pain, conjunctivitis, photophobia, hyperlacrimation, uveitis, and loss of visual acuity also seem to be common with reports in as much as half of survivors in certain regions during the West Africa outbreak.

Though Marburg and Ebola infections have not been reported in the transplant population, likely due to the barriers to the establishment of robust transplant program in these countries, recognition of risk factors for Ebola among potential donors during outbreak periods may be of importance. Symptomatic patients have virus disseminated in multiple organs and body fluids, and transmission occurs via contact with infected fluids. Donor-derived infection may involve a donor who died of unrecognized Ebola or an infected but not yet symptomatic donor. Donors who have traveled to areas with significant Ebola activity, health-care workers working directly with Ebola, and others with direct exposure to a patient with proven Ebola infection in the prior 21 days should raise caution for possible donor-derived Ebola transmission [217].

Xenotransplantation

Acellular xenografts have been in use for decades, and porcine islet cell transplantation recently entered clinical trials, but the xenotransplantation of organs remains experimental and beyond the realm of clinical medicine [218]. The scientific and ethical questions surrounding the transplantation of organs, cells, and tissues from nonhuman species have generated an independent body of literature. The handling of these questions is beyond the scope of this text, and we will only briefly discuss some of the concerns regarding the transmission of viral zoonoses to human xenograft recipients.

The porcine endogenous retroviruses (so called PERVs) are incorporated in swine DNA and genetically acquired [218, 219]. These viruses can be found in the genomes of all swine, and there is concern that they could infect transplant recipients, as human cells have been shown to be susceptible in vitro [219–224]. In a study using a pig-to-baboon model of SOT, PERV proviral DNA was found in the PBMCs of all ten animals, though viral RNA was not detected [223]. In studies of recipients of islet cell transplants, PERV transmission has not been documented, though in these studies, patients are rarely immunocompromised [224–226]. PERV transmission was not detected in liver allotransplant recipients who happened to be pig farmers [221]. If these infections do occur, their clinical significance still remains unclear.

Other viruses are also a concern in xenotransplantation. These include the porcine herpesviruses, porcine CMV (PCMV) and porcine lymphotropic herpesvirus (PLHV); HEV, particularly genotypes 3 and 4; and certain parvoviruses [218]. Many of these viral agents can be excluded from herds by careful breeding practices and frequent herd monitoring. A single study of islet cell transplant to human recipients did not detect PCMV or PLHV, which were also not detected in the herds prior to transplantation [225]. In the pig-to-baboon model of SOT, PCMV DNA was detected in two recipients and PLHV DNA was detected in six (of ten baboons). RNA was not detected for either of these viruses, supporting the conclusion that these were not productive infections. The outcome of these infections remains unclear, however, as the longest surviving recipient after transplantation was only 179 days [223].

Prevention and Reporting

The majority of viral infections discussed in this chapter appear to occur rarely in transplant recipients, though data are insufficient to determine the true incidence of disease. Measles, mumps, and yellow fever are vaccine-preventable illnesses, though these vaccines are all live-attenuated. Also,

the response to vaccines in this patient population is lower than the response in immunocompetent patients. Donor-transmitted rabies carries a dire prognosis, and though limited data exists, the use of PEP in transplant recipients appears safe.

Given their apparent rarity, screening for many of these diseases in organ donors cannot be recommended at this time. The examples of HTLV-1 and LCMV are illustrative of some of the difficulties involved with donor screening. In low-prevalence settings, HTLV-1 testing generates a large number of false-positive tests, and confirmatory testing can delay transplantation [37, 53]. Hence, this is no longer required by the US OPTN [37, 53]. In the outbreak investigations for LCMV, only one of four donors had detectable antibodies. Indeed, RT-PCR from multiple samples failed to detect LCMV from one donor and yielded a positive result in a single lymph node (but not other samples) in another [13, 86, 87]. It seems prudent to obtain a comprehensive history of potential organ donors, including all recent exposures and travel, though it remains unclear how certain findings, such as rodent ownership, should affect one's status as an organ donor.

Reporting rare or unusual infections in transplant recipients, though retroactive, will help to identify agents for which more research is needed and screening may be warranted. At this time, expectations in the United States are for transplant centers to report unexpected potential or proven infections discovered after procurement of a donor organ to the OPTN Patient Safety System [227]. This remains a passive reporting system, however, and it is possible that events are missed if these infections are underdiagnosed or if symptoms are attributed to more common, and potentially coincident, posttransplant infections.

Parasitic Infections in Transplant Recipients: Toxoplasmosis, Strongyloidiasis, and Other Parasites

46

Brian G. Blackburn and José G. Montoya

Toxoplasmosis

Toxoplasma gondii infects approximately one-third of the world's population and has the potential to cause significant morbidity and mortality in transplant recipients [1]. The term "toxoplasmosis" refers to symptomatic patients with ongoing clinical manifestations stemming from a recently acquired infection (primary infection) or reactivation of a previously acquired infection (chronic or latent infection). In contrast, the term "*T. gondii* infection" should be reserved for chronically infected patients without symptoms.

Immunocompromised individuals (including transplant recipients) are at higher risk of developing life-threatening toxoplasmosis. However, toxoplasmosis can be prevented and successfully treated if an early diagnosis is made. Toxoplasmosis in transplant patients can be the result of a primary infection (acquired orally or via the transplanted organ) or reactivation of a latent infection acquired prior to transplantation.

It is important to realize that toxoplasmosis should be suspected even in patients who do not appear to have conventional epidemiological risk factors such as cat ownership or ingestion of raw meat or history of an illness suggestive of toxoplasmosis. Approximately half of individuals infected with *T. gondii* do not recall traditional risk factors for infection with the parasite or experiencing a clinical illness consistent with toxoplasmosis. In order to determine whether an unexplained syndrome like pneumonia, fever, seizures, and/or brain abscesses in a transplant recipient can be attributed to toxoplasmosis, laboratory tests should be performed in the pretransplant period to establish the level of risk and need for empirical treatment including *Toxoplasma* serological screening in all transplant recipient candidates and all organ donors. In addition, testing should be performed in the posttransplant period in various body fluids or tissues according to the clinical scenario; this may include polymerase chain reaction in bronchoalveolar lavage, peripheral blood, cerebrospinal fluid, and immunohistochemistry in biopsy specimens.

The Organism

The infectious forms of *T. gondii* include the tachyzoite, the tissue cyst containing bradyzoites, and the oocyst containing sporozoites (Fig. 46.1). The tachyzoite is semilunar in shape, is 2–3 μm wide and 5–7 μm long, and is responsible for the clinical manifestations observed in patients with toxoplasmosis.

The tissue cyst measures up to 100 μm in diameter; it is responsible for chronic infection believed to be mostly asymptomatic, and establishes latency in organs such as the heart, skeletal muscle, eye, brain, liver, and kidney. The tissue cyst can be transmitted to transplant recipients through consumption of infected meat or implantation of an infected allograft from an infected donor with acute or chronic infection. Bradyzoites have limited metabolic activity and do not replicate but can reactivate and transform into tachyzoites, especially when significant impairments in T-cell-mediated immunity occur.

Oocysts are shed in soil and water by wild or domestic felids, measure 10–12 μm in diameter in the unsporulated form, and are responsible for transmission to patients via inadvertent oral ingestion of items contaminated by infected

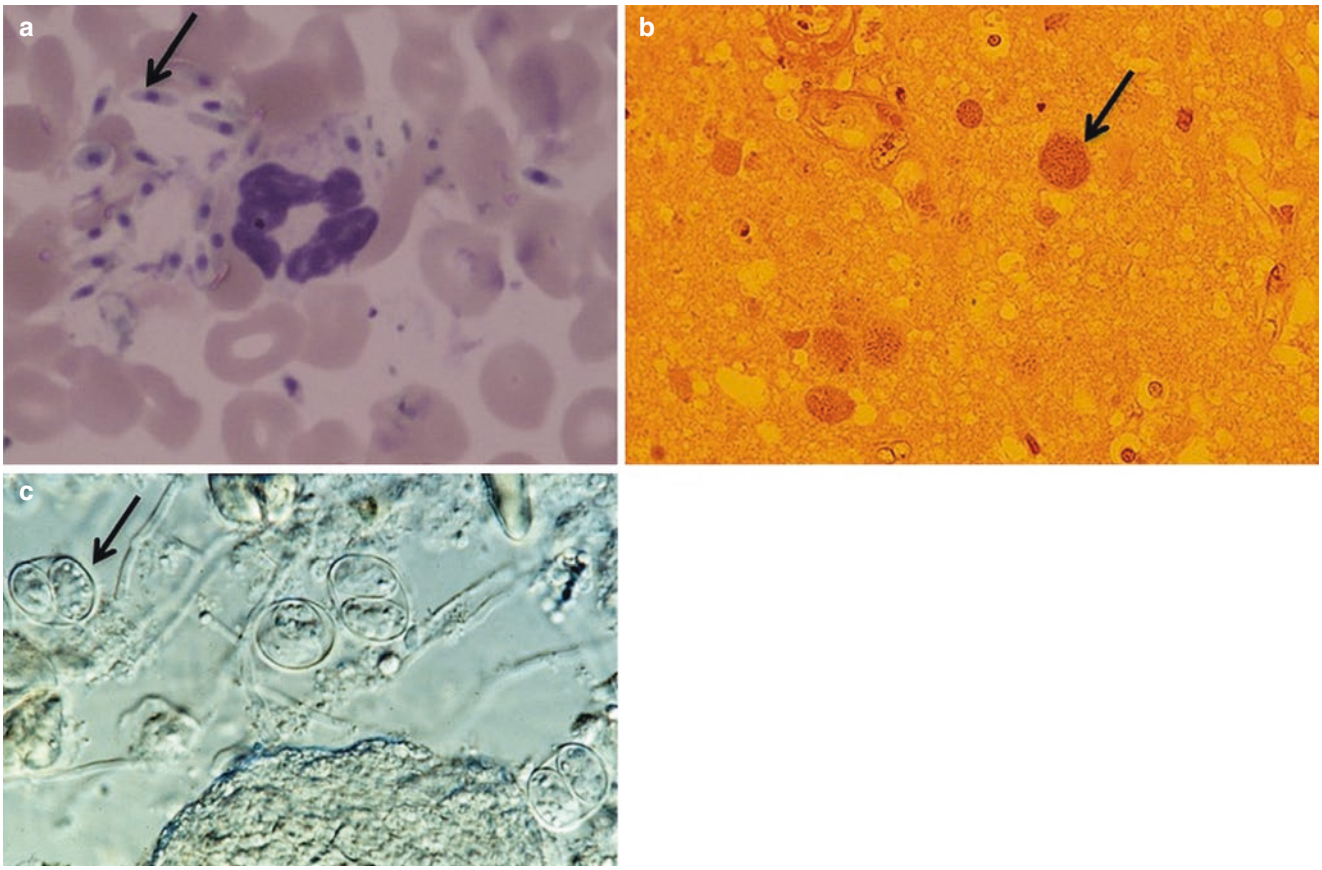

Fig. 46.1 (**a**–**c**). Main forms of *T. gondii* found in nature (see arrows). Tachyzoites (**a**), tissue cysts (**b**) containing bradyzoites, and oocysts (**c**) containing sporozoites

cat feces (e.g., water, vegetables, or other food; contact with infected soil or while gardening). As many as ten million oocysts can be shed by an infected cat in a single day. Sporulation is required for oocysts to become infectious and occurs outside the cat within 1–5 days depending on temperature and oxygen availability. Oocysts may remain viable for as long as 18 months in moist soil, resulting in an environmental reservoir from which incidental hosts may be infected.

Although toxoplasmosis is widely distributed across continents, a clonal expansion of few lineages appears to have occurred. *Toxoplasma* strains can be primarily classified as types I, II, III, and atypical. Type II strains appear to predominate in Europe and types I/III and atypical strains in South America. The United States appears to have both European-like type II and South American-like strains. In Latin America, for example, a more aggressive and lethal form of toxoplasmosis has been associated with atypical strains rarely found in Europe [2–4]. Pneumonia, disseminated disease, admission to intensive care units, and even death have been observed in immunocompetent individuals infected with these strains in South America. These emerging and more virulent strains have potentially serious implications for transplant patients who receive organs from individuals from those areas or travel to these places.

Life Cycle and Epidemiology

Humans are incidental hosts of the parasite and acquire infection primarily by the oral route. Two important additional routes of transmission to humans include vertical transmission from mother to unborn child and transmission via infected allografts during transplantation.

Domestic and feral cats are the definitive hosts of *T. gondii*. They can be infected with any of the primary infectious forms of the parasite including tachyzoites, tissue cysts, or oocysts. Once in their small intestine, the parasite undergoes asexual or sexual (gametogony) reproduction. Oocysts are subsequently excreted via their feces in soil or water.

Humans can acquire the parasite by ingestion of infected meat (containing tissue cysts) or other contaminated food or water (containing oocysts). Untreated water has been recognized as a major source of infection in community-acquired outbreaks of toxoplasmosis [5]. Exposure to contaminated cat feces, soil, or soil-related activities not limited to garden-

ing can also result in primary infection. Novel routes of transmission to humans have been identified over the past few years. Ingestion of raw shellfish like oysters, mussels, and clams has been recently recognized as a potential means of *T. gondii* transmission [6].

An epidemiological study in the United States revealed that an elevated risk for recent *T. gondii* infection was associated with the following factors: eating raw ground beef; eating rare lamb; eating locally produced cured, dried, or smoked meat; eating raw oysters, clams, or mussels; working with meat; drinking unpasteurized goat milk; and having three or more kittens [6]. However, 48% of the infected individuals did not have an identified risk factor for *T. gondii* infection in this study. This is consistent with findings from previous epidemiological studies where many infected individuals did not have a known epidemiological risk factor [7]. It appears that infected individuals are often unaware of their exposure or may have difficulty recalling specific risk behaviors.

Donor-derived *Toxoplasma* infection is a well-known risk for recipients of solid organ transplants. *Toxoplasma* seronegative recipients (R−) are at greater risk of developing toxoplasmosis when they receive infected organs from seropositive donors (D+) and do not receive anti-*Toxoplasma* prophylaxis. In a study performed at Stanford University Medical Center, 25% of D+/R− heart transplant recipients developed or died from toxoplasmosis in the absence of prophylaxis, whereas none of the D+/R− patients who received prophylaxis developed toxoplasmosis [8].

Transmission of *T. gondii* through hematopoietic stem cell transplants (HSCT) or blood transfusion products appears to occur but is considered rare. HSCT patients who are *Toxoplasma* seronegative prior to transplantation (R−) are at low risk of developing posttransplant toxoplasmosis; this has occurred in only a few cases where the recipient was seronegative and the HSCT donor was seropositive (D+/R−). Most HSCT patients who develop toxoplasmosis do so from reactivation of a previously acquired infection in the recipient (i.e., seropositive prior to transplantation; R+) [9].

The risk of toxoplasmosis in a given transplant center varies by geographic region and the age of donors and recipients because the *T. gondii* seroprevalence varies considerably by locale and socioeconomic strata and increases with age [10].

For solid organ transplant programs, patients should be screened for *T. gondii* infection prior to transplant so that high risk patients (D+/R−) can be identified prior to transplantation. For instance, at Stanford University Medical Center, results of serological testing for *Toxoplasma* were available prior to heart transplant for 575 D/R pairs; of these, 454 (79%) were D−/R−, 84 (14.6%) D−/R+, 32 (5.6%) D+/R−, and 5 (0.8%) D+/R+ [8]. Similarly for HSCT programs, identification of R+ patients is highly recommended [9]. Serological testing following transplantation is often not helpful since serologies may rise or change posttransplant without necessarily indicating that patients have toxoplasmosis. In addition, serologies may not change, become negative, or remain negative (due to immunosuppression), even in the setting of toxoplasmosis [11].

Immune Response and Genetic Susceptibility of the Host

Coordinated innate, humoral, and cellular immune responses are required to prevent morbidity and mortality from primary infection and reactivation of latent *T. gondii* infection. A well-orchestrated and effective systemic immune response results in early disappearance of *T. gondii* from peripheral blood during the acute infection limiting parasite burden in target organs and successfully maintains latency in chronically infected individuals. Immunity in the immunocompetent individual is lifelong. Macrophages; dendritic cells; natural killer cells; CD4+ and CD8+ T cells; Th1 cytokines (e.g., IFN-γ, IL-12), tumor necrosis factor-α (TNF-α); co-stimulatory molecules, (e.g., CD28 and CD40 ligand); and, to a lesser degree, immunoglobulins, appear to be essential for the effective disappearance of tachyzoites from peripheral blood, their conversion to bradyzoites, and subsequent formation of tissue cysts.

Clinical Manifestations

T. gondii infection can result in symptoms and signs of toxoplasmosis in the setting of a primary infection or reactivation of a previously acquired latent infection. The parasite has coevolved with humans to the point of being capable of causing asymptomatic primary infections. Therefore, transplant donors and recipients may have been infected without their knowledge and without recognition of conventional risk factors for acute infection. The most effective approach for early diagnosis and treatment is for high clinical suspicion and appropriate laboratory testing.

Toxoplasmosis in the setting of heart transplantation is most likely to occur in D+/R− patients. In other solid organ transplant recipients, toxoplasmosis can occur as a result of D+/R− mismatch as well, or reactivation of a latent infection (R+). Toxoplasmosis in the setting of HSCT most commonly occurs as a result of reactivation of a chronic infection in the recipient (R+).

In autologous HSCT patients, reactivation is rare. In allogeneic HSCT patients, reactivation (R+) occurs more frequently in those who have developed graft-versus-host disease (GVHD); the median day of onset for toxoplasmosis is day 64 (range = 4–516 days) posttransplant. Although reactivation of latent *Toxoplasma* infection in allogeneic HSCT recipients most often occurs in the first six months posttransplant (most in the first 30–90 days), late reactivation

has been observed and must be considered, especially in patients in whom late-onset (beyond six months posttransplant) GVHD occurs [9, 12, 13]. Conversely, an HSCT patient who is seronegative for *T. gondii* pretransplant has a very low risk of toxoplasmosis in the first 100 days after transplant [9, 12, 13].

Acute Toxoplasmosis

Although most individuals are asymptomatic, symptomatic primary infection may manifest as a painless, nonsuppurative lymphadenopathy. Lymphadenopathy develops more commonly in the cervical chain but can occur almost anywhere. A mononucleosis-like syndrome can be the presenting illness of the primary infection. Fever, headache, stiff neck, fatigue, arthralgia, myalgia, anorexia, skin rash, and visual symptoms (with retinal involvement) may also be present. When retinochoroiditis occurs, patients can develop blurred vision, eye pain, decreased visual acuity, floaters, scotoma, photophobia, or epiphora. Less frequently hepatitis, myositis, and myocarditis can occur. More aggressive disease including pneumonia, brain abscesses, and death has been observed in immunocompetent patients in Latin America [2]. Patients with these severe manifestations require admission to intensive care units and may have been infected with atypical strains of the parasite. Transplant patients may be at higher risk of developing severe toxoplasmosis if infected with these atypical strains. Acute toxoplasmosis has been reported when seropositive heart, liver, and kidney donors transmitted the parasite to seronegative recipients via the infected organ. In this setting, syndromes such as fever, sepsis, pneumonia, seizures, brain abscesses, and retinochoroiditis have occurred.

Reactivation of Latent Infection

In most individuals, primary infection is followed by chronic latency in which the parasite remains dormant for the life of the host. Aside from reactivation in the eye, which can also occur in immunocompetent hosts, overt reactivation including life-threatening clinical manifestations is only observed in patients with significantly impaired cell-mediated immunity. Reactivation in immunocompromised patients can present as pneumonia, fever, seizures, diffuse encephalitis, space-occupying brain lesions (Fig. 46.2), retinochoroiditis, myocarditis, hepatosplenomegaly, lymphadenopathy, and rash. Although multiple brain abscesses are commonly described in patients with toxoplasmic encephalitis, diffuse encephalitis without space-occupying lesions by MRI has been reported with a very high case-fatality rate. Fever and/or pneumonia can be the sole manifestation(s) of toxoplasmosis in immunocompromised patients including solid organ and HSCT recipients. Toxoplasmic pneumonitis can present with cough, dyspnea, hypoxia, and diffuse bilateral infiltrates, usually reported as ground glass opacities or localized lung infiltrates. Fever alone has frequently been described in allogeneic HSCT and liver transplant recipients.

Laboratory Diagnosis

Clinically available laboratory methods for the diagnosis of *Toxoplasma* infection and toxoplasmosis include serological tests, polymerase chain reaction (PCR), direct visualization of the parasite by Wright-Giemsa or immunoperoxidase stains, and parasite isolation (Table 46.1) [14]. It is critical to remember that symptoms and/or history of conventional epidemiological factors associated with acute *Toxoplasma* infection are often absent in patients with acute or chronic infection. Thus, all transplant recipients and donors should be serologically screened for toxoplasmosis before transplantation in order to establish their risk for primary infection (D+/R−) or reactivation (R+). It is important that screening be performed prior to transplantation because these results may not be reliable in the posttransplant period [11].

Diagnosis of Latent *T. gondii* Infection

Initial serological testing for *T. gondii*-specific IgG and IgM antibodies can be performed at non-reference commercial or hospital-based laboratories. Involvement of a reference laboratory, e.g., the Palo Alto Medical Foundation *Toxoplasma* Serology Laboratory (PAMF-TSL) in Palo Alto, CA (www.pamf.org/serology/ +1-650-853-4828; toxolab@pamf.org), is only required when positive or equivocal IgM test results are obtained or an equivocal IgG result is observed [15].

Transplant recipients and donors with negative IgG and IgM test results do not have serological evidence of prior exposure to *T. gondii* and are at low risk for developing toxoplasmosis. Transplant recipients who are *Toxoplasma* IgG positive and IgM negative have been infected for at least three months and are at risk for *Toxoplasma* reactivation if they are undergoing HSCT, liver, or kidney transplantation. Reactivation in heart, heart-lung, and lung transplant recipients occurs rarely in this setting. Donors who are seropositive for *T. gondii*, however, pose a serious risk to seronegative recipients (D+/R− mismatch) in the setting of heart, heart-lung, liver, kidney, and kidney-pancreas transplantation.

Diagnosis of Primary *T. gondii* Infection and Toxoplasmosis

Primary *T. gondii* infection should be suspected in a transplant candidate or donor with positive serum *Toxoplasma* IgG and IgM test results. However, this serum should be sent to a reference laboratory (e.g., PAMF_TSL) for confirmation, since

Table 46.1 Laboratory diagnosis of toxoplasmosis (acute infection or reactivation) in transplant patients

Serological tests
All transplant candidates and donors should undergo serological testing for *T. gondii*-specific IgG and IgM antibody tests before the transplant procedure or initiation of immunosuppression, whichever is first
Positive IgM test results should not be interpreted as necessarily indicative of a recently acquired infection. In these cases, serum should be sent for confirmatory testing to a reference laboratory specialized in the diagnosis of toxoplasmosis (e.g., the Palo Alto Medical Foundation *Toxoplasma* serology laboratory[a])
Serological test results confirmed by a reference laboratory as consistent with a recently acquired infection (e.g., within 6 months of sera sampling) should trigger consideration for treatment of the donor or recipient or postponing the transplant procedure
Serological tests performed posttransplant may not be accurate
Polymerase chain reaction (by PCR)
T. gondii DNA amplification by PCR can be performed on any body fluid including peripheral blood; cerebrospinal fluid; bronchoalveolar lavage fluid;vitreous fluid; aqueous humor; and peritoneal, pleural or ascitic fluids.
A positive PCR test result in any body fluid should be interpreted as laboratory confirmation of *Toxoplasma* reactivation or toxoplasmosis.
PCR can also be performed in tissues, but positive test results should be interpreted with caution since they may reflect chronic infection
Microscopy (direct visualization of the parasite)
Tachyzoite
Wright-Giemsa stain of any body fluid or "touch" preparation slides of any tissue. *T. gondii*-specific immunoperoxidase stains of biopsy specimens. Presence of tachyzoites in any fluid or tissue should be interpreted as laboratory confirmation of *Toxoplasma* reactivation or toxoplasmosis
Tissue cysts in histopathology samples
Hematoxylin and eosin or *T. gondii*-specific immunoperoxidase stains of any tissue or biopsy specimen. Numerous cysts or an associated strong inflammatory response is highly suggestive of toxoplasmosis and not simply *T. gondii* infection
Attempts to isolate the parasite
Attempts to isolate *T. gondii* can be performed in tissue culture or the peritoneal cavity of animals[a]
Establishing the strain of the parasite may have clinical and prognostic implications
Lymph node histology
Presence of a characteristic histologic triad in lymph node biopsy specimens can also be used for the diagnosis of toxoplasmosis (a reactive follicular hyperplasia; irregular clusters of epithelioid histiocytes encroaching on and blurring the margins of the germinal centers; and focal distention of sinuses with monocytoid cells)

[a]Palo Alto Medical Foundation Toxoplasmosis Serology Laboratory: http://www.pamf.org/serology/; telephone number (650) 853–4828; e-mail, toxolab@pamf.org

only 40% of such sera are confirmed to represent an acute infection when additional confirmatory testing is performed at a reference laboratory. Confirmatory testing of positive IgM test results at PAMF-TSL includes repeating the IgG and IgM tests, and performing IgA, IgE, differential agglutination (AC/HS), and IgG avidity assays [14]. If a primary infection is confirmed in a transplant candidate at PAMF-TSL, anti-*Toxoplasma* treatment should be promptly initiated in consultation with a transplant infectious diseases specialist. If a primary infection is confirmed in a potential donor following confirmatory testing, consultation with a transplant infectious diseases physician is strongly recommended since an evolving acute infection in the allograft may preclude utilization of these organs for transplantation purposes.

Toxoplasmosis from reactivation in transplant patients previously established as R+ is rarely diagnosed by serological tests alone. Additional laboratory methods are required including nucleic acid amplification such as PCR, stains to visualize the tachyzoite, histological methods to identify tissue cysts surrounded by inflammation or characteristic pathological findings, and parasite isolation (Table 46.1).

A positive *Toxoplasma* PCR test on any body fluid (e.g., peripheral blood, cerebrospinal fluid, bronchoalveolar lavage fluid, vitreous fluid, aqueous humor, and peritoneal, pleural, or ascitic fluids) is diagnostic of toxoplasmosis. PCR can

Table 46.2 Treatment regimens for immunocompromised patients with toxoplasmosis[a]

Pyrimethamine (PO)	200 mg loading dose followed by 50 mg (for patient wt. <60 kg) to 75 mg (for patient wt. >60 kg)/day
[b]Folinic acid (PO)	10–20 mg daily (up to 50 mg/day) (during and for one week after completing therapy with pyrimethamine)
plus	
Sulfadiazine (PO)	1000 mg (for patient wt. <60 kg) to 1500 mg (for patient wt. >60 kg) every 6 h
or	
Clindamycin (PO or IV)	600 mg every 6 h (up to 1200 mg every 6 h)
or	
Atovaquone (PO)	1500 mg orally twice daily
Trimethoprim/sulfamethoxazole (PO or IV)	10 mg/kg/day (trimethoprim component) in two to three doses (doses as high as 15–20 mg/kg/day have been used)
Atovaquone (PO)	1500 mg orally twice daily
plus	
Sulfadiazine (PO)	1000 (for patient wt.<60 kg) to 1500 mg (for patient wt. >60 kg) every 6 h
Pyrimethamine	200 mg loading dose followed by 50 mg (for patient wt. <60 kg) to 75 mg (for patient wt. >60 kg)/day
[b]Folinic acid	10–20 mg daily (up to 50 mg/day) (during and for one week after completing therapy with pyrimethamine)
plus	
Clarithromycin (PO)	500 mg every 12 h
or	
Dapsone (PO)	100 mg/day
or	
Azithromycin (PO)	900–1200 mg/day

[a]Prefered regimens: pyrimethamine/sulfadiazine/folinic acid or trimethoprim/sulfamethoxazole. Assistance is available for the diagnosis and manag ement of patients with toxoplasmosis at the Palo Alto Medical Foundation *Toxoplasma* Serology Laboratory, PAMF-TSL; Palo Alto, CA; www.pamf. org/serology/; +1-650-853-4828; toxolab@pamf.org

[b]Folinic acid = leucovorin; folic acid must not be used as a substitute for folinic acid

[c]After the successful use of a combination regimen during the acute/primary therapy phase, the same agents at half doses are usually used for maintenance or secondary prophylaxis

also be performed on tissues, but this method has not been standardized, and a positive result cannot be necessarily interpreted as diagnostic of toxoplasmosis since the presence of tissue cysts in chronically infected individuals can also yield positive test results. The two most commonly used gene targets are the multi-copy *B-1* and 529 genes. For maximum reliability, clinical samples should be sent to reference laboratories experienced in performing this assay.

Visualization of the tachyzoite form in any body fluid or tissue is also diagnostic of toxoplasmosis in the setting of primary infection or reactivation of a latent infection. In contrast, the visualization of tissue cysts in biopsy specimens may simply represent chronic infection and does not necessarily indicate that toxoplasmosis is the cause of a symptomatic patient's clinical manifestations since cysts are typically present in chronically infected individuals. However, the presence of "numerous" cysts surrounded by a prominent inflammatory response is suggestive of toxoplasmosis.

Attempts to isolate the parasite from any body fluid or tissue, as clinically indicated, can be attempted at reference laboratories (e.g., PAMF-TSL). A positive isolation test from any body fluid is diagnostic of toxoplasmosis, but tissue specimens share the same limitation with regard to specificity as noted above for the PCR test. If positive, strain typing and genotyping can be used to further study the emerging data which correlates certain strains with more aggressive disease. Characteristic lymph node histology can also be used to diagnose toxoplasmosis [16].

Treatment

Anti-*Toxoplasma* therapy should be initiated immediately in any transplant recipient with acute *T. gondii* infection or reactivation of a latent infection regardless of symptoms (Table 46.2). High morbidity and mortality is observed in transplant recipients if treatment for toxoplasmosis is delayed. Treatment is also indicated for transplant candidates and donors with acute infection if transplantation is likely to occur within six months of the primary infection.

High doses of anti-*Toxoplasma* drugs are typically indicated for posttransplant immunocompromised patients with toxoplasmosis (Table 46.2). Folate antagonists are preferred; monotherapy should be avoided. Pyrimethamine is probably the most active drug against *T. gondii* and appears to have the most synergy when combined with sulfadiazine. Pyrimethamine in

combination with clindamycin is an acceptable alternative regimen, as is trimethoprim/sulfamethoxazole (TMP/SMX).

Prevention

Primary Prophylaxis for Seropositive HSCT Recipients and D+/R− SOT Patients

Primary anti-*Toxoplasma* prophylaxis is indicated in allogeneic HSCT patients who are found to be *Toxoplasma* IgG positive before transplant (R+) as well as in solid organ transplant patients found to be D+/R−. Trimethoprim/sulfamethoxazole primarily used by transplant physicians to prevent *Pneumocystis jirovecii* pneumonia (PCP), has been successful in the prevention of toxoplasmosis in transplant patients. Effective regimens include one single-strength TMP/SMX tablet daily and one double-strength TMP/SMX tablet three times per week. For patients with allergy or intolerance to sulfa drugs, atovaquone 1500 mg daily is an alternative. Other drug regimens used to prevent PCP, e.g., pentamidine or dapsone alone, are not effective in preventing toxoplasmosis. Pyrimethamine 25 mg/day has also been reported to be effective *T. gondii* primary prophylaxis in D+/R- solid organ transplant patients [8, 17].

The use of TMP/SMX as primary prophylaxis for allogeneic or cord blood HSCT (R+) patients is usually delayed until after engraftment has been achieved due to the myelosuppressive potential of the drug. There are two strategies to address this window of vulnerability that can be implemented. Atovaquone prophylaxis can be used as the prophylactic drug until engraftment allows the use of TMP/SMX in these patients or screening for *Toxoplasma* reactivation can be done with the use of weekly PCR in peripheral blood for the first 100 days after transplant. PCR-positive patients should subsequently be treated with TMP/SMX or atovaquone at treatment doses plus an additional second drug. Of note, a negative blood PCR result does not rule out disease in a seropositive HSCT recipient who is symptomatic with clinical manifestations suggestive of toxoplasmosis [13].

Primary Prevention for Seronegative Transplant Candidates, Recipients, and Donors

Transplant candidates and recipients who do not have serological evidence of prior exposure to *T. gondii* should be aware of the risk factors for acute infection (Table 46.3). These same preventive measures also apply to seronegative donors prior to the transplant procedure.

Table 46.3 Measures suggested for the primary prevention of *T. gondii* infection in seronegative individuals[a]

Source	Measures
Meat and other edibles	Meat should be thoroughly cooked to 63 to 71 °C (74 °C for poultry) or to "well done"
	Meat should not be pink in the center
	Freezing and thawing meat can kill *T. gondii* tissue cysts, freeze meat to −20 °C for at least 48 h
	Infected meat that has been smoked, cured in brine, or dried may still be infectious
	Wash hands thoroughly following contact with raw meat
	Avoid mucous membrane contact when handling raw meat
	Wash (wearing gloves) kitchen surfaces and utensils that have come in contact with raw meat
	Abstain from skinning or butchering animals without gloves
	Avoid drinking unpasteurized goat milk
	Avoid eating raw oysters, clams, or mussels
	Thoroughly wash fruits, vegetables, or any organic edible
Cat feces and soil	Avoid contact with materials potentially contaminated exposure with cat feces
	Abstain from handling of cat litter or gardening
	Wearing gloves is recommended when these activities cannot be avoided
Untreated water	Avoid drinking untreated water including that from wells, ponds, or reservoirs that have not been secured from potential contamination with feces of infected felids

[a]Up to 50% of infected individuals are unable to recall behaviors known to be associated with *T. gondii* infection

Strongyloidiasis

Strongyloidiasis is caused by the intestinal nematode, *Strongyloides stercoralis*. Primarily transmitted in tropical areas, *S. stercoralis* usually causes a chronic gastrointestinal syndrome or can remain asymptomatic for decades [18]. The primary medical importance of this parasite in the developed world lies in its potential to cause the hyperinfection syndrome in immunocompromised patients, wherein larvae may disseminate throughout the body, with mortality rates of up to 70–80% [19–21].

The Organism

The life cycle of *S. stercoralis* is complex, alternating between free-living and parasitic cycles, and includes adult worms, two different larval stages, and eggs. These cycles form the basis for autoinfection and multiplication within the host, features relatively unique among helminths to *Strongyloides* [22, 23].

Soil-living adult worms produce eggs, which give rise to non-infective **rhabditiform larvae**. These either continue the free-living cycle by maturing into adults or become infective **filariform larvae**. Filariform larvae can penetrate intact human skin, after which they migrate to the lungs.

From there, they are expectorated, swallowed, and reach the small intestine; this journey takes about 3–4 weeks. In the intestine, *S. stercoralis* matures into adult worms, which are semitranslucent and about two millimeters long. These produce eggs, which hatch and become rhabditiform larvae. Although most of these larvae exit the gastrointestinal tract via the stool and subsequently develop into adult worms in the soil, a small number develop directly into infective (filariform) larvae within the gut and penetrate the intestinal mucosa or perianal skin, completing the life cycle without leaving the host. This is termed **autoinfection** and differentiates *S. stercoralis* from nearly all other helminths in several ways, including lifelong persistence in a host in the absence of treatment, multiplication in the absence of exogenous reinfection, and potential person-to-person transmission [24].

Epidemiology

Global estimates of strongyloidiasis prevalence vary widely, from 30 to 100 million people infected [21, 22, 25]. *S. stercoralis* is less common than other major intestinal nematodes such as *Ascaris*, *Trichuris*, and hookworms [18]. Strongyloidiasis is found throughout the tropics and subtropics and in limited foci of the United States (mostly Appalachia) and in Europe [25]. Transmission occurs via skin contact with fecal contaminated soil, so transmission is favored where poor hygienic conditions are combined with a warm, moist climate. Primary prevention involves improving social hygiene and universal use of footwear in endemic regions.

Studies based on stool examination in the 1960s and 1970s demonstrated prevalence rates of 0.5–4.0% in differing US cohorts, mostly in the Southeast and Appalachia [22, 25]. Although prevalence has subsequently decreased, infections are still seen in patients from those areas, especially those that are older than 50 years, institutionalized, of low socioeconomic status, or who have lived in rural areas [25]. In developing countries, strongyloidiasis prevalence rates can be striking in some cohorts, for example 25% in Thailand and Nigeria, 28% in Brazil, and 40% in Colombia [22, 25]. Because of the superior sensitivity of serology for diagnosis, seroepidemiology studies generally report higher prevalence rates than those based on parasite detection in stool samples; in one Peruvian cohort, 9% tested positive by stool examination for *S. stercoralis*, while 72% were seropositive [26]. Prevalence rates in resettled US refugees can also be high, where one recent study found 46% of a group of resettled Sudanese refugees to be seropositive for *S. stercoralis* [27]. Another study found that 39% of asymptomatic refugees in Boston with eosinophilia were *S. stercoralis* seropositive [28]. Given the high prevalence in many tropical and subtropical areas and the lifelong persistence of this parasite in the absence of treatment, physicians should consider strongyloidiasis both in persons with recent exposure to endemic areas and immigrant or refugee patients in developed countries even if they immigrated decades earlier.

Pathogenesis, Immunity, and the Hyperinfection Syndrome

Strongyloides infection is sustained over time in a given host by a small, stable number of intestinal adult worms. Although these die after a finite lifespan, autoinfection ensures the constant production of new worms, perpetuating the cycle even in the absence of reinfection [29]. In patients with chronic strongyloidiasis, autoinfection is normally well controlled by cell-mediated immunity, and the number of adult worms remains low and stable. With immunosuppression, more autoinfective larvae complete the cycle, and the population of parasitic adult worms increases, causing hyperinfection [29]. The large numbers of migrating larvae can disseminate, often associated with polymicrobial sepsis, pneumonia, and meningitis. Untreated, disseminated strongyloidiasis is usually fatal, and even with treatment, mortality approaches 25–30% [20, 30].

Both parasite and host factors affect regulation of this cycle. The population size of *S. stercoralis* in a host depends in part on secreted parasite hormones that regulate autoinfection [23, 31]. When the immune response is impaired, larger numbers of autoinfective parasites can develop, as reported in patients with hematologic malignancies, solid organ transplants (SOTs) and hematopoietic stem cell transplants (HSCTs), hypogammaglobulinemia, and those suffering from severe malnutrition [32–34]. Interestingly, there has been little association between cyclosporine use and hyperinfection syndrome; some evidence suggests cyclosporine may have an antihelminthic effect on *S. stercoralis* [35]. Conversely, tacrolimus does not appear to offer similar protection against *Strongyloides* [36].

Among HTLV-infected patients, there is a strong association with increased susceptibility to infection with *Strongyloides*, the hyperinfection syndrome, and poor response to treatment. Control of *S. stercoralis* in vivo is most dependent on the Th2 immune response, but the predominant immune response in HTLV-infected patients shifts from Th2 to Th1 [37–39]. There is some suggestion that *S. stercoralis* may hasten the development of leukemia among HTLV coinfected patients [40]. In contrast, there have been surprisingly few reports of hyperinfection among *S. stercoralis*-infected patients with AIDS. Although disseminated strongyloidiasis does occasionally occur in AIDS patients, this disease was removed from the list of AIDS-defining illness by the Centers for Disease Control and Prevention (CDC) in 1987 [41, 42].

Corticosteroid use carries a disproportionately high risk for disseminated strongyloidiasis compared to other forms of immunosuppression [43, 44]. Corticosteroids may upregulate growth of *S. stercoralis* and allow the parasite to develop preferentially into autoinfective filariform larvae, in addition to suppressing immunity [23, 45, 46]. They may also allow nonreproductive adult worms to regain reproductivity [31, 47]. Patients have developed hyperinfection after only a few days of corticosteroid administration [48].

Clinical Findings

Most patients infected with *S. stercoralis* are asymptomatic or have only mild symptoms. Shortly after infection, some patients develop a localized, erythematous, pruritic rash [30, 49–51]. Pulmonary symptoms and eosinophilia may appear several days later; diarrhea and abdominal pain may follow. Blood is occasionally detected in the stool, but over 50% of infected patients are asymptomatic. Chronic strongyloidiasis is not generally associated with pulmonary symptoms. Although about 75% of chronically infected patients have eosinophilia, it is usually low-grade [22, 52]. Migrating larvae may produce larva currens, a serpiginous, erythematous, track-like rash. Some chronically infected patients note epigastric pain, nausea, diarrhea, blood loss, and possibly malabsorption. Rarely, heavy infections can cause bowel obstruction. The majority of chronically infected patients are asymptomatic [43]. There has been an association between *S. stercoralis* infection and biliary cancer, but this observation requires confirmation [53].

With hyperinfection, the intestines and lungs harbor many larvae, and diarrhea is common (Fig. 46.3). When dissemination occurs, larvae are found widely, sometimes involving the central nervous system (CNS). Eosinophilia is usually absent during hyperinfection. Other gastrointestinal manifestations are common, including abdominal pain, vomiting, and intestinal obstruction. Hemorrhage, peritonitis, or bacteremia can occur. Pneumonitis is common, with cough, respiratory failure, and diffuse interstitial infiltrates or consolidation on radiographs; respiratory secretions often contain the parasite (Figs. 46.4a–b). CNS invasion may cause meningitis and brain abscesses, with larvae in the cerebrospinal fluid or tissue. An association with SIADH has been reported [54, 55].

Diagnosis

Uncomplicated strongyloidiasis can be diagnosed by finding rhabditiform larvae in microscopic stool examination; it is uncommon to find eggs in the stool. Because few larvae are shed, the sensitivity of a single stool examination is only about 30%; multiple samples should therefore be examined, preferably using concentration techniques. Examination of up to seven stool samples can significantly increase sensitivity [22, 56]. Sampling of duodenal fluid or a small bowel biopsy can increase sensitivity, but practical issues limit usefulness [57]. Placing stool samples on agar plates to observe tracks left by the motile larvae may be the most sensitive method among the stool examination techniques [58–60]. Although not yet in widespread use, PCR assays of stool samples for the diagnosis of intestinal strongyloidiasis have recently begun to show promise [61, 62].

Because of the difficulty with microscopic diagnosis, serologic tests (which are more sensitive) are often favored, such as the enzyme-linked immunoassay offered by CDC (Atlanta, GA). This assay is about 95% sensitive in stool-positive patients, although specificity is lower because of cross-reactivity with other helminths [26, 52]. The titer of *Strongyloides* antibodies in infected patients generally begins to decline 6–12 months after cure, as does the peripheral eosinophil count [52, 63, 64]. In contrast to chronic strongyloidiasis, hyperinfection and disseminated strongyloidiasis are easily diagnosed by microscopic stool examination (or other samples, such as sputum), which typically contain many filariform larvae (Figs. 46.5 and 46.6).

Strongyloidiasis in Transplant Patients

Given the risk of hyperinfection syndrome, identifying strongyloidiasis in transplant patients is critical. Although most common in endemic areas, this consideration is also paramount in non-endemic areas, given the global increase in travel and immigration. One retrospective review at a U.S. cancer center found 2.0 *S. stercoralis* infections per 10,000 leukemia patients and 0.8 infections per 10,000 cancer patients overall; however, systematic screening was not done, so these are likely underestimates. Among the infected patients, 48% had received systemic corticosteroids, and 36% had received anti-neoplastic therapy. Fifty-seven percent had diarrhea, 48% eosinophilia, and 24% developed the hyperinfection syndrome [65].

Strongyloidiasis has been well described in the posttransplant setting, and has been reported in scores of renal transplant recipients, most of whom developed the *Strongyloides* hyperinfection syndrome [66–68]; about 40% died as a result. These patients presented 18 days to over six months after their transplant, with most manifesting at least two months after transplant. Strongyloidiasis has also been reported in the recipients of over a dozen non-renal SOTs, including in heart, liver, lung, pancreas, pancreas-kidney, and intestinal transplant recipients [66, 69–71]. These patients presented 16 days to nine months after their trans-

plant, with over half occurring at least one month posttransplant. Most of these patients developed the *Strongyloides* hyperinfection syndrome, and over half died as a result. The *Strongyloides* hyperinfection syndrome has also been reported in several HSCT recipients (both in autologous and allogeneic HSCT recipients) [66, 72–74]. These patients presented a mean of 87 days after undergoing transplantation (range 2–480 days), and almost 90% died.

Almost all of these patients had been to a *Strongyloides* endemic area at some point in their lives, including the southeastern United States in half of these cases. In about 15% of these cases, no exposure history was present and the transplanted allograft was therefore suspected to be the source of the *Strongyloides* infection in the recipient [66–74].

Only 18 (34%) of the 53 patients for whom data were available had eosinophilia prior to their transplant, while only 13 (25%) of 51 patients had reported symptoms possibly consistent with chronic strongyloidiasis prior to transplant. Despite the high prevalence of exposure to *Strongyloides*-endemic areas among the recipient population, only six (21%) patients among 29 for whom data were reported had been screened for *Strongyloides* infection prior to undergoing transplantation, all by stool ova and parasite (O&P) examination, and none by serology.

Treatment

All persons infected with *S. stercoralis* should be treated. The drug of choice for uncomplicated strongyloidiasis is oral ivermectin, 200 μg/kg per day for two days, which cures 70–85% of chronically infected patients. One study demonstrated a higher cure rate with two-dose ivermectin regimens compared to previously used single-dose regimens [75, 76]. Alternatives include thiabendazole or albendazole for 3–7 days, although ivermectin appears more effective; thiabendazole is poorly tolerated, and albendazole has the lowest cure rate among these drugs [76–80]. Ivermectin is also preferred for hyperinfection/disseminated strongyloidiasis. It should be administered daily until symptoms have resolved and larvae have not been detected for at least two weeks [21, 43]. Several patients with disseminated strongyloidiasis have received veterinary formulations of subcutaneous ivermectin. Although still experimental, this is an alternative for patients poorly tolerant of oral therapy and for those with severe infection [81–84]. Some patients have received a combination of ivermectin and albendazole with success [85]. If possible, immunosuppressive therapy should be stopped (particularly corticosteroids) or at least decreased. Some recommend monthly treatment subsequently for patients who require continued immunosuppression [19–21]. Follow-up stool examinations should be repeated frequently to document cure. For long-term follow-up, serology and eosinophil counts may offer stronger evidence of treatment efficacy. These findings generally begin to normalize 6–12 months after cure [52, 63].

Prevention of Hyperinfection

For all patients who are (or will soon become) immunosuppressed, examination of stool and preferably serologic evaluation for latent/occult *S. stercoralis* infestation should be undertaken for those who have lived in an endemic area or had other possible exposure to *S. stercoralis* at any time in their life, particularly those infected with HTLV-1 or receiving high-dose systemic corticosteroids [86]. Though most important for persons from highly endemic developing countries, this is also a consideration for patients with potential exposure in the southeastern United States, especially older persons who lived in these areas during childhood when the prevalence of *Strongyloides* was higher. Such screening would be particularly important for those with clinical symptoms of strongyloidiasis (e.g., eosinophilia, larva currens, and abdominal pain), although as noted above, screening should not be limited only to patients with these findings, as most infected individuals are asymptomatic. All infected patients should be treated promptly, preferably prior to the initiation of immunosuppressive therapy.

Although data regarding the cost-effectiveness of routine screening remain scarce, transplant programs should consider implementation of such a screening strategy as part of their pretransplant evaluation, to reduce the risk of *Strongyloides* hyperinfection syndrome and life-threatening dissemination post-transplant. In our opinion, screening solely by stool studies during the pretransplant workup is not adequate, and we recommend using at minimum the more sensitive serological assays for diagnosing of *Strongyloides* infection, with . stool studies added for patients who may not be producing antibodies normally. If a patient's condition requires immunosuppression before *S. stercoralis* diagnostics are available, the risks of empiric antiparasitic therapy for strongyloidiasis must be weighed against the risks of disseminated infection [87].

Other Parasitic Infections of Importance in Transplant Recipients

Although *T. gondii* and *S. stercoralis* are the most important parasitic infections in transplant recipients, others also warrant discussion given the increased risk of severe disease due to infection with these parasites in immunocompromised hosts.

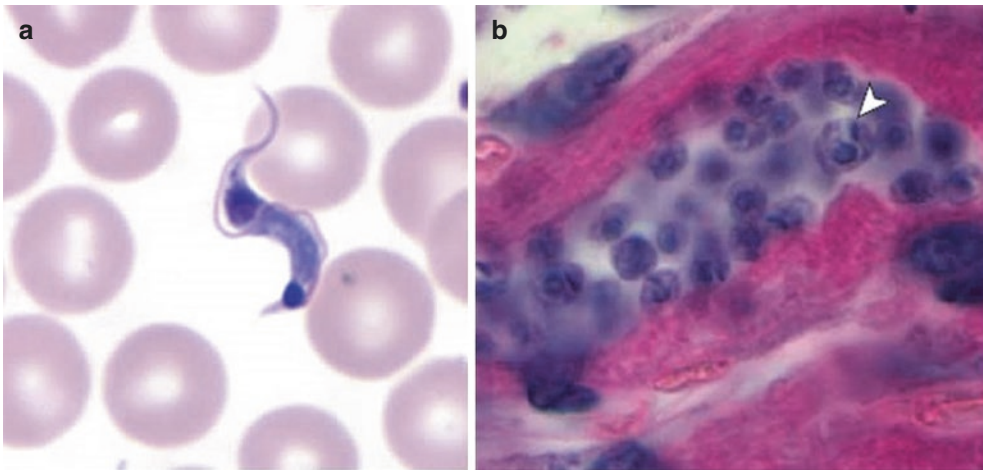

Fig. 46.7 (**a**) *Trypanosoma cruzi* trypomastigote in a thin blood smear. (**b**) *Trypanosoma cruzi* amastigotes in heart tissue [90]. (Courtesy Division of Parasitic Diseases and Malaria/Centers for Disease Control and Prevention, DPDx – Laboratory Identification of Parasites of Public Health Concern, https://www.cdc.gov/dpdx/trypanosomiasisAmerican/index.html)

***Trypanosoma cruzi* (Chagas Disease)**

T. cruzi is a protozoan endemic to the American tropics and subtropics, where it is transmitted primarily by bloodsucking triatomine insects, and transmitted occasionally by blood transfusion, the oral route, or vertically from mother to unborn child [88]. About 8–10 million people are chronically infected, 300,000 of whom live in the United States (almost all of whom were infected in Latin America) [89]. Acute infection is often asymptomatic, but patients occasionally suffer systemic symptoms in the weeks following infection such as fever, lymphadenopathy, hepatosplenomegaly, myocarditis, or meningoencephalitis; the parasite is often detectable in the peripheral blood during this phase of infection (Fig. 46.7a). Most patients recover and subsequently enter an asymptomatic *indeterminate phase* of infection, during which patients usually have only subpatent parasitemia. *T. cruzi* then persists indefinitely, causing end-organ disease in 20–30%, years to decades later [88]. Chronic heart disease is most common (e.g., conduction disease and heart failure), with chronic gastrointestinal disease (megaesophagus or megacolon) also seen. Diagnosis of chronic infection can usually be made serologically, although in immunocompromised hosts seroconversion may not occur.

Infection can also be transmitted by transplantation, as has been observed in 18% of kidney transplants involving *T. cruzi*-infected donors and in 22–29% of two small liver transplant cohorts who had received their organs from *T. cruzi*-infected donors in the United States and Argentina [91, 92]. Transmission rates from infected heart donors appears to be higher, and known *T. cruzi* infection of a potential donor is a contraindication to heart transplant, although the use of other organs from *T. cruzi*-infected donors might be considered in some situations [93]. Importantly, acute infection in transplant patients is more likely to be severe and may follow a prolonged incubation period (mean onset 112 days after transplantation) [92]. Several cases of SOT-associated transmission of *T. cruzi* have been reported in the United States [92].

A common indication for heart transplantation is chronic Chagas heart disease; in Brazil, it is the third most common indication for heart transplant [92]. Immunocompromised hosts chronically infected with *T. cruzi* are at increased risk for reactivation; this syndrome resembles acute infection but can be more severe. It can also resemble rejection, especially in heart transplant recipients. In these patients, reactivation rates of 20–90% have been reported with cyclophosphamide, and corticosteroid-containing regimens have been associated with higher rates; mycophenolate mofetil also appears to increase the risk of *T. cruzi* reactivation [92]. Atypical manifestations can be seen, including *T. cruzi* brain abscesses, skin lesions, and mucosal involvement [94, 95]. Treatment is with either nifurtimox or benznidazole; these drugs are relatively toxic, require 2–3 months of therapy, and in the United States are available only through CDC.

No consensus exists regarding an approach for detecting *T. cruzi* infection in U.S. transplant programs, but some form of serologic screening should be considered in all centers. For programs in areas with high *T. cruzi* prevalence in the population, universal screening could be considered, whereas in other areas, selective screening could be done based on any history of the donor or recipient living in a *T. cruzi*-endemic area (or being born to a mother that had lived in an endemic area). Posttransplant, if either the donor or recipient is infected with *T. cruzi*, guidelines now favor prospective monitoring of blood by Giemsa-stained peripheral blood smears and PCR, even if treatment had occurred earlier in life. Initiation of antiparasitic therapy is then recommended if this screening becomes positive [92, 93]. This approach detects most reactivation before patients become symptomatic while obviating the need for prolonged, toxic antiparasitic treatment regimens that most transplant recipients would receive if a preemptive, prophylactic treatment approach were used universally.

Such monitoring is recommended weekly for two months, every two weeks for the third month, and then monthly until

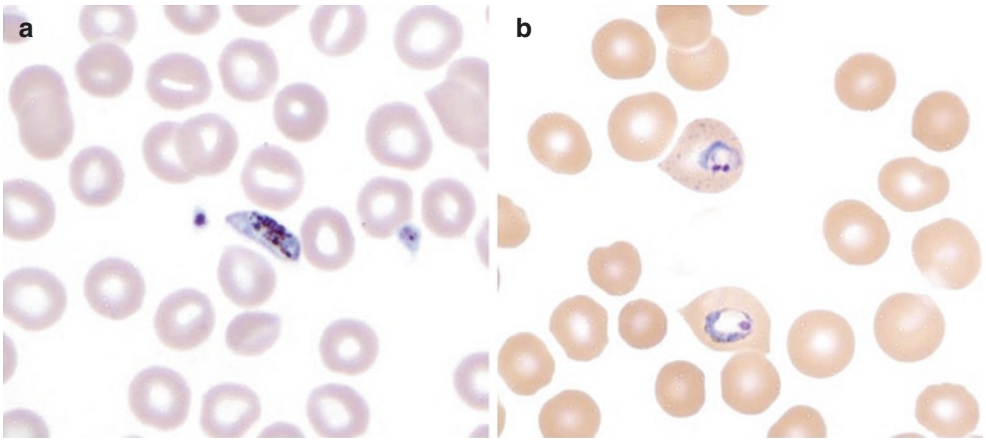

Fig. 46.8 (**a**) *Plasmodium falciparum* gametocyte in a thin blood smear. (**b**) *Plasmodium vivax* trophozoites (ring forms) in a thin blood smear

at least six months following transplantation [92]. Additional testing should accompany any febrile episodes or suspected rejection crises. In addition, endomyocardial biopsy specimens collected for routine monitoring or suspected rejection in heart transplant recipients should also be tested for *T. cruzi* by PCR and examined for the presence of the parasite and acute myocarditis [92, 96, 97] (Fig. 46.7b).

Malaria

Human malaria is caused by the mosquito-borne parasites *Plasmodium falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*, which parasitize (and subsequently hemolyze) red blood cells (Fig. 46.8a and b). Malaria is the most important parasitic infection globally, killing over 400,000 people annually and causing over 200 million symptomatic illnesses annually, with most of this morbidity and mortality attributable to *P. falciparum* [98]. Malaria is endemic primarily to sub-Saharan Africa, Asia, Oceania, and Latin America, with most of the mortality occurring in young African children. Diagnosis centers on the identification of parasites in blood smears, as well as by newer methods such as antigen and PCR detection. Uncomplicated malaria can manifest as fever, anemia, thrombocytopenia, myalgia, cough, and diarrhea. Severe malaria is defined in part by respiratory distress, renal failure, altered mental status, seizures, intolerance of oral medications, metabolic acidosis, hypoglycemia, or parasitemia greater than 5%. The mortality rate of severe malaria is high.

In the United States, the preferred treatment for uncomplicated *P. falciparum* malaria acquired in areas with chloroquine resistance is artemether-lumefantrine; atovaquone-proguanil, or oral quinine plus doxycycline are alternatives. The preferred treatment is chloroquine if malaria is acquired in one of the few remaining areas where *P. falciparum* is not chloroquine resistant (such as most of Central America and the Caribbean). Severe malaria (usually caused by *P. falciparum*) should usually be treated with intravenous artesunate plus doxycycline or alternatively intravenous quinine (quinidine in the United States) plus doxycycline. Chloroquine plus primaquine (or tafenoquine) is effective for uncomplicated *P. vivax* and *P. ovale* malaria in most of the world, and *P. malariae* or *P. knowlesi* infections can be treated with chloroquine.

Although not a disease classically associated with the immunocompromised state, malaria-infected patients who are coinfected with HIV are more likely to be febrile, have detectable parasitemia, and develop severe malaria compared with malaria-infected patients without HIV infection. Moreover, the clinical severity of malaria appears to worsen with advanced immunosuppression [99]. Malaria has been reported in over 50 SOT recipients, about three-quarters of whom were kidney recipients [100]. In at least 30% of these cases, the mode of transmission appears to have been the transplanted organ [100]. Cases have occurred in malaria-endemic areas, where both the donor and recipient could have been the source of the infection, and in non-endemic areas where the donor had previously visited malaria-endemic area and probably transmitted infection to the recipient. The incubation period for posttransplant malaria has ranged from three days to several months, with the potential for incubation periods as brief as a few days in contrast to naturally acquired malaria, for which the minimum is six or seven days [100]. The case-fatality rate has varied widely, depending on the infecting species, host immune status, and promptness of diagnosis and treatment.

Although malaria transmission due to blood transfusion is well established, transmission in the context of HSCTs has been described only rarely, possibly because *Plasmodium* spp. do not parasitize hematopoietic progenitor cells as they do mature red blood cells (RBCs). The risk of transmission thus appears to be lower for HSCTs and may depend on the small number of RBCs that inevitably accompany these transplants. An allogeneic HSCT donor transmitted malaria to a recipient in the United Kingdom in the 1990s, and recently, a peripheral blood stem cell transplant donor transmitted malaria to the recipient [101–103].

Although malaria in the transplant setting has been rare, screening for malaria by thick and thin blood smear assessment should be considered if the donor or recipient has traveled to a malaria-endemic region in the three years preceding transplantation. In addition, malaria can also be acquired posttransplant by a mosquito bite in an endemic area, and it is particularly important that immunocompromised patients who travel to malaria-endemic areas be administered a chemoprophylaxis regimen appropriate for that region.

Leishmaniasis

Leishmania spp. are intracellular protozoans usually transmitted by sandflies. Although cutaneous and mucocutaneous leishmaniasis can occur posttransplantation, the syndrome seen in most transplant patients is visceral leishmaniasis (VL) due to reactivation of subclinical infection or latent disease. Ninety percent of visceral leishmaniasis (VL) infections are acquired in South Asia, East Africa, or Brazil, although transmission also occurs in the Mediterranean littoral. A wide clinical spectrum exists, with most infections subclinical. Although immunocompetent patients can progress to symptomatic disease, immunosuppression is an established precipitant of progression [104–107].

Over 100 cases of leishmaniasis have been reported in the posttransplant setting, with about 75% in kidney transplant recipients and 12% in liver transplant recipients. Two-thirds of these cases were reported from the Mediterranean basin (mainly Spain, Italy, and France) [107–109]. Only ten cases have been reported in HSCT recipients [110].

Even in apparently immunocompetent patients who develop symptomatic VL, clinical disease often presents months or years after initial infection. When VL has occurred in transplant recipients, the onset was a median of 18 months after transplantation [109]. VL is characterized by fever, hepatosplenomegaly, weight loss, skin changes, pancytopenia, and hyperglobulinemia. Diagnosis is by biopsy and microscopic examination or culture of involved tissues, although serology can be an adjunct; untreated, progressive VL is usually fatal (Fig. 46.9). Treatment options include pentavalent antimony compounds, miltefosine, and paromomycin, but liposomal amphotericin seems to be the most effective drug. After clinical cure, relapse is a concern (although less than in AIDS patients), so secondary anti-*Leishmania* prophylaxis with various agents has been used in a small number of patients.

Acanthamoeba and *Balamuthia*

Acanthamoeba spp. and *Balamuthia mandrillaris* are free-living, ubiquitous environmental amoebae. Although clinically apparent human infection with these organisms is rare,

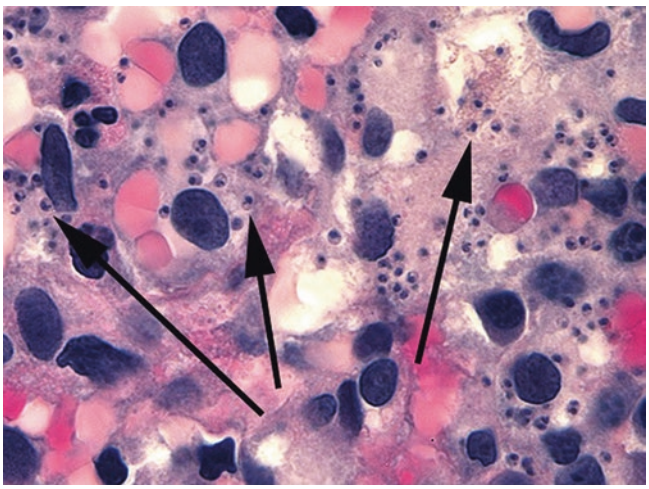

Fig. 46.9 *Leishmania* amastigotes in a bone marrow biopsy

immunocompromised hosts can develop granulomatous amebic encephalitis, a subacute or chronic syndrome manifested by altered mental status, focal neurologic deficits, fever, headache, seizures, and CNS mass lesions [111]. Disseminated disease can involve the skin, sinuses, lungs, liver, and bones; typical progression is over weeks to months [112]. Cutaneous lesions can be an early sign which heralds imminent dissemination and CNS involvement. Affected patients have included recipients of kidney, liver, heart, lung, and hematopoietic stem cell transplants [113–117]. *Balamuthia* transmission has also been reported as a result of graft-transmitted infection in a liver, heart, iliac vessel, and two kidney transplant recipients from a common donor in 2011; in liver and kidney-pancreas transplant recipients from a common donor in Arizona in 2010; and in two recipients of kidney transplants from a common donor in Mississippi in 2009 [118, 119]. Diagnosis typically requires microscopic examination of infected tissues, although serologic and PCR tests exist [120]. Case-fatality rates are high, even with combination antimicrobial therapy. There is no consensus regarding the best drug regimen to treat these devastating infections, but such regimens often include many of the following agents: pentamidine, azoles, sulfonamides, macrolides, albendazole, miltefosine, and flucytosine.

Schistosomiasis

Schistosoma spp. are blood flukes acquired through skin contact with infested freshwater; 200 million people worldwide are infected. *Schistosoma mansoni* is found primarily in Africa, the Arabian Peninsula, and South America, while *S. japonicum* is mostly seen in China, the Philippines, Southeast Asia, and Indonesia; both are associated with gastrointestinal or hepatic disease. *Schistosoma haematobium* is endemic to Africa and parts of the Middle

East, and it causes primarily genitourinary disease. Patients are often asymptomatic but with chronic infection can develop eosinophilia, abdominal pain, diarrhea, and hepatosplenomegaly. A minority may also develop symptoms with acute infection. Chronic infection can cause hepatic fibrosis, portal hypertension, and intestinal disease (due to *S. mansoni* or *S. japonicum*) or hematuria, urinary obstruction, and bladder cancer (due to *S. haematobium*) [121]. Diagnosis is classically through stool or urine examinations, but serologic assays and pathologic examination of infected tissues are more sensitive. Treatment with praziquantel is usually curative.

Over a dozen cases of schistosomiasis have been reported due to a transplanted graft mostly in liver recipients [122–124]. The course of schistosomiasis does not appear to be impacted by the immunocompromised state, and treatment is effective in most cases. The presence of schistosomiasis did not impact graft outcomes among a cohort of 240 kidney transplant recipients [125].

Intestinal Protozoa

Intestinal protozoa such as *Cryptosporidium* spp., *Cystoisospora belli*, and *Cyclospora cayetanensis* are transmitted by contaminated food and water, and can cause severe diarrheal illness in immunocompromised transplant recipients. Diarrhea is generally watery, and diagnosis is by stool studies. All three parasites can be detected through modified acid fast stains, *Cryptosporidium* and *Cyclospora* can also be detected through sensitive real-time PCR assays (often as part of an enteric pathogen diagnostic PCR panel), and *Cryptosporidium* can also be detected through sensitive stool immunoassays. Treatment of *Cryptosporidium* is with nitazoxanide, while *Cystoisospora* and *Cyclospora* are treated with trimethoprim-sulfamethoxazole [75].

Microsporida are protozoans that are closely related to fungi and can cause diarrheal disease in the immunocompromised patients. Disseminated microsporidiosis may also occur in this population, and can involve the CNS, lungs, or other internal organs [126]. Diagnosis is by trichrome staining of the stool, and treatment is with albendazole or fumagillin, depending on the species [75].

Part IV

Diagnosis of Infectious Diseases in Special Host

Impacts and Challenges of Advanced Diagnostic Assays for Transplant Infectious Diseases

47

N. Esther Babady, Yeon Joo Lee, Genovefa Papanicolaou, and Yi-Wei Tang

Introduction

The administration of immunosuppressive therapy to prevent rejection of allografts and graft-versus-host disease, although necessary, renders transplant recipients susceptible to opportunistic infections [1, 2]. As a group, transplant patients present a real challenge for initial diagnosis of infection partly due to lowered or absent markers of inflammation [2]. Traditionally, these infections have been diagnosed using bacterial, fungal, and viral culture as well as a variety of immunological assays. These methods still remain the standard of care for diagnosis of most infections. However, a series of advanced detection techniques led by nucleic acid amplification have now become prominent in most clinical microbiology laboratories, and novel proteomic assays are currently being added in the list of diagnostic tools available for infectious pathogen detection and identification.

The goal of this chapter is to review traditional and molecular methods used for the diagnosis of infectious diseases in transplants patients and discuss novel methodologies currently in development and their potential impact on clinical decisions.

Traditional Diagnostic Assays

Culture-Based Assays

Culture remains the gold standard for the diagnosis of most infectious diseases including those caused by bacteria, mycobacteria, and fungi [3, 4]. One of the advantages of culture is that it does not require a priori knowledge of the specific pathogen responsible for the infection as it casts a wide search net by using multiple growth media and incubation conditions. For example, diarrhea and vomiting are common symptoms in transplant patients, and determining the infectious cause for those symptoms can be challenging due to confounding factors such as intestinal graft-versus-host diseases (GVHD) in hematopoietic stem cell transplantation (HSCT) recipients, neutropenic enterocolitis, and immunosuppressive drugs [5]. A request for a bacterial stool culture will allow detection of the most common cause of bacterial gastroenteritis, namely, *Salmonella* species, *Shigella* species, *Campylobacter* species, and *E. coli* O157 with a recovery rate ranging from 0.2% to 2.4% [3, 6–8]. In addition, any other bacterial organisms growing on the culture media, with potential for causing gastrointestinal symptoms, will be detected and reported. However, culture of certain organisms, including *C. difficile*, the most common cause of bacterial diarrhea in hospitalized patients, requires special culture media and setup and has been replaced in most part by non-culture-based methods. Similarly, viral causes of diarrhea including cytomegalovirus (CMV), norovirus, adenovirus, rotavirus, and other small round viruses are better detected

by nucleic acid amplification tests (NAAT) and antigen tests [9–11].

The diagnostic yield of culture for various specimen types remains low. In one retrospective study, the yield of bronchoalveolar lavage (BAL) fluid culture for diagnosis of pneumonia in bone marrow transplant patients was reported at 2.2%, 3.0%, and 16.4% for bacteria, fungi, and viruses, respectively [4]. In contrast, the use of PCR tests and antigen testing increased the overall diagnostic yield to 22%, although the increased detection of CMV by PCR was not deemed clinically significance for all cases. The diagnostic yield of BAL in other studies was higher with one study reporting rates of 31%, 12.7%, and 23.6% for detection of bacteria, fungi, and viruses, respectively, in cancer patients [12]. For solid organ transplants (SOT), the overall recovery of pathogens by culture can be higher, up to 58.9% in lung transplants [13–15].

Blood culture is important for diagnosis of bacteremia and fungemia [16]. Unfortunately, the yield of blood culture remains low for both conditions [17–20]. Current blood culture systems are automated and set up to continuously monitor blood culture for the detection of microorganisms. An exception to continuous monitoring is the use of the isolator tube system, a manual lysis-centrifugation system (Wampole Laboratories, Cranbury, NJ). Performance of the isolator tube has been evaluated extensively against other automated blood culture systems designed to improve recovery of fungi such as the MYCO/F Lytic bottle (BD Diagnostics, Sparks, MD) with some studies showing increased recovery of *H. capsulatum* and *C. neoformans* [21, 22], while other concludes that the two systems performed equally well [23, 24]. A study by Creger et al. retrospectively analyzed the performance of the isolator tube system specifically in a cancer population and did not observed an advantage over conventional blood culture methods [25]. Even with the use of the isolator tube, the detection of fungi in blood culture is low, and in biopsy-proven candidiasis, only 50% of patients had a positive blood culture [26].

In transplant patients, the yield of blood culture varies with the type of transplant and the degree of immunosuppression. In lung transplant patients, the yield of blood culture can be as high as 25% with *S. aureus*, *P. aeruginosa*, and *Candida* species being the most common isolates recovered [27, 28], while in HSCT, the yield varies greatly from 4.9% to 8.7% and is dominated by Gram-positive bacteria [29–32].

The majority of fungal isolates from blood culture are *Candida* species, *with C. albicans* being the most common species isolated [18]. Although rare, other non-*Candida* yeasts including *Trichosporon* species, *Rhodotorula* species, and *Saccharomyces cerevisiae* are being recovered with increased frequency from blood cultures of immunocompromised patients [33, 34]. Fungemia caused by molds, including *Aspergillus* species, is rarely detected by blood culture [35–37]. In patients with indwelling devices, molds such as *Fusarium*, *Paecilomyces*, *Scedosporium*, and *Wangiella* have been recovered from blood culture [38–40].

A recent study by Limmathurotsakul et al. highlighted the limitation of culture as a diagnostic tools and an imperfect gold standard [41]. The authors applied Bayesian latent class models (LCM) to establish the true sensitivity of culture and the true specificity of four serological tests for detection of pathogens using *Burkholderia pseudomallei* and melioidosis as a model system. Using Bayesian LCM with either conditional independence (i.e., no single test considered gold standard and no correlation among tests) or conditional dependence (i.e., correlation among all tests), the sensitivity of culture was estimated to be 61% with a negative predictive value of 62.1% [41]. The specificity and positive predictive value of the four serological tests increased significantly using both Bayesian LCM models, emphasizing the limitation of using the culture as an imperfect gold standard.

Recent studies defining microbial populations of various organs using deep sequencing and high-density sequencing methods have now revealed the complexity of microbial organisms, many of them non-culturable, present in various tissues and the difference in composition for transplants versus healthy patients [42, 43]. The significance of detecting these non-culturable organisms for infectious diseases management remains to be established.

Antigens and Antibody Assays

Depending on the degree and type of immunosuppression, transplant patients may not be able to mount a sufficient antibody response to pathogens limiting the use of serological assays to detect antibodies [2]. On the other hand, antigen testing can be beneficial, especially for fungal infections where results of these tests are used as one of the mycological criteria to define invasive fungal disease (IFD) [44]. Some of the most commonly used antigen tests include the galactomannan (GM) antigen produced by members of the *Aspergillus* family and the (1,3) β-D (BD) glucans, present in the cell wall of *Aspergillus* and a variety of other molds and yeasts [45].

The serum GM assay (Platelia *Aspergillus* EIA, Bio-Rad Laboratories) was approved by the United States Food and Drugs Administration (FDA) in 2003. The assay is an enzyme immunoassay that uses rat monoclonal antibody EBA-2 to detect circulating GM antigen in serum. The GM assay has been evaluated extensively in various patient populations with sensitivity ranging from 30% to 100% and specificity ranging from 38% to 98% in serum with greater utility in HSCT patients than in SOT recipients [46]. In a study by Jathavedam and colleagues, the GM assay was shown to have limited utility within the first 100 days after auto-SCT

and therefore not useful for patient management decision [47]. In another study conducted in patients with hematologic malignancies, the sensitivity of the GM assay was 49% for invasive fungal infections caused by *Aspergillus* species other than *A. fumigatus* and only 13% for IFD caused by *A. fumigatus* [48]. Results of these various studies suggested that the performance of the GM assay depends on several factors including the infecting species of *Aspergillus*, the type of transplant populations, the frequency of testing, and the duration of antifungal therapy [45, 49]. The sensitivity of the GM assay in BAL of HSCT recipients and patients with hematological malignancies is higher than that reported for serum and ranges between 88% and 100% using the same optical density cutoff value used for serum [45, 50, 51]. In solid-organ transplant patients, the sensitivity and specificity of the GM assay in BAL ranged from 60% to 100% and 84–98%, respectively, depending on the optical density cutoff value used [50, 52–56]. Thus, the GM assay in BAL is a useful additional test for diagnosing IFD. False-positive results were observed in patients receiving piperacillin, amoxicillin, or ticarcillin with or without a beta-lactamase inhibitor, in patients being administered electrolyte replacement fluids (i.e., PlasmaLyte), and in patients infected with molds other than *Aspergillus* for a low specificity and positive predictive value [45, 57]. However, a study by Vergidis et al. showed that the current formulation of piperacillin-tazobactam do not appear to be contaminated with galactomannan [58].

Four assays, the Fungitell (Associates of Cape Cod Inc., East Falmouth, MA, cutoff, 60–80 pg/mL), the Fungitec-G (Seikagaku, Tokyo, Japan, cutoff, 20 pg/mL), the Wako (Wako Pure Chemical Industries, Tokyo, Japan, cutoff, 11 pg/mL), and Maruha (Maruha-Nichiro Foods, Tokyo, Japan, cutoff, 11 pg/mL) are commercially available for the detection of (1,3)-β-D (BD) glucans, a cell wall antigen found in most fungal species cell wall excluding *Mucormycetes* and *Cryptococcus* species [59]. A recent meta-analysis review of studies conducted in adult hemato-oncology patients showed similar performance for all four assays in the diagnosis of IFD, a higher diagnostic yield for performance of two consecutive tests, and an overall low sensitivity (52%) and high specificity (99%) for proven or probable IFD [59]. In another meta-analysis study, which included reports with various patient populations, the sensitivity and specificity of the BD glucans test were 77% and 85%, respectively [60]. Both studies concluded that the BD glucans assay was a useful adjunct test, especially for diagnosis of IFD due to *Candida* and *Aspergillus*. However, a recent report of high-false positive in patients with hematologic malignancies puts in question the value of this test as a stand-alone test for diagnosis of IFD [61].

The sensitivity of BD glucans is highest (90–100%) for the diagnosis of *Pneumocystis jirovecii* pneumonia (PCP), although its specificity in non-HIV immunocompromised patients varies widely (42–98%); therefore, results of the test taken alone are not conclusive for making a diagnosis of PCP [62, 63]. However, studies have shown that serum BD glucan levels correlate well with *P. jirovecii* fungal load in BAL as determined by *Pneumocystis* PCR, supporting the use of the assay to monitor response to therapy [62, 63].

Other useful antigens tests used for diagnosis of fungal infections include the latex agglutination cryptococcal antigen, which has higher sensitivity for central nervous system infection than disseminated disease, and the urine and serum antigen for endemic mycoses (*Blastomyces dermatitidis* and *Histoplasma capsulatum* antigens), although some cross-reaction occurs among targets [64].

The diagnosis of viral infections has been replaced in most instances by nucleic acid-based tests. Antigens testing and serological assays by methods such as direct fluorescent antibody (DFA) staining and enzyme immunoassays (EIA) do still play a part in the diagnosis of certain infections including diagnosis of acute or chronic hepatitis, infectious mononucleosis, and HTLV-1-/HTLV-2-associated T-cell leukemia [65]. One of the most common viral antigens tested in transplant patients is the CMV pp65 antigen for monitoring of viral loads [66]. The reported sensitivity and specificity of the CMV antigenemia test varies greatly due to lack of standardization in protocols including specimen processing, monoclonal antibody used, slide processing, and quantification [67]. Advantages of the antigenemia assay include its low cost in terms of reagents and equipment, but due to its disadvantages including the need for rapid specimen processing, the labor-intensive nature of the assay, and the subjectivity in reading of the slides, the antigenemia test has been replaced in many institutions by molecular tests for monitoring of CMV viral loads [67–69].

Bacterial antigen tests of importance for transplant patients include the urinary antigen tests for *Legionella pneumophila* serotype 1 (Binax, Scarborough, Maine, USA) and *Streptococcus pneumoniae* (Binax, Scarborough, Maine, USA), which are rapid, noninvasive tests useful in the diagnosis of both community- and hospital-acquired pneumonia [70, 71].

New Generation Diagnostic Assays

Although the use of culture and serological assays provides important information, their shortcomings created a need to develop faster and more sensitive assays. The following sections will cover the more rapid methods currently in use in most laboratories for diagnosis of infection and the newer methods being developed and conclude with the impact of these methods on the diagnosis and management of transplant patients.

Genomic Assays

The first published polymerase chain reaction (PCR) report described the amplification of specific target sequences of the β-globin gene for diagnosis of sickle cell anemia [72, 73]. Several modifications and improvements have occurred since that first report, ultimately resulting in the transfer of PCR from research laboratories to clinical diagnostic laboratories [74, 75]. Alternative nucleic acid amplification formats have since been developed including ligase chain reaction (LCR), nucleic acid sequence-based amplification (NASBA), branched DNA (b-DNA) signal amplification, strand displacement amplification (SDA), helicase-dependent amplification (HDA), and loop-mediated amplification (LAMP) [76, 77]. Numerous commercial molecular assays have been approved by DFA for diagnosis of microbial infections in transplant patients (Table 47.1).

The development of real-time PCR, combining rapid thermal cycling and real-time monitoring of amplification

products [78, 79], completely revolutionized the practice of clinical microbiology [80, 81]. Today, real-time nucleic acid amplification methods are mainstream in most sections of clinical microbiology, and their impact on care of transplant patients is significant.

Several real-time PCR laboratory-developed tests (LDT) as well as a few FDA-approved assays are used for the diagnosis of bacterial infections in transplant patients. Bacteria targeted for assays development have traditionally been those related to nosocomial infections. For example, until recently, most PCR assays for detection of *C. difficile* were LDT assays that resulted in an increased sensitivity and turnaround time for results [82–85]. At the time of this chapter preparation, the FDA had cleared over eight molecular assays for the diagnosis of *Clostridium difficile* infection (CDI). Similarly, rapid molecular assays have been developed for a variety of bacterial targets including difficult-to-culture or slow-growing organisms (i.e., *Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*, *Borrelia burgdorferi*), targeted diagnosis (i.e., group A *Streptococcus* in throat swabs), and nosocomial pathogens (methicillin-resistant *S. aureus*, methicillin-sensitive *S. aureus*, and vancomycin-resistant *Enterococci*) [80].

The turnaround time and identification of the most common *Mycobacteria* species were greatly improved with the introduction of nucleic acid hybridization probes in the laboratory. Nucleic acid hybridization probes are single-stranded or double-stranded DNA/RNA fragments complementary to a sequence in the target organisms and most commonly labeled with a fluorescent or chemiluminescent marker for detection [86]. Probes for same-day identification of *M. tuberculosis* complex, *M. kansasii*, *M. avium* complex, and *M. gordonae* from either solid or liquid cultures have been commercially available since the early 1990s (Gen-Probes, San Diego, CA). These probes show excellent sensitivity and specificity, although cross-reaction has been reported between *M. tuberculosis* complex and *M. terrae* [87–90]. Similar probes are available for identification of medically important filament fungal species.

The current trend for molecular diagnosis is a move toward syndromic, highly multiplexed real-time PCR assays and newer technologies including various solid and liquid microarray formats. Currently, FDA-cleared molecular syndromic panels are available for the diagnosis of respiratory tract infections, bloodstream infections, gastrointestinal infections, and meningitis/encephalitis (Table 47.2). These panels differ on the numbers of pathogens they can detect (5–27 targets), the type of pathogens included (e.g., bacteria, viruses, or yeasts), the level of complexity (low versus high), and the turnaround time to results (from 1 h to 12 h). Performance characteristics, however, are comparable with sensitivity and specificity greater than 90% when compared to culture or bi-directional sequencing as the gold standard [91].

Other multiplexed bacterial assays are available outside of the United States, for example, the LightCycler Septi*Fast* (Roche Diagnostics GmbH, Wien/Austria), a multiplexed real-time PCR-based assay that can detect bacteria and yeasts directly from whole blood. An agreement of up to 83% between SeptiFast and blood culture results has been reported with the overall conclusion that in its current form, the assay can be used to supplement rather than replace blood culture methods [92–94]. The SeptiFast assay has been shown to be especially useful in providing additional information for immunocompromised patients including liver transplants, septic ICU patients, and neutropenic patients, for fungal infection and in cases of prior antibiotic administration [93–96].

Other potential molecular methods have been developed and evaluated for the diagnosis of bacterial infections including sequencing [97], quantitative loop-mediated isothermal amplification [98], PCR hybridization [99], and mass spectrometry [100].

As described in the previous section, the diagnosis of IFD currently relies on microscopic examination, recovery of molds or yeasts in culture, detection of fungal antigens including galactomannan and BD glucans, and various radiological findings of pulmonary infiltrates [45, 101]. Although useful, these methods can lack specificity, be time-consuming, or result in inconclusive findings. A study by Lin et al. [102] suggested that earlier diagnosis of fungal infection could result in decreased mortality in neutropenic and cancer patients. Molecular diagnosis of fungal infections has relied mostly on the identification of organisms growing in culture. Nucleic acid hybridization probes for identification of *Blastomyces dermatitidis*, *Histoplasma capsulatum*, and *Coccidioides immitis* from culture isolates have been available since the early 1990s (AccuProbes, Gen-Probe, San Diego, CA) with sensitivity ranging from 87.8 to 100% and specificity nearing 100% [103, 104]. The hybridization probes are rapid and demonstrate good sensitivity and specificity from culture, although some cross-reactivity with uncommon fungal organisms has been reported [104, 105]. More recently, peptide nucleic acid fluorescent in situ hybridization (PNA FISH) probes and syndromic panel for bloodstream infections (FilmArray Blood Culture ID panel) have become available for rapid identification of *C. albicans/Candida*

parapsilosis, *C. glabrata/Candida krusei*, and *Candida tropicalis* from positive blood cultures [91, 106–108].

Several real-time PCR assays have been developed over the last few years with varied level of sensitivity and specificity and often with limited range, only targeting a few *Candida* or mold species [109–113]. A recent shift toward development of pan-fungal assay can be observed in the literature and reflect the need for tools that detect most of the clinically relevant fungal pathogens in patient specimens [114–117].

More recently, a few commercial assays and reagents have become available for the detection of mold directly from specimens. Several MycArray™ assays (Myconostica Ltd., UK) targeting yeasts, *Aspergillus* species, and *Pneumocystis jirovecii* are commercially available outside of the United States and demonstrates high sensitivity and specificity compared to culture or LDT assays [118–120]. Other molecular methods used for fungal diagnosis include sequence-based identification using the ITS1 and ITS2 regions between the 18S and 28S rRNA subunits and the D1/D2 region of the 25–28S large ribosomal subunit [121]. Several studies have been published showing the utility of sequencing for fungal identification, and in some laboratories, sequencing has completely replaced the use of phenotypic methods to identify fungi growing in culture [122–126].

Unlike bacteria and fungi, molecular methods for detection of viruses are well established and for most pathogens are considered the gold standard. As such, there is extensive literature on the development and applications of molecular assays for the detection of viruses of importance to transplant patients including herpesviruses (*Cytomegalovirus* and Epstein-Barr viruses), polyomavirus (BK and JC virus), hepatitis viruses, and respiratory viruses [80, 127].

One of the first application of molecular assays in virology included qualitative and quantitative real-time PCR assays for the diagnosis and monitoring of human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV). These assays have been extensively evaluated and shown to be useful for the management and monitoring of patients with these infections [128–132]. A variety of commercial tests based on PCR (or RT-PCR) combined with sequencing (i.e., TRUGENE HIV-1 Genotyping Kit and ViroSeq genotyping system) or hybridization (i.e., INNO-LiPA HBV DR v2) are available for genotypic resistance testing of HIV [133, 134], HBV [135, 136], and HCV [137, 138].

Similarly, quantitative viral load testing has been developed for monitoring of viruses of importance to various transplant groups including cytomegalovirus (CMV), Epstein-Barr virus (EBV), BK virus, JC virus, and adenoviruses [80]. However, the biggest challenge associated with the use of these laboratory-developed quantitative assays is the inability to compare viral load results obtained across laboratories due to differences in genomic target (single vs multi-copy genes), extraction methods (manual vs automated), detection platforms, and lack of international standards and calibrators [139]. These limitations of quantitative assays have made the establishment of useful quantitative threshold for treatment difficult to establish [140–145]. The recent introduction of the first World Health Organization (WHO) international standards for cytomegalovirus [146] and Epstein-Barr viruses [147] as well as the availability of the first FDA-approved commercial real-time quantitative assay for monitoring of CMV viral loads was aimed at decreasing the variability in viral loads measured across methods, but a recent study by Hayden et al. showed that although improved, the standardization challenge remains in the field [148].

Other useful molecular assays for transplant patients include genotypic assays for drug resistance testing. Because transplant patients are often on prolonged antiviral therapy, these patients tend to develop mutations. These mutations can be detected by real-time PCR assays targeting known existing mutations that confer resistance to certain drugs, i.e., CMV UL97 mutations for ganciclovir or sequencing assay to detect all wild-type variants [149].

Several molecular assays have received FDA clearance for detection of respiratory viruses (Tables 47.1 and 47.2). The configuration of these assays varies from single target to highly multiplexed assays. The first FDA-cleared multiplexed molecular assay for respiratory viruses, the xTAG® Respiratory Viral Panel (RVP) (Luminex Molecular Diagnostics, Toronto, Canada), targets 12 viruses and subtypes (respiratory syncytial viruses A and B; influenza A (H1 subtype, H3 subtype, and untypeable); influenza B; parainfluenza 1, 2, and 3; human metapneumovirus; adenovirus; and enterovirus/rhinovirus). This assay provided a significant improvement in the diagnosis of respiratory viral infections compared to conventional method and was instrumental in the rapid diagnosis of influenza A H1N1 during the 2009 outbreak in New York City [150, 151]. Additional multiplex molecular assays have since been approved including the FilmArray Respiratory Viral Panel (FA RVP) (BioFire Diagnostic Inc., Salt Lake City, Utah) FDA cleared for the detection of 17 viruses and subtypes including the virus targets in xTAG RVP plus human coronaviruses (NL63, HKU1, 229E, and OC43) and parainfluenza 4 as well as three bacterial targets: *Bordetella pertussis*, *Chlamydia pneumoniae*, and *Mycoplasma pneumoniae*. Multiple studies have been published comparing these highly multiplexed assays against each other, against monoplexed assays, and against traditional methods in various patient populations [152–157]. Results have shown comparable performance with overall sensitivity and specificity between 90% and 100%, although differences were detected for specific targets including adenoviruses, which are detected with higher sensitivity by

single target assays than by highly multiplexed PCR [156]. Other molecular devices for detection and identification of a panel of respiratory viral pathogens are also commercially available from several manufacturers including Gen-Probes (Prodesse assays), Focus Diagnostics (Simplexa assays), and Nanosphere, Inc. (Verigene assays) [158, 159].

A parasite of interest for transplant patients, especially those undergoing heart transplantation, is *Toxoplasma gondii*, which can be due to either reactivation of latent infection or acquisition of parasites from transplanted organs [160]. Unlike immunocompetent hosts, the diagnosis of toxoplasmosis in immunocompromised patients, including transplant recipients, is most effectively done using PCR on the appropriate specimens [160, 161].

Transcriptomic Assays

Genomic assays detect microbial organism-specific nucleic acids; therefore, a positive result can occur with both alive and dead microorganisms, which is particularly true for those pathogens that have protective cell wall. The best example of this is the detection of *Mycobacterium tuberculosis* DNA in sputum where the dead microbial pathogen DNA can remain un-degraded due to the fatty acid-rich cell walls [162, 163]. Unlike the results of a function-based testing method, such as mycobacterial cultures, in the clinical setting, a positive PCR result after antituberculosis therapy does not necessarily mean treatment failure. Therefore, DNA-targeted molecular assays are usually not considered to be tests of cure. This is also true for sexually transmitted pathogens such as *Chlamydia trachomatis* and *Neisseria gonorrhoeae* [164]. A positive result may reflect treatment failure with persistent infection but may also reflect resolved infection by detecting the mere presence of ribosomal RNA debris and nonviable *C. trachomatis* DNA [165].

To overcome this disadvantage, transcriptomic assays have been explored. The ability of mRNA-based assays to distinguish viable from nonviable organisms suggests that such assays should be useful in monitoring the efficacy of antituberculosis therapy [166–170]. For monitoring efficacy of therapy, mRNA RT-PCR results paralleled well with those of culture at the follow-up time points [163]. Another study further demonstrated sputum *M. tuberculosis* mRNA is a reliable marker of bacteriologic clearance in response to several mono or combined antituberculosis therapies [162]. Nucleic acid amplification assays targeting microbial mRNA have also been used for diagnosis and assessment of human papillomavirus (HPV) infections. Several reports have shown not only the ubiquitous presence of E6 and E7 mRNA in cervical cancer but also a quantitative difference in the overexpression of E6/E7 depending on the severity of the cervical lesion [171]. Several E6 and E7 mRNA qualitative assays including Aptima (Gen-Probe), NucliSENS EasyQ HPV (bioMérieux), and PreTect HPV-Proofer (NorChip) have been reported to improve the low specificity and positive predictive value of HPV DNA assays [172].

Advances in molecular biology technologies, especially the real-time quantitative PCR formats, have made the implementation of mRNA-based assay relevant and accurate. Another novel approach known as RNA-seq, which uses next-generation sequencing technologies to generate transcriptome profiling [173], is starting to come into the diagnostic microbiology field [174, 175]. Using dual-species transcriptional profiling in a murine model of systemic candidiasis, Hebecker et al. observed a delayed transcriptional immune response accompanied by late induction of fungal stress response genes in the kidneys. In contrast, early upregulation of the proinflammatory response in the liver was associated with a fungal transcriptome resembling response to phagocytosis, suggesting that phagocytes contribute significantly to fungal control in the liver [176]. Rasmussen et al. combined longitudinal, dimensionality reduction and categorical analysis of the transcriptome from 111 liver biopsy specimens taken from 57 HCV-infected patients over time and identified alterations in gene expression that occur before histologic evidence of liver disease progression, suggesting that events that occur during the acute phase of infection influence patient outcome [177].

In contrast to these “fancy” and advanced technologies, transcriptomic assays face basic specimen source-related challenges. Currently, there are limited methods which can be used to differentiate and overcome the DNA contamination when mRNA targets are tested. Theoretically, specimens can be pre-treated with DNAase prior to the mRNA amplification and detection [178, 179]. However, absolutely RNase-free DNAase is rarely available to actually do the job. Designing primers/probes to cover RNA splicing sites has been demonstrated efficient if relevant RNA splicing sites are available in targeted bacteria and viruses [180, 181]. Indirect methods have been reported to determine antimicrobial susceptibility by selectively detecting viable microorganisms. This assay uses a DNA-binding dye that penetrates damaged bacterial cells and renders DNA un-amplifiable, thereby decreasing background amplification from killed organisms [182, 183].

Proteomic Assays

One leading proteomic technology, matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS), has emerged as a rapid and powerful tool for microbial species identification [100]. The analyte molecules embedded within the saturated matrix on the target plate are irradiated by a laser of special wavelength and intensity, inducing desorption and ionization; the charged

analytes then are accelerated by an electric field in a flight tube to a detector, where they are captured. The separation of various molecules depends on the time of flight, which is reversely proportional to the mass of molecules. After detection signals are processed and interpreted into the mass spectra, the characteristic mass peaks are used to characterize and eventually identify the microorganisms. By measuring the exact sizes of peptides and small proteins, which are assumed to be characteristic for each bacterial species, it is possible to determine the species within a few minutes of when the analysis is started with whole cells, cell lysates, or crude bacterial extracts [184–186].

Numerous reports have shown that MALDI-TOF MS has revolutionized the routine identification of microorganisms in clinical microbiology laboratories by introducing an easy, rapid, high-throughput, low-cost, and efficient identification technique [187–190]. Two such systems, the Bruker Biotyper (Bruker Daltonics Inc., Billerica, MA) and Vitek MS (bioMérieux Inc., Durham, NC), have been successfully used in the routine clinical microbiology laboratory [191, 192]. A recent comparative study was performed on five methods for differentiation of coagulase-negative staphylococci (CoNS), i.e., Vitek2 (Gram-positive card REF 21342; bioMérieux), the ID 32 Staph strip (bioMérieux), partial 16S rRNA gene sequencing (MicroSeq; Applied Biosystems), partial *tuf* gene sequencing (in-house), and MALDI-TOF MS (Bruker Daltonics), on 142 CoNS clinical isolates. MALDI-TOF MS showed the best results for rapid and accurate CoNS differentiation with 99.3% of strains correctly identified [193]. In addition to microbial identification from purified colonies, the MALDI-TOF MS has been successfully used directly from urine and positive liquid culture media [194–197].

In addition to rapid identification of microorganisms, MALDI-TOF MS has been explored for determining epidemic relatedness and antibiotic resistance of microbial isolates. The utility of MALDI-TOF MS for microbial typing was investigated in *Staphylococcus aureus* in two recent studies. The composition correlation index analysis of the MALDI-TOF MS data demonstrated the similar inter-strain relatedness found with the standard typing methods used to confirm the outbreak [198, 199]. These data indicated that this technology is a potential rapid screening tool for nosocomial infection investigations. The MALDI-TOF MS was capable of rapidly and accurately identifying *mecA*-positive *S. aureus* and *vanB*-positive *Enterococcus faecium* from susceptible isolates [200, 201]. The MALDI-TOF MS has been directly used to determine mechanisms of antibiotic resistance [202]. Bittar et al. described the use of a MALDI-TOF MS profile and a ClinPro Tools software to detect and identify staphylococcal Panton-Valentine leukocidin [203]. The detection and identification of a series of β-lactamases from Gram-negative bacilli by MALDI-TOF MS seem to be a powerful, quick, and cost-effective method for clinical microbiology laboratories [204–207]. These studies represented a proof of concept for the use of MALDI-TOF MS technology as a rapid method to timely monitoring microbial infections.

Numerous proteomic biomarkers have been used to diagnosis and monitoring of microbial infections. One of the most promising biomarkers in recent years is procalcitonin (PCT). PCT has many favorable properties as it is rapidly induced during infections and has a long half-life with capacity to differentiate bacterial from viral etiologies [208]. For the use and value of procalcitonin in SOT transplantation, the existing literature suggests reasonable sensitivity and specificity for the PCT test in identifying infection complications among patients undergoing transplantation. Monitoring PCT in the early posttransplant period seems to be a promising method for early detection of infectious complications; however, given the imperfect sensitivity and specificity of the PCT test, medical decisions should be based on both PCT test results and clinical findings [209, 210]. Recently, van Houten et al. reported the use of a three-host protein (TRAIL, IP-10, and CRP)-based assay to differentiate between bacterial and viral infections in children with lower respiratory tract infection or fever without source [211].

Metabolic Assays

Diagnosing bacterial infections by smell has been practiced for millennia. Volatile organic compounds (VOCs), produced by bacteria as metabolites, may be produced in different quantities and combinations by each bacterial species or serovar, generating characteristic odors. These compounds, in combination with other VOCs, could be used as a volatile fingerprint of each bacterium. Recently, fast and sensitive techniques, led by a variety of mass spectrometry platforms, have been developed and implemented to detect and characterize microbial pathogens based on microbial metabolite analysis [212]. In addition, metabolic analysis can be used for functional characterization including virulence and resistance determination. Gilreel et al. recently examined the metabolic potential of multidrug-resistant uropathogenic *Escherichia coli* and demonstrate metabolic activity of members of the ST131 lineage correlated with antibiotic susceptibility profiles [213].

Direct detection of exogenous fungal metabolites in breath may be used as a novel, noninvasive, species-specific approach to identify patients with invasive aspergillosis (IA), potentially allowing more precise targeting of antifungal therapy and fewer invasive diagnostic procedures. Gas chromatography coupled with mass spectrometry (GC-MS) has been the mainstay for the detection and characterization of VOCs produced by a panel of Gram-negative bacilli [214–216]. Unique GC-MS VOCs were found to be produced by

five *Aspergillus* species such as *A. fumigatus*, *A. versicolor*, *A. sydowii*, *A. flavus*, *and A. niger* cultivated on malt extract agar and gypsum board [217]. In another study, 2-Pentylfuran (2PF) was consistently detected in the media of *A. fumigatus*, *Fusarium* spp., *A. terreus*, and *A. flavus* and to a lesser extent by *A. niger*. 2PF was detected in breath samples from 4/4 patients with cystic fibrosis and *A. fumigatus* colonization, 3/7 patients with cystic fibrosis but no microbiological evidence of *A. fumigatus*, and none of the 10 healthy controls [218]. Using thermal desorption-GC-MS, Koo et al. characterized the in vitro volatile metabolite profile of *A. fumigatus*. A pathogen-specific metabolic signature combined with β-trans-bergamotene, α-trans-bergamotene, a β-vatirenene-like sesquiterpene, and trans-geranylacetone accurately discriminated patients with IA from patients with other pneumonia [219]. Besides *Aspergillus* species, VOCs such as nicotinic acid have been found to be promising biomarkers for *Mycobacterium tuberculosis* infections [220].

Clinical Perspective

During the last 10 years, mortality related to infection after HSCT has declined substantially [221]. Nonetheless infection remains a substantial cause of non-relapse mortality. Use of alternative donors such as cord blood and haploidentical donors, older age at transplant, and increased comorbidities continue to increase [222, 223]. These transplant characteristics have been associated with increased infection risk. Furthermore neutropenia, T-cell depletion, GVHD, and immunosuppressive agents continue to shape the spectrum and period of risk for specific infections. Our expanding knowledge of the role of the human microbiome in the outcomes of transplantation provides new challenges and opportunities for clinical interventions.

Management of infections in the immunocompromised host poses several challenges. Inflammatory host responses are usually reduced or absent. Patients with life-threatening infections may present with minimal signs and symptoms and deteriorate rapidly often developing disseminated disease. Organisms of little or no pathogenicity for healthy individuals may cause life-threatening infections, and multiple pathogens may coexist in the same patient. Invasive procedures needed to maximize diagnostic accuracy may be not feasible due to thrombocytopenia or other conditions. Timely institution of broad empiric therapy is essential to improved outcomes; yet polypharmacy may lead to substantial toxicities and serious drug interactions.

The increasing implementation of nucleic acid-based assays in clinical practice has enabled rapid and often quantifiable diagnosis of an expanding list of organisms. Clinical decision-making is complex as quantification enables real-time monitoring of pathogen replication dynamics.

Table 47.3 Clinical applications of diagnostic assays in immunocompromised patients

Level	Goal
Prevention	Risk assessment
Preemptive	Testing asymptomatic patients at risk for disease
Diagnostic	Testing patients with clinical signs and symptoms of infection for specific pathogens
Therapeutic	Testing patients with established infection to direct treatment, assess response to therapy, and evaluate prognosis
Prognostic	Test patients at risk for recurrence of disease

Diagnostic assays are used by the clinicians to predict risk of infection in asymptomatic patients, monitor patients at risk for disease, diagnose disease in symptomatic patients, or monitor response to therapy or predict outcomes in patients with established disease (Table 47.3).

Prediction of Risk for Infection

The pretransplant evaluation of donors and recipients of HSCT includes serology to determine prior exposure to pathogens. The Federation for Accreditation of Cellular Therapies (FACT) requires donors and recipients to be tested for antibodies to HIV, human T-cell lymphotropic viruses I and II, HBV, HCV, and herpes viruses (HSV, VZV, CMV, EBV). Donors and recipients are tested for exposure to West Nile virus and *Trypanosoma cruzi*. Donors should be tested within 30 days prior to collection. Emergence of pathogens with potential for transmission through cellular products requires development of new diagnostic assays. A recent example is Zika virus. A non- FDA approved test is currently used to screen blood donors (https://www.cdc.gov/zika/transmission/blood-transfusion.html). However the current CDC recommendations to reduce transmission of Zika through human cells and cellular-based products are based on epidemiologic history (https://www.fda.gov/downloads/BiologicsBloodVaccines/GuidanceComplianceRegulatoryInformation/Guidances/Tissue/UCM488582.pdf).

Based on the results of the pretransplant tests, clinicians assess risks, benefits, and alternatives to HSCT or implement preventive treatment. For example, recipients with positive IgG antibody for hepatitis B (HBV) core antigen (with negative HBV surface Ag and negative HBV PCR) are treated with entecavir to prevent reactivation of HBV posttransplant.

CMV serology of the donor and recipient has major implications. For recipients with acute CMV infection indicated by positive CMV IgM (negative IgG), transplant may be delayed, and treatment may be required. The CMV serostatus of the recipient is the most important predictor for development of CMV infection posttransplant. Combined results of donor and recipient serology is used to optimize donor selection [224] . Given the availability

several donors with similar degree of HLA match, preference is given to donor matching the CMV serostatus of the recipient. For CMV-seronegative patients, the use of a CMV-seronegative donor alleviates the risk of CMV transmission through the allograft [225]. CMV-seropositive recipients who receive conventional allografts from CMV-seropositive donors are receiving CMV-specific cytotoxic T lymphocytes (CTL) contained in the allograft. Lymphocytes from CMV-seropositive donors can also be used to generate ex vivo CMV CTL for adoptive immunotherapy posttransplant [226]. The CMV serostatus of donor and recipient also determines the need for posttransplant serial monitoring for CMV. Recipients who are CMV positive or receive grafts of CMV-seropositive donors are monitored by CMV PCR, and preemptive therapy is initiated, if CMV infection occurs [227]. Another approach is antiviral prophylaxis for CMV for high-risk groups such as recipients of mismatched or T-cell-depleted allografts [228]. It will be interesting to assess whether CMV monitoring by the PCR will eliminate survival differences between CMV-seropositive and CMV-seronegative recipients.

Additional screening may be indicated for donors and recipients of T-cell-depleted grafts. Toxoplasma serology is not required by FACT and is tested per institutional practices. Patients receiving T-cell-depleted allografts are at higher risk of toxoplasmosis compared to patients who receive conventional allografts. Thus recipients of T-cell-depleted allografts may be candidates for prophylaxis against toxoplasma posttransplant. At present the interpretation of serology is qualitative (positive vs negative). Recent studies suggest that the magnitude of titers may be relevant in predicting disease risk. Meers et al. reported that high titers of toxoplasma IgG pretransplant were associated with increased risk of toxoplasmosis after HSCT [229]. Given the low frequency of toxoplasmosis in HSCT, a multicenter study would be required to confirm these findings.

The notion that the magnitude of IgG titers may be useful as a predictor for infection posttransplant was also supported by a pilot study assessing pretransplant antibodies to adenovirus (ADV). In that study, patients with high pretransplant IgG titers to a specific ADV serotype were more likely to develop ADV infection with the same ADV serotype after HSCT [230].

Patient exposures may also indicate the need for additional testing. For example, QuantiFERON Gold ™ testing for detection of latent tuberculous infection is pertinent for transplant candidates from endemic areas for *M. tuberculosis* [231, 232]. Patients with latent tuberculous infection pretransplant will require treatment posttransplant. Pretransplant stool examination for ova and parasites for transplant candidates coming for endemic areas of *Strongyloides stercoralis* or empiric treatment for *Strongyloides stercoralis* pretransplant could be employed for such individuals [233].

PCR Assays for Detection of Double-Stranded (ds) DNA Viruses

The availability of commercially available quantitative PCR assays for many dsDNA viruses has enabled the detection of these viruses in body compartments such as blood, urine, stool, bronchoalveolar lavage (BAL), or cerebrospinal fluid. While PCR assays provide accurate and rapid identification and quantification, several challenges remain regarding their optimal use and interpretation of results.

Cytomegalovirus (CMV)

CMV is an important cause of morbidity and mortality in transplantation. The biologic properties and natural history of CMV are well defined [234]. CMV viremia occurs frequently after HSCT and in most instances precedes development of end-organ CMV disease. Effective antiviral treatment is available, and preemptive treatment of CMV infection has been shown to be effective in preventing end-organ disease [235]. Routine monitoring is recommended for patients at risk for CMV disease [236, 237]. Currently PCR-based assays for CMV have replaced pp65 antigenemia assay in most centers. Green et al. reported that transition of preemptive therapy strategy from antigenemia to PCR-based monitoring and host risk factors successfully prevented CMV disease without increasing the proportion of patients receiving preemptive therapy and attributable toxicity [238]. The performance characteristics of individual CMV PCR assays vary; thus cutoff values and thresholds for treatment are not comparable among laboratories [145]. The availability of the World Health Organization (WHO) International Standard (IS) for CMV for nucleic acid amplification techniques is an important development for decreases variance between laboratories and enables to develop international clinical practice guideline [227]. Even with the WHO standardized assay, there is considerable variability (up to 1.5 $\log_{10}$ IU/mL) in different determinations of viral load from the same specimen [239].

Other Double-Stranded (ds) DNA Viruses

BK polyomavirus (BKV), adenovirus (ADV), and human herpesvirus 6 (HHV-6) are detected with variable frequencies in HSCT patients, yet their natural history is not fully understood. All these viruses have been associated with potentially serious end-organ disease and adverse transplantation outcomes. Yet the utility of routine monitoring and preemptive intervention have not been evaluated in prospective clinical trials. Because of the relatively low frequency of end-organ disease caused by these viruses, multicenter studies would be better suited to address such questions. Differences in diagnostic assays and clinical practices among institution and lack of approved treatments for these pathogens pose logistical difficulties.

BK Polyomavirus (BKV)

BK polyomavirus (BKV) is identified as a cause of allograft nephropathy in kidney transplants (BKVAN) and a cause of hemorrhagic cystitis in HSCT recipients [233, 240]. In renal transplant recipients, several studies have directly linked BKV replication to BKV nephropathy (BKVN), and BKV viremia is a predictor of BKVN in renal allografts [241]. Furthermore an association between the magnitude of BKV viral load in the blood and development of BKVN has been well described, and appropriate cutoffs have been established for the clinical significance of BKV viremia. BKVN cases have been reported in HSCT recipients [242–244]. The diagnosis for BKVN in HSCT recipients is challenging as kidney biopsy is oftentimes not feasible due to thrombocytopenia and bleeding risk.

The exact biologic relationship between BKV and hemorrhagic cystitis in HCT recipients is not well understood [245–252]. Some studies have shown a relationship between the magnitude of urine BKV viral load and development of hemorrhagic cystitis [253–255]. However the concentrations of virus vary widely and often overlap with patients who do not develop hemorrhagic cystitis. Unfortunately, no effective therapy is currently available for the prevention or treatment of symptoms associated with BKV, in large part due to a lack of understanding about its etiology and pathogenesis [256–261]. It is likely that the pathophysiology of cystitis in this setting is multifactorial with BKV reactivation as a contributing factor. The level of BKV viruria in HSCT exceeds by several logs the levels observed in renal transplants [250, 251, 254, 262]. Reduction of immunosuppression, the mainstay for management in renal transplantation, is not an option in the allogeneic HSCT due to the risk of triggering or exacerbating graft-versus-host disease. Despite the lack of established guidelines for the interpretation of BKV PCR results in HSCT and paucity of therapeutic measures for BKV in HSCT, BKV PCR is frequently ordered in symptomatic patients.

At our institution we prospectively monitored in 100 adult HSCT recipients for BKV in the urine by Q-PCR every 2 weeks from beginning of conditioning until week +15 posttransplant [252]. We found that 50% of patients had BKV viruria by day +30, and the rate remained stable for the duration of the study. Ten (10%) patients developed hemorrhagic cystitis (grade ≥2 by Bedi et al. [245]. Seven (70%) patients with hemorrhagic cystitis had BKV in the urine (two with concomitant adenovirus). In univariate analyses, high BKV viral load ($\geq 1.0 \times 10^7$ copies/mL) and older age were predictors of hemorrhagic cystitis. During the study period, 36 patients died and 8 patients had autopsies performed. One patient was found to have BKVN at autopsy. Our findings suggest that factors in addition to BKV are likely involved in the pathogenesis of hemorrhagic cystitis posttransplant. At present, we do not recommend monitoring asymptomatic patients for BKV in urine. In patients with symptoms of cystitis and no other identified etiology, we suggest checking BKV PCR once. We discourage monitoring of BKV viral load in the urine in patients with known BKV viruria. BKV nephropathy should be considered as a cause of renal dysfunction in severely immunosuppressed HSCT patients without any other obvious etiology.

Adenovirus (ADV)

Adenovirus infection occurs in <5–20% of HCT recipients depending on patient age, type of transplant, and degree of immunosuppression [263–265]. ADV-associated hepatitis, pneumonitis, and encephalitis are frequently fatal, while colitis and hemorrhagic cystitis cause substantial morbidity and may contribute to mortality [266–268]. More than 50 ADV serotypes are identified and differ in terms of frequency, tropism, and potential for disease severity [269]. ADV viremia has been associated with decreased overall survival after HSCT [270, 271].

Quantitative PCR assays for ADV have replaced for most part culture or antigen assays. Routine surveillance for ADV is suggested for high-risk patients such as recipients of T-cell-depleted transplant (TCD), cord blood transplant, or haploidentical transplant or for patients with refractory GVHD [272–274]. The American Society of Bone Marrow Transplant recommends serial monitoring for ADV by PCR during the first 6 months after HSCT or for the duration of severe immunosuppression and/or lymphopenia for patients at highest risk [275]. These recommendations are based on single-center experience and expert opinion but not validated in controlled trials. Ohrmalm et al. found little utility in serial monitoring of plasma ADV PCR in a cohort of 97 HSCT comprised of 64% T-cell-depleted allografts [276]. High level or rising ADV viremia has been reported to predict disseminated ADV disease and death [277–280]. Rising ADV viral load in the stool has also been reported as a useful predictor of ADV disease [279]. T-cell depletion, younger age, and GVHD have been associated with invasive ADV disease [266, 277–279]. Cidofovir has been used in established ADV disease and ADV viremia, yet its efficacy is based on small noncontrolled studies and case series [272–274]. Brincidofovir, a novel, orally administered, broad-spectrum antiviral active against ADV, has shown promising results in case reports [277, 281, 282]. A small randomized placebo-controlled clinical trial of preemptive treatment of ADV viremia with brincidofovir confirmed the antiviral activity in HCT patients however [283]. A subsequent open-label phase III study evaluated brincidofovir treatment for localized or disseminated ADV infection in adult and pediatric HSCT recipients. Virologic response was correlated with lower ADV viral load at start of treatment and earlier start of brincidofovir after ADV diagnosis. Gastrointestinal-related (abdominal pain, diarrhea, nausea, vomiting) symptoms

were most common adverse events and led to treatment discontinuation especially in adult HCT.

Since 2012, we have implemented routine blood PCR monitoring from day+14 until day+100 posttransplant in TCD and cord blood HSCT recipients. The rate of ADV viremia was 8%, and 33% of viremic patients developed ADV disease in TCD HSCT recipients. ADV disease was diagnosed within 60 days posttransplant, and 85% of patients with ADV diseases died. The benefit of preemptive therapy for ADV for prevention of ADV disease in recipients of TCD grafts should be evaluated in prospective clinical trials.

Human Herpesvirus 6 (HHV-6)

HHV-6 infects over 90% of individuals in the first 18 months of life. After resolution of the primary infection, the virus establishes latency mainly in CD34+ cells including monocytes and macrophages. An alternative form of HHV-6 persistence is integration of viral sequences into host cell chromosomes [284]. Approximately 40% of all HSCT recipients develop HHV-6 reactivation, and the cords rates may be >90% [285]. At our Institution 61% CD34+ selected HCT and 94% cord blood recipients (without ATG) developed early HHV6 viremia. Rates of HHV6 encephalitis were low in our patients, 0.7% and 1.6% in Cd34+ and cord blood, respectively [286].

HHV6 has been associated with a host of indirect consequences such as acute GVHD, CMV reactivation, and mortality after HSCT [287]. Zerr et al. suggest HHV-6 reactivation is associated with delirium and neurocognitive decline after HSCT [288]. The most recognized and severe form of HHV-6 is posttransplant acute limbic encephalitis (PALE). Hill et al. examined a cohort of 1243 adult donor HSCT and 101 umbilical cord transplants to identify risk factors for PALE. In multivariate analyses cord blood transplant, grade II-IV GVHD and adult mismatched donor were significant. While viral loads for HHV-6 were higher in patients with PALE, values greatly overlapped. Furthermore, peak values were detected a median 1 day to 9 days form symptom onset [289]. Foscarnet, cidofovir, and ganciclovir are available antiviral agents that demonstrated in vitro activity against HHV-6, but there are no controlled trials to study these agents for HHV-6 therapy. A few studies evaluating the efficacy of preemptive or prophylactic therapy to prevent PALE have been disappointing [290–292].

Diagnostic Evaluation of Specific Syndromes

Challenges

Infectious complications in transplant patients are often extremely complex to assess since there is a wide array of pathogens that can cause infections, including bacteria, viruses, fungi, and parasites. Further, patterns of pathogen infectivity vary tremendously, particularly in the setting of HSCT in which immune recovery plays a major role in defining the type and clinical presentation of many infections. Infections may occur as acute events such as a pneumonia or bloodstream infection, reactivation of latent organisms as in the case of herpesvirus infections, and colonization without true invasive infection or as recurrent, nonresponding, or resistant infections. Furthermore, sites of infections may be localized to a single body area or tissue or may be disseminated. HSCT recipients may be suffering from immune incompetence that can last for years.

Multiplex assays offer the advantages when the quantity of sample is limited as they provide information on multiple pathogens. Combination of multiple diagnostic platforms in the same sample and testing of several body compartments cast a wider net and expand diagnostic capabilities. We present specific challenges in clinical evaluation of pulmonary syndromes in HSCT patients.

Evaluation of Pulmonary Syndromes

Viral Infections

The use of PCR to analyze samples from HSCT recipients may facilitate early detection of respiratory viruses, even prior to onset of symptoms when viral loads are likely to be low. For symptomatic patients, PCR testing provides a sensitive diagnostic approach to identify the etiology of respiratory symptoms and an appropriate isolation of the ill patient. Additionally, quantitative RT-PCR assays can be used to initiate appropriate treatment and monitor changes in viral load during therapy.

Some respiratory viruses such as RSV, parainfluenza viruses, adenovirus, and influenza viruses are known to cause low respiratory infections associated with substantial morbidity and mortality in immunosuppressed patients. In contrast the correlation of the presence of rhinovirus or coronavirus in the upper respiratory tract with development of lower respiratory infection in HSCT is not clear [293]. The correlation between magnitude of viral load in bronchoalveolar lavage fluid and pneumonia or transplant outcomes is currently being investigated for a variety of viruses [294, 295].

The use of nucleic acid assays may contribute to identification of organisms not previously associated with pulmonary disease. Enterovirus D68 was recently associated with acute respiratory distress syndrome in infants and HSCT [293, 296]. Human metapneumovirus (hMPV) and human bocavirus have been reported as a cause of severe lower respiratory tract infection [297–299]. Two new human polyomaviruses, KI polyomavirus (KiPyV) and WU polyomavirus (WUPyV), are found in one third of allogeneic HSCT recipient's respiratory specimens during the first year posttransplant, but the associations with respiratory symptoms are unclear [300].

Invasive Fungal Infections

Diagnosing invasive pulmonary aspergillosis (IPA) remains a challenge. Tissue diagnosis is ideal, yet invasive procedures may not be feasible in critically ill patients especially those with cytopenia. Isolation of *Aspergillus* species from BAL may represent colonization or invasive infection depending on species and clinical context. For example, *Aspergillus versicolor* and *Aspergillus niger* are often not associated with disease when they were isolated from BAL specimens [301, 302]. Cytology in combination with traditional culture techniques may improve diagnostic yield. In a retrospective study comparing diagnostic yield of cytology and culture for septate, mold infections (cytology of BAL and bronchial wash specimens) had higher yield compared to culture of tissue (autopsy and biopsy) samples (58% vs 30%, $P < 0.03$) [303].

Noninvasive sensitive tests are needed for the diagnosis of mold infections. Detection of an *Aspergillus* secondary metabolite signature in a simple breath test showed 94% sensitivity and 93% specificity in diagnosis of IPA in a small preliminary study [219]. Such tests offer promising alternatives for patients that cannot undergo bronchoscopy.

Molecular-based assays are expected to allow a rapid diagnosis of *Aspergillus* and non-*Aspergillus* invasive fungal infections with a high sensitivity. In a recent multicenter prospective study evaluation, addition of PCR to GM in BAL sampling improved the diagnosis of invasive aspergillosis [51]. Initial validation studies of the serum GM assay reported 61% sensitivity and 93% specificity in probable and proven IPA; however, the sensitivity of serum GM is considerably lower in setting of mold-active azole prophylaxis [304, 305]. Determination of GM in the BAL fluid may improve the diagnostic utility of this assay. In a prospective cohort study including 530 patients with hematologic malignancy, the sensitivity and specificity of BAL GM was 50% and 73% for detecting probable and proven IPA [306]. Further prospective studies are needed for the combination of these two diagnostic modalities for the diagnosis of proven and probable aspergillosis.

Fungal PCR has been useful in confirming diagnosis of invasive fungal infections when traditional cultures are negative especially in patients previously treated with antifungal agents. At our institution among 46 patients participating in a randomized trial for antifungal prophylaxis of fungal infection in neutropenic patients undergoing induction or re-induction chemotherapy, six patients underwent bronchoscopy for evaluation of pulmonary infiltrates. BAL was tested by cytology, traditional fungal cultures, GM, and universal fungal PCR. None of the patients had positive fungal cultures or positive GM in the BAL. Fungal PCR identified *Rhodotorula nogopathi* and *Cryptococcus saitoi* in one patient each. While these fungi are not recognized previously as pathogens in humans, our patients responded clinically when antifungal therapy was adjusted to target these organisms.

Traditional culture techniques are routinely used for diagnosis of candidemia. The clinical relevance of non-*Candida* species isolated from blood has to be interpreted with caution. In a retrospective study of non-*Candida* fungemia episodes in allogenic HSCT recipients, 42% of patients did not have clinically significant fungemia [307].

Therapeutic Monitoring

Viral PCR

Monitoring of the viral load to assess response to treatment is a well-established practice for CMV. CMV viral replication in the blood usually correlates with disease activity. Depending on CMV viral load, clinicians may continue treatment, change dose or type of antiviral, or discontinue treatment. Less evidence exist on the correlation of ADV or HHV-6 viral loads with disease activity, yet clinicians routinely use viral loads as an aid to treatment decisions.

Monitoring of viral load of respiratory viruses as a prognostic indicator of lower respiratory tract infection in HSCT patients is not a routine clinical practice at present. Recent studies suggest that this approach may be of value [294, 308].

Genotypic Assays for Mutations Conferring Resistance to Antivirals

Genotypic assays for antiviral resistance may offer clinical guidance in a timely fashion. Commercially available assays are available for cytomegalovirus. Resistance usually emerges after prolonged or subtherapeutic exposure to antivirals in the setting of immunosuppression [309]. CMV resistance to current antiviral agents is mediated by alterations in either the UL97 kinase or DNA polymerase, encoded by the UL97 and UL54 genes, respectively. UL97 mutations are capable of conferring resistance to ganciclovir, while UL54 mutations can impart resistance to ganciclovir, cidofovir, and foscarnet [310].

Studies correlating CMV genotypes and drug susceptibility phenotypes may further guide treatment decisions. This will improve the interpretation of sequence-based assays currently used for clinical diagnosis and guide the development of new antiviral drugs [311].

Resistance of influenza virus to antiviral agents is a concern in immunocompromised HSCT patients due to high grade and prolonged viral replication and prolonged exposure to antivirals. Rapid identification of emerging resistance during treatment would be helpful in modifying treatment [312, 313].

Serial Monitoring of Fungal Burden Markers

In patients with invasive aspergillosis and positive serum GM at baseline, serial monitoring of serum GM provides useful information on response to treatment and prognosis. Koo et al.

reported that the combination of GM at baseline and at 1 week was predictive of all-cause mortality independent of other traditional risk factors for mortality and antifungal exposure [314]. In a prospective study, Bergeron et al. showed that (i) a poor day 45 outcome was strongly associated with a high baseline serum GM index; (ii) a consistently negative serum GM index during the follow-up was associated with a good outcome, in contrast to either a steady or an emerging positive GM index; and (iii) the day 14 clinical evaluation was predictive of the day 45 outcome [315]. In patients with treated *Aspergillosis*, rising GM levels after initial normalization raise concern for breakthrough infection and inadequate exposure of development of resistance to ongoing antifungal therapy.

Summary

In the last decade, nucleic acid-based assays have enhanced diagnostic sensitivity and specificity, shortened test turnaround time, provided automatic and high-throughput processing, and enabled quantification of microbial pathogens. A positive molecular test result indicates that targeted pathogen-specific nucleic acids are detected. For opportunistic pathogens in particular, clinical interpretation is crucial in determining the clinical significance of a positive test. Evolving genomics, transcriptomic, proteomic, and metabolomic technologies are being translated into clinical applications at a fast pace. Collaboration between laboratory and clinical medicine is paramount to ensuring optimal utilization and interpretation of diagnostic modalities.

Diagnosis of Systemic Fungal Diseases

48

Simon Frédéric Dufresne, Kieren A. Marr, and Shmuel Shoham

Introduction

Rapid and accurate diagnosis of invasive fungal infections (IFI) is critical to the care of solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients. Such infections are a by-product of immunosuppression and carry substantial morbidity and mortality. Improved diagnostic approaches and new and safer broad-spectrum antifungal agents have revolutionized treatment in these patients. This chapter will review the major diagnostic tools and their role in patients with suspected fungal infections. Diagnosis will be approached from the laboratory perspective, with an overview of methods used in clinical laboratories. Major organisms will then be presented separately, incorporating relevant clinical aspects that guide diagnostic approach.

Overview of Diagnostic Laboratory Methods in Clinical Mycology

General Principles

Until recently diagnosis centered upon detection of fungi from clinical samples using traditional staining and culture techniques, with nucleic acid and antibody-based assays playing a supportive role. The testing paradigm is shifting, with nonculture tests moving to the fore. Such assays are increasingly used as primary methods of diagnosis in a variety of invasive mycoses, including aspergillosis, candidiasis, cryptococcosis, and histoplasmosis [1–3]. Traditional and newer diagnostic approaches are complementary, and multiple tests are frequently employed simultaneously.

The major diagnostic modalities are (A) microscopic examination of biological specimens, including direct microscopy, cytopathology and histopathology; (B) culture followed by speciation using morphological, biochemical, and/or molecular methods and antifungal susceptibility testing; (C) serodiagnosis, antigen or antibody detection; and (D) nucleic acid amplification techniques (NAAT). The relative contributions of these methods for diagnosis of systemic fungal diseases are presented in Table 48.1.

Histopathology

Microscopic examination of thin-sectioned formalin-fixed paraffin-embedded tissue (histopathology) is generally sensitive and can provide definitive proof of infection when tissue invasion is seen. Major limitations are the requirement for an invasive procedure and the effort required for specimen preparation and processing. As for direct microscopy and cytopathology, unique morphological features can be used to differentiate hyalohyphomycosis (hyaline, septate, acute-angle branching hyphae), phaeohyphomycosis (darkly pigmented, septate hyphae), and mucormycosis (hyaline, non-septate, large ribbon-like, right-angle branching hyphae) and to identify *Cryptococcus neoformans/gattii*, *Pneumocystis jiroveci*, and the endemic fungi to the genus or species level. In addition, histopathology can demonstrate host responses, such as patterns of inflammation and tissue damage. For example, the asteroid bodies (Splendore-Hoeppli reaction) are associated with several fungal infections, including sporotrichosis [4].

Table 48.1 Relative contribution of different diagnostic modalities for detection of invasive fungi

Organisms	Histopathology	Direct microscopy/cytopathology	Culture	Antigen detection	NAAT	Host immune response	
						Humoral	Cellular
Aspergillus	++	++	++	+++	++	–	+
Other filamentous fungi[a]	++	++	++	–	+	–	+
Candida	+	++	+++	+	+	+	–
Cryptococcus	+	++	+++	+++	+	–	–
Pneumocystis	+	+++	–	++	++	–	–
Endemic	+++	++	+++	+++	+	++	–

–: not useful or available
+: rarely contributive; important limitations with regard to safety, availability, or performance (including lack of clinical data)
++: sometimes contributive; some limitations with regard to safety, availability, or performance
+++: often contributive; considered standard method for diagnosis
[a]Includes *Fusarium* species, *Scedosporium* species, *Mucorales*, dematiaceous fungi, and others

Modern histopathology relies on a combination of dyes with immunological and molecular techniques. Most fungi can be observed with hematoxylin-eosin (H&E), but specialized stains such as GMS and periodic acid-Schiff (PAS) are preferred and facilitate visualization of certain fungal structures. Certain stains are useful for specific fungi. For example, Giemsa is helpful for identifying *P. jiroveci* trophic forms, mucicarmine for *Cryptococcus* spp. (stains capsule), and Fontana-Masson for dematiaceous molds (stains melanin). When fungal structures are observed in tissue, formalin-fixed paraffin-embedded specimens can be analyzed further with immunohistochemistry [5] and in situ hybridization [6–8] to facilitate identification. Furthermore, DNA can be extracted from paraffin-embedded tissue, allowing nucleic acid amplification and sequencing [9–11]. This procedure may prove extremely useful when fungal elements are visualized in tissue, but concomitant culture is negative or not available.

Direct Microscopy and cytopathology

Microscopic examination of clinical samples is an extremely valuable tool. Despite lacking sensitivity, it is relatively simple, rapid, and reasonably specific. Visualization of fungal structures by direct microscopy serves three main purposes: 1) primary detection of a fungal pathogen in the sampled body site, 2) identification of the fungal pathogen based on morphological features (it reliably distinguishes major fungal groups such as yeasts, hyphomycetes and Mucorales, and even various species including Pneumocystis jirovecii, Coccidioides immitis/posadasii, Blastomyces dermatitidis and Paracoccidioidesbrasiliensis), and 3) interpretation of positive cultures, by helping determine whether growth from non-sterile specimens is clinically significant. Direct microscopy involves fresh specimens, which can be either directly mounted using saline alone (plain preparation), or stained with a dye that facilitates fungal visualization (with or without prior smear fixation). Common stains are the chitin-binding fluorescent dye calcofluor white (CFW), India ink, toluidine blue and immunofluorescent stains using P. jirovecii-directed antibodies. Cytopathology refers to examination of fixed free cells, usually obtained from liquid specimens such as bronchoalveolar lavage and pleural fluid. Solid tissues may also be sampled using fine-needle aspiration. Several stains are then used to visualize fungal elements, including Grocott-Gomori's methenamine silver (GMS) and Giemsa. Accurate microscopic examination relies on the experience and skills of the operator.

Culture

Culture is a cornerstone of fungal diagnostics. It is generally more sensitive than microscopy alone and facilitates fungal identification and antimicrobial susceptibility testing. Major limitations include suboptimal sensitivity, prolonged turnaround time, and biosafety issues. The significance of a positive culture depends upon the site from which the specimen was obtained, the organism isolated, and the clinical scenario. Growth from a normally sterile site is indicative of invasive infection. Isolation of certain pathogens (e.g., *Cryptococcus neoformans*, *C. gattii*, the endemic fungi) from any body site is virtually synonymous with disease. Conversely, recovery of *Candida*, *Aspergillus*, *Scedosporium*, *Mucorales*, and dematiaceous fungi from sites that are not normally sterile does not necessarily indicate infection and requires careful consideration of both the host and clinical context.

The initial steps involved in fungal culture are specimen collection and inoculation on media. Specimen quality is critical for optimal fungal recovery and to minimize contamination. Table 48.2 summarizes adequate specimens for recovery of different fungi.

Table 48.2 Adequate specimens for culture of pathogenic fungi

Organisms	Blood	Bone marrow	CSF	Respiratory secretions	Urine	Skin
Aspergillus	+	–	+	++	–	++
Other filamentous fungi	+[a]	–	+	++	–	++
Candida	+++	–	++	+	++	++
Cryptococcus	+++	–	+++	++	+++	++
Endemic	+++[b]	+++	++	++	++	++

CSF cerebrospinal fluid
–: virtually never recovered from this site
+: may be recovered, but generally considered colonization or contamination, or yield is very low
++: may be recovered only if site is clinically infected
+++: may be recovered in invasive disease and can be done even if site is not clinically infected or infection is not apparently disseminated
[a]Except for *Fusarium* spp. (+++)
[b]For *H. capsulatum*, using lysis-centrifugation methods or mycological media blood culture bottles for continuous monitoring blood culture systems; low yield for *Coccidioides* spp. (+)

In general, tissue and fluids are preferred over swabs. Volume should be ≥2 ml for cerebrospinal fluid and as much as possible for other sterile fluids. Most specimens should be transported to the laboratory as soon as possible, and some (e.g., corneal scrapings, prostatic fluids) require direct inoculation. Fungal culture media such as Sabouraud dextrose agar (SDA), inhibitory mold agar (IMA), brain-heart infusion (BHI) agar, and malt extract agar usually contain antimicrobial agents to prevent overgrowth by competing microbiota [12–14]. Many fungi grow within a few days, but some, including *Histoplasma capsulatum*, may need up to 6 weeks. Few studies have directly compared the yield of different media in a clinical setting. IMA was recently shown to recover more isolates than SDA in cultures of specimens from various sites, including yeasts and hyaline hyphomycetes and *Mucorales* [15]. For recovery from the blood, modern aerobic bottles in continuously monitored blood culture systems are adequate for yeasts and *Fusarium*. Special lytic mycological media bottles or the lysis-centrifugation procedure may be preferable for fastidious fungi such as *Histoplasma capsulatum* [16, 17].

Once an isolate is grown, identification is typically achieved using standard procedures. Macroscopic and microscopic morphology remain the mainstay of mold identification. Several vegetable-based or poor media (e.g., potato dextrose agar, Czapek-Dox agar, tap water agar) enhance conidiation and/or pigment production of some fungi and facilitate identification. Simple biochemical tests are also commonly used for yeasts. Other techniques include thermotolerance, nutritional requirements, and conversion assays for thermally dimorphic fungi [12, 18]. Molecular methods, such as simple hybridization [19] and genomic DNA sequencing [20], are increasingly used, especially when a higher taxonomic resolution is needed. Matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) mass spectrometry is emerging as a powerful tool for identification [21–24]. With the exception of some saprophytic filamentous fungi, identification should be made to the species level. Because many species have well established and predictable susceptibility patterns, identifying the species can have important prognostic and treatment implications.

Biosafety of laboratory personnel is a concern when culturing fungi, especially the thermally dimorphic fungi. Biosafety level 3 (BSL-3) practices, containment equipment, and appropriate facilities are required for handling sporulating mold-form cultures of *B. dermatitidis*, *C. immitis/posadasii*, and *H. capsulatum* [25]. *Coccidioides* poses a particular threat to laboratory workers [26]. This fungus can grow rapidly on bacterial primary isolation plates, and clinicians should alert the microbiology laboratory when infection with one of these organisms is suspected.

Antigen Detection

Assays that detect fungal antigens now assume an important role in the evaluation of patients with suspected invasive mycoses and are indispensible aids for diagnosing cryptococcosis, histoplasmosis, and aspergillosis. Their role in candidiasis, pneumocystosis, and other fungal infections is evolving. Favorable aspects of antigen detection assays include rapidity, ease of performance, and potential for diagnosing infections early in the disease course. Sensitivity and specificity remain a concern. Considerations of their pros and cons are important in developing preemptive strategies and point-of-care fungal antigen testing.

Various commercially available assays detect polysaccharides released from the cryptococcal capsule and cell walls of *Histoplasma* and *Aspergillus* and *Candida*. Suitable samples include serum, cerebrospinal fluid (CSF), bronchoalveolar lavage (BAL) fluid, urine, and other body fluids. Methodologies include latex agglutination (LA), enzyme immunoassays (EIA), and lateral-flow immunochromatographic assays (LFIA). Performance characteristics vary by kit, organism, specimen, clinical context, and cutoff used. A summary of commercially available assays is presented in Table 48.3.

(1-->3) β-D-glucan (BG) is an important fungal marker. This polysaccharide cell wall component is found in many fungi, with the notable exceptions of *Cryptococcus* spp. and the *Mucorales*, making it an almost "panfungal" marker.

Table 48.3 Commercial assays for detection of fungal antigens

Assay (manufacturer)	Method	Antigen detected	FDA-approved kit	Approved or most studied specimens (other specimens with clinical data)
Cryptococcus neoformans/gattii				
CALAS®: Cryptococcal antigen latex agglutination system (Meridian Bioscience Inc.)	LA	GXM	Yes	Serum, CSF
Latex-*Cryptococcus* antigen detection system (Immuno-Mycologics Inc.)	LA	GXM	Yes	Serum, CSF
Remel™ Cryptococcal antigen test kit (Thermo Fisher Scientific, Inc.)	LA	GXM	Yes	Serum, CSF
ALPHA cryptococcal antigen EIA (Immuno-Mycologics, Inc.)	ELISA	GXM	Yes	Serum, CSF
Premier® Cryptococcal antigen (Meridian Bioscience Inc.)	ELISA	GXM	Yes	Serum, CSF
CrAg lateral-flow assay (Immuno-Mycologics Inc.)	LFIA	GXM	Yes	Serum, plasma, CSF (urine)
Histoplasma capsulatum				
ALPHA *Histoplasma* antigen EIA (Immuno-Mycologics Inc.)	ELISA	N/A	Yes	Urine
MVista® *Histoplasma capsulatum* quantitative antigen EIA (MiraVista Diagnostics)	ELISA	GM	No	Urine, Serum (BALF, CSF)
Blastomyces dermatitidis				
MVista® *Blastomyces dermatitidis* quantitative antigen EIA (MiraVista Diagnostics)	ELISA	GM	No	Urine, serum (BALF, CSF)
Coccidioides immitis/posadasii				
MVista® *Coccidioides* quantitative antigen EIA (MiraVista Diagnostics)	ELISA	GM	No	Urine, serum (BALF, CSF)
Candida albicans				
Platelia™ *Candida* Ag Plus	ELISA	M	No	Serum
Aspergillus fumigatus				
Platelia™ *Aspergillus* Ag	ELISA	GM	Yes	Serum, BALF (urine, CSF)

LA latex agglutination, *ELISA* enzyme-linked immunosorbent assay, *LFIA* lateral-flow immunochromatographic assay, *GXM* glucuronoxylomannan, *GM* galactomannan, *M* mannan, *CSF* cerebrospinal fluid, *BALF* bronchoalveolar lavage fluid, normally sterile body fluids

Serum BG measurement has been mostly studied for diagnosis of aspergillosis, candidiasis, and, more recently, pneumocystosis. Four commercial assays are currently marketed, but only Fungitell® (Associates of Cape Cod) is available in the United States and Canada.

Nucleic Acid Amplification Techniques

NAATs are characterized by high analytical sensitivity and specificity and may allow reliable fungal identification directly from clinical samples, independently of culture. These assays are rapid (especially real-time PCR) and amenable to automation. However, discriminating infection from colonization or environmental contamination, especially when analyzing specimens from non-normally sterile sites, can be difficult. The reliability of these tests is impacted by fungal concentration, ease of DNA extraction (typically difficult for fungi), specimen type, and clinical scenario.

Most effort has focused on *Aspergillus* spp., *Candida* spp., and *Pneumocystis jirovecii*, but NAATs have been developed for most pathogenic fungi. Some target specific genera or species, while others are "panfungal," targeting universal sequences in the fungal genome [27]. Suitable samples include whole blood, serum, plasma, BALF, sputum, CSF, and tissue. Techniques include PCR, semi-nested PCR, nested PCR, PCR-ELISA, nucleic acid sequence-based amplification (NASBA), and real-time PCR. Novel technologies include PCR coupled with electrospray ionization mass spectrometry (PCR/ESI-MS) [28–30], PCR coupled with surface-enhanced Raman scattering (PCR-SERS) [31], and PCR with magnetic resonance [32].

For now, NAATs are not part of standard diagnostic definitions of IFI [33], although many experts advocate for their inclusion [34]. Many centers use "home-brewed" fun-

gal NAATs, and standardization and reproducibility of the assays are areas of ongoing efforts. The recent development of commercial assays will likely pave the way to wider availability and routine use.

Host Response

Another approach to fungal diagnosis is by measurement of antifungal host responses. This includes serology for detection of specific antibodies (humoral immunity) and detection of specific cell-mediated immunity. Serological methods include immunoprecipitation, complement fixation (CF), immunodiffusion (ID), counterimmunoelectrophoresis (CIE), and EIA. Cell-mediated immunity can be tested in vivo or ex vivo, with hypersensitivity skin testing and enzyme-linked immunoblot (ELISPOT) assay, respectively. While providing useful information, limitations of host response assays are that they may lack sensitivity in immunocompromised patients and may not be able to differentiate from active, quiescent, or past infection. Clinically, serology is most commonly used for coccidioidomycosis and histoplasmosis, and the tests are generally performed at reference laboratories.

Diagnosis by Organisms

Aspergillus

Clinical Syndromes and Diagnostic Approach

Invasive aspergillosis (IA) is a disease of immunocompromised patients. At highest risk are patients with profound quantitative and/or qualitative neutrophil abnormalities. Major risk factors include hematological malignancies and their treatment, allogeneic hematopoietic stem cell transplantation (HSCT), receipt of corticosteroid-based therapy (e.g., solid organ transplant recipients and patients with graft-versus-host disease), advanced HIV, and chronic granulomatous disease. *Aspergillus fumigatus* is the leading species involved, followed by *A. flavus*, *A. niger*, and *A. terreus* [35–40].

The most common sites of infection are the respiratory tract and sinuses. However, almost any organ can be involved with hematogenous seeding and continuous spread or due to inoculation at non-respiratory sites (e.g., skin, ears). The most common presentations include airway and sinus disease, which may manifest as antibacterial-refractory undifferentiated fever in the setting of prolonged and profound neutropenia. Given the wide spectrum of clinical disease, IA is included in the differential diagnosis of many pathogenic processes in susceptible hosts [40, 41].

The typical diagnostic approach includes pulmonary imaging followed by microbiological testing. For example, an HSCT recipient with fever, neutropenia, and lung abnormalities on computed tomography (CT) scan may have respiratory samples evaluated by direct microscopy, culture, galactomannan antigen detection, and possibly NAAT while simultaneously having blood tested for circulating biomarkers (GM, BG, DNA). With regard to respiratory sample, fiber-optic bronchoscopy with BAL is generally helpful and safe [42]. In HSCT recipients, the procedure may have a higher diagnostic yield and improve outcome when performed early after presentation [43]. Transbronchial biopsies are riskier, thereby limiting their utility in HSCT recipients [44].

In some high-risk populations, a preemptive approach is favored. In this setting, surveillance assays are performed regularly and trigger antifungal treatment upon positivity. Among allogeneic HSCT recipients (along with other high-risk hematologic patients), this strategy reduces antifungal consumption without affecting survival [45–49]. A recent meta-analysis suggested that a combination of GM and NAATs provides optimal performance, and aspergillosis is extremely unlikely when both biomarkers are negative [50]. Importantly, surveillance GM and PCR testing is not recommended for patients receiving anti-mold prophylaxis, in which context the very low prevalence of IA leads to a poor positive predictive value [51, 52]. In lung transplant recipients, limited data suggest that a culture-based preemptive strategy may reduce the occurrence of IA [53].

Laboratory Detection

Visualization of fungal structures by microscopy provides rapid and definitive evidence of infection when the sample is obtained from a normally sterile site. When the source is from a non-sterile site (e.g., respiratory secretions), results should be interpreted more cautiously. *Aspergillus* species appear in vivo as narrow (3–6 μm), septate hyphae with dichotomous 45° branching. The hyphae are hyaline after staining and usually indistinguishable from other hyalohyphomycetes [18]. Conidia are not typically seen in vivo, except in lesions with air-tissue interface, and in infections caused by *A. terreus*, in which vegetative conidia (aleurioconidia) can be observed along the hyphae [54, 55].

Culture is an important diagnostic modality but may remain negative even with positive stains. This may be due to disruption of delicate fungal structures during acquisition, transport, and processing of the specimen prior to inoculation onto fungal media. Moreover, host-adapted hyphae growing in a microaerophilic environment may not be fit for usual laboratory conditions [56]. It is extremely rare to

grow *Aspergillus* from blood cultures and such growth often represents a laboratory contaminant [57, 58]. *Aspergillus* isolates that do grow in culture can generally be identified further by simple phenotypic characteristics such as macroscopic and microscopic morphology (morphotyping) and thermotolerance. Occasionally, dysgonic isolates may grow as nonsporulating molds (i.e., sterile mycelium), which prevent identification through morphotyping. Such isolates may be mistaken as environmental contaminants or colonizers [59–61], but simple laboratory procedures can avoid such misidentification [62]. Some species (e.g., *A. fumigatus*, *A. terreus*, and *A. calidoustus*) are now recognized as complexes (sections) comprising groups of genetically and biologically distinct species [63], which may have differing susceptibility patterns and clinical presentations [64–67]. Species-level identification is best achieved by molecular methods (e.g., PCR-RFLP [68] and sequencing [69]), although thermotolerance at 50 °C allows definitive identification of *A. fumigatus* sensu stricto within the section Fumigati [70]. Internal transcribed spacer (ITS), beta-tubulin (*BenA*), and calmodulin (*CaM*) are standard gene targets for sequence-based identification.

Galactomannan (GM) testing has assumed an increasingly important role. This antigen is released by the growing *Aspergillus* hyphae and detected using the FDA-cleared double-sandwich ELISA Platelia™ *Aspergillus* Ag (Bio-Rad Laboratories Inc., Marnes-la-Coquette, France) [71–73]. An Optical Density Index (ODI) value of ≥0.5 is considered positive for serum [74]. With this cutoff, overall sensitivity and specificity for probable and proven IA are approximately 70–80% and 80–90%, respectively [75, 76], but vary according to clinical setting (diagnosis of active disease versus surveillance), use of concomitant anti-mold prophylaxis, number of tests performed, and patient population. Cross-reactivity can be seen with *Penicillium* spp., *Fusarium* spp., and *Histoplasma capsulatum* [77–80]. Treatment with piperacillin-tazobactam was a cause of false positivity [81–86], but this problem has almost disappeared [87–89]. GM can be used on a range of fluids including BALF, urine, and CSF [90]. When using an ODI cutoff of ≥0.5, the sensitivity and specificity of BALF GM are ~90% [91, 92], although some have reported much lower performances and GM alone cannot distinguish airway colonization from invasive disease [93]. Baseline GM indices and GM dynamics can be used as prognostic and treatment response markers [94, 95]. Assays targeting other antigens and using the lateral-flow technology are in development and could be useful as point-of-care tests [96–100].

Serum BG testing is another important diagnostic approach. The sensitivity and specificity of serum BG for aspergillosis are in the mid 70–80% range, although data from transplant recipient populations are very limited [101–105]. Of note, circulating BG is not specific for *Aspergillus* and false positives due to a range of non-fungal causes are not uncommon.

Tests of antifungal host immune responses have a limited role for diagnosis of IA. In immunocompromised hosts anti-*Aspergillus* antibody titers do not correlate well with invasive infection [35], but may be useful for identifying patients at higher risk for developing invasive infection following HSCT [106–108].

Multiple NAATs have been developed for *A. fumigatus* and are used at some centers. Earlier generation assays were largely "home brewed," lacked standardization, and exhibited variable performance characteristics [109–116]. Efforts at standardizing NAATs have been made [52, 117–120] and several commercially available assays have emerged. The LightCycler® Septi*Fast* (Roche Diagnostics) test detects 25 bacterial and fungal pathogens from whole blood samples, including *A. fumigatus*. Limited clinical data is available for hematological and solid organ transplant patients [121–124]. The MycAssay™ *Aspergillus* (Trinity Biotech) is a real-time PCR assay targeting the 18S rRNA gene and that evaluated for BALF, serum, and tissue samples [125–130]. The AsperGenius® (PathoNostics) is a multiplex real-time PCR assay detecting multiple *Aspergillus* species (*A. fumigatus*, *A. terreus*, and other *Aspergillus* species) along with major *cyp51a* mutations associated with azole resistance (TR34/L98H, T289A, and Y121F) and has been studied in both BALF and serum samples [34, 131–133]. The RenDx Fungiplex assay (Renishaw Diagnostics) uses the PCR-surface-enhanced Raman scattering (PCR-SERS) technology and detects four *Aspergillus* species (*A. fumigatus*, *A. flavus*, *A. niger*, and *A. terreus*) [31]. Finally, the MycoGENIE® *Aspergillus fumigatus* kit (Ademtech) is designed to detect *A. fumigatus* and the TR34/L98H mutation from various clinical samples (biopsies, respiratory tract samples, and sera), although no clinical performance data is available to this date. None of these assays have FDA clearance for use as in vitro diagnostics. Overall, clinical data on commercial *Aspergillus* NAATs remain scarce, but available studies have yielded encouraging results. Collectively, NAATs are thought to perform at least as well as the galactomannan antigen and many advocate for their inclusion within standard definitions [34].

Non-*Aspergillus* Opportunistic Molds

Clinical Syndromes and Diagnostic Approach

The *Mucorales*, *Fusarium*, *Scedosporium/Pseudallescheria*, and to a lesser extent the dematiaceous molds are the most important non-*Aspergillus* filamentous pathogens in organ transplant recipients [36, 37, 134, 135]. Infections may be limited to the lung or skin or involve multiple sites including the CNS, bones and joints, and the eyes [136]. They

are usually included with *Aspergillus* species in differential diagnosis of relevant clinical syndromes, and the diagnostic approach is similar, albeit with less reliance on circulating biomarkers and more on traditional diagnostic methods.

Laboratory Detection

In stained specimens, the hyphae of *Mucorales* fungi appear as broad, ribbon-like, and twisted with rare septa and irregular branching. Dematiaceous fungi appear darker on H&E and generally show moniliform (bead-like) hyphae along with large vesicular swellings. The dematiaceous molds are highlighted by the melanin-specific Fontana-Masson stain. *Fusarium*, *Scedosporium*, and *Aspergillus* appear very similar on microscopy of stained tissue and are difficult to differentiate from each other (collectively referred to as hyalohyphomycetes) [18].

Tissue should not be homogenized aggressively (with a mechanical tissue homogenizer or using a mortar and pestle) prior to culturing, as this may reduce the organism's viability. This is particularly critical for *Mucorales*. *Mucorales* are inhibited by cycloheximide contained in some selective media. Malt extract agar may increase primary isolation of the *Mucorales* from clinical samples [12]. *Fusarium* and to a lesser extent *Scedosporium* species may grow in blood cultures [137]. Growth from a non-sterile site does not necessarily indicate infection and must be evaluated in the context of the clinical scenario and direct staining results [138]. Identification to the species level and susceptibility testing can be very helpful for many non-*Aspergillus* molds.

There is only a limited role for serologic and NAAT-based techniques in non-*Aspergillus* mold infections. With the exception of the *Mucorales*, serum BG may be detected in such infections. Some *Fusarium* antigens cross-react with the GM-EIA [78]. Detection of *Mucorales*-specific T cells has shown promise as an adjunct to diagnosis of mucormycosis [139]. Innovative NAATs, including panfungal assays, have been developed but are limited to specialized laboratories [27, 140]. There are currently no commercial NAAT assays targeting those pathogens.

Candida

Clinical Syndromes and Diagnostic Approach

Candida species are normal commensals of the gut, skin, and female genital tract. Clinical manifestations can range from benign superficial infections to life-threatening deep-seated disease. The most common species are *C. albicans*, *C. glabrata*, *C. krusei*, *C. parapsilosis*, and *C. tropicalis*. Manifestations of superficial infection include thrush, esophagitis, intertrigo, and vulvovaginitis. Invasive candidiasis (IC) occurs when *Candida* gain access to deeper tissues, usually from an enteric or cutaneous source, with possible hematogenous dissemination to distant organs such as the liver, spleen, kidneys, lungs, heart, eyes, and skin. Candidemia is the most recognized form of IC and occurs with or without clinical evidence of deep-seated candidiasis. Conversely, deep-seated candidiasis is often not associated with candidemia [141].

It the SOT population, IC is mostly seen as a typical nosocomial infection, related to postoperative care, occurring during the weeks following transplantation in non-neutropenic hosts. Infection of the allograft itself, or at the site of surgery, is often found with concomitant bacterial infection [37, 39]. Conversely, most IC episodes after HSCT arise during or shortly after neutropenia, and the gut is the main source [38, 142].

Laboratory Detection

Microscopic examination may be useful for diagnosis of IC. Suitable stains include Gram stain, CFW, GMS, and PAS. Microscopically, most *Candida* species appear as oval-shaped 3–6 μm budding yeast cells with pseudohyphae and hyphae when invading tissue. Distinctively, *C. glabrata* produce smaller blastoconidia (2–5 μm) and do not form hyphae [18]. Results from non-normally sterile sites need to be interpreted cautiously, and histopathology is critical for distinguishing invasive disease from colonization.

Growth from a sterile body site, including blood, remains the principal means for diagnosis. *Candida* spp. are non-fastidious, fast-growing organisms that can be recovered on most routine media. Traditionally, *Candida* spp. were best cultured from blood by using a lysis-centrifugation method [143–147], but continuous monitoring blood culture systems (mycological media bottles or regular aerobic bottles) are as effective [16, 148, 149]. Regardless of the method, blood cultures are relatively insensitive because many IC forms do not have circulating viable organisms (candidemia) [141]. For instance, only about 10% of patients with candida endophthalmitis or chronic disseminated candidiasis (also called hepatosplenic candidiasis) have positive blood cultures [150, 151].

Identification of *Candida* to the species level following growth on primary culture is important for invasive infection. Methods include microscopic morphology (germ tube test and Dalmau method), biochemical tests, chromogenic media, and peptide nucleic acid fluorescence in situ hybridization (PNA FISH) [152–154]. MALDI-TOF is routinely used in many laboratories [23, 155–157] and can be performed directly from positive blood culture bottles [158].

Nonculture-based techniques are important adjuncts. The most developed of these is serum BG measurement. Many fungi including *Candida* produce BG. A cutoff of 60–80 pg/ml suggests invasive disease. Sensitivity and specificity are typically in the ~80% range [102]. False-positive results may be seen in a variety of circumstances including severe burns, extensive gauze packing, various blood products, renal replacement therapy with cellulose containing membranes, and infection with

Pseudomonas aeruginosa [159–161]. Accuracy is highest with candidemia, as compared to other forms of invasive candidiasis. The role of serial BG to guide early antifungal therapy in high-risk patients is unclear. There is a paucity of data evaluating BG-based preemptive therapy in the transplant population [104]. Controlled studies in high-risk intensive care unit patients have failed to demonstrate benefits over prophylaxis or empiric strategies [162–164]. Other biomarkers include mannan antigen (Platelia™ *Candida* Ag Plus, Bio-Rad Laboratories), anti-mannan antibody (Platelia™ Candida Ab Plus, Bio-Rad Laboratories), and the *Candida albicans* germ tube antibody (CAGTA) (invasive candidiasis (CAGTA) VirClia® IgG Monotest, Vircell), but clinical data are limited and the assays are not commercialized in North America [165–171].

Numerous NAATs have been developed for detection of *Candida* spp. directly from clinical specimens [172]. Until recently, standardization and clinical data was insufficient to support widespread use. A few commercial NAAT assays are currently available. The LightCycler® Septi*Fast* (Roche Diagnostics) detects five different *Candida* species (*C. albicans*, *C. tropicalis*, *C. parapsilosis*, *C. krusei*, *and C. glabrata)*, while the RenDx Fungiplex assay (Renishaw Diagnostics) targets three additional species (*C. guilliermondii*, *C. lusitaniae*, and *C. dubliniensis*) [31], from blood samples. Neither is currently available in North America and the data from transplant recipients is scanty [31, 123, 173].

The T2Candida® Panel (T2 Biosystems) uses a novel approach for diagnosis of invasive candidiasis from whole blood samples. This FDA-cleared test uses the T2Dx® instrument to extract and amplify *Candida* DNA (internal transcribed spacer 2) and then detects it via agglomeration of supermagnetic particles (attached to species-specific probes) and T2 magnetic resonance (T2MR) measurement. This technology exhibits high analytical sensitivity with limit of detection of 1 CFU/mL for *C. tropicalis* and *C. krusei*, 2 CFU/mL for *C. albicans* and *C. glabrata*, and 3 CFU/mL for *C. parapsilosis* [32]. The assay has a specificity of 99.4%, sensitivity of 91.1%, and negative predictive value reaching 99.5% (in a population with 5% prevalence of candidemia) [174]. Because of this high negative predictive value, the assay may serve to limit antifungal therapy in a low-to-moderate risk population, especially if coupled with an antimicrobial stewardship program. The cost-effectiveness of the test remains unclear based on model-derived analyses and should be assessed in prospective comparative trials [175, 176].

Cryptococcus

Clinical Syndromes and Diagnostic Approach

Cryptococcosis is caused by the ubiquitous *Cryptococcus neoformans* (serotypes A, D, and AD) and the more geographically confined *C. gattii* (serotypes B and C). Both encompass multiple phylogenetically distinct species, and some propose renaming them as "*C. neoformans* species complex" and "*C. gattii* species complex" [177]. Cryptococcosis is a major problem in patients with advanced HIV/AIDS but also affects other immunocompromised hosts such as SOT recipients. It is rare in HSCT recipients [36, 38, 39, 135, 178–180]. Primary infection occurs in the lungs, but CNS and disseminated diseases are common [181]. Virtually any organ can become infected including the skin, eyes, lymph nodes, and prostate. The latter can serve as a sanctuary for this yeast.

It is important to maintain a high clinical suspicion for cryptococcosis in immunocompromised patients. CNS, pulmonary, cutaneous, and lymph node abnormalities in an appropriate host should raise the possibility of this infection. Sometimes subtle neuropsychiatric symptoms or fever alone may be the only clues. Therefore, cryptococcal antigen testing is frequently done in transplant patients when an infection is considered. When cryptococcal infection is confirmed at any site in a transplant recipient, investigation of the CNS is recommended [182, 183].

Laboratory Detection

Cryptococcus can be observed directly in infected tissue and body fluids, including CSF, lung tissue, lower respiratory secretions, skin, and urine. Histopathology is sometimes required and is most helpful for skin biopsies. In clinical specimens, microscopic examination reveals GMS-positive round to oval yeasts, with a single narrow-base budding. Size may vary significantly (2–20 um for regular cells; up to 50–100 um for Titan cells), even within a microscopic field. The organism can be visualized with GMS, H&E, and even Gram staining. The thick polysaccharide capsule is a major feature and can be visualized with mucicarmine dye (for FFPE tissue). Occasionally, acapsular strains are encountered. Fontana-Masson, which stains melanin, is useful in such situations [18]. Visualization of the yeast cells in CSF with the India ink preparation is rapid but lacks sensitivity, especially in non-HIV/AIDS patients in whom the organism burden is lower [184].

Growth in culture is an important part of the diagnostic evaluation. *Cryptococcus* spp. can grow on most primary isolation media in 36–72 h but sometimes require longer incubation. Blood, CSF, respiratory specimens, and urine [185, 186] are all appropriate materials for culture. Identification is straightforward using standard biochemical tests. Differentiating between *C. neoformans* and *C. gattii* may have important clinical and therapeutic implications. This can be achieved using L-canavanine glycine bromothymol blue (CGB) agar, MALDI-TOF, or molecular methods [187–192], but most clinical laboratories do not currently distinguish between the two species.

The importance of the capsular polysaccharide antigen (glucuronoxylomannan, GXM) for diagnosis cannot be overstated. It has been used for diagnosis of cryptococcosis for more than half a century [193]. Suitable fluids include

serum, CSF, BALF, and urine. Various immunoassays (e.g., LA, ELISA, lateral flow) have been developed and commercialized for this purpose [194–200]. Pretreatment of serum samples with pronase improves sensitivity and specificity of the LA-based tests [201]. Cross-reactivity with *Trichosporon* has been reported, but this is uncommon [202]. Conversely, serum antigen may not be detected in primary pulmonary cryptococcosis [203, 204]. A next-generation lateral-flow immunoassay for point-of-care diagnosis is now available. This test can be applied to a range of specimens including CSF, serum, and urine and compares favorably to other assays [200, 205–207]. Probably because of the high performance of antigen detection, NAATs for *Cryptococcus* detection directly from clinical specimens contribute only marginally to the diagnostic arsenal [208, 209].

Pneumocystis

Clinical Syndromes and Diagnostic Approach

Pneumocystis jirovecii is a human-specific fungal pathogen that colonizes both immunocompetent and immunocompromised hosts. In patients with defects in cell-mediated immunity, mostly in the context of advanced HIV/AIDS or transplantation, it can cause severe pneumonia. Mortality is especially high among non-HIV-infected patients. Extrapulmonary sites are rarely involved (e.g., lymph nodes, liver, spleen, bone marrow) [210, 211]. When *Pneumocystis* pneumonia (PCP) is suspected, respiratory tract specimens (e.g., sputum, induced sputum, BALF, lung tissue) should be obtained for microbiological testing. Serum beta-D-glucan (BG) is increasingly used as a noninvasive diagnostic test for PCP.

Laboratory Detection

Pneumocystis jirovecii is not routinely cultivatable (achieved by one laboratory using a complex cellular culture system [212]); hence diagnosis is via culture-independent methods including microscopy, BG, and NAATs.

Definitive diagnosis is achieved by microscopic evidence of infection. In vivo, two different forms can be observed: cystic and trophic. This nomenclature is a relic of its former (obsolete) classification as a parasite. Giemsa stains the trophic form, while CFW, GMS, and toluidine blue are useful for visualization of the cyst form. The cysts are 4–7 μm and display one or two dark dots on their surface. The cysts have an oval (intact) or crescent (collapsed) shape and often form aggregates in a foamy substance [18]. Monoclonal antibodies are available in commercial kits for direct or indirect immunofluorescence [213–215]. The sensitivity of immunofluorescence-aided microscopy is superior to other stains [215, 216]. For microscopic methods, sensitivity of BALF is superior to that of less invasive specimens [216–221]. Generally, microscopy lacks sensitivity when compared to other methods. Immunofluorescence was reported to detect as few as a third of positive samples as determined by PCR [222]. However, as discussed below, some PCR-positive/microscopy-negative samples represent *Pneumocystis* colonization; sensitivity of microscopy for actual *Pneumocystis* pneumonia is estimated at 55–60% [223, 224]. This is particularly relevant for non-AIDS patients, in whom the fungal burden is generally lower [224, 225]. Consequently, in transplant recipients with suspected PCP, negative microscopic examination of BALF cannot rule out PCP.

Polysaccharide detection (BG) is an important adjunct for PCP diagnosis. BG serum levels correlate well with fungal burden [223, 226, 227]. Most studies have reported serum BG detection to be >90% sensitive [102, 228]. In contrast with microscopic methods, BG accuracy for PCP is not affected by HIV status [102, 228]. BG results must be interpreted with caution as the assay is not specific, but in the appropriate context, it is a good screening test, and a negative result is reassuring for absence of PCP.

Multiple NAATs using respiratory samples have been developed. Many are "in-house" assays, but several commercial kits are available, including the *Pneumocystis jirovecii* PCR kit (Bio-Evolution) [229–231], the AmpliSens® *Pneumocystis jirovecii* (*carinii*)-FRT PCR kit (InterLabService) [229], the PneumoGenius® (PathoNostics) [231], and the MycAssay™ *Pneumocystis* (Trinity Biotech) [126, 222, 229, 232]. The latter has been the most extensively studied. None are FDA-cleared. Most *P. jirovecii* NAATs are real-time PCR assays targeting the multicopy mitochondrial large subunit ribosomal RNA gene (mtLSU). The PneumoGenius® allows detection of two mutations in the dihydropteroate synthase (DHPS) domain of the FAS gene that confer resistance to sulfa drugs. As a general rule, PCR assays are extremely sensitive with a limit of detection 100 times lower than microscopic methods [233]. This difference is due to the methods' intrinsic analytical sensitivities and because NAATs detect both trophozoites and cysts, while microscopic methods are unreliable for trophozoites [233]. Sensitivity is virtually 100%, but the assay cannot clearly distinguish between infection and colonization with clinical false positivity ranging from 6% to 17% [126, 229, 232]. Efforts to establish a fungal load cutoff that would discriminate pneumonia from colonization have proved difficult [223, 230, 231, 234, 235]. Compared with microscopy, NAATs' sensitivity is more homogenous across different types of respiratory samples [229]. Serum DNA level correlates with pulmonary fungal burden [227], but is detectable only in high-burden infections and hence adds little to other diagnostic methods. NAAT testing can be applied to nasopharyngeal aspirates where sensitivity is slightly better than BALF microscopy, but less than BALF NAAT [236, 237].

Overall, microscopic methods suffer from a low sensitivity in transplant recipients, while NAATs are very sensitive

but also detect colonization. Blood BG testing could offer the best trade-off between sensitivity and specificity and is noninvasive. NAAT performed on a noninvasive respiratory sample such as nasopharyngeal aspirate may also become a useful tool for PCP diagnosis, but more data is needed.

Geographically Limited/Endemic Fungi

Histoplasmosis

Clinical Syndromes and Diagnostic Approach

Histoplasma capsulatum is associated with a range of clinical manifestations including asymptomatic infection (most common), acute and chronic pulmonary histoplasmosis, and progressive disseminated histoplasmosis (PDH). Disease may be due to reactivation or new infection [238]. Immunocompromised patients, such as SOT recipients, are particularly prone to PDH, which can take on a chronic-subacute to fulminant course [239]. Most infections become clinically apparent within 12–18 months after transplantation but may sometimes present much later [240, 241]. Typical sites of infection are organs of the reticuloendothelial system (RES) and the lungs. Other sites include the gastrointestinal tract (mucosa), genitourinary tract, adrenal glands, and skin. CNS disease is uncommon, even with disseminated infection [239]. Because of its protean manifestations, histoplasmosis is often part of the differential diagnosis of many clinical syndromes in SOT recipients, including various respiratory, hepatic, and febrile illnesses. When PDH is suspected in a transplant recipient, noninvasive assays such as antigen detection and blood culture are usually performed first. Additionally, samples from almost any clinically infected sites can be used for histopathology, culture, and/or antigen detection.

Laboratory Detection

Blood, bone marrow, lymph nodes, BALF, lung tissue, and occasionally CSF are important sources of specimens for staining and culture. On microscopy, the organism appears as small (2–4 μm) yeast cells with single narrow-base budding and a pseudocapsule. *Histoplasma capsulatum* var. *duboisii* is much larger (8–15 μm) with thick-walled budding. Yeast forms can be visualized extracellularly or within monocytes [18]. The latter can sometimes be seen in peripheral blood smear or a buffy coat preparation with Wright or Giemsa staining [242].

H. capsulatum can be grown using rich media such as brain-heart infusion (BHI) agar and incubated for at least 4 weeks [14]. Recovery in blood cultures is facilitated when a lysis-centrifugation system or an automated system with mycological blood culture bottles is used [16, 17, 148, 149]. In ambient temperature *H. capsulatum* grows as a mold on solid media. Once grown in this form, any manipulation of the fungus should be done in strict adherence to biosafety requirements [25]. Confirmation of *H. capsulatum* can be attained by the exoantigens method and by nucleic acid probes (AccuProbe® *Histoplasma capsulatum* Culture Identification Test, Gen-Probe®) [243] and PCR followed by sequencing [244].

Antigen testing is important for evaluation of disseminated histoplasmosis. For histoplasmosis after solid organ transplantation, antigenuria is the most common positive test (93% of cases in one study) [245]. The *Histoplasma* polysaccharide antigen (HPA), which is a galactomannan [246], is found in serum, urine, and BALF during infection. Detection of HPA is achieved mainly via the MVista® *Histoplasma capsulatum* quantitative antigen EIA (MiraVista Diagnostics, MVD). This test was first developed as a radioimmunoassay [247] and subsequently evolved over four generations of ELISAs [246, 248–250]. In certain circumstances, sensitivity can exceed 90% and tends to be highest with disseminated disease and when the test is performed on urine [239, 245, 246, 251–253]. Addition of EDTA-heat pretreatment for dissociation of immune complexes has further improved sensitivity [250]. The level of antigenuria correlates with severity of disease [254], and low-positive HPA results should be interpreted carefully considering the host, clinical presentation, and complementary tests [255–257]. Detection of HPA on BALF may complement antigenemia and antigenuria [258]. Cross-reactivity may be seen with other endemic mycoses, particularly blastomycosis and paracoccidioidomycosis [246]. The ALPHA *Histoplasma* antigen EIA (Immuno-Mycologics) was approved by the FDA in 2011 and remains the only commercially available kit for HPA detection. Similar to the MVD test, it is a sandwich ELISA utilizing polyclonal rabbit antibodies. This assay may be less sensitive than the MVD test, albeit proper clinical evaluation and comparison by independent laboratories have not been performed [259–265]. More sensitive second-generation reagents, based on a monoclonal antibody, are still less sensitive than the MVD test and are neither commercially available nor FDA-cleared at this time [266–268]. Of note, the HPA can be detected by the Platelia™ *Aspergillus* EIA, but at a lower magnitude [80, 269]. This can be particularly useful in areas where specific HPA assays are unavailable [79, 270]. While BG may be detectable during histoplasmosis [271, 272], it is not routinely used in this setting.

Serology is mainly performed using either CF or ID [1, 238]. Generally, serology lacks both sensitivity and specificity. Low sensitivity is particularly problematic in immunocompromised hosts. The two tests are complementary with ID being less sensitive, but more specific than CF. Combining both techniques may increase sensitivity. In CF, antigen extracts from the yeast and mold phases of the organism are used separately (the culture filtrate of the mold phase is histoplasmin). Results are reported as antibody titers against

each of the antigen preparations. A titer ≥1:32 is suggestive of infection (recent of remote), while a fourfold increase in titers between acute and convalescent sera is diagnostic for recent infection. ID is a qualitative method that detects two antibodies, the H- and M-precipitins, which bind the H and M antigens, respectively (both are glycoproteins contained in histoplasmin). In the ID test an M band in seen in both acute and chronic forms, whereas the H band is encountered less commonly, usually in chronic or severe infections. The M band may persist for years even after complete resolution of the infection. Serology is best for mild-to-moderate acute pulmonary histoplasmosis, chronic pulmonary histoplasmosis, pericarditis, and acute rheumatologic forms. It is less useful for progressive disseminated histoplasmosis [238].

Several in-house NAATs have been developed for detection of *H. capsulatum* from clinical samples [209, 273–278], but their use remains marginal.

Coccidioidomycosis

Clinical Syndromes and Diagnostic Approach

Coccidioidomycosis is caused by *C. immitis* and *C. posadasii*. The majority of infections are either asymptomatic or mild and self-limited. The lungs are the most commonly affected organs. Disseminated disease can involve extrapulmonary sites including bones, joints, skin, and CNS [279]. Organ transplant recipients are at increased risk for more severe and disseminated disease [280]. Microbial investigation for coccidioidomycosis can be undertaken in the context of compatible clinical disease or as part of pre-immunosuppression serology-based preemptive strategy [281, 282].

Laboratory Detection

Suitable samples for testing include respiratory secretions, CSF, and material from almost any site of infection (e.g., bones, joints, skin, bone marrow, and urine). On microscopy, spherules that range from 10 to 100 μm and typically contain 2–5 μm endoconidia (endospores) can be seen [18]. Visualization of spherules filled with endoconidia is diagnostic, while empty spherules are strongly suggestive of coccidioidomycosis [283]. Endoconidia-containing spherules may resemble *Prototheca* or *Rhinosporidium* sporangia, but size helps distinguish between those organisms. Endoconidia can also be seen alone, in which case they may be confused with *Histoplasma*, *Cryptococcus*, or *Candida* yeast cells. Tissue preparations, stained with fungi-specific dyes (e.g., CFW, GMS, PAS), facilitate detection of the fungal structures.

Coccidioides grows well on a variety of fungal and bacterial media (e.g., sheep blood agar and BCYE) [283]. The incubation period for initial growth is 3–5 days (range 2–16 days), at which point another ~10 days are needed for the colonies to reach maturity. Yield from CSF is poor but can be improved with a large volume sample (>10 mL) [284]. Growth in blood culture is uncommon and more likely to be detected with lysis-centrifugation and the continuously monitored blood culture systems [285, 286]. In culture, *Coccidioides* grows as a filamentous fungus with arthroconidia, which appear as alternating barrel-shaped structures and are highly infectious. Because this appearance can be mistaken for the nonpathogenic environmental mold *Malbranchea*, at least one confirmatory test is required for definitive identification [18]. This is usually accomplished with the exoantigen assay, DNA-rRNA hybridization using commercial probes (AccuProbe® *Coccidioides immitis* Culture Identification Test, Gen-Probe®) [19], or with in-house PCR-based methods [287]. Older confirmatory tests such as the conversion assay (to yeast form) and animal inoculation for in vivo production of spherules are too cumbersome for widespread use. Because the arthroconidia are highly infectious, any manipulation of suspected or confirmed isolates should be done in strict adherence to biosafety regulations [25, 288].

Detection of specific anti-*Coccidioides* antibodies is helpful for diagnosis. Suitable specimens include serum and CSF. The traditional methods are tube precipitation and complement fixation. The former detects mainly an IgM antibody directed against a heat-stable antigen, often referred to as "TP" antibody or "precipitin" and "TP" antigen, respectively. The latter involves predominantly an IgG antibody specific to a heat-labile antigen, respectively, called "CF" antibody and "CF" or "F" antigen [1, 283, 289]. Both assays have been adapted to the immunodiffusion format. Because they could detect the same antibodies as TP and CF, they were named "immunodiffusion TP" (IDTP) and "immunodiffusion CF" (IDCF), a nomenclature that might be confusing [289]. These assays use heated or unheated coccidioidin (mycelial-phase broth culture filtrate) as antigen, although purified or recombinant antigens have also been studied [1]. EIAs detecting both IgM and IgG have been developed for serum and CSF [290–294]. The Premier® *Coccidioides* EIA test has been the most extensively studied. The CF assay is quantitative (titers), while ID and EIA are qualitative or semiquantitative. TP antibody (IgM) is detected early during acute infection and disappears after a few months, while the CF antibody (IgG) appears later and lasts for a longer time. IgM antibody may persist in chronic pulmonary forms, while IgG titers correlate with the extent of disease. As seen for *Histoplasma* serology, traditional methods (CF and ID) may lack sensitivity in immunocompromised hosts [289]. However, they are considered highly specific [293]. EIA is considered more sensitive but less specific than traditional methods (especially for IgM); hence many still recommend confirmation of EIA-positive results with ID or CF [283, 284]. From a limited number of cases, sen-

sitivity of the recently developed MVista® *Coccidioides* Antibody IgG IgM EIA was reported to be unaffected by the immune status of the host [294].

Antigen and NAAT assays for *Coccidioides* are in various stages of development. These include a *Coccidioides* antigen that may be detected in serum or urine, which showed a sensitivity of 50–70% in severe disease [295, 296]. PCR-based methods for detection of *Coccidioides* DNA directly from clinical samples have also been described, but more work is needed before these can be widely used in clinical practice [297–299].

In Practice: The Clinician Perspective

From the practitioner standpoint, clinical presentation usually drives investigation, and hence a syndromic approach prevails. Figure 48.1 illustrates a stepwise diagnostic process for the investigation of fungal etiologies in a transplant recipient presenting with pulmonary infiltrates, a very common encounter in this population. This schematic representation is not meant as a formal guideline, but as an example of how different diagnostic tools might be used in a particular clinical context.

Conclusion

The epidemiology of fungal infections has changed rapidly over the last decades, an evolution largely driven by advances in transplantation. In response, the growing threat posed by fungi has led to a dramatic improvement in the antifungal arsenal. Equally important has been the ongoing development of powerful tools that facilitate early and accurate diagnosis of fungal infections.

While tremendous progress has been made with regard to assay technology and analytical performance, major challenges remain. Widespread use of promising diagnostic tests has been limited by the complexity of the assays, costs related to infrastructure and reagents, and lack of standardization. Therefore, important future avenues in assay development include further advances in point-of-care technologies and automation, as well as commercialization. Finally, assays are commonly compared with one another using banked samples, but there is relative paucity of prospective data defining real clinical performance and usefulness. Further clinical evaluation of assays is needed, and this will be eased by standardization and accessibility, essential attributes for conducting large multicenter efforts.

Viral Diagnostics

49

Robin K. Avery and Belinda Yen-Lieberman

Background and Introduction

Advances in diagnostic testing for transplant-related infections, particularly molecular viral diagnostic assays, constitute one of the most notable changes in transplant infectious disease over the last two decades [1, 2]. This chapter discusses recent developments in diagnostics for cytomegalovirus (CMV), Epstein-Barr virus (EBV), BK virus (BKV), community respiratory viruses (CRVs), parvovirus, hepatitis viruses, HIV, and other viral agents of importance in solid organ and hematopoietic stem cell transplantation. The recent debate regarding the extent of nucleic acid amplification (NAT) testing for HIV, HBV, and HCV in proposed transplant donors is reviewed [3]. Different uses for molecular viral tests in the transplant recipient are discussed, ranging from facilitation of antiviral preventive strategies to determination of length of therapy for active infections. The advantages and disadvantages of single vs. multiplex assays are explored [2]. Challenges in this field include interlaboratory variation [4], management of false-positive and discordant test results, and need for consensus on which patients should receive which testing, at what intervals, and for what period of time. Despite these challenges, molecular viral diagnostics have clearly contributed significantly to the reduction of infectious morbidity, by enabling early diagnosis and intervention, resulting in such notable examples as the reduction in severe CMV disease [5, 6] and in kidney allograft loss due to BKV [7]. Future clinical trials in the field of transplantation should incorporate accepted definitions of infection and practices of viral monitoring for transplant-associated viruses [8].

General Considerations, Definitions, and Uses of Viral Diagnostic Tests

The term "serology" or "serologic test" refers in general to an assay which detects an antibody to a specific pathogen, usually IgG or IgM. A panel of serologic tests is performed on both donor and recipient prior to transplantation. The results may be used to disqualify a prospective donor or to restrict the use of the donor to a specific subgroup of recipients or more commonly may be used for risk stratification and posttransplant management for particular infections (e.g., the donor-seropositive, recipient-seronegative or D+/R- group which is the subgroup at the highest risk for both CMV and EBV, respectively, in solid organ transplantation) [9]. Serologies are of limited value in diagnosing active infections in the posttransplant patient, since immunosuppressed patients may not mount an IgM response even in the setting of an active infection and some recipients with de novo posttransplant hypogammaglobulinemia have globally low IgG levels [10]. IgG serology remains positive for life, and pathogen-specific IgG titers do not usually correlate with the activity of infection, so obtaining an IgG level (for CMV or EBV, among others) is not generally helpful in diagnosing an acute illness in a transplant recipient (an exception is when the clinician wants to know if a previously seronegative patient has seroconverted, which might have prognostic value, for example, in predicting ongoing risk for recurrences of CMV viremia) [11].

Antigen-based testing, such as the pp65 antigenemia test for CMV, does have a potential role in posttransplant recipients, as this is a direct detection of the virus and not a reflection of the patient's immune response to the virus [12, 13]. However, in most cases, antigen detection is semiquantitative and does not provide an exact viral load to follow over time. In addition, some antigen tests (such as the pp65 antigenemia test for CMV) decay with time, and thus lose sensitivity, if the sample is mailed into a central laboratory or if there is a delay between obtaining the blood sample and laboratory performance of the test.

Table 49.1 Molecular tests for selected transplant-related viruses

Test Name	Method	Dynamic range at Copies/ml	Sensitivity	Specificity	Test Status
Qiagen Artus CMV RGQ	Real-time PCR	159 IU/ml–1.0 × 10^7 IU/ml	96.6%	100%	IVD
Abbott RealTime CMV	Real-time PCR	31.21 IU/ml–156 × 10^6 IU/ml	95–97%	99%	IVD
Roche CMV [19]	Real-time PCR; CAP/CTM	137 IU/ml–1 × 10^6 IU/ml	97.5–98.0%	100%	IVD
RealStar qCMV (Altona) CMV	Real-time PCR	150 IU/ml–1 × 10^6 IU/ml	100%	100%	ASR
Qiagen Artus EBV	Real-time PCR	500–5.0 × 10^6 IU/ml	95–97%	99%	ASR
RealStar EBV qPCR (Altona)___	Real-time PCR	500–10,000,000 copies/ml	94.5%	98.1%	ASR
Qiagen BKV	Real-time PCR	500–5.0 × 10^6 copies/ml	95–97%	99%	ASR
RealStar BKV (Altona)	Real-time PCR	300–100,000,000 copies/ml	100%	100%	ASR

ASR analyte-specific reagents, *IVD* in vitro diagnostic test (FDA-cleared)

Molecular testing has revolutionized viral diagnosis in transplantation [14–16]. Molecular diagnostic tests are generally highly sensitive assays that directly detect the virus' genetic material such as DNA or RNA (depending on the type of virus) and can be qualitative or quantitative. There are a variety of methodologies, including polymerase chain reaction (PCR) technologies, hybrid capture assay, nucleic acid sequence-based amplification (NASBA), transcription-mediated amplification (TMA), and others [1, 2, 17, 18]. Performance characteristics of some of these tests in comparative studies are shown in Table 49.1**.** Testing may be *monoplex* (a single pathogen tested at one time) or *multiplex* (which refers to several or many pathogens tested in one sample).

The advantages and disadvantages of each strategy are discussed below. The uses of molecular diagnostic assays are many. Most commonly these tests are performed on whole blood or plasma (and may be referred to as the blood "viral load") when quantifying the virus, although other relevant samples may be tested, such as urine in the case of BK virus or a nasopharyngeal swab or bronchoalveolar lavage fluid in the case of respiratory viruses. A list of potential uses for quantitative molecular diagnostic tests is shown in Table 49.2. The most common uses are in preemptive therapy or screening for viral infection prior to symptoms, in diagnosis of an acute infectious syndrome, and in monitoring for blood viral clearance to help determine the duration of therapy for an infection episode**.**

An even newer set of diagnostic tests is currently under development, namely, pathogen-specific assays of cellular immune function. Of these, the one in widest use so far is the interferon-gamma release assay (IGRA) for tuberculosis (QuantiFERON-TB Gold in-tube, Cellestis/Qiagen Inc., Germantown, Maryland) [20]. This assay is specific for *Mycobacterium tuberculosis* and avoids false-positive results due to BCG vaccination, as with the tuberculin skin test [20]. Similar assays for CMV and BKV have been an area of intense research interest. Recent results suggest that measurement of CMV-specific immune function is useful in risk stratification of high-risk organ transplant recipients [21] and in hematopoietic stem cell transplant recipients [22]. It is likely that these tests will be more commonly used in the future in transplant virology, with an eye to devising personalized prevention programs using assessments of individual patients' pathogen-specific immunity. However, testing for virus-specific cell-mediated immunity has not yet become widely performed at the time of this writing, so the current chapter will focus mainly on molecular diagnostic testing.

Table 49.2 Potential uses for quantitative molecular diagnostic tests

Screening of living or deceased prospective organ donors
Diagnosis of an acute infectious syndrome
Preemptive therapy or monitoring/screening for viral infection
Prediction of severity of disease (quantitative viral load)
Monitoring for resolution of infection and guidance for duration of therapy
Monitoring for recurrence of infection after completion of therapy
Determining the success of viral suppression or secondary prophylaxis
Clues to the presence of antiviral resistance (rise in viral load or failure to decrease on therapy)
Genotypic antiviral resistance testing (e.g., UL97 or UL54 mutations in CMV)

Cytomegalovirus

CMV remains one of the most common viruses to reactivate in the posttransplant patient. In the early years of transplantation, diagnosis of CMV infection relied on detection of viral growth in tissue culture, which was laborious and could take several weeks for a positive result to be obtained, particularly if the samples have low viral load. The advent of shell-vial centrifugation culture methodology shortened the turnaround time from 4–5 days to 48 h, but this test was less sensitive at lower viral loads and did not provide quantitative results [13]. The pp65 antigenemia test was then devised, and multiple studies have validated its utility in posttransplant monitoring and as a basis for preemptive therapy [12, 13, 23]. The pp65 antigenemia test detects CMV-infected white blood cells in peripheral blood using a

fluorescent assay which requires the laboratory technician to visually scan the slide and to report the number of positive (infected) cells per unit of area. It is thus a semiquantitative test. Although this does give some idea of the magnitude of the viral load, it is not as definitive in viral load measurement as quantitative molecular tests, which are usually expressed as DNA copies/ml or, most recently, in international units. The pp65 antigenemia assay is labor-intensive for the laboratory and thus may be problematic for transplant centers with very high volumes of tests. In addition, the results decay after obtaining the blood sample, so it is less suitable for mailing in to a central laboratory from patients who live a long distance away from the transplant center.

Molecular diagnostic tests for CMV have largely supplanted previous tests at many centers. Their quantification of the blood viral load, ease of handling high volumes of samples, and lack of decay with time if properly handled make the CMV DNA by PCR a useful choice for a transplant center with high volumes of samples and/or patients outside the immediate area. Quantitative viral loads often correspond to severity of disease, although interlaboratory variation has hampered the attempt to describe universal cutoff values for clinical categories and decision-making [4, 24, 25]. In solid organ transplant recipients, tissue-invasive CMV episodes generally have the highest viral loads (e.g., >50,000–100,000 copies/ml); asymptomatic viremia has the lowest viral loads (e.g., <5000 copies/ml); and the intermediate category of "CMV syndrome" has viral loads in between the other two categories, although exceptions may occur. However, widespread adoption of the WHO standard should allow for more reliable, shared correlations between viral loads and clinical manifestations, after the initial period of clinician adjustment to a new scale [25]. The quantification of the viral load also allows for following levels over time, so that treatment decisions, including when to initiate antiviral therapy, when to discontinue antiviral therapy, or when to switch from full-dose therapy to secondary suppressive dose prophylaxis, can be based on serial results of these quantitative tests (Table 49.2). A notable example of the use of sequential viral load measurements is the use of a risk-adapted, CMV viral load-based preemptive therapy program for CMV prevention in hematopoietic stem cell transplant recipients, utilized at the Fred Hutchinson Cancer Research Center [26].

Molecular tests are not without problems, however. PCR is a highly sensitive test, and false positives can occur, leading to unnecessary therapy or unnecessary concern on the part of patients and clinicians; such false-positive tests, however, are usually low level and may be subjected to repeat analysis or verified by obtaining a new sample. The risks of false-positive testing in disqualification of potential donors have been a topic of discussion regarding the revised solid organ transplant donor guidelines [3].

Other potential problems with molecular testing include logistics. A highly developed system must be in place, particularly for preemptive therapy, for the loss of even one sample or failure to act upon one sample result might lead to full-blown symptomatic infection. But perhaps the most problematic aspect is that of interlaboratory variation [4, 24, 25], depending on the use of whole blood versus plasma; commercial versus individually developed assays, different reagents, and primers; and a host of other factors. The American Society of Transplantation (AST)'s Infectious Disease Community of Practice, together with the Canadian Society of Transplantation, published an interlaboratory comparison of CMV PCR testing involving 33 laboratories, showing wide variation in results (between a 2- and 4-$\log_{10}$ copies/ml difference in some cases) and need for more standardization [4]. The World Health Organization (WHO)'s standardization initiative should help to ameliorate this situation and to improve the comparability of viral loads obtained in different laboratories. As of 2010, the WHO announced an international standard for CMV molecular testing, which enables laboratories to calibrate their assays and which involves reporting in international units per mL [25]. Another recent development, in 2012, was the first FDA approval of a quantitative CMV PCR test (the COBAS AmpliPrep/COBAS TaqMan CMV test or CAP/CTM CMV test) which is a fully automated test, and the one copy of CMV DNA (as defined by the COBAS® AmpliPrep/COBAS® TaqMan® CMV test) is equivalent to 0.91 international unit (IU) on the First WHO International Standard for Human Cytomegalovirus for Nucleic Acid Amplification Techniques (NIBSC 09/162) [19, 25]. An international multicenter comparison of the CAP/CTM CMV test in five laboratories at transplant centers compared the performance of this test with local assays, using blinded samples and clinical specimens [19]. This study showed high interlaboratory agreement of the CAP/CTM test and quantification differences using local assays [19]. It has been suggested that this test might serve as the basis for more widely accepted cutoffs for prediction of CMV disease and thresholds for preemptive therapy [25].

A final category of molecular diagnostic tests for CMV is those used to determine genotypic resistance, on analogy to HIV. CMV antiviral resistance commonly occurs in two sites, known as UL97 and UL54 [27, 28]. UL97 relates to the ability of a viral-encoded thymidine kinase to initiate triphosphorylation of ganciclovir to its active form, and thus UL97 mutations confer resistance to ganciclovir but not to foscarnet or cidofovir. UL54 mutations, on the other hand, affect the viral DNA polymerase and so may confer resistance to ganciclovir, foscarnet, or cidofovir or more than one of these [27, 28]. Phenotypic resistance testing is less commonly used now, as it is time-consuming and labor-intensive. Genotypic resistance testing should be obtained in any clinical situation where resistance is suspected, such as a

persistently high CMV viral load, failure of the viral load to decrease on therapy, or clinical lack of response to therapy after sufficient time has elapsed.

Epstein-Barr Virus

The utility of EBV serologic testing such as EBV VCA-IgG is principally in the pretransplant period, establishing whether or not the donor and the recipient have ever been infected with EBV. Most adults, 90% or greater, are EBV-seropositive, although pediatric transplant recipients are more likely to be seronegative [29]. As with CMV, the donor and recipient serogroups carry differential risks for the development of serious infections. In the case of EBV, the main issue is risk for EBV-related posttransplant lymphoproliferative disorder (PTLD). The highest-risk category in solid organ transplantation is the EBV D+/R- category; as similar to the case of CMV, there is no antecedent immunity in the recipient, but a viral load is acquired from the donor at the time of transplantation [29]. Knowledge of this D+/R- status may allow for closer surveillance, modulation of immunosuppression, and, at some centers, serial monitoring of the EBV DNA viral load [30, 31]. There are several different EBV serologies that are commonly performed: the Epstein-Barr nuclear antibody (EBNA), Epstein-Barr early antigen (EA), viral capsid antigen (VCA) IgG, and VCA-IgM. Of these, the VCA-IgG is the most reliable test for assessing whether or not the patient is seropositive (i.e., whether they have ever had EBV infection), while the VCA-IgM correlates better with current or recent disease although IgM response may be blunted in an immunocompromised host, so there is limited utility in ordering EBV serologies in patients following transplantation. For the diagnosis of active EBV infection and the assessment of PTLD risk, obtaining quantitative blood PCR testing is more helpful than serologies [29, 30]. EBV DNA viral loads may be performed on plasma or on whole blood. As in the case of CMV, interlaboratory variation also exists with respect to EBV DNAemia measurement [24]. EBV DNA viral loads may be followed over time in high-risk patients and may be useful as a gauge of the degree of success of interventions such as reduction of immunosuppression, which should be followed by a corresponding decrease in the EBV DNA blood viral load, unless the patient has active PTLD. Green et al. have demonstrated the predictive value of this monitoring [30], and McDiarmid has shown the utility of EBV DNA monitoring, coupled with reduction of immunosuppression and ganciclovir therapy, in the reduction of PTLD risk (from 10% to 5%) in a cohort of pediatric liver transplant recipients [31]. Successful therapy of PTLD with rituximab or rituximab plus combination chemotherapy is often associated with a rapid fall of the EBV DNA blood viral load to undetectable levels. However, later rebounds of EBV DNAemia may occur and do not necessarily portend recurrences of PTLD [30].

BK Virus

BK virus (BKV) is a member of the polyomavirus family, along with JC virus, SV40, and others. Acquisition of BKV is common in the general population and may occur early in life in asymptomatic form. BKV has a predilection for cells of the urinary tract including the bladder, ureters, and kidneys. BKV can cause hemorrhagic cystitis in HSCT recipients. In kidney recipients, its effects can be devastating [7]. After kidney transplant, BKV can silently reactivate and can cause a type of allograft nephropathy (BKVAN) that begins with interstitial nephritis and progresses to fibrosis and nonfunctioning allograft tissue. If no prevention program is in place, between 4% and 8% of all kidney allografts may be lost to BKV.

Screening and early intervention for BKV have been a major advance over the last 10 years and have led to an approximately eightfold reduction in kidney graft loss due to BKV. Most kidney transplant centers now employ BKV screening of asymptomatic patients using one of several available tests on blood or urine [7]. Serial screening for BKV allows for early reduction of immunosuppression, which is the most established therapy for BKV, and may reduce viral load by allowing for a more vigorous host immune response to BKV [7, 32, 33].

The tests available for BKV screening include urine cytology for the evidence of polyomavirus-related changes in the form of inclusion-containing "decoy cells," quantitative or qualitative BKV DNA performed on urine or blood, and BKV VP1 mRNA [34]. If urine is screened, a positive test might trigger testing of blood for the BKV DNA viral load. Blood BKV DNA viral loads correlate more with the presence of BKV in renal allograft tissue, as urine may frequently be positive for lower levels of BKV DNA without active involvement of renal tissue. Urine BKV DNA viral loads are typically several logs higher than blood viral loads. International consensus guidelines have established the blood viral load of 10,000 copies/ml as a common threshold for intervention in kidney recipients [35]. By contrast, BKV blood viral load has not traditionally been considered as predictive of symptomatic disease in HSCT recipients, although recent results by Gilis et al. suggest that BKV viremia is correlated with severity of disease in HSCT also [36].

BKV DNA testing is also useful for monitoring responses to interventions such as reduction of immunosuppression. If reduction of immunosuppression appears not to have produced the desired reduction in viral load, some centers employ off-label antiviral therapies for BKV [37] such as cidofovir, quinolones, intravenous immune globulin (IVIg),

and leflunomide. There are no randomized trials to date comparing these therapies, and reduction of immunosuppression remains the cornerstone of management. Thus, BKV DNA quantitative monitoring can serve as a guide to institution of interventions and as a guide to resumption of full-dose immunosuppression after an episode has resolved.

Routine serial monitoring of BKV DNA is not currently recommended in solid organ transplant recipients other than kidney or kidney-pancreas recipients. In liver, lung, and heart transplant recipients, reactivation of BKV may also occur, but the clinical significance is less certain. In hematopoietic stem cell transplant recipients, routine serial BKV viral load monitoring has not been standard in the past, but may emerge as a strategy in the future based on recent results [36].

Community-Acquired Respiratory Viruses

Community-acquired respiratory viruses (CRVs) pose a threat to transplant recipients in two ways: the risk of severe respiratory involvement during an infection episode and the late risk in lung transplant recipients for transient or permanent decreases in lung allograft function after a CRV infection has resolved [38]. Early diagnosis is crucial in allowing for rapid treatment; a multicenter study of pandemic H1N1 influenza in SOT recipients demonstrated that early treatment, within 2 days of onset of symptoms, was associated with lower risk of ICU admission and respiratory failure [39]. Early and rapid influenza diagnosis is particularly important, as antiviral medications effective against influenza are available. The CDC and Advisory Committee on Immunization Practices (ACIP) publish an annual guide to prevention and treatment of influenza which contains antiviral resistance information pertinent to the particular strains that are circulating in any given influenza season [40]. For other respiratory viruses, there is less agreement on treatment protocols, but many transplant centers use ribavirin (inhaled or oral) for treatment of respiratory syncytial virus (RSV) [41] and sometimes parainfluenza virus and human metapneumovirus (hMP) infections as well [42].

Diagnosis of CRV infections is also very important for infection control programs, as such viruses can spread rapidly through transplant wards and may have devastating effects particularly in patients with recent transplants or active rejection. Different respiratory viruses have different modes of transmission, so droplet precautions, contact precautions, or both may be appropriate. In any case, rapid application of appropriate precautions can prevent harm to other vulnerable hospitalized patients.

Diagnosis of CRVs has traditionally been performed on respiratory samples, most commonly nasopharyngeal (NP) swabs or washes or BAL fluid. Diagnosis may be accomplished by direct fluorescent antibody testing (DFA), by PCR, or by culture in tissue culture. Since culture-based diagnostics take at least several days, these are not suitable for rapid diagnosis and are now utilized primarily for determination of viral viability in a patient who is persistently PCR-positive, for example.

The choice of DFA or PCR for initial testing depends upon the virus(es) being detected. Some multiplex assays are wholly PCR-based and some are a combination of DFA and PCR tests. Since respiratory viruses have considerable overlap in their clinical presenting symptoms, and coinfections may occur, it makes sense to perform a multiplex assay incorporating the most likely agents, rather than testing for a single virus at a time. Common combinations of tests include influenza/RSV, influenza/RSV/parainfluenza/adenovirus/human metapneumovirus, and other more extensive combinations including rhinovirus and coronaviruses. Even rhinovirus infection (the "common cold") may have severe consequences in immunocompromised patients [43], so expanded multiplex testing is increasingly of interest.

In addition to initial diagnosis of an infection episode, repeat testing may be used for assessment of viral clearance in patients with ongoing symptoms or for infection control purposes in determination of the length of isolation precautions. It should be noted, however, that testing which does not rely on viral viability may be detecting residual fragments of nonviable virus.

There are special considerations for lung transplant recipients with regard to respiratory viruses, since long-lasting allograft dysfunction may result some months after resolution of the viral illness [38]. This may be true even for such common viruses as rhinoviruses and also for asymptomatic or minimally symptomatic infection episodes. At such times, viruses are not usually detectable, but progression to bronchiolitis obliterans syndrome (BOS), a chronic progressive form of lung allograft dysfunction, may occur due to cytokine release and injury and repair processes that are the subject of current research. It is thus of particular importance to test lung transplant recipients early, even if they are only minimally symptomatic, as viral detection might lead to therapy that can lessen the risk of this later allograft dysfunction. Obtaining a nasopharyngeal swab on all lung transplant recipients with new-onset respiratory symptoms is reasonable (Table 49.3).

Parvovirus

Parvovirus B19 is an under-recognized cause of anemia in transplant recipients [44]. While many centers test for parvovirus in patients who present with anemia without other

explanations, it has only recently been recognized that parvovirus can also cause milder degrees of anemia in a larger number of patients [45]. Diagnosis by serology is less useful, as the majority of adults are IgG-seropositive and transplant recipients may not mount an IgM response even during active infections. Bone marrow examination may reveal disordered erythroid progenitors including giant erythroblasts. Parvovirus PCR testing on blood is the most useful noninvasive test for diagnosing active parvovirus infection in a transplant recipient. This testing is important both as a basis for therapy with IVIg and reduction of immunosuppression and also for infection control and isolation purposes. Molecular testing has also led to the suggestion that viral loads of parvovirus from the donated organ, detected in graft preservation solution, may correlate with increased risk for posttransplant parvovirus infection in the recipient [46].

Agents of Viral Hepatitis

Viral hepatitis agents include hepatitis A, hepatitis B, hepatitis C, hepatitis D, and hepatitis E abbreviated as HAV, HBV, HCV, HDV, HEV, respectively. Of these, HBV and HCV are most commonly found in transplant recipients, although recently detection of hepatitis E has been on the rise [47]. HBV or HCV may be pre-existing in the recipient or may be acquired de novo posttransplant, either from the donor or from transfusions [48]. In the pre-existing category, HBV or HCV may be the reason for performing a liver transplant or may be a comorbidity in a patient receiving a non-liver transplant.

Hepatitis B

Serologic testing for HBV is complex and relies on an understanding of the timing of detection of several different HBV antigens and antibodies. Active infection is characterized by a rise in the hepatitis B surface antigen (HBsAg), which then falls to undetectable in about 90% of patients; then subsequently there is a rise in the anti-HBs (hepatitis B surface antibody) titer. Between the time that HBsAg becomes undetectable and anti-HBs appears, there is a "window period" during which time neither is detectable, but the HBV core IgM antibody (anti-HBc IgM) and HBV DNA are detectable. After natural infection, the anti-HBc IgM disappears and the anti-HBc IgG appears, so persons in whom HBV infection has been successfully controlled by the immune system generally are positive for both anti-HBc and anti-HBs, but negative for HBsAg. In about 10% of infected individuals, antibody seroconversion does not occur and the HBsAg is persistently positive in chronic infection. Such individuals may progress to cirrhosis and/or hepatocellular carcinoma and may require a liver transplant with the goal of eradicating HBV infection, utilizing posttransplant prophylaxis with hepatitis B immune globulin (HBIg) and an anti-HBV antiviral agent such as entecavir. In such individuals the blood HBV DNA is also commonly positive pretransplant and may be serially followed posttransplant to detect any recurrence early.

Pretransplant screening of the recipient commonly includes HBsAg, anti-HBc, and anti-HBs. A positive HBsAg is indicative of current infection which may represent either recent infection or chronic carriage. An isolated positive anti-HBs is usually the result of HBV vaccination, as the

vaccine is produced from recombinant HBsAg. A positive anti-HBc and anti-HBs are indicative of natural infection which has been controlled by the immune system. An isolated positive anti-HBc may either be a sign of recent or ongoing infection during the window period with positive IgM antibodies or past resolved infection if IgG antibodies are positive, where the anti-HBs titer has waned below the level of detectability. Alternatively, an isolated positive core antibody may be a false-positive test.

Occasional potential organ donors may be identified as "core-positive" donors, that is to say, the HBsAg is negative but anti-HBc is positive. Often only the total core antibody result is available and not whether it is IgM or IgG; also donor anti-HBs information may not be available. Although such donors may be in the "window period" between disappearance of HBsAg and appearance of anti-HBs, the risk of transmission of HBV to non-liver recipients is low ranging from 1:30 to 1:60 [49, 50] and can be further reduced by immunization of the recipient prior to transplantation; in some cases, antiviral prophylaxis is also given [48, 51]. The risk of transmission to a liver recipient from an HBV core-positive donor is higher, about 1:2 [49], but also can be minimized by use of pretransplant immunization and intensive posttransplant prophylaxis with hepatitis B immune globulin and an antiviral agent such as lamivudine or entecavir [48].

For any patient who is at risk for posttransplant HBV, either as a recurrence of their own previous infection or through donor-derived transmission, it is recommended to include serial posttransplant monitoring of the HBV DNA since posttransplant patients may not seroconvert but would still have viral DNA detectable if reactivation or transmission had occurred [48].

Hepatitis C

Hepatitis C is one of the most common indications for liver transplantation. In the past, HCV recurrence posttransplant was frequent and could be either early and aggressive or later and more slowly progressive [48]. Until recently there were no prophylactic antiviral protocols available for prevention of posttransplant HCV recurrence, although this has rapidly changed in the era of new and more effective HCV drugs.

In both liver and non-liver solid organ transplantation, donor-derived de novo HCV is a clinical concern because of poorer graft and patient outcomes in some settings in patients who are hepatitis C seronegative but experience HCV transmission from the donor [52], although a large study by Abbott et al. of kidney transplant candidates and recipients demonstrated improved survival with transplantation with HCV+ donors compared with the remaining on the waiting list [53]. The risk of transmission of HCV from a seropositive donor to a naïve recipient varies in different series, but has been reported to be as high as 75% in some studies [48]. An HCV-seropositive, HCV RNA-negative donor appears to be less likely to transmit HCV than a donor with detectable HCV RNA, but further data are awaited. Unlike the HBV core-positive donor, until recently the risk could be mitigated by prior immunization since there is no vaccine for HCV. Thus, transplantation from an HCV-seropositive donor to an HCV-seronegative recipient (HCV D+/R-) was usually reserved for situations where other donor offers were unlikely, with stringent informed consent [9]. However, the advent of effective HCV therapy is expected to change practice rapidly.

By contrast, the transplantation of a solid organ like a kidney from an HCV-positive donor to an HCV-positive recipient (HCV D+/R+) has been an accepted practice [53, 54]. Multiple studies have suggested that outcomes for transplantation are superior to those remaining on dialysis for an HCV+ transplant candidate [55], even if the donor is HCV+ [53, 54]. Since the waiting list is long and deceased-donor kidney transplants may not occur for years, it makes sense for the HCV-seropositive kidney transplant candidate to consider accepting an organ from an HCV-seropositive donor [53, 54].

In any of the above cases, where either the donor or the recipient (or both) is seropositive for, or at risk for, HCV, monitoring posttransplant for HCV reactivation in the recipient is important [48]. However, antibody seroconversion may be delayed or absent in the immunocompromised patient, even though HCV serology testing has undergone considerable evolution and improvement over time. Since HCV seroconversion may be delayed or absent in posttransplant patients experiencing transmission of HCV from the donor, molecular testing of HCV RNA is important in serial monitoring of the posttransplant patient at risk of HCV acquisition.

HIV

In the early years of transplantation, HIV seropositivity in the donor or the recipient was held to be an absolute contraindication. However, in recent years, a multicenter study of outcomes of solid organ transplants in selected HIV-positive recipients has been found to be comparable to those of HIV-negative recipients for kidney and liver transplantation [56, 57]; although the incidence of acute rejection in 150 HIV-positive kidney recipients was higher than expected, patient and graft survival were high [56]. These recipients are chosen because their kidney or liver disease is more clinically significant than their HIV-related illness, they have not had certain HIV-related opportunistic infections, and their HIV viral loads are well controlled except in the case of some liver candidates who could not tolerate antiviral therapy in

the setting of end-stage liver disease. Careful monitoring of the drug interactions between calcineurin inhibitors and protease inhibitors by an experienced pharmacist is necessary, but excellent outcomes can be achieved in certain patients in this category.

Until recently, HIV-seropositive donors were not accepted for donation in the United States, but data from South Africa suggested that HIV-seropositive donors can be associated with acceptable outcomes in selected HIV-seropositive recipients [58]. This is an evolving field, spurred by the shortage of deceased donors and restricted availability of dialysis in resource-limited settings, and further data are awaited. In the United States, the HIV Organ Policy Equity (HOPE) Act was passed in 2015 [59], which allows for research into transplantation from HIV-positive donors to HIV-positive recipients; and the first such transplants in the United States were performed at Johns Hopkins in 2016 [60].

As with HBV and HCV, HIV antibody seroconversion may be delayed or absent in the transplant recipient, and serial monitoring with HIV molecular testing is suggested for any patient at risk for HIV acquisition or reactivation posttransplant [61]. Patients who are HIV-seropositive pretransplant should have HIV RNA viral loads and CD4 counts serially monitored in addition to drug levels and posttransplant lab testing.

NAT of Donors and CDC/PHS High-Risk Donors

For many years, until the development of rapid molecular tests that could be performed in the deceased donor testing time frame, testing of prospective deceased donors relied on antibody serologies for HIV, HBV, and HCV, which are performed as part of a serologic panel by the organ procurement organization (OPO). However, the window period prior to seroconversion that can occur for each of these viruses resulted in infection transmissions from apparently seronegative donors, yielding for a search for more accurate laboratory tests. For example, a donor transmitted HIV and HCV to multiple organ transplant recipients after testing negative for antibody serology for both of these viruses [62]. In addition, a case was reported of a living donor that transmitted HIV after initially testing negative but then continuing risky behavior between the time of initial donor evaluation and the time the transplant was performed [63].

Nucleic acid amplification testing (NAT) is a technology for rapid molecular testing that is highly sensitive and has been used in blood banking. In recent years it has become possible to perform this testing in the rapid time frame needed for making decisions about whether or not to accept a deceased donor, including nights and weekends. The availability of NAT has spurred a national debate in the United States regarding whether all potential deceased donors should be subjected to NAT for HIV/HBV/HCV or just those in the CDC-specified high-risk categories including sexual promiscuity, injection drug use, incarceration, and other categories of behavioral risk. A survey of OPOs revealed a heterogeneity of practices in this regard, with some OPOs performing NAT on all donors, some on a subset of donors, and some not at all [64]. In 2010, an expert consensus panel recommended restricting NAT to donors in the above risk categories, citing concerns about false-positive testing that could lead to discarding otherwise potentially acceptable donors and thus leading to increased deaths on the waiting list for transplantation [3]. Then in the fall of 2011, the Centers for Disease Control and Prevention (CDC) and the US Public Health Service (USPHS) published a comprehensive guideline which recommended NAT of all deceased donors and also retesting of potential living donors shortly before intended donation. After discussion within the transplant community, these recommendations were revised, and the current guidelines call for HCV NAT testing of all donors, with HIV NAT testing only of PHS/CDC high-risk donors, and with a revised list of risk categories [65]. All parties in this discussion are interested in protecting potential organ recipients from harm; the differences in opinion arose in balancing the risks of donor-derived transmission versus the risks of disqualifying donors through false-positive testing.

Multiplex Versus Single-Virus Testing

The fact that there are multiple transplant-associated viral infections, which are amenable to serial monitoring, has given rise to the development of multiplex assays that allow for the detection of more than one virus at any given time point from a single blood sample [2]. Viruses which are frequently serially monitored posttransplant, such as CMV, EBV, and BKV in kidney recipients and adenovirus particularly in pediatric HSCT recipients, would be candidates for inclusion in a blood multiplex viral molecular detection panel. In addition, the existence of a large number of respiratory viruses that produce similar symptomatology makes the use of a respiratory virus multiplex a natural one [2]. Potential advantages of a multiplex assay on blood or plasma would include the following: less blood drawn from the recipient for blood assays, detection of unsuspected coinfections, and rapid and sometimes quantitative results to facilitate preemptive strategies. The cost-effectiveness of multiplex testing has been evaluated in a study by Mahony et al., in which four strategies were compared for diagnosis of respiratory viral infections in pediatric patients (direct fluorescent antibody or DFA alone, DFA plus shell-vial culture, the xTAG RVP test alone, or the xTAG RVP test plus DFA) [66]. These authors reported that the least costly strategy was the xTAG RVP

multiplex test alone when the prevalence was >11% and was DFA alone when the prevalence was <11% [66].

Disadvantages of some multiplex tests have included occasional lower sensitivity for one or more individual viruses on the panel, although that finding has led to alterations of the multiplex test such as the RespPlex test vis-à-vis adenovirus testing [2]. Potential disadvantages of multiplex testing of disparate viruses, for example, a panel that includes CMV, EBV, and BK virus and others, also include the clinical quandary of what to do with low-level positive results or results in a subgroup of patients in whom a particular virus is of less clinical importance like BKV in non-kidney organ transplant recipients. For certain subgroups of patients, all of the assays on a multiplex test might provide valuable information; but for others, the clinicians may be interested in only one or two viruses. In that situation, should the information on detection of the other viruses be routinely provided in laboratory reports? These and other questions remain to be fully addressed. The issue of cost also needs careful scrutiny. Costs could potentially decrease because of ordering fewer tests if the clinicians intended originally to monitor more than one virus, but costs could also increase if the cost of the multiplex assay exceeds that of the single-virus assay for clinicians who intended to monitor only one virus. Mahony et al. reported the cost-effectiveness may also depend on the prevalence of the viral infections being tested and so may vary from one region to another or one season to another [66].

Conclusion

Molecular testing for transplant-related viruses has revolutionized posttransplant care and is having a significant impact on pretransplant testing of donors. Serial monitoring for CMV, EBV, and BKV has become a cornerstone of management, as this monitoring allows for early detection and intervention in appropriate subsets of transplant recipients. The utility of quantitative molecular testing is supported by a variety of studies and facilitates the timing of starting and stopping antiviral therapy, assessing the effectiveness of therapy, monitoring for recurrences of viremia, and deciding when to test for antiviral resistance. Multiplex testing for panels of respiratory viruses has demonstrated utility and cost-effectiveness in certain scenarios. The use of NAT in potential deceased and living donors is promising for reduction of donor-derived transmission from donors in the window period of HIV, HBV, and HCV infection, but the recent vigorous national debate, regarding whether all or a subset of potential donors should be subjected to NAT, reflects the complexity of the issues involved. Finally, the availability of both multiplex and single-virus molecular tests will present challenges to the clinician as to how best to utilize the additional information provided by these tests.

Introduction

Transplant patients are uniquely predisposed to infections. Severe iatrogenic immune suppression following allogeneic hematopoietic stem cell or solid organ transplantation predisposes such patients not only to increased risk of infection with conventional pathogens, but organisms with inherently low virulence and pathogenicity may result in devastating systemic disease. The severity of compromised hosts' immune defenses and patients' extensive exposure to the healthcare environment promote colonization and invasive systemic disease due to multidrug-resistant bacteria during the early and late phases after transplantation. Similarly, recipients of stem cell or solid organ allografts are also susceptibile to drug-resistant bacterial infections upon returning to their community and home environment.

Bacterial infections seen during the pretransplant period reflect upon the complications resulting from the treatment of underlying neoplastic processes in patient being considered for hematopoietic stem cell transplantation (HSCT). In patients awaiting solid organ transplantation, a series of complications arising from the end-stage organ disease predisposes them to a host of locally invasive and systemic bacterial infections.

Major risk factors for bacterial infections in patients undergoing transplantation procedures include prolonged and recurring hospitalization, prior exposure to a variety of broad-spectrum antibiotics, pre-engraftment neutropenia, extensive surgical procedures, need for critical care unit stay, assisted ventilatory support, and presence of indwelling intravascular catheters and other body cavity or organ system drains and devices. Antibiotic regimens are often more complex compared with general population and in a vast number of transplant recipients antimicrobials are given empirically or preemptively. Drug-drug interactions with immunosuppressive medications and serious, treatment-limiting adverse reactions further complicate management of infectious diseases in such high-risk individuals. Use of prophylactic antibiotics also contributes to selection of antibiotic resistance organisms. Furthermore, newly acquired drug resistance or more importantly, selection of less drug susceptible pathogens under the unsettling external influence(s) resulting in tandem of permutations in the composition of hosts' external microbiome and orointestional microbiota is an emerging area of research.

Bacterial infections in a variety of transplant population that places patients at a greater risk for higher morbidity and risk of death include *Pseudomonas aeruginosa*, *Stenotrophomonas maltophilia*, *Burkholderia cepacia*, *Acinetobacter baumannii*, MDR *Enterobacteriaceae*, methicillin-resistant *S. aureus*, and vancomycin-resistant enterococci [1–5]. This chapter provides a detailed review of major classes of antibiotics including conventional drugs and new antimicrobials in development, mechanisms of resistance, and the indications for use in the transplant population.

Beta-Lactams

Mechanism of Action

All β-lactam antibiotics share a common structure of a four-membered β-lactam ring. The penicillins have a thiazolidine

ring as a side chain, and the cephalosporins have a dihydrothiazine ring as a side chain. Carbapenems differ from penicillins and cephalosporins in two ways: first, a methylene group replaces a sulfur atom and double-bond in the five-membered ring, and, second, a hydroxyethyl side chain in the *trans*-configuration is attached to the β-lactam ring instead of the *cis*-configuration acylamino chain found in the penicillins and cephalosporins. This structural configuration allows binding to high molecular weight penicillin-binding proteins (PBPs), stability to β-lactamases, and rapid transit through the outer membrane of Gram-negative bacteria (GNB). Monobactams have a monocyclic β-lactam ring. β-Lactamase inhibitors are weak β-lactams that bind to select β-lactamases hydrolytic enzymes and restore activity of the parent β-lactam drug [6, 7].

β-Lactams are bactericidal antibiotics that act via time-dependent killing by inhibiting bacterial growth by covalent binding with and inactivation of serine protease enzymes located in the bacterial cell membrane (PBPs). β-Lactams bind to PBPs in the bacterial cell membrane involved in the transpeptidation step of peptidoglycan synthesis, conferring osmotic stability to the bacterium by cross-linking the peptidoglycan strands. There are between three and five different PBPs in Gram-positive organisms and seven to twelve in Gram-negative bacilli. Each PBP is responsible for distinct reactions in cell wall synthesis. Different β-lactam antibiotics may bind preferentially to and inhibit certain PBPs, producing characteristic effects on bacterial morphology such as cell lysis, elongation, and cell division and different efficacies in inhibiting bacterial growth or cell death. PBPs are divided according to high and low molecular weight [8]. The high molecular weight PBPs are responsible for peptidoglycan polymerization and insertion into a preexisting cell wall. The seven low molecular weight proteins found in *E. coli* are responsible for cell separation, peptidoglycan maturation, or recycling. The final common pathway of β-lactam killing involves autolysin release; these enzymes are present in the bacterial cell membrane that mediate autolysis of peptidoglycan to allow breakdown of peptidoglycan for remodeling at the points of bacterial growth. β-Lactam inhibition of cell wall synthesis leads to activation of the autolytic system, which initiates cell death, which is a two-component VncR system [9, 10].

Mechanisms of Resistance

The most common mechanism of resistance to this class is mediated by β-lactamases enzymes that covalently bind and hydrolyze the critical β-lactam ring. Other mechanisms include production of low-affinity PBPs, changes in membrane permeability involving downregulation of porin channels, and increased expression or upregulation of complex drug efflux pumps as seen with strains of multidrug-resistant *Pseudomonas aeruginosa* [11].

β-Lactamases can be encoded chromosomally or on plasmids, with either constitutive or inducible expression. The evolution of a number of novel β-lactamases has paralleled the development of new β-lactam antibiotics. Differences in Gram-positive and Gram-negative bacterial cellular structure greatly influence the action of β-lactamases. In GNB, β-lactamases may be trapped in the periplasmic space leading to an increased enzyme concentrations and more efficient hydrolysis of the β-lactam ring, whereas in Gram-positive bacteria (GPB) the outer cell membrane is lacking and antibiotics can more readily access PBPs without the exposure to high localized concentration of the enzyme-assisted hydrolysis. There are two main classification systems for β-lactamases, Ambler classes A through D, which are based on molecular structure, and the Bush-Jacoby-Medeiros classification which is based on functional similarities (Table 50.1). With over 900 known enzymes, classification is difficult [12–14]. Due to their ability to facilitate rapid dissemination of resistance, plasmid-mediated β-lactamases pose the greatest challenge to clinicians.

The TEM-1 and TEM-2 enzymes were the earliest β-lactamases observed in *E. coli* and SHV-1 enzyme in *K. pneumoniae*. These are considered narrow-spectrum β-lactamases and confer resistance to penicillins and early-generation cephalosporins. As more extended spectrum β-lactam drugs were introduced, the extended-spectrum β-lactamases (ESBLs) evolved, primarily from mutations in the TEM and SHV enzymes. ESBLs are a heterogeneous group of enzymes that confer resistance to some or all of the β-lactams with the exception of the cephamycins and carbapenems. ESBLs, when found in combination with mutations, lead to increased gene expression and downregulation of porins resulting in high-level resistance to third-generation cephalosporins and monobactams as well as low-level resistance to the carbapenems [12, 15]. β-Lactamase inhibitor combinations may still be active against certain ESBL producers. ESBLs are found exclusively in GNB, such as *Klebsiella* spp. and *E. coli* and in clinical isolates of *Acinetobacter*, *Burkholderia*, *Citrobacter*, *Enterobacter*, *Morganella*, *Proteus*, *Pseudomonas*, *Salmonella*, *Serratia*, *Shigella*, *H. influenzae*, and *N. gonorrhea.* There are currently over 200 enzymes of this type [12, 16].

The CTX-M family of β-lactamases has recently emerged and is now the predominant ESBL enzymes worldwide [17]. Natural CTX-M enzymes are found on the chromosome of *Kluyvera* and have since spread to the *Enterobacteriaceae*, including *K. pneumoniae*, pathogenic *E. coli*, and *Salmonella* spp. [12]. More than 120 CTX-M enzymes have been described, with CTX-M-15 and CTX-M-14 as the most frequently encountered members [18].

The latest β-lactamases to emerge are the carbapenemases, which have the widest spectrum of activity and can hydrolyze most beta-lactams. These include the *K. pneumoniae* carbapenemases (KPCs) which are encoded on transposons and are now seen in a wide variety of GNB. Metalloenzymes

Table 50.1 Classification of beta-lactamases

Ambler class	Bush-Jacoby-Medeiros group	Major subtypes	Substrate	Model organisms	Genetic location	Potential antibiotic alternatives
A	2a	Gram-positive	Penicillins	Ampicillin-R *E. coli* *H. influenzae*	Chromosomal or plasmid, inducible	Clavulanate
	2b	Gram-negative (TEM-1 and SHV-1)	Penicillins, some cephalosporins	*E. coli* *K. pneumoniae*	Plasmid or chromosomal	Clavulanate
	2be	Extended spectrum (TEM, SHV, CTX-M)	Penicillins, 3rd-generation cephalosporins, monobactams	*Enterobacteriaceae*	Plasmid	Carbapenems Tigecycline Piperacillin-tazobactam[a] Fluoroquinolones[a] Colistin
	2br	Inhibitor-resistant TEM (complex mutant TEMS)	Penicillins	*Klebsiella*, *Proteus*, *Citrobacter*, *Shigella* species	Plasmid	Carbapenems Cefepime[a]
	2e	Cephalosporin hydrolyzing	Extended spectrum cephalosporins	*Proteus* species	Chromosomal, inducible	Piperacillin-tazobactam
	2f	Carbapenem hydrolyzing β-lactamase (KPC, GES, SME)	Penicillins, cephalosporins, carbapenems	*Klebsiella*, *E. coli*, *Enterobacter*, *Pseudomonas*	Plasmid Transposons, chromosomal	Tigecycline Colistin[a] Polymyxin[a]
B	3	Metallo-β-lactamase 3 (VIM, IMP)	All β-lactams except monobactams	*Acinetobacter*, *Pseudomonas*, *Stenotrophomonas maltophilia*	Chromosomal Transposon	Monobactam Piperacillin-tazobactam[a] Ampicillin-sulbactam[a] Tigecycline[a]
C	2d	AmpC-type cephalosporinase 1	Cephalosporins, penicillins	*Enterobacter* *Citrobacter* *Serratia* *P. aeruginosa* *Providencia* Indole-positive *Proteus*	Chromosomal (inducible); constitutive, plasmid	Cefepime[a] Carbapenems
D	2df	Oxacillin-hydrolyzing carbapenemases (OXA)		*Acinetobacter* *Pseudomonas*	Chromosome	Cefepime Monobactam Polymyxin Aminoglycoside Fluoroquinolone

[a]In vitro confirmation by additional testing is necessary to confirm susceptibility

such as VIM-1 and NDM-1 are another class of carbapenemases that require metallic cations as cofactors and are carried on plasmids, integrons, and transposons. These enzymes hydrolyze aztreonam poorly, leaving this monobactam as a potential treatment option in cases where other classes of β-lactamase are not present. OXA β-lactamases are a diverse group of enzymes classically associated with *Acinetobacter* species but have widely disseminated among clinically important GNB [19]. Detection of carbapenemases may be difficult using common automated identification systems, which often report these organisms as falsely susceptible. The significance of infection with either carbapenem-resistant and ESBL *K. pneumonia* was studied in lung transplant recipients and found to be an independent risk factor for mortality compared with carbapenem-sensitive or ESBL-negative bacterial strains [20]. The chromosomal enzymes, predominantly class C cephalosporinases such as AmpC, are mostly inducible and are found in *Enterobacter* species, indole-positive bacteria like *Proteus*, *Serratia*, *Citrobacter*, and *Pseudomonas* species, among others.

Resistance in GPB occurs predominantly through mutations in PBPs that result in decreased binding affinity. Methicillin resistance in staphylococci including MRSA is mediated by a mobile chromosomal element known as staphylococcal chromosomal cassette mec (SCC*mec*) [21]. SCC*mec* encodes for the low-affinity PBP2a, which in turn results in complete resistance to most β-lactam antibiotics. The classical community-acquired strains of MRSA contain a smaller SCC*mec* than hospital-acquired strains. Methicillin resistance may also involve other mutations known as fac-

tors for methicillin resistance or auxiliary factors that encode functions involved in cell wall precursors [12].

Ampicillin resistance in *E. faecium* is due to expression of a low-affinity PBP-5. Penicillin-resistant *S. pneumoniae* has low-affinity PBPs that use genes referred to as "mosaic" [12] derived from recombination between *S. pneumoniae* and less susceptible viridans-group streptococcal genes. Penicillin resistance in *S. pneumoniae* is typically of low level, with the greatest clinical impact on the treatment of pneumococcal meningitis. Certain GNB such as *Neisseria* species may also contain mosaic resistance genes. A strain of *N. gonorrhea* containing a novel penA mosaic allele was recently identified with high-level resistance to ceftriaxone [22].

Penicillins

The penicillins are divided into five classes based on the bacterial spectrum: the natural penicillins, the penicillinase-resistant penicillins, the aminopenicillins, the carboxypenicillins, and the ureidopenicillins. The representative antibiotics and spectrum of activity are outlined in Table 50.2. Penicillins have short half-lives of <60 min and are administered every 4–6 h in patients with normal renal function. Most penicillins are excreted unchanged by renal tubular cells and require dose adjustment in patients with renal insufficiency. The antistaphylococcal penicillins and extended spectrum penicillins undergo considerable biliary excretion. Piperacillin has the longest half-life and can be administered every 6 h and requires dose adjustment only in patients with severe renal dysfunction. With most penicillins, therapeutic levels are achieved in most organs, including the central nervous system even in the absence of meningeal inflammation and compromised blood-brain barrier [23].

Beta-Lactamase Inhibitors

β-lactamase inhibitors are weak β-lactam drugs that are potent inhibitors of many class A serine β-lactamases. These drugs react with the serine enzymes to form a covalent acyl-enzyme intermediate. After opening of the β-lactam ring, the intermediate can undergo additional rearrangements or be hydrolyzed to regenerate the active β-lactamase enzyme. When combined with a β-lactam, they prevent hydrolysis of the parent antibiotic and preserve activity. The major bacteria producing class A enzymes include *S. aureus*, *H. influenzae*, *M. catarrhalis*, *Bacteroides* spp., and some *Enterobacteriaceae*. Some ESBL produced by *E. coli* and *Klebsiella* spp. may be inhibited in vitro by these inhibitors. The chromosomal β-lactamases, such as those produced by *Pseudomonas*, are generally not inhibited by these compounds with the occasional exception of tazobactam [24, 25].

The β-lactamase inhibitors in clinical use are clavulanic acid combined with amoxicillin for oral use and ticarcillin for parenteral use, sulbactam combined with ampicillin for parenteral use, and tazobactam combined with piperacillin for parenteral use. The main β-lactam generally determines the antimicrobial spectrum, with the β-lactamase inhibitor enhancing activity through inhibition of acquired or intrinsic β-lactamases. Sulbactam has a broader spectrum of activity but is less potent than clavulanic acid and tazobactam. The combination of amoxicillin and clavulanic acid has activity against most penicillinase-producing *S. aureus* (MSSA), β-lactamase-producing strains of *H. influenzae*, and some *Enterobacteriaceae*. It is used predominantly for respiratory tract and soft tissue infections when MRSA is not suspected. Ampicillin plus sulbactam has a similar spectrum of activity, including *B. fragilis*, and is used for

Table 50.2 Penicillin classes and spectrum

Class	Representative drugs	Gram-positive spectrum	Gram-negative spectrum	Atypical spectrum	Anaerobic spectrum
Natural penicillins	Penicillin G, Penicillin V	Streptococci including *E. faecalis* (static), Penicillinase negative *S., aureus, Listeria* spp., *C. diphtheriae*	*Neisseria* spp., *H. influenza*, *Pasteurella multocida*	*T. pallidum*	Peptostreptococci *Clostridium* spp. *Fusobacterium*
Penicillinase-resistant penicillins	Nafcillin, oxacillin, dicloxacillin	PCN-R *S. aureus*, CoNS, PCN-S streptococci (lacks *Enterococcus*)	None	None	Most anaerobic Gram-positive cocci
Aminopenicillins	Ampicillin, amoxicillin	Same as PCN G	PCN G plus β-lactamase-negative *H. influenzae*, *E. coli*, *P. mirabilis*, *Salmonella*, *Shigella*, *H. pylori*	*B. burgdorferi*	Same as PCN G
Ureidopenicillins	Piperacillin	PCN G including *E. faecalis*; less active against CNS	AMP-R Gram-negatives including *Pseudomonas*, *Serratia*, *Klebsiella*, *Enterobacter*, *Providencia* spp.	None	Similar to ampicillin

Abbreviations: *CoNS* coagulase-negative staphylococci, *PCN-S* penicillin susceptible, *PCR-R* penicillin resistance, *AMP-R* ampicillin resistant

skin and soft tissue infections, community-acquired, intra-abdominal, and pelvic infections. Tazobactam enhances the piperacillin spectrum to include some *Enterobacteriaceae* and *B. fragilis* [26, 27].

Sulbactam is a unique β-lactamase inhibitor because it has activity against metallo-β-lactamase-producing strains of *Acinetobacter baumannii* [28]. A single-entity product is currently not available in the United States; therefore sulbactam is still clinically used in combination with ampicillin. Variable dosing regimens of sulbactam have been used against *A. baumannii* including 1 gram every 8 h in moderate infections and 1 gram every 6 h in serious infection with cure rates of 93% and 76.9%, respectively [29]. Lower cure rates seen with more aggressive dosing were likely due to the severity of infection. Higher sulbactam doses up to 12 grams a day have been reported for the treatment of MDR *Acinetobacter* ventilator-associated pneumonia (VAP) [30]. Paralleling the escalating carbapenem resistance, sulbactam-resistant *Acinetobacter* strains have been reported [31, 32].

The emergence of enzymes that are not inhibited by approved inhibitors has prompted research into new drugs. Avibactam, previously known as NXL-104, is a novel, non-β-lactam β-lactamase inhibitor that was recently approved in the United States in combination with ceftazidime. Avibactam is a structural class of inhibitor without a β-lactam core and retains capacity to covalently acylate β-lactamase targets. Deacylation of the enzyme occurs through regeneration of intact avibactam rather than the hydrolysis seen with other β-lactamase inhibitors [33]. Avibactam can inhibit β-lactamase enzymes in molecular classes A, C, and to a lesser extent D. Notably, avibactam does not have inhibitory activity against Class B metallo β-lactamases. In vitro data demonstrates that avibactam potentiates the activity of aztreonam against a broad array of *Enterobacteriaceae*, including metallo β-lactamase-producing strains [34, 35]. Other novel β-lactamase inhibitors, including relebactam combined with imipenem was accepted by FDA for regulatory review and vaborbactam paired with meropenem was recently approved by FDA for clinical use in treatment for carbapenemase-producing GNB [36, 37].

Cephalosporins

Since the first cephalosporin was introduced in the 1960s, cephalosporins have become one of the most widely prescribed classes of antibiotics. Most are semisynthetic derivatives of cephalosporin C and consist of a β-lactam ring attached to a six-membered dihydrothiazine ring containing a sulfur moiety. The cephamycins, which have a methoxy group at C-7, are included in this class due to the structural similarity. Cephalosporins have two variable side chains, R1 (C-7) and R2 (C-3); modifications in the R1 side chains usually result in β-lactamase stability and improved spectrum, whereas modification at R2 results in altered pharmacokinetics. The fourth-generation drug, cefepime, has a positively charged quaternary ammonium in the C-3 position which creates a zwitterion, enhancing penetration through the outer membrane of GNB [38].

There are five "generations" of cephalosporins, based predominantly on microbial spectrum (Table 50.3). Most cephalosporins are excreted unchanged in the urine and require dose adjustment in patients with renal insufficiency or renal failure. Ceftriaxone has dual hepatic and renal clearance and the longest half-life of 8–9 h among the cephalosporin class. Cefoperazone is eliminated through biliary clearance. Cefotaxime is metabolized to a weakly active deacetyl metabolite in the liver [39].

Cefepime, a zwitterion, has enhanced activity against *Enterobacter*, *Citrobacter*, and *Serratia* species compared to other cephalosporins. Cefepime is less susceptible to AmpC β-lactamase inactivation and may be active in vitro against some ESBL-producing *Klebsiella* and *E. coli*, although it is inactive against organisms producing the predominant CTX-M-type enzymes. Cefepime in combination with tazobactam is in clinical development, expanding the natural spectrum of cefepime to include a wider variety of ESBL-producing organisms [40]. Cha et al. observed bactericidal activity against ESBL *K. pneumoniae* and *E. coli* in 50% of isolates compared to 100% with imipenem [41]. Lee and colleagues noted increased mortality with bacteremia caused by ESBL-producing pathogens treated with cefepime compared to carbapenems [42]. Additionally, Chopra and colleagues found a trend toward increased mortality risk with cefepime versus a carbapenem in bloodstream infections caused by ESBL *K. pneumoniae* and *E. coli* [16] suggesting that transplant patients should receive a carbapenem for serious ESBL infections.

The recent addition of another zwitterionic compound, ceftolozane, in combination with tazobactam adds to the anti-pseudomonal armamentarium. Ceftolozane is highly resistant to hydrolysis via AmpC β-lactamases and is less affected by porin and efflux pump mutations than other cephalosporins. These characteristics make ceftolozane a potential option in the treatment of multidrug-resistant *Pseudomonas aeruginosa* [43–45]. The addition of tazobactam grants some protection to ceftolozane against class A ESBLs (2be); however, the clinical significance of this additional activity remains unclear [46]. A novel siderophore cephalosporin in clinical development, cefiderocol, utilizes bacterial iron transport systems to gain active transport into GNB and demonstrates potent in vitro activity against most GNB, including metallo β-lactamase producers, *S. maltophilia* and *A. baumannii* [47, 48].

Table 50.3 Classification of cephalosporins and spectrum

Class	Representative drugs	Gram-positive spectrum	Gram-negative spectrum	Atypical spectrum	Anaerobic spectrum
First generation	Cefazolin, cephalothin, cephalexin, cefadroxil	PNS-S streptococci except enterococci, MSSA	Some *E. coli*, *Salmonella*, *Shigella*	None	Gram-positive cocci
Second generation Cephamycins	Cefotetan, cefuroxime Cefoxitin, cefotetan	PNS-S streptococci except enterococci, MSSA	*H. influenzae*, *Neisseria* spp., *E. coli*, *Klebsiella*, some *Proteus* spp.	None	*B. fragilis*
Third Generation Pseudomonas	Cefotaxime, ceftriaxone, cefixime Cefoperazone, Ceftazidime	PNS-S and R *S. pneumoniae* (outside CoNS), streptococci MSSA	*H. influenzae*, *M. catarrhalis*, *Neisseria* spp., *Salmonella*, *Shigella* *Pseudomonas*	*B. burgdorferi* (ceftriaxone)	*Peptostreptococcus*, *Clostridium* spp. (excluding *C. difficile*), *Porphyromonas*, *B. melaninogenicus*
Fourth Generation	Cefepime	PCS-S streptococci except enterococci, MSSA	Third generation plus *Pseudomonas*, *Enterobacter*, *Citrobacter*, *Serratia*, *Enterobacteriaceae*		*Peptostreptococcus*
Fifth Generation	Ceftaroline	PCN-S and PCR streptococci, MSSA, and MRSA	*H. influenzae*, *M. catarrhalis*, *Neisseria* spp., *Salmonella*, *Shigella*		

Abbreviations: *CoNS* coagulase negative staphylococci, *PCN-S* penicillin susceptible, *PCR-R* penicillin resistance

Carbapenems and Monobactams

Carbapenems are among the smallest of the β-lactam antibiotics and exist as zwitterions, a compound with overall no electric charge, albeit containing separate positive and negatively charged parts. These antibiotics require channels created by porin proteins such as OprD that are open water-filled channels spanning the outer membrane of GNB and allow passive penetration of hydrophilic compounds into the periplasmic space. The *trans*-configuration of the hydroxyethyl side chain on the β-lactam ring confers resistance to cleavage by most plasmid and chromosomal β-lactamases including class A and C enzymes. Carbapenems have the broadest spectrum of the β-lactam class which is attributed to improve ability to penetrate the cell membrane of GNB, high affinity for critical PBPs, and resistance to multiple β-lactamases [49]. Increasing resistance has been seen with *P. aeruginosa* due to altered permeability secondary to mutations and downregulation of the OprD membrane proteins or both [50]. Carbapenem-hydrolyzing β-lactamases of the class B metalloenzymes have been increasingly isolated from Gram-negative bacteria and may limit therapy with these agents. Gram-positive resistance in MRSA and *E. faecium* is caused by production of low-affinity PBPs [7].

The GNB activity of carbapenems includes ESBL-producing *Enterobacteriaceae*, *P. aeruginosa*, anaerobes such as *B. fragilis*, MSSA, MSSE, *E. faecalis*, *Listeria monocytogenes*, *Bacillus* spp., and *Nocardia* spp. among the GPB. The gaps in coverage include *Stenotrophomonas maltophilia*, *Burkholderia cepacia*, *Enterococcus faecium*, MRSA, and JK diphtheroids. Ertapenem differs from the other marketed carbapenems in that it lacks significant activity against *P. aeruginosa* and *Acinetobacter* and is only approved for complicated skin and soft tissue infections, intra-abdominal infections, and community-acquired pneumonia [51].

Imipenem is readily cleaved by the renal dehydropeptidase 1 (DHP-1) and is combined with cilastatin, a DHP-1 inhibitor, to prolong the imipenem half-life and increase serum drug concentration. The other carbapenems such as meropenem, ertapenem, and doripenem are more stable in the presence of DHP-1 and do not require combination with DHP-1 inhibitor. All carbapenems require adjustment in patients with renal insufficiency. Imipenem, meropenem, and doripenem have half-lives of about 1 h and are dosed every 6–8 h. Ertapenem has a longer half-life of approximately 4 h and can be dosed once daily. Imipenem has the greatest potential to cause seizures compared to the other carbapenems, especially at higher doses and in individuals with impaired renal function [52].

Doripenem is the newest carbapenem, approved in 2007 for the treatment of complicated urinary tract and intra-abdominal infections [53]. Doripenem is more active against MSSA and methicillin-sensitive coagulase-negative staphylococci than meropenem and ertapenem. It tends to be less active against *E. faecalis* compared with imipenem. The Gram-negative activity is similar to meropenem with greater activity against *P. aeruginosa*. One study showed that doripenem retained activity against 29.4% of *P. aeruginosa* strains [54] that were resistant to imipenem and 20.8% of carbapenem-resistant *Acinetobacter* spp. [55]. Similar mechanisms of resistance are seen with doripenem, including metallo-β-lactamases, OprD outer membrane porin protein mutations, and upregulation of multidrug efflux pumps.

Some studies suggest that doripenem may have a higher threshold for the development of resistance, requiring more than one resistance mechanism [56]. The adverse reactions seen with doripenem are similar to meropenem, including gastrointestinal disturbances, rash, transaminase elevations, and, to a lesser extent, seizure activity. The clinical efficacy of doripenem in transplant recipients is very limited.

Aztreonam, the only marketed monobactam, has a sulfonic acid group on the nitrogen at the N-1 position of the β-lactam ring. Aztreonam penetrates quickly through the outer membrane of GNB and is resistant to hydrolysis by B class enzymes, many class C β-lactamases, but not ESBLs. The drug has a half-life of 2 h and undergoes renal excretion; therefore dose adjustment is necessary in patients with renal insufficiency. Aztreonam has a spectrum of activity similar to the aminoglycosides, including *Pseudomonas*. Most *S. maltophilia*, *B. cepacia*, and many *Acinetobacter* spp. are resistant; *Enterobacter* spp. and *C. freundii* demonstrate variable susceptibility. It lacks Gram-positive and anaerobic activity and is often used with another antibiotic-like clindamycin or vancomycin for additional Gram-positive coverage [57, 58]. A new aerosolized formulation of aztreonam lysine is approved for the treatment of respiratory infections in patients with cystic fibrosis [59]; its role in other patient populations remains to be explored.

Aztreonam is a weakly immunogenic compound which can be safely administered to penicillin-allergic patients. The site of antibody recognition against aztreonam differs from the bicyclic β-lactams. Hypersensitivity is secondary to antibodies against the side chain and occurs in under 1% of patients allergic to penicillin [60]. Other nonimmune adverse reactions include rash, diarrhea, nausea, vomiting, and local injection reactions (Table 50.4).

Beta-Lactams with MRSA Activity

Ceftaroline is a broad-spectrum cephalosporin developed with enhanced activity against GPB. Ceftaroline fosamil, the prodrug, was approved in 2010 for the treatment of complicated skin and skin-structure infections and community-acquired pneumonia. Ceftaroline binds to PBP2a, a PBP found in staphylococci with reduced affinity for other β-lactam compounds. The high-affinity binding of ceftaroline to PBP2a leads to rapid bactericidal activity against methicillin-resistant staphylococci, including MRSA. Ceftaroline is also active against heteroresistant vancomycin-intermediate *S. aureus*, vancomycin-resistant *S. aureus*, penicillin-resistant *S. pneumoniae*, certain strains of vancomycin-resistant *E. faecalis*, and common respiratory pathogens such as *H. influenzae*. Non-ESBL *Enterobacteriaceae* are susceptible, but ESBL-producing strains are resistant. Ceftaroline has minimal activity against *P. aeruginosa* and *A. baumannii* and has limited activity against anaerobic GNB. It also lacks activity against *E. faecium.* Of 12,000 isolates of MSSA, MRSA, and *S. pneumoniae* tested in vitro, both the MIC_{50} and MIC_{90} against MRSA were 1 μg/mL, and the drug was active against 95.6% of multidrug-resistant *S. pneumoniae* [61].

In two large phase III trials for patients with community-acquired pneumonia (CAP) and acute skin and skin structure infections (ASSSI), ceftaroline was shown to be noninferior to ceftriaxone in patients with CAP and vancomycin plus aztreonam in ASSSI treatment group. Clinical cure rates for ceftaroline were higher than ceftriaxone, particularly when the penicillin-resistant *S. pneumoniae* serotype 19A was the primary pathogen. The clinical cure rate in microbiologically evaluable patients with MRSA was similar to vancomycin plus aztreonam, and the drug was well-tolerated [62]. Dose adjustments are required in patients with moderate renal insufficiency. Further clinical studies are needed to determine the efficacy and safety of ceftaroline and to define its role in treating immunocompromised patients undergoing allograft transplantation.

Beta-Lactam Allergy and Other Adverse Reactions

The beta-lactams are reported to cause allergic events in 1 to 10% of patients, with life-threatening allergies observed in 0.01 and 0.05% of cases. Penicillins are quickly metabolized into benzylpenicilloyl, also known as the major antigenic determinant, by opening of the β-lactam ring [63]. This sta-

Table 50.4 Carbapenems and monobactams

Class	Representative drugs	Gram-positive spectrum	Gram-negative spectrum	Atypical spectrum	Anaerobic spectrum
Carbapenems	Imipenem-cilastatin meropenem, ertapenem, doripenem	MSSA, CoNS, streptococci, *B. anthracis*, *Listeria*, *Corynebacterium* spp., PCN-S *E. faecalis* (imipenem)	*H, influenzae*, *Neisseria* spp., *Klebsiella*, *Enterobacter* spp., *E. coli*, *Serratia*, *Citrobacter*, *Acinetobacter*, *Proteus* spp., *Pseudomonas*	*Nocardia*, rapidly growing Mycobacterium spp. (imipenem)	*B. fragilis*, *Prevotella* spp., *Clostridium* spp., Gram-positive cocci, *Actinomyces*
Monobactams	Aztreonam	None	*Pseudomonas*, *Enterobacteriaceae*, *Neisseria*	None	None

ble metabolite can bind to protein conjugates through amide linkages in solution or with human proteins after administration, forming potentially immunogenic haptens. The minor determinants include penilloate, penicilloate, and benzylpenicillin that account for a minority of allergic reactions. Both can cause either anaphylaxis or urticarial reactions mediated by IgE antibodies. The β-lactam and dihydrothiazine rings of cephalosporins rapidly fragment into unstable compounds that are usually not similar in structure to the penicillin allergic determinants. Fragments of the cephem nucleus and parts of the cephalosporin side chains can act as haptens and lead to sensitization [63].

Type I immediate hypersensitivity reactions are mediated by IgE antibodies and result in anaphylaxis, urticaria, laryngeal edema, angioedema, and hypotension within minutes to hours through release of histamine and mediators such as vasoactive amines, cytokines, and proteases from mast cell degranulation. Type II reactions are mediated by complement and result in hemolytic anemia, thrombocytopenia, and neutropenia. Type III reactions occur later after exposure due to precipitation of immune complexes and activation of the complement system manifesting as serum sickness with fever, rash, and arthritis and allergic vasculitis. Type IV, or delayed type hypersensitivity, causes maculopapular and morbilliform rashes thought to be T cell-mediated. Exfoliative dermatitis, Stevens-Johnson syndrome, erythema multiforme, and drug reaction with eosinophilia and systemic symptoms (DRESS) fall under the idiopathic hypersensitivity reactions [63].

The rate of cross-allergy in penicillin allergic patients receiving a cephalosporin ranges from 1% to 5.5% with first-generation cephalosporins [64, 65]. Cross-reactivity between cephalosporins and penicillins is thought to be mediated as a result of similarities in the structural side chains as opposed to the β-lactam ring [63]. The carbapenem primary metabolite, a stable carbapenoyl, is structurally similar to benzylpenicilloyl, accounting for the higher rate of cross-reactivity seen with carbapenems [66]. Monobactam allergy is mediated by allergy to the sidechains acting as haptens which are the major determinants of allergy [60].

Other beta-lactam adverse reactions include reversible neutropenia, Coombs-positive hemolytic anemia, and platelet dysfunction with the extended spectrum penicillins; central nervous system toxicity consisting of seizures, myoclonus, and hyperreflexia is associated with extremely high doses of β-lactams and in patients with preexisting neurologic disorders and/or those with acute renal insufficiency. Elevations in transaminase levels are seen mostly with penicillinase-resistant penicillins. Antistaphylococcal penicillins are associated with interstitial nephritis. Gastrointestinal disturbances and *C. difficile* colitis may occur with the use of any beta-lactam antibiotic. Pulmonary infiltrates with eosinophilia syndrome have been described. Ceftriaxone-calcium complex may precipitate in the gallbladder leading to the development of stones consisting of ceftriaxone crystals, more commonly in children or patients in whom prolonged high-dose therapy is given [67]. Hypoprothrombinemia and a disulfiram reaction can occur with cephalosporins that possess an N-methylthiotetrazole substitution including cefamandole, moxalactam, cefotetan, and cefoperazone [68]. However, only cefoperazone and cefotetan are currently available for use in the United States, and moxalactam was withdrawn from the US market.

Vancomycin

Isolated from *Streptomyces orientalis* in 1952, vancomycin was originally utilized in penicillin-allergic patients or those infected with penicillin-resistant *Staphylococcus* [69]. The FDA originally approved vancomycin in 1958. Early on, serious drug toxicity reflected difficulties with the antibiotic purification methods, yielding to high rates of nephrotoxicity and concentration-related ototoxicity, in addition to a distinct brown color noted in infusion apparatus invoking the moniker "Mississippi mud." These early difficulties, in combination with the approval of methicillin in the same year, vancomycin use fell out of favor. With the emergence of MRSA in the 1980s as an important nosocomial pathogen, more recently, community-acquired pathogen saw a resurgence of vancomycin use [70–72]. Vancomycin continues to remain an important component of the antibiotic armamentarium.

Vancomycin is the representative agent of the glycopeptide class of antimicrobials. Teicoplanin, oritavancin, dalbavancin, and telavancin are the other agents that belong to the glycopeptide group. Vancomycin exhibits antimicrobial activity through disruption of peptidoglycan synthesis via high-affinity binding to the D-alanyl-D-alanine terminus of the N-acetylglucosamine (NAG) and N-acetylmuramic acid (NAM), leading to interruption in transglycosylation and further polymerization of peptidoglycan precursors. The bactericidal effects in replicating organisms are due to expression of autolytic enzymes that destroy damaged and incomplete cell walls [73].

Spectrum of Activity

The spectrum of activity of vancomycin includes most GPB such as staphylococci, streptococci, and enterococci. As with other cell wall active agents, minimum bactericidal concentrations of vancomycin are higher against enterococci (>32 mcg/ml) due to reduced expression of autolytic proteins [74]. Vancomycin is also active against *Bacillus* spp., *Corynebacterium* spp., and *Rhodococcus equi*. *Lactobacillus*

acidophilus is the only susceptible member of this genus. *Erysipelothrix rhusiopathiae*, *Leuconostoc* spp., and *Pediococcus* spp. are inherently resistant to vancomycin. Anaerobes susceptible to vancomycin include most strains of *Clostridium* spp., *Actinomyces* spp., *Peptostreptococcus* spp., and *Propionibacterium* spp. With the exception of certain strains of *Neisseria*, GNB are uniformly resistant to vancomycin [75]. *Listeria monocytogenes* frequently show in vitro susceptibility to vancomycin although discouraging clinical response with vancomycin therapy to treat invasive listeriosis cautions against its use.

Resistance and Reduced Susceptibility

In 1988, European researchers identified the first vancomycin-resistant *Enterococcus* [76, 77]. Almost a decade later, *S. aureus* isolates with reduced vancomycin susceptibility were isolated in Japan [78]. In 2002, the first vancomycin-resistant *S. aureus* (VRSA) was isolated from patients in Detroit, Michigan [79]. Fortunately, VRSA has been isolated only rarely since 2002. As transplant patients are exposed to vancomycin frequently, understanding the mechanism of resistance among the GPB is essential for appropriate treatment selection.

Vancomycin resistance in *Enterococcus* spp. is attributed to specific gene clusters, specifically VanA, VanB, VanC, VanD, VanE, and VanG [80]. VanA is a prominent resistance genotype; it is plasmid bound and inducible. VanA and VanB are the only nonchromosomal resistance types. VanC and VanD are the non-inducible clusters. VanC confers intrinsic, albeit low-level vancomycin resistance in *E. gallinarum* and *E. casseliflavus–E. flavescens* [77, 81]. Vancomycin-resistant enterococcal clusters modify the terminal d-alanyl-d-alanine to either d-alanyl-d-lactate (VanA, VanB, VanD) or d-alanyl-d-serine (VanC, VanG, VanE) [82]. These amino acid alterations significantly decrease the affinity of the terminal NAG and NAM polymers for vancomycin. Interestingly, some strains of *E. faecalis* and *E. faecium* require vancomycin for growth. These isolates, known as vancomycin-dependent enterococcus (VDE), do not constitutively express d-alanyl-d-alanine ligase, necessary to produce d-alanyl-d-alanine. Instead, VDE strains produce inducible d-alanyl-d-lactate ligase present on VanA/VanB operons [83, 84]. As a result of this mutation, VDE will only grow in the presence of vancomycin. VDE has been isolated from liver transplant patients [83]. Discontinuation of vancomycin is occasionally insufficient for bacterial eradication as reverting mutants have been reported [85].

Vancomycin resistance in staphylococci was induced in laboratory experiments shortly after the drug was introduced. Clinical vancomycin-resistant isolates were not isolated, leading to speculation that vancomycin was intrinsically resilient in *Staphylococcus* [86, 87]. In the late 1970s however, cases of *S. epidermidis* with increased minimum inhibitory concentrations (MIC) to vancomycin were observed [88]. Diminished susceptibility of the more virulent *S. aureus* was first seen in 1997 [78]. Transference of the VanA gene from *E. faecalis* to *S. aureus* was experimentally accomplished by Nobre and colleagues in 1992. However, clinical isolates of vancomycin-resistant strains with this mechanism of resistance were not identified until 2003 in Michigan [79, 89]. Despite several documented cases of vancomycin-resistant *S. aureus* (VRSA), the majority of *S. aureus* strains with reduced susceptibility to vancomycin are identified as vancomycin-intermediate *S. aureus* (VISA) [90] or glycopeptide-intermediate *S. aureus* (GISA) [91]. VISA strains have an MIC of 4–8 mcg/ml based on the most recent recommendations from Clinical & Laboratory Standards Institute (CLSI) [92]. Increased cell wall thickness, decreased peptidoglycan cross-linking, and disorganized cell wall structure are salient mechanisms for reduced vancomycin activity among the VISA strains [93–95]. The irregularly thick peptidoglycan wall in VISA sequesters vancomycin away from the cell membrane where the drug would normally bind cell wall precursors. Colonies of VISA can coexist with vancomycin-susceptible colonies; these isolates known as heterogeneous vancomycin-intermediate *S. aureus* (hVISA) may have elevated MICs and are antecedent to VISA. While hVISA will usually maintain MICs in the CLSI susceptible range, infections due to hVISA, especially in the immunosuppressed patients, may result in failure to vancomycin therapy and should be approached with caution [96].

In recent years, investigators have noted an MIC creep in *S. aureus* isolates [97, 98]. The increased prevalence of hVISA strains may play an important role in this phenomenon. Additionally, the occurrence of vancomycin tolerance, where bactericidal activity is lost and physiologically unobtainable minimum bactericidal concentrations are observed while MICs appear to be in the susceptible range (MBC/MIC ≥32), is a concern [99, 100]. Loss of bactericidal activity may be the result of a downregulation of autolytic enzymes due to loss of function of the accessory gene regulator (*agr*) [101, 102]. Given this phenomenon, it is be prudent to select alternative drug to treat MRSA infection, especially in the severely immunocompromised patients following transplantation (Table 50.5).

Adverse Reactions

Much of the early toxicity noted with vancomycin use is attributed to suboptimum purification methods at the time. The adoption of an ion-exchange resin method of purification resulted in a significant decline in the frequency of drug-

Table 50.5 Agents with activity against MRSA/VRE

Drug	Usual dose	Route	VRE active	Prominent toxicity	Comments
Vancomycin	15 mg/kg q12h-q8h	*IV, PO/PR**	*N*	*Nephrotoxic at high doses, especially with concomitant nephrotoxins* *Ototoxicity with high peaks*	*First-line therapy for MRSA, efficacy may be decreasing with MIC creep* *Dose adjustment for renal impairment required* **PO/PR route for C. difficile*
Daptomycin	4–10 mg/kg q24	*IV (IVP over 2 min is an acceptable route)*	*Y*	*Myopathy, less prevalent now with once-daily dosing*	*Ineffective for pneumonia due to inactivation by surfactant* *Dose adjustment for renal impairment required*
Telavancin	10 mg/kg q24h	*IV*	*Y*	*Nephrotoxicity*	*Dose adjustment for renal impairment required*
Oritavancin	1200 mg once	*IV*	*Y*	*Nausea*	*Half-life approximately 250 h*
Dalbavancin	1500 mg once or 1000 mg followed by 500 mg in 1 week	*IV*	*Y*		*Half-life approximately 350 h* *Dose adjustment for renal impairment required*
Linezolid	600 mg q12h	*IV, PO*	*Y*	*Myelosuppression with thrombocytopenia predominance with prolonged use due to mitochondrial toxicity*	*Bacteriostatic agent* *May inhibit toxin production in toxic shock syndrome/ necrotizing fasciitis*
Tedizolid	200 mg q24h	*IV, PO*	*Y*	*Myelosuppression*	
Quinupristin/ dalfopristin	7.5 mg/kg q8–q12h	*IV*	*Y*	*Thrombophlebitis*	Only active against *E. faecium*
Ceftaroline	*600 mg/kg q12h*	*IV*	*N*	*Similar to other cephalosporins*	*Dose adjustment for renal impairment*
Tigecycline	*100 mg loading dose, then 50 mg q12h*	*IV*	*Y*	*Dose dependent, transient, nausea/ vomiting*	*Significant volume of distribution, primarily to bile results in low serum levels*
Sulfamethoxazole/ trimethoprim (SMX/ TMP)	*8–20 mg/kg/day, div q6–12 h*	*IV, PO*	*N*	*Hyperkalemia* *Myelosuppression* *Stevens-Johnson syndrome/TEN* *Hepatotoxicity*	*Dose adjustment required in renal impairment* *Dose dependent hyperkalemia due to inhibition of the ENaC in the cortical collecting ducts* *Antifolate effects can delay bone marrow engraftment* *Active only against certain community-acquired strains*
Tetracyclines Tetracycline Doxycycline Minocycline	*250–500 mg q6h* *100 mg q12h* *200 mg loading dose, 100 mg q12h*	*IV, PO*	*N*	*Fanconi syndrome with outdated tetracyclines* *Tooth discoloration with pediatric use*	*Active only against certain community-acquired strains*

induced renal failure and ototoxicity [70]. Drug-attributable nephrotoxicity caused by current formulations of vancomycin is a matter of some controversy. Early retrospective data suggested that rates of renal failure in patients using vancomycin were approximately 5% although concurrent use of other nephrotoxic drugs may be a potential confounding factor in these analyses [103]. Concomitant vancomycin and aminoglycoside therapy has been recognized to heighten the risk for renal failure, especially with serum trough concentrations greater than 10 mcg/ml [104]. More recent clinical data suggests that nephrotoxicity associated with vancomycin may be more common in patients treated concomitantly with piperacillin-tazobactam in comparison to other β-lactam agents, although the mechanism by which this synergistic nephrotoxicity may occur remains unclear [105, 106]. In light of recent recommendations to target vancomycin trough concentrations between 15 and 20 mcg/ml range, vancomycin-related nephrotoxicity has become a greater concern [107]. Vancomycin has also been associated with acute interstitial nephritis [108].

Vancomycin-related ototoxicity is rare, generally reversible and observed with peak serum concentrations of greater than 50 μg/ml [109, 110]. Neutropenia and thrombocytopenia have been rarely seen and occur after a prolonged treatment course [103, 111, 112]. Thrombocytopenia is rare, immunologically mediated, but may not be readily appreciated

[113]. Infusion-related adverse reactions are not uncommon in patients receiving intravenous vancomycin. The non-IgE, histamine-related reaction known as the red man syndrome is associated with a pruritic erythematous rash from the head to the trunk which is occasionally accompanied by an anaphylactic picture [114]. Red man syndrome is related to the infusion rate of vancomycin. Infusing the drug at 500 mg/h greatly reduces the incidence of red man syndrome, and premedication with a histamine-1 receptor antagonist may be useful [115].

Vancomycin Use in the Transplant Patient

Vancomycin is commonly used in transplant patients. In a study of GPB infection in patients following liver transplantation, vancomycin-susceptible *S. aureus* and *Enterococcus* spp. were the predominant pathogens with MICs <2 μg/ml. Risk factors for infection included perioperative antibiotics, increased intraoperative blood transfusion, and renal failure after transplant surgery [116]. In a retrospective study among lung transplant recipients, vancomycin prophylaxis for transplant candidates with nasal MRSA carriage was continued for 7 days. MRSA infection increased over the first 90 days and was associated with a 7 and 12% mortality 30 and 90 days later, respectively. *S aureus* infection within the first 90 days after transplant was associated with an increased rate of acute and chronic rejection [117]. There is considerable literature about treatment of *C. difficile* infection (CDI) with oral vancomycin in transplant patients. One study showed a rate of CDI of 13% in stem cell transplant recipients. There was no increase in mortality, but recurrence was noted in 11% of patients; 2/3 of these patients were given vancomycin for CDI [118].

Aminoglycosides

Streptomycin was isolated from *Streptomyces griseus* in 1944. This first aminoglycoside was followed by neomycin and kanamycin in 1949 and 1957, respectively [119]. In 1963 gentamicin was isolated, "micin" ending to designate its origin from the *Micromonospora* genus as opposed to "mycin" for aminoglycosides isolated from *Streptomyces* spp. [120]. Additional aminoglycosides became available for clinical use, including sisomicin, netilmicin, tobramycin, and amikacin. To date, gentamicin, tobramycin, and amikacin have remained clinically useful agents against many bacteria, while streptomycin is used in the treatment of drug-resistant tuberculosis. A novel aminoglycoside, plazomicin, is in clinical development and has retained in vitro activity against bacteria resistant to earlier-generation aminoglycosides [121]. Aminoglycosides have maintained their clinical utility in the face of many multidrug-resistant GNB that poses a daunting management challenge for patients undergoing allograft transplantation.

Aminoglycosides are rapidly bactericidal poly-cationic sugars that exhibit concentration-dependent killing. The primary mechanism of action is through inhibition of protein translation. Aminoglycosides bind to the A site on the 16 s subunit of the prokaryotic ribosome and interfere with tRNA-mediated translocation [122]. Subsequently, incomplete protein products are inserted into the bacterial cell membrane causing leakage of cellular contents from the porous cell [123]. The rapid bacterial killing seen after aminoglycoside administration is not easily explained by this mechanism. A more rapid mode of killing displayed shortly after administration is binding to lipopolysaccharides (LPS) and disruption of adjoining calcium and magnesium bridges [124]. Disruption of bacterial membrane integrity precedes increased permeability and loss of intracellular content. This mechanism is similar to that seen with the cationic polymyxin class. The binding of aminoglycosides to LPS before their subsequent cytoplasmic infiltration is the first of three phases of drug transport, the latter two being energy dependent [125, 126]. The first energy-dependent phase (EDP1) is the slower of the two and relies on a sufficient negative membrane potential generated by proton motive force for drug entry [127]. Since aminoglycosides are positively charged in a physiological pH range, an acidic extracellular environment severely limits cellular entry due to a loss of electrochemical potential. In addition to low pH, anaerobic conditions and site-competitive Mg^{2+} and Ca^{2+} are antagonistic to aminoglycoside entry during EDP1 [128]. Anaerobic bacteria, lacking oxidative aerobic metabolism to establish a sufficient electronegative intracellular space, are intrinsically resistant to aminoglycosides. The final phase of cellular entry, known as EDP2 or energy-dependent phase II, is manifested as the ribosomal-binding phase and is initiated when sufficient porosity has been attained on the cell membrane.

Spectrum of Activity

The aminoglycosides in clinical use have consistent activity against the non-lactose-fermenting *P. aeruginosa* and *Acinetobacter* spp. while lacking activity against *S. maltophilia* and *B. cepacia.* All *Enterobacteriaceae* species are susceptible. Certain intracellular pathogens are susceptible, including *Bartonella* spp., *Brucella* spp., *Yersinia* spp., and *Francisella tularensis.* Amikacin is active against *Mycobacterium avium-intracellulare.* Select aminoglycosides display synergistic bacterial killing when combined with cell wall active agents due to enhanced cell entry [129] against GPB such as *Staphylococcus* spp., β-hemolytic *Streptococcus*, *S. viridans*, enterococci, and *Listeria mono-*

cytogenes. Aminoglycosides also exhibit synergistic properties against *P. aeruginosa* and *Enterobacteriaceae*.

Mechanisms of Resistance

A desirable attribute of the aminoglycosides is the preserved spectrum of activity against multidrug resistant bacteria that are often encountered in the transplant population. The predominant mechanisms of resistance to aminoglycosides are enzymatic drug alterations, ribosomal alterations, efflux pumps, and diminished cellular entry through porin mutations [130–133]. Resistance mechanisms in GNB can be chromosomal or acquired via plasmids or transposons. Mobile resistance elements often travel with genes for multidrug resistance and can be especially problematic [134].

Enzymatic modification of aminoglycosides is the most common and clinically important mechanism for acquired drug resistance. Drug modification is accomplished by three major classes of enzymes: acetyltransferases (AAC), adenylyltransferases (ANT), and phosphotransferases (APH). Numerous enzymes in each family have been identified, and a systematic nomenclature has been implemented to delineate the drug-inactivating proteins [134]. AAC enzymes target amino groups on the aminoglycoside molecule and are dependent on acetyl CoA, while ANT and APH enzymes are specific for hydroxyl groups and rely on ATP for activity. After enzymatic modification, the antibiotic has significantly less affinity for the ribosomal binding site. Compared to gentamicin and tobramycin, amikacin is susceptible to fewer modifying enzymes and may be more likely to retain activity against pathogenic isolates resistant to other aminoglycosides [135, 136]. Clinical strains may still possess modifying enzymes allowing susceptibility to one or more aminoglycosides. A detailed table of aminoglycoside modifying enzymes can be found in Shaw's review [134]. Reduced membrane permeability and drug efflux pumps are two additional resistance modalities. Alterations in the LPS structure from a smooth to a more rough form may be responsible for certain cases of low-level resistance [137]. The aminoglycoside efflux pump, designated MexXY-OprM, has been implicated in the transient loss of bactericidal activity of aminoglycosides in the time frame spanning between initial drug administration and several hours afterward [138]. This phenomenon, known as adaptive resistance, has been demonstrated in clinical isolates of *P. aeruginosa* [132, 139].

Adverse Reactions

Aminoglycosides are some of the most commonly used nephrotoxins in clinical practice of infectious diseases. The incidence of nephrotoxicity with aminoglycosides has been reported to be as high as 25% [140, 141]. Newer, extended-interval dosing regimens have resulted in reduced potential for nephrotoxicity, but risk still exists [142]. Data suggest that the nephrotoxic potential among the various aminoglycosides is not equivalent. Gentamicin is likely accompanied with a greater risk for nephrotoxicity than amikacin and tobramycin [140, 143–145]. The proposed pathogenesis for aminoglycoside-induced kidney injury comes mostly from animal data [146, 147]. After filtration in the glomerulus, approximately 5% of the aminoglycoside dose is reabsorbed in the proximal tubule via endocytosis by megalin receptors where they are sequestered in lysosomal vacuoles and the Golgi apparatus [148–150]. Gentamicin experiences the greatest cortical concentrations which may explain the perceived enhanced nephrotoxicity with this agent [147]. Altered cellular protein synthesis and mitochondrial toxicity after aminoglycoside exposure lead to necrosis of the tubules, manifested by loss of K^+, Mg^{2+}, and Ca^{2+} cations, HCO_3^-, glucose, and findings of proteinuria and cast in the urine [151–153]. Patients usually experience non-oliguric or polyuric renal failure with reduced glomerular filtration rate and elevations in blood urea nitrogen and serum creatinine; rarely, Fanconi's syndrome may be observed [154]. Aminoglycoside-induced acute tubular necrosis is generally reversible. Tubular regeneration begins to restore kidney function despite continued exposure to aminoglycosides [155, 156]. Administration of aminoglycosides with concomitant nephrotoxic drugs such as vancomycin, amphotericin B, and calcineurin inhibitors increases the risk for kidney injury. Sparse data suggests that penicillins with significant sodium content may reduce the risk for aminoglycoside-induced nephrotoxicity [157, 158].

Ototoxicity from aminoglycosides can present as cochlear toxicity and vestibular toxicity or both. Ototoxicity may occur in as many as 14% of patients, but asymptomatic loss of high-frequency sound perception has been reported more often when audiometric assessment is undertaken [159, 160]. While vestibular damage is usually reversible, injury to cochlear cells is generally not. The pathophysiology of ototoxicity is similar to the cellular changes occurring in the proximal renal tubule with uptake and accumulation occurring in type 1 hair cell lysosomes [161, 162]. The greatest risk factors are duration of exposure to aminoglycoside, renal failure, and concurrent therapy with other ototoxic agents such as loop diuretics and vancomycin [163–165]. Additionally, several mitochondrial rRNA mutations at the 12S ribosome subunit place patients at an increased risk for ototoxicity [166].

Neuromuscular blockade is a rare side effect of aminoglycosides and caused by prevention of postsynaptic and presynaptic acetylcholine release by interfering with the preceding calcium signal [167]. Major risk factors are predisposing conditions that impair neuromuscular junction

activity such as co-administration of depolarizing or non-depolarizing neuromuscular blockers and potentially myasthenia gravis [168]. Additional risk factors include elevated aminoglycoside concentrations, hypomagnesemia, hypocalcemia [169], and use of calcium channel blockers [170]. The effects are not effectively reversible by acetylcholinesterase inhibitors like neostigmine; infusion of intravenous calcium restores neuromuscular function quickly and reliably [171].

Use in the Transplant Patient

An important potential use of aminoglycosides, especially amikacin, would be expected in the transplant patient with multidrug-resistant *Acinetobacter* and *Pseudomonas* infections. In a study of renal transplant patients, amikacin was used in 12% of patients, second to carbapenems. *Enterococcal* infection was associated with the highest mortality. No mention was made of renal toxicity from amikacin [172]. In another review of KPC infections in renal transplant recipients, gentamicin was used in one patient for 43 days along with polymyxin; the patient died 84 days after transplantation [173].

Oxazolidinones

The oxazolidinones are a class of synthetic antimicrobials discovered in the 1970s, with earnest clinical development in the late 1980s [174]. Due to favorable toxicology and pharmacokinetics, linezolid became the first marketed member of this novel class, with tedizolid as a more recent addition [175, 176]. The oxazolidinones inhibit bacterial protein synthesis through binding to the 50s ribosome at a site close to that of clindamycin and chloramphenicol, although the molecules have a distinct mechanism of action [177]. Crystal structure analysis of the linezolid-ribosome complex shows that linezolid binds to the A-site of the peptidyl transferase center, the universally conserved U2585 nucleotide of the 23S ribosomal subunit, interfering with proper tRNA positioning and leading to gross translational inaccuracy through frameshift mutations [178]. Early studies pointed toward inhibition of the ribosomal initiation complex as the primary mechanism of action; however, subsequent research has shown that while this may be an effect of linezolid, the drug concentrations at the ribosome required are higher than may be achievable in vivo [179]. Various oxazolidinone structures induce unique conformational changes at their binding sites, providing a starting point for the development of compounds that may overcome mutational resistance. Furthermore, oxazolidinones have been shown to serve as a cross-link between LepA and the ribosome, inhibiting a crucial cellular quality-control mechanism [180].

Spectrum of Activity

Linezolid is active against a broad variety of GPB, with MIC90 values of 1 μg/mL for most clinically relevant isolates, including MRSA and vancomycin-resistant enterococci. Linezolid is active against other less common Gram-positive organisms such as *Rhodococcus*, *Listeria*, and *Erysipelothrix* [181], although clinical experience is limited. *Nocardia* spp. also exhibit in vitro susceptibility to linezolid with an MIC of 4 mcg/mL for most clinical isolates [182]. Due to active efflux pumps and poor membrane penetrability, linezolid is inactive against most Gram-negative bacteria, with variable activity against *Moraxella* and *Haemophilus* spp. Linezolid has in vitro activity against anaerobes, including *C. difficile*, *Fusobacterium*, and *B. fragilis* although there is little clinical information and sporadic resistance may be noted among some anaerobes [183].

Linezolid has variable activity against acid-fast bacilli. Among isolates of rapidly growing *Mycobacteria*, linezolid inhibited most *M. fortuitum* isolates, whereas other rapid growers such as *M. abscessus* and *M. chelonae* demonstrated higher MICs to linezolid than that are physiologically achievable to treat an infection. Due to this high variability in susceptibility, determination of MICs to linezolid in rapidly growing *Mycobacteria* should be confirmed [184]. Against non-tuberculous slow-growing *Mycobacteria*, linezolid demonstrates good activity against *M. marinum*, *M. gordonae*, *M. szulgai*, and *M. kansasii*; however, less than half of *M. avium* complex strains tested showed in vitro susceptibility [185]. Linezolid is also active against clinical isolates of *M. tuberculosis* and has demonstrated utility as salvage therapy for MDR and XDR strains of *M. tuberculosis* [186]. Tedizolid has a similar spectrum of activity as linezolid, although with enhanced activity against certain linezolid-resistant strains [187].

Resistance

As synthetic antimicrobials, it was hoped that the development of resistance to oxazolidinones would be hindered by lack of a natural reservoir of resistance that has evolved in bacteria through the millennia [188]. Despite this theoretical advantage, a naturally occurring resistance gene was identified in a veterinary *Staphylococcus* isolate the same year that linezolid was marketed and was linked to an outbreak of linezolid-resistant *Staphylococcus* in Spain less than a decade later [189]. Single nucleotide polymorphisms near the target site of linezolid on the 23S ribosome may confer clinical resistance [190]. The first report of clinical resistance to linezolid came from two isolates of *E. faecium* identified in a compassionate-use trial that demonstrated a G2576T mutation in the 23S ribosome, with reduced susceptibility corre-

lating to a greater amount of mutant ribosome. This mutation and numerous other single-nucleotide polymorphisms on the 23S bacterial ribosome have also been selected for in vitro in *Staphylococcus* spp. and enterococci [191]. While the risk for selection of de novo-resistant mutants appears to be low, with an estimated frequency of 10^{-10}, however, nosocomial spread of such mutant strains may potentially become a clinical problem [192]. In an early case control study of linezolid-resistant *Enterococcus* spp., prior exposure to and prolonged treatment with linezolid were identified as major risk factors for presence of linezolid resistance [193]. In subsequent analyses, solid organ transplantation, peripheral vascular disease, total parenteral nutrition, and exposure to a variety of antimicrobials were identified as risk factor for linezolid resistance [194]. Interestingly, this study failed to demonstrate an association between prior linezolid exposure and subsequent development of drug resistance; horizontal spread of the drug-resistant organism(s) is presently supported by epidemiologic data [195]. Mutational resistance to linezolid may also occur through alteration of the ribosomal L3 and L4 proteins, which facilitate the process of ribosomal translation and elongation [196]. The exact mechanism behind reduced susceptibility conferred by mutations in these proteins has yet to be elucidated fully, although they often coexist with and may facilitate subsequent development of ribosomal mutations [197].

Resistance to linezolid may also occur via enzymatic modification of the ribosomal target. Various modifications of nucleotides known to confer resistance to other protein synthesis inhibitors binding at sites near the peptidyl transferase center have also been shown to confer resistance to the oxazolidinones [198]. The *cfr* gene, encoding for an rRNA methyltransferase, is the most prominent mechanism, conferring resistance to a group of antimicrobials known as $PhLOPS_A$ (for phenicols, lincosamides, oxazolidinones, pleuromutilins, and streptogramin A) [199]. First identified in 2005 in livestock, a transposon bearing this gene in addition to *ermB* was identified in a clinical isolate of *S. aureus* [200]. This gene has subsequently been shown to be responsible for resistance in clinical isolates of *S. aureus*, *S. epidermidis*, and *E. faecalis* [201–203]. Based on US surveillance data, overall resistance rates to linezolid are stable at 0.3–1.48%, depending on the organism. However, local resistance rates may be as high as 7% in *E. faecalis* [204]. Linezolid resistance has recently been described in *S. pneumoniae* [204], warranting continued susceptibility surveillance among pneumococcal clinical isolates.

Adverse Reactions

Brief courses of linezolid are well-tolerated. Common adverse events include diarrhea, nausea, and vomiting. Serious adverse events may emerge with extended duration of therapy. Myelosuppression occurs in a dose- and duration-dependent manner, primarily causing thrombocytopenia, although trilineage suppression of hematopoiesis has been observed [205]. This effect becomes prominent if treatment is extended beyond 2 weeks and may be predicted on the basis of overall exposure to the drug and baseline hematologic parameters [206]. The mechanism for anemia appears similar to that of chloramphenicol, namely, inhibition of mitochondrial protein synthesis [207], and is likely a class effect of the oxazolidinones [208]. Thrombocytopenia is likely an immunologically mediated phenomenon [207]. Myelosuppression is generally reversible; however, use in hematopoietic stem cell transplant recipients may lead to prolonged pancytopenia and rarely permanent graft loss [209]. Prolonged use of linezolid may predispose to peripheral and optic neuropathy [210, 211] secondary to mitochondrial protein synthesis inhibition and may be irreversible [212]. Mitochondrial inhibition may also lead to lactic acidosis and the posterior reversible leukoencephalopathy syndrome [213, 214]. As an inhibitor of monoamine oxidase (MAO), linezolid has been associated with the serotonin syndrome when used with other serotonergic drugs in the general population and in patients undergoing HSCT [215]. An analysis of phase III and IV trials failed to support this association when compared to non-serotonergic antimicrobials [216], and clinical data supports the rarity of this event [217]. Tedizolid appears to have a diminished capacity to inhibit MAO and potentiate serotonin toxicity when compared to linezolid, although clinical trials have notably excluded recipients of MAO inhibitors [176].

Use in Transplant Patients

Linezolid has been studied in 25 HSCT recipients who received at least 3 days of linezolid versus 24 controls. There was no difference in the duration of thrombocytopenia or neutropenia but a trend toward difference in time to engraftment. In patients treated with 10 days or less of linezolid, duration of thrombocytopenia, time to engraftment, and need for platelet transfusions were not greater compared with controls. The conclusion from this review was that linezolid can be used safely for greater than 10 days with close monitoring of platelet counts and time to engraftment [209].

Daptomycin

Daptomycin is a cyclic lipopeptide antibiotic discovered in the early 1980s. Daptomycin exerts rapid bactericidal activity in a concentration-dependent manner by insertion of daptomycin's lipophilic decanoyl side chain into the bacterial cell membrane, forming an efflux channel that extrudes

potassium ions down their concentration gradient. While the initial binding occurs independently, deeper membrane insertion and channel formation require the presence of calcium ions [218]. The depolarization that follows daptomycin binding destroys bacterial cells without inducing lysis and subsequent release of intracellular contents [219]. Due to its unique mode of killing, daptomycin continues to display bacterial killing in the presence of nondividing organisms [220]. Daptomycin binds to lung surfactant which inactivates the drug and renders it ineffective in treating lung infections: however effectiveness may still be sufficient in hematogenous lung infections such as septic emboli; however, no rigorous clinical data supports such use [221].

Spectrum of Activity

Daptomycin has activity against *Streptococcus* spp., *Enterococcus* including VRE, *Staphylococcus* spp. including VISA and VRSA, and specific Gram-positive anaerobes such as *Peptococcus* spp., *Peptostreptococcus* spp., and *C. perfringens* [222]. Daptomycin also has activity against *Bacillus* spp., *Corynebacterium* spp., and *Propionibacterium* spp.

Resistance and Reduced Susceptibility

Daptomycin is often used when vancomycin resistance and therapeutic failure are present and the potential for resistance is a concern. The overall incidence of daptomycin remains low, although a number of resistance mechanisms have been delineated. Investigators noted the relationship between increased daptomycin MICs during the course of treatment for *S. aureus* systemic infection. This was probably in part due to daptomycin membrane binding site interference resulting from thickened peptidoglycan wall among some VISA isolates [223, 224]. This has not been noted with the rare VRSA isolates due to a different resistance mechanism. Multiple additional distinct membrane alterations have been described as resistance mechanisms among *S. aureus* isolates [225] including decreased membrane fluidity, increased positive membrane surface charge, reduced sensitivity to permeability changes, decreased autolysis, reduced affinity to daptomycin, decreased membrane surface acidity, and finally diminished susceptibility to human neutrophil peptide-1 and thrombin-induced platelet microbicidal protein [226, 227]. It is likely that more than one of these mechanisms may be present in concert among resistant isolates as each individual mode of resistance generally causes a minor increase in daptomycin MIC. The *mprF* gene plays a major role in *S. aureus.* The product of *mprF* is an enzyme that couples phosphatidylglycerol to a lysine residue and subsequently mobilizes the lysyl-phosphatidylglycerol (LPG) to the outer cell membrane. Decreased acidity and increased positive charge due to the presence of LPG compromise calcium-mediated daptomycin binding to the deeper bacterial cell membrane. A distinct mechanism is responsible for daptomycin resistance in enterococci, and clinical resistance is increasingly observed in these organisms [228–230]. Gene mutations involving *liaF* and *gdpD* were identified in daptomycin-resistant *Enterococcus* strains, which appear to regulate cell membrane stability and phospholipid production. Recent data suggest that enterococci with an MIC of 3–4 mcg/mL harbor mutations in the *liaF* gene [231, 232]. Certain β-lactam antibiotics may potentiate daptomycin activity against *S. aureus* and enterococci [233, 234].

Adverse Reactions

Skeletal muscle toxicity is a relatively common adverse event seen in patients given prolonged courses of daptomycin. Initial trials utilizing 4 mg per kg twice daily dosing noted an unacceptable rate of creatinine kinase (CK) elevations [235]. Daptomycin was approved by the FDA after once-daily dosing was shown to cause significantly less muscle toxicity than seen with more frequent drug administration. The mechanism responsible for daptomycin-related CK elevations involves degeneration and regenerations of myofibers [236]. Clinical trials have shown that CK elevations occur in up to 6.7% of patients on once-daily dosing. The CK elevation is reversible and often returns to baseline in several weeks. Despite the relative safety of daptomycin, cases of rhabdomyolysis with subsequent renal failure have been reported [237–239]. Renal impairment without proper dose adjustment and concomitant administration of HMG-CoA reductase inhibitors have been considered as a potential risk for this toxicity. Additional adverse effects reported with daptomycin use are gastrointestinal disturbances and injection site reaction.

Daptomycin in Transplant Patients

Daptomycin is used in the transplant population to treat vancomycin-resistant enterococcal infections and as initial or salvage therapy for serious MRSA infections [240, 241]. In 72 patients with VRE bacteremia, including HSCT recipients and patients with acute myeloid leukemia, 43 received daptomycin and 29 received linezolid. The 30-day success rate was 76.7% with daptomycin and 75.9% with linezolid. Three patients in daptomycin treatment group developed CK elevations, which was mild in two but 28 times the upper limit of normal in one patient who complained of muscle weakness. This patient was switched to linezolid with resolution of symptoms and return of CK to baseline [240]. A

retrospective review of stem cell transplant recipients from 2007 to 2010 revealed eight daptomycin non-susceptible *E. faecium*. Close to 90% had received daptomycin previously for a mean duration of 19 days. Interestingly, two of eight daptomycin non-susceptible enterococci were susceptible to vancomycin, and all eight retained susceptibility to linezolid [242]. Clinicians should be aware of potential emergence of daptomycin non-susceptibility enterococci and monitor daptomycin MICs during the course treatment, especially for patients with severe immune suppression with persistent and recurrent bcteremia. Synergistic combination of daptomycin with β-lactams such as ampicillin and ceftaroline has resulted in markedly reduced daptomycin MICs among *S. aureus* and enterococcal clinical isolates [243, 244].

Tetracyclines: Focus on Tigecycline

Tetracyclines bind reversibly to the 30S ribosomal subunit, inhibiting protein synthesis by preventing incorporation of amino acid residues into elongating peptide chains. The reversible binding renders this class bacteriostatic. Among GNB, tetracyclines diffuse through the outer membrane porin channels to gain access in the periplasmic space; however, it requires an energy-dependent mechanism to cross through cytoplasmic inner membrane to reach bacterial cytosol. Resistance is mediated by active efflux transport protein pumps, inhibition of binding to the ribosomal site by cytoplasmic protective proteins, and enzymatic inactivation. The most significant mechanism of resistance is active efflux [245].

Tigecycline is the first of the glycyclcyclines to be approved by the FDA for treatment of complicated skin and soft tissue infections, complicated intra-abdominal infections, and community-acquired pneumonia. Tigecycline is a structural analogue of minocycline that binds with fivefold higher affinity to the ribosome than tetracyclines [246]. The structural modifications and enhanced binding overcome the ribosomal and efflux pump mechanisms of resistance to the tetracycline class and extend the antimicrobial spectrum. Tigecycline is a poor substrate for the tetracycline efflux pumps and can still attach to ribosomes with the Tet(M) protein modification [247]. Resistance can develop in GNB due to the overexpression of multidrug efflux pumps. *P. aeruginosa* naturally expresses these multidrug efflux pumps, which explain the intrinsic resistance to tigecycline.

Spectrum of Activity

The spectrum of activity includes multidrug-resistant organisms such as MRSA, CoNS, *E. faecalis*, VREF, ESBL- and carbapenemase-producing GNB including *Acinetobacter* spp., *Enterobacteriaceae*, penicillin-resistant *S. pneumoniae*, β-lactamase-producing *H. influenzae*, and anaerobes, including *C. difficile*. *Pseudomonas* and *Proteus*, *Providencia*, and *Morganella* species are intrinsically resistant to tigecycline [247, 248]. Cases of tigecycline resistance developing after treatment were reported by Spanu et al., in ESBL-*Klebsiella* and a carbapenemase *E. coli* [249]. Emergence of tigecycline resistance during therapy has been described in *A. baumannii* [250]. A recent in vitro surveillance report of GPB in the United States showed that tigecycline maintained high rates of susceptibility to MRSA and enterococci, with susceptibility to *S. pneumoniae* varying by geographical region from 80.9% to 95.2% [251].

Use of Tigecycline in Transplant Recipients

The pharmacokinetics of tigecycline show a large volume of distribution of 7–10 L/kg and a half-life of 42 h after multiple doses [246], which was long enough to allow once-daily dosing. With standard intravenous dosing of an initial loading dose of 100 mg followed by 50 mg twice daily, the C_{max} was 1.45 mg/L after a 30-min infusion and 0.63 mg/L after a 60-minute infusion. The serum levels are low with an area under the curve at 12 h following a 50 mg dose of 3.07 ± 0.6 μg × h/mL. Concentrations in alveolar macrophages were 78 times higher than serum, and concentrations in neutrophils are 20–30 times higher than serum; penetration into skin blister fluid was 74% of serum concentration. Tigecycline has time-dependent killing mechanism and exhibits a postantibiotic effect for *K. pneumonia*, *E. cloacae*, and *E. coli* [247]. Tigecycline has been shown to be bactericidal against MRSA and MSSA in animal models and primarily bacteriostatic against experimental *E. faecalis* infections. The primary route of elimination is via biliary tract; 33% of the drug is excreted unchanged or as metabolites. Therefore, no drug modification is required in patients with renal insufficiency. Tigecycline is only available in an intravenous formulation.

The major adverse reactions include nausea, vomiting, elevated liver enzymes, and few case reports of pancreatitis [252]. It is labeled as a class D drug during pregnancy. The low serum concentrations of tigecycline have called into question the efficacy of drug for the treatment of bacteremia. Case series of bloodstream infections have been reported with varying results. In a study by Gardiner et al., patients with secondary bacteremia from biliary and urinary sources, tigecycline demonstrated cure rates comparable to conventional antibiotic therapy of 81% vs. 78%, respectively [253]. In September of 2010, the FDA released a warning for increased mortality in patients treated with tigecycline compared with other conventional antibiotics. Prasad and

colleagues performed a meta-analysis of 13 trials of tigecycline including approved and off-label indications [254]. Tigecycline use was associated with 30% relative risk mortality and a 12% relative increase in non-cure rates. This result was independent of infection type and use in FDA approved and non-approved indications. The conclusion of these authors is that tigecycline should be used only when there are few or no alternatives. More prospective studies are needed to determine the cause for the higher mortality with tigecycline.

Tigecycline has been used in the transplant population to treat MDR GNB infections. Bergamasco and colleagues describe an outbreak of KPC-producing *Klebsiella* infections in solid organ transplant unit, including four patients with bacteremia [255]. Three patients were treated with tigecycline plus polymyxin and one with tigecycline plus imipenem-cilastatin. All four patients survived as did the single patient treated with polymyxin plus imipenem-cilastatin and two with polymyxin alone. Another study [256] used combination therapy with tigecycline, amikacin, and colistin. Emergence of tigecycline resistance during therapy for MDR *K. pneumoniae* and *E. coli* has been reported [249]. A case of recurrent renal graft infection and bacteremia due to ESBL *K. pneumoniae* was recently reported. The patient had a mixed population of carbapenem- and tigecycline-resistant isolates that emerged during antibiotic therapy. Tigecycline MIC increased from 0.5 to 8 μg/mL during therapy. The patient eventually required removal of the transplanted kidney due to severe graft rejection [257].

Macrolides and Streptogramins

Erythromycin is the prototype of the macrolide class, which includes clarithromycin and azithromycin, an azalide. Erythromycin is a 14-membered macrocyclic lactone ring attached to two sugar moieties. Macrolides and azalides insert into a pocket of the 23S subunit of the 50S ribosome, by attaching at domain V of the peptidyl transferase loop and blocking protein assembly by inhibiting the translocation step. Gram-positive bacteria accumulate about 100 times more erythromycin than GNB; *Pseudomonas* and *Acinetobacter* spp. are intrinsically resistant to this class of drugs. These drugs are generally regarded as bacteriostatic; high concentrations against susceptible organisms such as *S. pneumoniae* may be bactericidal [258].

Erythromycin use has been limited due to gastrointestinal intolerance, cholestatic hepatitis with the estolate form, and increasing drug resistance. It is still frequently used in colonic surgery bowel preps and topical dermatologic preparations. The newer macrolides, clarithromycin, and azithromycin were specifically developed to improve bioavailability, pharmacodynamics, pharmacokinetics, and antimicrobial spectrum of activity.

Azithromycin is an azalide because it has a methyl-substituted nitrogen in the 15-member lactone ring. Azithromycin has a half-life in many tissues that extends to 2–4 days and an average terminal half-life of 68 h. Clarithromycin has the 14-member lactone with modification of the C6 site with a methoxy ring. The major metabolite, 14-hydroxy-clarithromycin, has antibacterial activity. The mechanism of action and resistance of the newer macrolides are similar to erythromycin, and cross-resistance exists among the drugs within the class. Azithromycin has better penetration through the outer membrane envelope of GNB, especially *M. catarrhalis* and *H. influenzae*. Although the entire class is considered bacteriostatic, these agents are bactericidal against *S. pneumoniae*, *H. influenzae*, and S. *pyogenes* [259]. The newer macrolides also have the anti-inflammatory properties as described with erythromycin. These include suppression of proinflammatory cytokine release from endothelial cells, acceleration of neutrophil apoptosis, and inhibition of nuclear factor kappa B and activation protein-1, which regulate the chemoattractant chemokine, interleukin-8 [260, 261].

Resistance

Resistance to macrolides occurs through four mechanisms. Drug efflux by active drug efflux pumps is encoded by *mrs*A, *mef*A, or *mefE* in staphylococci, *S. pyogenes*, and *S. pneumoniae*. *MefA* encodes an efflux pump that extrudes macrolides at a lower level (<16 mcg/mL); high antibiotic concentrations might overcome the pump, forcing enough antibiotic into the bacterial cytosol to exert a measurable antibacterial effect. Clarithromycin and azithromycin are more active against pneumococci than erythromycin; however the level of resistance in *Mef*A-containing strains is on the rise [262]. Inducible or constitutive production of methylase enzymes is mediated through expression of *ermA*, *ermB*, and *ermC* that decrease binding of drug to the ribosomal target. *ErmB* encodes methylation of a base in domain V of the 23S rRNA altering the site of attachment and resulting in high-level resistance with MIC >64 mcg/mL [259]. Since the macrolides, lincosamides, and streptogramins share the same binding site, the MLS_B phenotype conferred by *erm* genes causes cross-resistance in all three classes. *Enterobacteriaceae* may produce esterases that hydrolyze the macrolide. The fourth mechanism of resistance is through chromosomal mutations that alter the 50S ribosomal protein, leading to resistance to macrolides and azalides. This mechanism can be found in *B. subtilis*, *Campylobacter* spp., mycobacteria, and Gram-positive cocci.

Spectrum of Activity

The spectrum of the newer macrolides includes GPB such as *S. pneumoniae*, *S. pyogenes*, *S. agalactiae*, *S. viridans*, *B. pertussis*, *Listeria monocytogenes*, *Corynebacterium diphtheria*, and some strains of MSSA although resistance among clinical MSSA and *S. pneumoniae* isolates is emerging. The Gram-negative activity includes *H. influenzae*, *M. catarrhalis*, *H. pylori*, *B. pertussis*, *Neisseria* spp., *P. multocida*, and some clinical strains of *Salmonella* and *Shigella*. Atypical activity includes *Legionella* spp., *Chlamydia trachomatis*, *Chlamydophila pneumoniae*, *Borrelia burgdorferi*, *H. pylori*, *Mycoplasma pneumoniae*, *Bartonella henselae*, *C. jejuni*, and *M. avium* complex. Anaerobic activity includes *C. perfringens* and *Propionibacterium* spp. Azithromycin and clarithromycin may differ in their activities against specific pathogens.

Adverse Reactions

Adverse reactions seen with the newer macrolides are predominantly gastrointestinal. Allergy has been reported with azithromycin. Higher doses can cause dizziness, tinnitus, and reversible hearing loss. Torsades de pointes have been reported in older patients, especially with concomitant use with cisapride. Clarithromycin can have cytochrome P450 interactions with drugs metabolized by CYP3A.

The emergence of erythromycin resistance in clinical *S. pneumoniae* and *S. pyogenes* isolates had an impact on susceptibility trends for the newer macrolides. Streptococci and staphylococci that are resistant to erythromycin are often resistant to clarithromycin and azithromycin. In Canada, over the past 20 years, pneumococcal surveillance studies have shown a steady rise in macrolide resistance correlated with declining prescriptions for erythromycin and higher clarithromycin and azithromycin use. In cities in the United States where pneumococcal vaccination of children has been widely used, a distinct reduction in the overall prevalence of macrolide resistance among invasive isolates was an encouraging trend. The explanation is that the serotypes most likely to express resistance are also the ones included in the pediatric vaccines and disease caused by these serotypes has declined dramatically as a result of strict adherence to childhood vaccination protocols.

Streptogramins

The streptogramins are a family of compounds divided into two groups based on structure. Dalfopristin (group A) and quinupristin (group B) are combined in a ratio of 30:70 and available for intravenous use. The combination of both drugs produces increased in vitro bactericidal activity. Quinupristin and dalfopristin bind to sequential sites on the 50S ribosomal subunit. Dalfopristin binding results in a conformational change in the ribosome that increases quinupristin binding. Inhibition of protein synthesis occurs through preventing peptide chain formation. Resistance occurs through several mechanisms including enzymatic inactivation by a hydrolase for quinupristin and acetyltransferase for dalfopristin, efflux or active transport, and alteration in ribosomal binding sites, which is the most common resistance mechanism. The combination of the two drugs requires multiple mutations targeting both components. Staphylococci can develop resistance to quinupristin by the *erm*A (MSL_B) mutation. A comparative study of linezolid and quinupristin-dalfopristin in VREF infection showed no difference in 30-day mortality; however, 11% of blood isolates developed resistance to quinupristin-dalfopristin compared with 0% in the linezolid arm [263].

Quinupristin-dalfopristin was approved by FDA in 1999 for the treatment of bloodstream infections due to vancomycin-resistant *Enterococcus faecium* (VREF) and skin and skin structure infections (SSSI) caused by MSSA and *S. pyogenes*. It was the first antibiotic to be indicated for the treatment of patients with serious or life-threatening infections associated with VREF bacteremia. Quinupristin-dalfopristin is bactericidal against most susceptible organisms and demonstrates a postantibiotic effect against *B. anthracis* for 7–8 h, longer than the other classes of antibiotics tested [264]. The recommended dose is 7.5 mg/kg every 8 h and produces plasma concentrations of 11–12 μg/ml. Both drugs undergo hepatic metabolism with most metabolites eliminated by fecal excretion (75%), and a smaller amount is via kidneys.

Quinupristin-dalfopristin is active against *E. faecium*, including VRE, but not *E. faecalis* due to intrinsic resistance. Other susceptible GPB include *S. aureus* including MRSA and CoNS and streptococci, except for *S. pneumoniae*. The susceptible MIC is <1 μg/ml. The combination has activity against most Van A and Van B strains of *E. faecium*. The anaerobic activity is mostly against *Lactobacillus* spp., *P. acnes*, *C. difficile*, and *C. perfringens*. It has some activity against upper respiratory pathogens except for *Haemophilus* species. It has no activity against *Enterobacteriaceae*, *Pseudomonas*, and *Acinetobacter* due to inability to enter the inside of the bacterial cell.

Adverse reactions include a high incidence of infusion irritation (30%), arthralgias, myalgias, gastrointestinal disturbances, and elevated liver enzymes and bilirubin. In vitro drug interaction studies have demonstrated that quinupristin-dalfopristin significantly inhibits cytochrome P450 3A4 metabolism of cyclosporin, tacrolimus, and other medication. Therapeutic level monitoring of cyclosporine should be performed when cyclosporine must be used concomitantly with

quinupristin-dalfopristin. A kidney transplant recipient on both drugs had a threefold increase in the cyclosporine blood concentration 3 days after starting quinupristin-dalfopristin, reinforcing the need for frequent monitoring of cyclosporine levels in such patients [265]. The hyperbilirubinemia during quinupristin-dalfopristin in liver transplant recipients was found on liver biopsy to be multifactorial, including graft rejection, cholestasis, and periportal inflammation without specific drug-related hepatocyte injury [266].

Use in Transplant Patients

Despite the potentially serious interactions with cyclosporine and tacrolimus, quinupristin-dalfopristin has been used in the transplant population, mostly to treat VRE infections. In a study of mostly liver transplant recipients with VRE infections, including 19 with bacteremia, the clinical response was 80% using standard drug dose. Two of four treatment failures were associated with a decrease in in vitro susceptibility, myalgias and arthralgia occurred in 33%, and the mortality from VRE infection was 17% [267]. In another study of 28 VRE infections in 19 patients, 8 patients received quinupristin-dalfopristin for 9 infection episodes; only 2 of the patients survived [268]. In this report, linezolid therapy showed a trend toward improved survival. Quinupristin-dalfopristin has been used in pediatric stem cell transplant recipients with resolution of bacteremia in all five patients [269]. One case of successful treatment of VRE meningitis with quinupristin-dalfopristin combined with daptomycin has been reported [270]. The safety of quinupristin-dalfopristin was evaluated in 19 pediatric liver transplant recipients with VRE infection; infection resolution occurred in 74% of these patients. Adverse reactions were reversible elevation of the alkaline phosphatase, rash, itching, nausea, and vomiting; none of these adverse reactions necessitated discontinuation of therapy [271].

Clindamycin

Clindamycin is a lincosamide antibiotic developed by modification of lincomycin. Clindamycin binds to the 50S ribosomal subunit, disrupting protein synthesis by interfering with the transpeptidation reaction. The lincosamides may also stimulate dissociation of peptidyl-tRNA from ribosomes, similar to the macrolides. The lincosamide-binding site is in close proximity to that of the macrolides, so binding of one antibiotic may reduce binding of the other. Clindamycin is considered bacteriostatic, although bactericidal activity for some strains of staphylococci, streptococci, and anaerobes may exist. It may also exhibit a postantibiotic effect against some bacterial strains [264]. An attractive feature of clindamycin is that it promotes opsonization and phagocytosis of bacteria at a subinhibitory concentrations. Clindamycin causes changes in the cell wall surface, which decreases the adherence of bacteria to host cells and augments intracellular bacterial killing. Another quality of clindamycin is the ability to inhibit production of intracellular toxins, particularly those of *S. aureus* and *S. pyogenes* [272, 273].

Resistance

Resistance occurs through four mechanisms and may be plasmid and chromosomally mediated. The most common mechanism is alteration in the 23 rRNA of the 50S subunit by methylation of adenine. Plasmid-mediated resistance via MLS_B is present in some strains of *S. aureus*, *S. pyogenes*, and *B. fragilis*. In *S. aureus*, the *ermA* or *ermC* gene encodes this type of resistance. Mutations in the bacterial rRNA may confer resistance to clindamycin as do alterations in specific 50S ribosomal proteins at the receptor site. The fourth type of resistance is inactivation through adenylation, which affects lincomycin more than clindamycin; however this can reduce bactericidal activity of clindamycin. GNB are intrinsically resistant to clindamycin due to poor permeability of the outer membrane envelope, similar to what was seen with macrolide antibiotics [259].

Spectrum of Activity

Clindamycin has similar activity to the macrolides against *S. pneumoniae*, *S. pyogenes*, *S. viridans*, and MSSA. It continues to be active against over 90% of the USA300 strain of MRSA [274]. Clindamycin is most active against anaerobes, especially *B. fragilis*, *Fusobacterium* spp., *Peptostreptococcus*, *Peptococcus*, and *C. perfringens*. *C. difficile* is resistant to clindamycin. Atypical bacteria such as *Actinomyces israelii* and *Nocardia asteroides* are sensitive. Clindamycin is also active against parasitic organisms including *Toxoplasma gondii*, *Babesia*, and some strains of *P. falciparum* and *vivax*. Increasing resistance to clindamycin has been reported to *S. pneumoniae*, *S. aureus*, and *S. pyogenes*. Erythromycin-resistant bacteria may develop rapid resistance when exposed to clindamycin. Increasing resistance among *Bacteroides* species has been observed from 3% in 1987 to 26% in a study between 1997 and 2004 [275].

Adverse Reactions

Toxicity is mainly gastrointestinal and hypersensitivity reactions. Antibiotic-associated diarrhea has been reported

in 2–20% of patients. *C. difficile* colitis has been reported to occur in up to 10% of clindamycin-treated patients. The current epidemic BI/NAP1/027 strain of *C. difficile* is more strongly associated with the use of broad-spectrum cephalosporins and fluoroquinolones [276, 277]. Allergic reactions may clinically present as fever, skin rash, and rarely as erythema multiforme. Other adverse reactions include elevation of hepatic transaminases and neutropenia, which is often reversible after discontinuation of therapy.

Use in Transplantation

Clindamycin is available in oral and intravenous formulations and has excellent oral bioavailability. The half-life is 2.4 h, and the drug is metabolized in the liver to active and inactive metabolites which are excreted in bile and urine. Dosage adjustments are not necessary in patients with kidney or liver disease. Clindamycin penetrates well into the bone and achieves high intracellular drug concentration. It achieves suboptimum drug concentration in CSF following parenteral, intravenous administration.

Clindamycin traditionally has been used predominantly to treat *B. fragilis* in polymicrobial intra-abdominal and pelvic infections, as second line to penicillins in anaerobic bronchopulmonary infections, and may be considered first line in serious skin and soft tissue necrotizing infections. The poor CSF penetration limits its use for treatment of meningitis and other intracranial infections. The emergence of the USA300 clone of MRSA has provided an additional role for clindamycin, especially in the outpatient setting. Studies have shown an incidence of MRSA cultured from 67% of skin and soft tissue infections, requiring empiric coverage for CA-MRSA in addition to beta-hemolytic streptococci [278]. A study of clindamycin resistance in CA-MRSA demonstrated that exposure to clindamycin or macrolides within the prior 3 months was an independent predictor for clindamycin-resistant MRSA. Other risk factors were infection or colonization with MRSA within the previous 12 months, surgery, and presence of intravenous catheter [279]. Cases have been reported of clindamycin-susceptible/erythromycin-resistant MRSA that did not respond to clindamycin. The double-disk diffusion test using clindamycin and erythromycin disks (D test) confirms the presence of in vitro inducible macrolide-lincosamide-streptogramin B resistance (iMLS) due to presence of *erm* genes. Additional testing in pediatric and adult isolates demonstrated that 56% had the iMLS phenotype, 50% among MRSA isolates and 63% in MSSA isolates. There was a higher rate in isolates from pediatric patients amounting to 77% in MSSA. It is therefore suggested that in patients with erythromycin-resistance/clindamycin-susceptible *S. aureus*, D test should be performed prior to commencing clindamycin therapy [280]. A multiresistance conjugative plasmid, pUSA03, has recently been isolated from men who have sex with men in San Francisco and Boston [281]. This isolate is resistant to β-lactams, clindamycin, fluoroquinolones, tetracycline, macrolides, and mupirocin. Both *ermC* and *mupA* genes are carried on this plasmid. Of note, 23% of the USA300 isolates without this plasmid were resistant to clindamycin in this population.

Hospital-acquired MRSA is a major cause of morbidity during the early period after transplantation [282, 283]. These infections are treated with parenteral agents such as vancomycin and daptomycin since these isolates, usually belonging to USA 100PFGE profile, are associated with a lower clindamycin susceptibility of nearly 54% [284]. Colonization of MRSA postoperatively has been shown to increase the risk for MRSA infection [285]. Limited data exists on the USA300 clone except for failed renal transplant patients followed in hemodialysis center who had higher risk for USA300 MRSA colonization. Clindamycin should be used with caution in this population; it may still be a valuable agent for anaerobic and parasitic infections.

The Quinolones

Derived from nalidixic acid and originally developed in the 1960s as a by-product of chloroquine synthesis, the fluoroquinolones share a common two-ring core structure, with a side-chain-bearing nitrogen located at position 1, carbon at position 8, and fluorine substituent at position 6. Addition of a halide group at position 8 enhanced activity against anaerobes and improved oral bioavailability. A methoxy group at position 8 enhances anaerobic activity; addition of a piperazinyl or methylated piperazinyl ring at position 7 enhances activity against GPB. A cyclopropyl group at position 1 greatly enhances activity against GNB [286].

Fluoroquinolones exert their antimicrobial activity through two distinct, yet related and overlapping drug targets: DNA gyrase and topoisomerase IV (Top IV). Both enzymes facilitate the highly regulated coiling necessary to fit the entirety of a bacterial chromosome into a relatively small area, and both serve unique functions [287]. DNA gyrase is a tetramer of two subunits A_2B_2, encoded by *gyrA* and *gyrB*, respectively [288]. The two subunits wrap around a DNA strand and introduce a negative supercoil into bacterial DNA, first through the formation of a positive supercoil and then passing one DNA region through another. Through an ATP-dependent process, DNA gyrase accomplishes this via a series of DNA strand breakages and rejoining [289]. Together, these functions serve a vital purpose in the facilitation of migration of fork through the DNA strand. Top IV, homologous to DNA gyrase, is encoded by the *parC* and *parE* genes and is primarily involved in the process of separating daughter chromosomes, known as decantation. In

some cases, DNA gyrase is able to fulfill the functionality of topoisomerase IV at a reduced efficiency; however, Top IV is unable to introduce negative supercoils into bacterial DNA [290, 291]. Top IV functions by direct binding to sections of DNA crossover, rather than through wrapping around the target portion of the DNA strand. Through binding to topoisomerase IV and DNA gyrase with Top IV as the primary target in GPB and DNA gyrase in GNB, the quinolones inhibit bacterial DNA synthesis and lead to rapid bacterial cell death [292, 293]. The mechanism of this rapid bactericidal action has not yet been fully characterized. Prior to the introduction of a DNA break, the quinolones bind to the DNA-enzyme complex after which DNA cleavage occurs, with the quinolone-enzyme complex "locking" the cleaved complex in place [294, 295]. The formation of this cleaved complex causes rapid inhibition of DNA synthesis, which occurs more quickly when DNA gyrase is the target [296, 297]. The inhibition of DNA replication leads to several downstream effects ultimately responsible for rapid bacterial killing or slow cell death. The formation of multiple cleaved complexes throughout the bacterial chromosome leads to fragmentation and rapid cell death through induction of apoptosis [298]. This mechanism is unlikely the only explanation for rapid bacterial killing, as rapid cell death still occurs in the absence of the protein synthesis required for the induction of apoptosis [299]. Further investigation into the mechanism of rapid bacterial killing by quinolones is ongoing.

In a dose-dependent manner, exposure to quinolones induces bacterial expression of the SOS regulon, a global stress-response mediator carrying over 40 genes and controlled by the *lexA* gene [300]. This stress response is a characteristic shared by all bactericidal antibiotics [301]. Included in the SOS regulon is the gene *sfiA*, which codes an inhibitor of cell division in *E. coli* and leads to a change in bacterial morphology to an elongated, filamentous structure [302]. Low-level quinolone exposure and subsequent induction of the SOS response contribute to the dissemination of antibiotic resistance elements and bacterial virulence factors [303, 304].

Spectrum of Activity

The fluoroquinolones are active against a broad variety of enteric GN bacilli and cocci. Ciprofloxacin and levofloxacin retain sufficient in vitro potency for use against *Pseudomonas* species, with ciprofloxacin generally being more potent than levofloxacin against GNB. The activity of ciprofloxacin is limited against GPB, whereas moxifloxacin, levofloxacin, and gemifloxacin are highly active against most clinical strain of *Streptococcus* species. Moxifloxacin may retain activity against *S. aureus* isolates with low-level resistance to ciprofloxacin, while the use of levofloxacin is associated with the rapid selection of mutant colonies [305].

The next-generation fluoroquinolone, delafloxacin, demonstrated potent in vitro activity against *S. aureus* including MRSA and MSSA strains that exhibit high-level resistance to the currently marketed fluoroquinolones [306]. This agent demonstrates a low propensity for the development of resistant mutants as compared to other fluoroquinolones. All currently marketed fluoroquinolones have in vitro activity against the atypical respiratory pathogens such as *L. pneumophilia*, *C. pneumoniae*, and *Mycoplasma pneumoniae*. Other intracellular pathogens, including *C. trachomatis* and *U. urealyticum*, are also inhibited. *Ehrlichia* species show variable sensitivity due to the presence of natural mutations in the QRDR [307], with similar variability displayed by *Bartonella*, *Rickettsia*, and *Coxiella* species [308]. The fluoroquinolones are also active against a variety of *Mycobacteria*, including *M. tuberculosis*, *M. kansasii*, *M. xenopi*, *M. marinum*, and *M. leprae*, with members of the *M. avium* complex and *M. chelonae* displaying little to no susceptibility to these agents [309].

Resistance

Multiple mechanisms for quinolone resistance exist. Reduced susceptibility may arise through spontaneous chromosomal mutations particularly in regions that code for DNA gyrase and Top IV or through recently discovered plasmid-mediated resistance mechanisms [310, 311]. Plasmid-transferrable resistance mechanisms generally do not lead to MICs above the CLSI breakpoint for resistance but facilitate the acquisition of additional resistance factors that may further elevate MICs [312]. Point mutations in the vital *gyrA* may lead to high levels of quinolone resistance [293]. Due to the structural homology between DNA gyrase and Top IV, mutations conferring reduced susceptibility to quinolones occur at homologous points in the respective enzymes, known as the "quinolone-resistance determining region" (QRDR) [313–315]. Numerous point mutations throughout the QRDR contribute to reduced susceptibility; however proximity to the enzyme-DNA binding site is a common feature to many of the known mutations [316]. The primary target of a quinolone in a bacterial species is determined by genetic testing, in which the primary target is presumed to be that with the highest degree of inhibition [317]. Due to this structural preference, the relative overall decrease in quinolone susceptibility as mutations accumulate may be a result of declining inhibitory potential against the preferred target or a reflection of the inhibitory capacity of the quinolone against the wild-type secondary target [296].

Single-step mutations that reduce quinolone-binding affinity arise in an exposure-related manner, at a rate of 10^{-6}

to 10^{-11} as quinolone concentrations increase relative to the MIC of the organism. These mutations confer different degrees of reduced susceptibility dependent upon the quinolone agent studied, with point mutations in *S. aureus* conferring a 32-fold rise in MICs to ciprofloxacin and MICs to gemifloxacin demonstrating only a fourfold rise [318]. These mutations facilitate the development of additional mutations in both *gyrA* and *parC*, leading to high-level quinolone resistance [310]. Spontaneous double mutations, affecting both DNA gyrase and Top IV, are uncommon, occurring at a frequency of 10^{-14} to 10^{-16}. Interestingly, the accumulation of multiple mutations throughout these crucial enzymes does not appear to impact the fitness of the bacteria due to accumulation of a variety of compensatory mechanisms [319].

Active drug efflux by MDR efflux pumps also plays an important role in resistance. Drug efflux pumps are broadly categorized into five families of ancient evolutionary origin in bacteria that have evolved to facilitate intracellular communication and extrude environmental toxins in addition to contributing to resistance [320, 321]. The presence of one or more drug efflux pumps may promote resistance to multiple classes of antimicrobials. Efflux-mediated resistance to quinolones is most commonly mediated by chromosomally encoded RND pumps [322]. In *P. aeruginosa*, an example of this type is the MexAB-OprM pump, a tripartite pump composed of an outer membrane spanning domain, inner membrane efflux pump, and a membrane fusion protein [323]. *Enterobacteriaceae* can use the AcrAB-TolC efflux pump [324]. When co-expressed with other efflux pumps or *gyrA* mutations, GNB exhibits higher levels of drug resistance. The concomitant downregulation of outer membrane porins and overexpression of efflux pumps may also contribute to quinolone resistance among the GNB [325]. In *S. aureus*, low-level quinolone resistance is constitutively expressed by the norA pump [314], and, in *S. pneumoniae* by an efflux pump homologous to norA, pmrA conforms drug resistance [326].

Enzymatic modification of quinolones was first described in 2003, a variant of the aminoglycoside AAC which acetylates the piperazinyl group on ciprofloxacin and decreases binding affinity to its intracellular target [327]. This mutation does not produce MIC values above the CLSI breakpoint, but its presence increases the frequency of selection for chromosomal mutants [328]. Plasmid-mediated fluoroquinolone resistance was first described in a clinical isolate in 1998, encoded by the *qnr* genes, that generates a Qnr protein belonging to the pentapeptide repeat family [329, 330]. In addition to the unique Qnr proteins, both the AAC and two novel efflux pumps have been described on transmissible plasmids [331]. The prevalence of the pentapeptide Qnr proteins appears to be relatively low, among clinical isolates of *Enterobacteriaceae*, ranging from approximately 1.5% to 4.6%. Plasmid-mediated pumps are even less common. The AAC is more prevalent in clinical isolates, in nearly 10% of such isolates, and importantly, often coexists with genes encoding ESBLs [329].

Central to this progressive rise in quinolone resistance is the tendency of bacteria to evolve in a stepwise fashion. Mutations arise or plasmids are acquired in discrete steps, with one final step often a mutation in DNA gyrase or Top IV creating frank resistance [332]. Since these spontaneous mutations occur infrequently, a concept in quinolone dosing, referred to as the "mutant prevention concentration" (MPC), was proposed by Xiao and Drlica in 2001, which advocates for the use of doses that achieve drug concentrations above the level at which no resistant mutants will be selected, an inoculum of 10^{10} organisms rather than traditional dosing which focuses on MICs [333]. While this concept has not been tested clinically, it provides insight as to how low doses of quinolones contribute to high-level resistance, as well as potential pathways for development of future quinolone agents.

Adverse Reactions

The fluoroquinolones have a rate of adverse reactions similar to those of comparator agents in clinical trials. Gastrointestinal disturbances are the prominent adverse effects. Central nervous system toxicities are the second most common adverse effects, occurring in 1–2% of patients. CNS toxicities are thought to result from competitive inhibition of γ-aminobutyric acid ($GABA_A$) receptor and commonly manifested as headache and nausea, although grand mal seizures may occur [334]. Fluoroquinolones with a piperazinyl side chain at the 7-position have the highest potential for epileptogenesis. Levofloxacin, moxifloxacin, and gemifloxacin lack the structure-toxicity relationship associated with the development of seizures; however, caution should still be exercised in patients with history of seizure disorders. Through an unknown mechanism, the fluoroquinolones may cause exacerbation of myasthenia gravis and now carry an FDA "black box" warning for this occurrence [335].

The fluoroquinolones have been associated with prolongation of the QTc interval and risk for Torsades de pointes, although the causal link remains unclear [336]. Numerous case reports described the potential for fluoroquinolone-induced cardiac arrhythmias, and in vitro data showed that the fluoroquinolones have the potential to block delayed rectifier K+ current (I_{Kr}) through blockade of the human ether-a-go-go (hERG) K+ channel [337], although only moxifloxacin achieves this blockade at physiologic concentrations after standard treatment dose. A recent population-based, case-control study demonstrated a 3.3-fold greater risk for moxifloxacin, twofold higher risk with ciprofloxacin, and no such increased risk for levofloxacin [338]. Gatifloxacin,

a quinolone that was shown to be associated with serious dysglycemic events, showed a fourfold greater risk for the development of arrhythmias. Based on these data, fluoroquinolones should be used with caution in patients at risk for the development of cardiac arrhythmias.

Quinolone-induced phototoxicity manifests shortly following exposure to UVA light in a dose-dependent manner and is believed to result from free radical generation, cellular toxicity, and local inflammation [339]. Moxifloxacin contains a protective 8-methoxy group and has not been associated with the development of phototoxicity, whereas levofloxacin and ciprofloxacin lack this group and are associated with phototoxicity. Patients should be warned to limit exposure to sources of UV light when using fluoroquinolones agents with known phototoxic potential.

Like all antimicrobial agents, the fluoroquinolones are associated with the development of *C. difficile* infection (CDI). The fluoroquinolones were historically thought to be agents that would result in less perturbation of the hosts' resident microbiota, therefore having a low risk for promoting CDI. Recent epidemiologic studies have shown that fluoroquinolone is a substantial risk factor for the development of CDI [340, 341]. This has been associated with the spread of the epidemic BI/NAP1/ribotype 027 strain, which is frequently resistant to the fluoroquinolones [342, 343].

Role of Fluoroquinolones in Transplantation

Fluoroquinolones are used in a variety of setting including treatment and prevention of bacterial infections. In 1 study, *S. viridans* bacteremia developed in 6 of 37 patients receiving levofloxacin neutropenic prophylaxis following autologous HSCT. The mean duration of neutropenia was 4.5 days; and three patients developed septic shock. All *S. viridans* isolates exhibited reduced levofloxacin susceptibility due to GYRA mutations and ParC mutation in one patient [344]. In 48 patients given gatifloxacin or moxifloxacin prophylaxis while undergoing HSCT, organisms showing fluoroquinolone class resistance were recovered from the oropharynx in greater frequency revealing gyrA and/or parC mutations among the resistant isolates [345].

Therriault and colleagues undertook a retrospective analysis of HSCT recipients given levofloxacin with penicillin or doxycycline combination prophylaxis through stem cell engraftment. Over time, GPB infections declined; however, it was noted that fluoroquinolone-resistant GNB emerged. Of note, resistance due to ESBL did not change. In this study, an increased colonization with VRE was an alarming finding [346]. Another study looked at bloodstream infections after allogeneic HSCT and found that among GNB only half were susceptible to fluoroquinolone [347]. Vehreschild and colleagues used moxifloxacin versus placebo in patients on high-dose chemotherapy followed by autologous HSCT for chemoprevention of bacteremia. Breakthrough bloodstream infections occurred in three prophylaxis group (8.8%) whereas 28% among patients given no antibiotic prophylaxis. In this study, moxifloxacin was effective in preventing bacteremia and shortened length of febrile episodes. Two of the isolates, *E. coli* and MSSA, were susceptible to moxifloxacin. The third episode occurred due to *P. aeruginosa* which was susceptible to ciprofloxacin and levofloxacin and as expected, resistant to moxifloxacin that is known to have limited activity against this pathogen [348].

An unusual use of fluoroquinolones is to reduce the incidence of BK virus-associated hemorrhagic cystitis in allogeneic HSCT recipients. Fluoroquinolones have been shown to inhibit polyoma virus BK replication through inhibition of viral-encoded DNA gyrase. A retrospective analysis of 48 patients received ciprofloxacin from day 0 through 60 following transplantation, versus a control group of similar patients given fluoroquinolone prophylaxis. The cumulative rate of hemorrhagic cystitis was significantly reduced from 20.9% to 2.6% in the patients given ciprofloxacin. Patients on ciprofloxacin did not experience an increased rate of CDI and were also less likely to develop bacteremia [349].

Yoon and colleagues investigated rifampin versus an oral fluoroquinolone in 109 renal transplant patients with latent tuberculosis. The incidence of adverse reactions was higher in the rifampin group, and the quinolone group showed a significantly higher 10-year graft survival compared with the rifampin group. In addition to being safe in this population, fluoroquinolones may lower the risk for graft failure [350].

Unusual toxicities are also seen in this population. A high incidence (5.8%) of Achilles tendinitis or rupture was seen in heart transplant patients. Independent risk factors were renal failure and increased time between transplantation and treatment with a fluoroquinolone advising providers to consider alternative therapy for such patients [351]. A case was reported in a HSCT recipient who developed a lymphomatoid hypersensitivity reaction to levofloxacin, an illness difficult to differentiate from recurrent or de novo lymphoid malignancy [352].

Metronidazole

Metronidazole is a synthetic drug discovered in the 1950s. Originally recognized for its activity against *Trichomonas vaginalis*, *Giardia*, and *Entamoeba*, a decade later, it was recognized as highly effective against anaerobes. Metronidazole remains a useful drug for the treatment of anaerobic, polymicrobial infections, *H. pylori*, and protozoa and as first-line treatment for patients with mild to moderate *C. difficile* infection (CDI).

Metronidazole enters the cell through passive diffusion as a prodrug, activated in the cytoplasm of susceptible bacteria and in specific organelles in protozoa. It is cytotoxic through production of free radicals. The molecule is converted by intracellular reduction to a short-lived nitroso free radical by intracellular reduction, which involves the transfer of an electron to the nitro group of the drug [353], a reaction that is catalyzed by a nitroreductase such as pyruvate. Reduction of the prodrug creates a concentration gradient, increasing uptake of metronidazole and leading to free radical formation [354]. The free radicals are highly unstable and interact with nucleic acids prior to decaying, resulting in breakage and destabilization of nucleic acids and proteins eventually leading to bacterial cell death [355]. The mechanism of action differs in facultative anaerobes such as *G. vaginalis* and *H. pylori*, where metronidazole reduction to active metabolite can occur by a one electron-transfer step; metabolites are re-oxidized with formation of toxic oxygen radicals that are then neutralized by an active scavenger system [356]. More recently, activation by a two electron transfer step in *H. pylori* was documented, allowing for activation in a microaerophilic environment. In parasites, the enzyme pyruvate/ferredoxin oxidoreductase activates metronidazole with energy provided by glycolysis of glucose in an organelle called the hydrogenosome [357].

Spectrum of Activity

Metronidazole is active against a broad array of anaerobes, protozoa, and microaerophilic bacteria. Metronidazole exerts rapid bactericidal effects against anaerobic bacteria and is rapidly bactericidal [358]. Metronidazole exhibits concentration-dependent kinetics in susceptible anaerobes, *Entamoeba histolytica* and *T. vaginalis* [358–360]. Metronidazole is potent against *B. fragilis*, *Fusobacterium* spp., *Prevotella*, and *Porphyromonas* spp. [361]. *Clostridium* species are susceptible, although *C. difficile* and *C. perfringens* are susceptible at slightly higher concentrations than Gram-negative anaerobes. The activity against Gram-positive cocci is variable, and most strains of *Actinomyces*, *Lactobacillus*, and *Propionibacterium* are resistant [362]. *Treponema pallidum*, oral spirochetes, *Campylobacter fetus*, *Gardnerella vaginalis*, and *H. pylori* are sensitive, although *H. pylori* resistance is increasing [363]. Anaerobic cocci such as *Peptostreptococcus* and *Veillonella* spp. are also inhibited. *Capnocytophaga* spp. are usually sensitive. Metronidazole also demonstrates concentration-dependent killing against *Entamoeba histolytica* and *Trichomonas vaginalis* [360] and is active against other protozoa including *Giardia lamblia*, *Blastocystis hominis*, and *Balantidium coli.*

Resistance

Several mechanisms of resistance to metronidazole have been observed that differ among organisms. The primary mechanisms of resistance are decreased uptake of the prodrug and/or altered efficiency of intracellular reduction. These mechanisms may act together with reduced activity of nitroreductase resulting in decreased uptake of metronidazole [364]. The level of susceptibility and rate of drug uptake vary with the level of pyruvate/ferredoxin oxidoreductase activity. Resistant bacteria compensate for reduced action of pyruvate/ferredoxin oxidoreductase by increasing pyruvate dehydrogenase activity [364]. It has been suggested that more than one mechanism may be required to confer clinical drug resistance [365]. Other resistance mechanisms include active efflux, drug inactivation, and heightened bacterial DNA damage repair [364]. Resistance genes, called *nim*, encode an alternative reductase that converts nitroimidazole to a nontoxic compound [366]. Transfer of these genes on plasmids can confer metronidazole resistance in *B. fragilis* [367].

In one large study over a 4-year period, overall resistance rates varied between 1.8% and 2.5% [368]. Studies have shown that more than 95% of anaerobic isolates in the United States remain susceptible to metronidazole [369]. Among *Bacteroides* spp., a large multicenter study over a 7-year period revealed no resistance to metronidazole among greater than 4000 clinical isolates tested [370]. In Canada, rates of resistance to metronidazole remained unchanged in *Bacteroides* spp. over a 6-year period, while resistance to clindamycin had increased [371]. In *Bacteroides* species, resistance is conferred by both plasmid- and chromosomally mediated mechanisms, although plasmid-mediated transfer of resistance to susceptible strains is rare. Multiple steps appeared to be necessary for development of resistance, which may explain why resistance is rare and infrequent in the absence of long-term therapy [365].

Although metronidazole resistance among anaerobic bacteria is rare, it has been reported more frequently with *H. pylori*. A large multinational, multicenter randomized clinical trial tested 516 clinical isolates and found resistance to metronidazole (>8 μ/ml) in 27% of strains by agar dilution method [372]. The mechanism of resistance to metronidazole is not well understood; resistant *H. pylori* strains may accumulate lesser amounts of metronidazole and at a slower rate [373]. The acquisition of resistance is associated with a mutation, resulting in inactivation of the *rdzA* gene that encodes an oxygen-insensitive NADPH nitroreductase [374].

Metronidazole-resistant *T. vaginalis* strains have been isolated from patients with refractory infections. Resistance is associated with reduced transcription activity of the ferredoxin gene, which results in decreased intracellular levels of ferredoxin and reduced pyruvate/ferredoxin oxidoreductase

activity. In addition, oxidation of pyruvate to lactate within hydrogenosomes stops and occurs in the cytosol via lactate dehydrogenase [375, 376]. Resistance to metronidazole has also been found in *Giardia* [377]. In amebae, an increase in iron superoxide dismutase has been described as a mechanism of resistance [357].

Metronidazole is rapidly absorbed by the oral route, and serum levels are similar to intravenous doses. Metronidazole reaches all tissues and body fluids [378] including the central nervous system. Patients with meningitis achieve similar cerebrospinal fluid and serum concentrations. Metronidazole also penetrates into brain abscesses and is considered the most effective therapy for *B. fragilis* meningitis. [379]. Metronidazole has a mean plasma half-life of 8.3 h and a systemic oral bioavailability of 98.9%. Metronidazole is metabolized in the liver to glucuronide and oxidative products, including an active hydroxy metabolite [380]. Unchanged drug and the metabolites are excreted in the urine. The half-life of the drug may be as high as 20 h in patients with hepatic failure, and decreased doses are recommended for such patients.

Adverse Reactions

Nausea, vomiting, diarrhea, and metallic taste are common adverse events. *Candida* overgrowth may result in glossitis and stomatitis. More serious events involve the central and peripheral nervous systems that are usually associated with prolonged therapy and high doses or both. These can manifest as seizures, ataxia, dysarthria, cerebellar dysfunction, and often reversible peripheral neuropathy [381, 382]. Pancreatitis is an unusual complication of therapy [383]. Although the drug is active against *C. difficile*, paradoxically, cases of CDI have rarely been reported in patients on metronidazole [384]. Hypersensitivity reactions have been reported including urticaria, erythematous rash, flushing, bronchospasm, and serum sickness [385]. Genitourinary reactions include transient darkening of the urine to a deep red-brown color and dysuria. Patients should abstain from alcohol while taking the drug since a disulfiram-like reaction may occur characterized by flushing, tachycardia, palpitations, nausea, and vomiting [386]. Intravenous trimethoprim-sulfamethoxazole and over-the-counter cold syrups containing alcohol can also lead to a disulfiram-like reactions when taken along with metronidazole. Sudden deaths have been attributed to the metronidazole-ethanol disulfiram-like reaction [387]. Metronidazole is classified by the US Food and Drug Administration as category B during pregnancy.

Drug interactions can occur with phenytoin, carbamazepine, and lithium [388]. Metronidazole can increase the anticoagulant effect of warfarin, and preemptive dose reduction has been successful [389]. A potential interaction between metronidazole and amiodarone was reported resulting in QTc prolongation and torsades de pointes [390]. Of particular importance to transplant patients, metronidazole inhibits metabolic clearance of busulfan, and concomitant use may dramatically increase toxicity in HSCT patients receiving busulfan-containing conditioning regimens [391].

Use in Transplant Recipients

A few investigators have reported significant rise in cyclosporine and tacrolimus serum concentrations after patients were commenced on metronidazole therapy [392–394]. In one patient, cyclosporine increased 97% during concomitant metronidazole treatment and then returned to baseline after metronidazole was discontinued. In another patient, tacrolimus increased 99% and then returned to baseline levels after cessation of metronidazole. These reports suggest that caution should be used when dosing these agents concomitantly, with dose adjustments of cyclosporine and tacrolimus made as necessary. Another small study reported a significant interaction between metronidazole and busulfan. HSCT recipients given metronidazole for GVHD prophylaxis had significantly higher levels of busulfan than controls who received busulfan alone [391]. More adverse events were noted in the group of subjects receiving metronidazole and busulfan together such as multiorgan failure, veno-occlusive disease, and hemorrhagic cystitis; therefore, authors recommended avoiding these agents together in patients undergoing HSCT [395].

A sizable literature concerns treatment of CDI in the transplant population. One study identified over 49,000 cases following SOT among which 2.7% had CDI. Univariate comparisons of transplant cases with and without CDI revealed that CDI cases were independently associated with greater mortality, longer length of hospitalization, more complications for the transplanted solid organ graft, and increased need for colectomy [396]. Patients following liver transplantation were found to be at particularly high risk of developing CDI. The prevalence of CDI in this population was 2.7% versus 0.9% in other SOT recipients and a higher CDI mortality of 5.5% in liver vs. 3.2% in non-liver-transplant patients. CDI was an independent risk factor for death in this population [396].

In another study of CDI in SOT, *C. difficile* was the most common cause of diarrheal illness accounting for 2.7%. They also reported higher deaths, longer hospital stay, more complications for the transplanted organ, and increased need for colectomy in SOT recipients with CDI [395]. In children after lung transplantation, the incidence of CDI was 5.4%. One patient required a diverting ileostomy; another developed renal failure and expired. Overall 75% survival was

encouraging; however, a significant morbidity and mortality in these children with CDI were for serious concern [397]. In recipient of SOT with CDI, metronidazole and vancomycin were equally effective for the treatment of mild to moderate disease, whereas vancomycin demonstrated superiority in patients with severe disease [398], an observation echoed among non-transplant population with CDI.

Rifamycins

The rifamycins were discovered in 1957 as a fermentation product of *Streptomyces mediterranei* and named after a popular French crime film Rififi [399]. There are four currently marketed rifamycins: rifampin, rifabutin, rifapentine, and rifaximin. Rifamycin B was the first marketed agent. Through binding to DNA-dependent RNA polymerase, rifamycins exert a potent antibacterial effect against a broad array of prokaryotes [400]. Crystal structure analysis of the rifampin-RNA polymerase complex in *Thermus aquaticus* shows that rifampin binds to the β-subunit of RNA polymerase at a site far from the active site of the DNA/RNA channel and physically blocks the elongation of RNA once the transcript is 2–3 nucleotides in length [401]. Rifabutin inhibits transcription between the first and second nucleotides, indicating that steric hindrance may not completely explain the mechanism behind the blockade of RNA polymerase. Further modeling of the rifabutin-RNA polymerase complex demonstrates an allosteric signal leading to unfavorable binding of the crucial Mg^{2+} catalytic ion at the active site resulting in a slowed biochemical reaction and dissociation of unstable nucleotide hybrids [402].

Spectrum of Activity

Rifampin, rifabutin, and rifapentine are all highly active against *M. tuberculosis* and other organisms in the *M. tuberculosis* complex. Rifabutin MIC values against wild-type *M. tuberculosis* are generally narrowly distributed, with most values ≤0.06 mcg/mL, and MIC values between 0.25 and 0.5 mcg/mL against isolates with low-level rifampin resistance. Isolates with high-level resistance to rifampin demonstrate cross-resistance with rifabutin [403, 404]. These MIC values are approximately two- to fourfold higher than those observed for rifampin among *M. tuberculosis* strains. For MAC, the differential MIC values are more pronounced, with MIC values for rifampin ranging from 2- to 16-fold higher than those of rifabutin. Rifapentine demonstrates similar in vitro activity to rifabutin against members of the *M. tuberculosis* family; however, rifampin-resistant isolates are often resistant to rifapentine [405]. Due to the highly conserved structure of RNA polymerase across bacteria, the rifamycins are highly active against a wide variety of Gram-positive, Gram-negative, and intracellular bacteria. A summary can be found in an excellent review by Thornsberry [406]. Rifaximin demonstrates a similarly broad spectrum of activity, but due to poor systemic absorption, its use is limited to the treatment of localized gastrointestinal infections [407].

Resistance and Decreased Susceptibility

Approximately 95% of the cases of resistance to rifampin may be mapped to the enzyme-coding RNA polymerase, *rpoB*, with the majority of these mutations in region I of the gene [408]. Most are single-point mutations; however, insertions and deletions are possible. Each mutation confers a different spectrum and level of resistance; however, due to decreased bacterial fitness, many of the possible mutations are not propagated in a clinical environment [408]. These mutations alter the binding affinity of rifamycins to the target enzyme. Resistance to rifampin due to spontaneous mutations in the *rpoB* gene occurs at a frequency of approximately 10^{-8} in staphylococci and 10^{-9} in *Mycobacterium tuberculosis*, with combination therapy effectively decreasing the development of resistance in clinical isolates [409]. Due to the rapid development of resistance when used as monotherapy, rifampin is used in combination with other antibiotics in the treatment of serious infections [410].

In addition to target-site alterations, other mechanisms of resistance or reduced susceptibility may arise. A rifamycin derivative, CGP 4832, is highly active against rifampin-resistant strains of *E. coli*, due to increased cellular uptake via the FhuA-TonB active transport system [411], indicating that decreased cell permeability may be responsible for the reduced rifamycin susceptibility among the GNB. However, this does not seem to be a factor in mycobacterial resistance including *M. tuberculosis*, *M. avium-intracellulare* complex (MAC), and *M. smegmatis* [412, 413]. Enzymatic modification of rifampin was identified in *Rhodococcus* and *M. smegmatis*, with the *arr* gene leading to inactive ribosylated derivatives of rifampin [414]. Variant *arr* genes with similar functionality have been found on plasmids in *P. aeruginosa*, *K. pneumoniae*, *E. coli*, and other *Enterobacteriaceae*; notably, these plasmids also contained mutations conferring mutations to other classes of antimicrobials [415–417].

Adverse Reactions

Rifampin is generally well-tolerated, with a surveillance population of patients receiving rifampin for the treatment of tuberculosis discontinuing therapy only 1.9% of the time, with over half of these discontinuations being inappropriate

[418]. A well-known side effect of rifampin is red-orange discoloration of body fluids as a result of distribution of the brightly colored drug into these fluids. This is most often a harmless cosmetic disturbance; however, it may lead to permanent discoloration of contact lenses or, in cases of overdose, cutaneous discoloration and periorbital edema, and intense pruritus may occur [419]. Hepatotoxicity from rifampin may manifest as hyperbilirubinemia, elevated liver enzymes or drug-induced hepatitis. Elevations in both conjugated and unconjugated bilirubin occur predictably shortly following the administration of the drug, and are thought to the result of impaired biliary excretion [420]. Elevations in transaminases are infrequent in patients treated for latent tuberculosis or brucellosis [421, 422], although combination with isoniazid leads to more frequent elevation than expected with either agent alone [423]. There are few case reports of fulminant hepatitis resulting in liver failure due to rifampin monotherapy, occurring mostly in patients with preexisting liver disease [424]. Mild suppression of all marrow lines may occur during rifampin therapy, leading to granulocytopenia, thrombocytopenia, and anemia. True hemolytic anemia and immune-mediated thrombocytopenia may rarely occur during treatment with rifampin as a result of immune complexes and during re-exposure to the drug [425, 426]. Through similar immunologic mechanisms, rifampin has been associated with the development of acute renal failure [427]. Manifestations of renal failure are predominantly oligo-anuric acute tubular necrosis associated with systemic symptoms; however, recovery is slow and may occur during renal replacement dialysis. Other causes of renal failure, such as glomerulonephropathy, acute interstitial nephritis, and light-chain proteinuria, may occur; these are not associated with the development of antibodies to rifampin [428]. Increased levels of rifabutin in patients receiving clarithromycin or fluconazole during treatment of MAC infections have been reported and are probably due to inhibition of the CYP450. Patients with AIDS receiving rifabutin therapy at 600 mg daily dose are at risk for uveitis, risk adjusted with total body weight (TBW) of the patient, ranging from 64% in <55 kg TBW to 14% in patients with >65 kg TBW. Additionally, reduction in the dose to the currently recommended 300 mg/day, the risk dropped dramatically to 13% overall, with two of the three cases occurring in patients weighing <55 kg.

Use in Transplant Patients

Several interactions are particularly relevant in transplant population through induction of CYP-450 enzyme system [429, 430]. The use of rifampin with cyclosporine has been associated with numerous reported acute allograft rejections due to sub-therapeutic concentration of antirejection medicine, as well as acute GVHD for the same reason in pediatric and adult HSCT recipients [431, 432]. In a case series of four patients receiving cyclosporine and rifampin, the AUC of cyclosporine was found to be reduced by approximately two-fold, with a dose increase of 2.5–3 times baseline required to maintain adequate levels of immune suppression [433]. Similar potential for interactions with tacrolimus, sirolimus, everolimus, and, to a lesser extent, mycophenolate mofetil exists [433, 434]. A consensus statement on the use of rifamycins in the treatment of tuberculosis in patients undergoing SOT was published by the Spanish Society of Infectious Diseases and Clinical Microbiology, supporting the need for careful therapeutic drug monitoring of these agents and avoidance of rifamycins, when possible [435].

Rifaximin was evaluated in liver transplant recipients with *C. difficile* infection that was refractory to both metronidazole and vancomycin. Rifaximin at a dose of 400 mg TID for 28 days was initiated in three patients after oral vancomycin was discontinued; diarrhea resolved in all patients treated with rifaximin. Patients remained symptom-free for 155–250 day afterward [436]. Favorable observation in this very limited study needs to be assessed in a larger cohort of transplant patients with difficult-to-treat CDI diarrheal illness.

Sulfonamides

The sulfonamides were the first effective antimicrobials used to treat and cure infections in humans [437]. In 1932 the first sulfonamide, sulfachrysoidine, was found to be active against *Streptococcus*. The drug was marketed in Germany as prontosil. Sulfanilamide was introduced into the United States in the 1930s, and trimethoprim was synthesized several decades later. The combination of trimethoprim-sulfamethoxazole (TMP-SMX), also known as co-trimoxazole, was introduced in the 1970s and continues to be one of the most widely used compound for bacterial and parasitic infections. This section will concentrate on TMP-SMX, which is most commonly used sulfonamide and more relevant to the transplant patient population.

The sulfonamides are bacteriostatic antibiotics similar in structure to para-aminobenzoic acid (PABA) which is required for folic acid synthesis. The sulfonamides are competitive inhibitors of dihydropteroate synthase, the bacterial enzyme that incorporates PABA into dihydropteroic acid, the immediate precursor of folic acid. Sulfonamides have a higher affinity for the microbial enzyme tetrahydropteroic acid synthetase than PABA. Only bacteria that synthesize folic acid are susceptible; those that used preformed folic acid are resistant. Mammalian cells are comparable to resistant bacteria in requiring preformed folic acid; approximately 100,000 times more drug is required to inhibit the human enzyme than the bacteria enzyme [438]. TMP and

SMX work sequentially to inhibit enzymes involved in the bacterial synthesis of tetrahydrofolic acid (THF) and act synergistically in vitro and in vivo [439]. SMX competes with PABA to inhibit the synthesis of dihydrofolic acid, an intermediate step in the formation of THF, and TMP binds to bacterial dihydrofolate reductase also preventing the formation of THF [440]. The final results in decreased folic acid synthesis, reduced bacterial nucleotides, and inhibition of bacterial growth.

Spectrum of Activity

TMP-SMX is effective against a wide variety of aerobic Gram-positive and Gram-negative bacteria including *S. pneumoniae* and other streptococci, staphylococci including CA-MRSA, *H. influenzae*, *Enterobacteriaceae*, *Salmonella*, *Shigella*, *Listeria*, and *Nocardia* spp. It is active against *P. jirovecii*, *M. marinum*, and some protozoa including *Plasmodium*, *Cyclospora*, and *Toxoplasma* spp. [441]. Other nosocomial pathogens are susceptible, such as *B. cepacia*, *S. maltophilia*, and *S. marcescens*. Pathogens resistant to TMP-SMX include *P. aeruginosa*, most anaerobes, *M. tuberculosis*, *T. pallidum*, *Campylobacter*, and PCN-R S. *pneumoniae*. MRSA is variably susceptible, dependent upon whether the isolate is community or hospital acquired, as discussed in the sections on clindamycin and vancomycin.

Resistance

Different mechanisms mediate resistance to the two components and can be transferable on transposons of the *Tn*21 family [442]. Resistance to TMP-SMX is widespread and has developed in most bacterial species [443–445]. Multiple mechanisms have been described including permeability barriers and/or efflux pumps, bacteria with target enzymes that are not susceptible, regulational changes in target enzymes, mutations in target enzymes, and drug-resistant target enzymes. *P. aeruginosa* is one of the organisms known to have an active efflux pump, overexpressing the MexA-MexB-OprM system to eliminate the drug from the cell [446]. Naturally insensitive dihydrofolate reductase enzymes are found in *Bacteroides* spp., *Clostridium* spp., *Neisseria* spp., and *M. catarrhalis* [442].

Organisms can develop overproduction of PABA such as *N. gonorrhoeae* and *S. aureus* or altered dihydropteroate synthetase in the case of *E. coli*. Transferable resistance of approximately 20 genes conferring TMP resistance through mutations in dihydrofolate reductase genes has been reported over the past 40 years. Plasmid transfer can occur in the gastrointestinal tracts among various bacteria belonging to *Enterobacteriaceae*. Mutations in the chromosomal *dhps* gene of *E. coli* confer resistance to the sulfonamide component. These mutations may also mediate resistance in *S. aureus*, *S. haemolyticus*, *C. jejuni*, and *H. pylori* [442]. *S. pyogenes* is thought to have a change in the gene via transformational mutations [447] and *N. meningiditis* through recombination of mutations in the *folP* and *dhps* genes [448].

Plasmid-mediated SMX and TMP resistance is increasing worldwide. Studies have shown rates of resistance to *Salmonella* of 37% [449] and 76% in *Shigella* spp. [450]. A study of college student with urinary tract infections showed that *E. coli* resistance to TMP-SMX was 29.6% [451]. *S. pneumoniae* resistance to TMP-SMX varies geographically and may be as high as greater than 40% [452]. Resistance to *S. maltophilia* is also on the rise; a recent study reported 30.4% TMP-SMX-resistant isolates demonstrating a novel gene cassettes embedded in class 1 integrons [453].

Pneumocystis jirovecii resistance has been correlated with dihydropteroate synthase gene mutations [454], while dihydrofolate reductase gene mutations can account for high-level resistance in other organisms such as *E. faecalis* and *C. jejuni* [455, 456]. Naturally resistant bacteria to SMX such as *E. faecalis* are typically auxotrophic for folic acid. Maximal synergy occurs when organisms are susceptible to both drugs. However, bacteria naturally resistant to one of the drug component at a low level and susceptible to the other compound may still remain susceptible to the drug combination.

Adverse Reactions

TMP-SMX is generally well tolerated in non-HIV-infected patients, where HIV patients have a much greater rate of adverse reactions [457]. These include severe and life-threatening hypersensitivity reactions. Sulfamethoxazole hypersensitivity may involve the increased formation and decreased detoxification of reactive metabolites. The adverse reaction rate is as high as 50% in HIV-infected patients, with many of the reactions being severe [458]. The more common adverse reactions to TMP-SMX involve the gastrointestinal tract such as nausea and vomiting; skin rash and pruritus are also not uncommon. Life-threatening effects, more likely to occur in HIV-infected patients and older adults, include neutropenia and severe dermatologic reactions such as Steven-Johnson syndrome, exfoliative dermatitis, and toxic epidermal necrolysis [459]. TMP-SMX desensitization can be performed successfully in as many as 75% of HIV patients [460, 461].

There is data supporting an elevated risk of hypersensitivity to non-antibiotic sulfonamides such as loop and thiazide diuretics and sulfonylureas in patients with sulfonamide allergy. TMP-SMX should not be given to patients

who have folic acid deficiency or who are pregnant. As a weak inhibitor of dihydrofolate reductase in high doses, it has been implicated in megaloblastic pancytopenia [462]. Co-administration of folinic acid may prevent or reduce the antifolate activity of TMP-SMX without affecting its antimicrobial activity; such results are controversial [463, 464]. TMP-SMX should be given with caution to patients with glucose-6-phosphate dehydrogenase deficiency; however, convincing data regarding drug-induced hemolysis in patients with heterozygous G6PD deficiency is rare [465]. Other adverse effects such as anaphylaxis, hepatitis [466], hyperkalemia [467], aseptic meningitis [468], and hypoglycemia have been reported [469].

Nephrotoxicity associated with TMP-SMX is uncommon. TMP can lead to decline in renal tubular secretion of creatinine resulting in higher serum creatinine levels through interference with certain assays that is not reflective of a true reduction in glomerular filtration rate [470]. Adequate hydration should be maintained in order to minimize the risk for urinary tract crystal formation. Patients with low urine output and low urinary pH are at an increased risk for SMX crystalluria [471]. The older sulfonamides are less soluble and can precipitate in the tubules when used in high doses. Patients in whom TMP-SMX were previously discontinued due to skin reactions, especially in HIV-infected patients, a successful desensitization attempt should be considered when treatment resumption is being contemplated [472]. TMP-SMX can interact with a variety of drugs including warfarin, cyclosporin, rifampin, dapsone, and phenytoin [473–475]. Hyperkalemia has been described in elderly patients on spironolactone [474, 476].

Use in Transplant Patients

The combination of TMP and SMX is highly bactericidal with maximum synergy at a ratio of 1:20. The optimal ratio is calculated by the ratio of the MICs of the drugs acting alone. Because TMP is more lipid soluble than SMX, resulting in a larger volume of distribution, the drug is formulated to achieve a SMX concentration in vivo that is 20 times greater than TMP. The drug is available in a fixed ratio of 1:5 for oral/intravenous use [441, 477]. Bioavailability of TMP-SMX is approximately 85%. The peak TMP concentration is achieved in 2 h, whereas the peak SMX concentration is achieved in 4 h [438]. The drug is widely distributed in the body with tissue concentrations usually less than serum concentrations. Peak concentrations of TMP and SMX in the CSF are 1 μg/ml and 13.8 μg/ml, respectively, and penetration was 18% for TMP and 12% for SMX [478]. The half-life of TMP is 8–10 h and SMX is 10 h [441].

TMP-SMX is excreted in the urine, 50% of the drug eliminated in the first 24 h. SMX is approximately 70% protein bound; it is acetylated and glucuronide-conjugated in the liver. TMP is excreted in the urine unchanged. There are four major TMP metabolites with little antibacterial activity. Renal dysfunction results in prolongation of the half-lives of each drug; necessitating dose adjustment creatinine clearance is less than 30 mL/min. Dosing of TMP-SMX is based on the TMP dose and expressed as mg/kg per day of TMP. Oral doses of TMP-SMX are usually given as a single strength or more commonly a double-strength (DS) tablet once to four times daily depending upon the indication and renal function [479]. Intravenous TMP-SMX is usually dosed at a concentration of 5 mL which contains 80 mg of TMP. TMP-SMX dosing should be altered for patients with renal insufficiency with a creatinine clearance ≤30 mL/ min. Dose adjustment guidelines are available for patients with a creatinine clearance ≤15 mL/min [480].

TMP-SMX is commonly used to treat *P. jirovecii* pneumonia (PCP) which remains an important opportunistic fungal infection in patients undergoing allograft transplantation. Outbreaks of PCP have occurred in renal transplant centers secondary to person-to-person transmission resulting in loss of allograft and high mortality. For this reason, TMP-SMX prophylaxis is routinely used after transplantation and continued for 4–12 months after transplantation procedure [481]. Prophylaxis reduced the incidence of PCP infection to less than 1% in renal transplant recipients and considered favorable for reducing risk for toxoplasmosis, listeriosis, and urinary tract infections in such patients. The most common side effects include hemolytic anemia and methemoglobinemia, which are less common with the lower prophylaxis TMP-SMX dose. Breakthrough PCP is exceedingly rare in patients compliant to TMP-SMX prophylaxis.

Nocardia infection is an opportunistic pathogen in transplant patients, especially in lung transplants due to the mode of acquisition. *Nocardia* infection occurs in 2.1–3.5% of lung transplant patients [482–484]. TMP-SMX remains a mainstay of treatment, sometimes combined with imipenem, amikacin, and ciprofloxacin. Most isolates are susceptible to TMP-SMX despite breakthrough infections. Patients experience a high rate of adverse effects including gastrointestinal, renal failure, and cytopenias. Adverse effects may also occur with imipenem when given in combination, albeit most patients tolerate TMP-SMX induction and maintenance therapy for invasive nocardiosis well.

Community-acquired MRSA retained susceptibility to TMP-SMX despite frequent use of the drug in outpatient settings [485]. Susceptibility to *E. coli* and *Proteus* spp. decreased slightly, whereas susceptibility among clinical *K. pneumonia* isolates improved. Continued surveillance is ongoing; TMP-SMX remains a first-line drug in all populations for treatment of infections due to CA-MRSA.

The Polymyxins

The polymyxins are a group of closely related cyclic, positively charged peptide antibiotics discovered in the 1940s [486]. Only polymyxin B and colistimethate, the prodrug of colistin, are available in the United States. These two drugs differ by one amino acid which changes the potency and pharmacokinetics [487]. The intravenous formulations available are polymyxin B and E; polymyxin E is also known as colistin. Polymyxins were largely abandoned secondary to the nephrotoxicity toxicities manifested as proteinuria, oliguria, and acute renal failure and neurotoxicity presenting as paresthesias, neuromuscular blockade, and ataxia. The emergence of MDR GNB, especially *Pseudomonas* and *Acinetobacter* spp., has created a need to form clinical revival of these agents.

The polymyxins are bactericidal agents classified as cationic detergents. The polymyxins interact with phospholipids in the cell membrane by competitively displacing divalent cations from the phosphate groups of the membrane lipids, causing an immediate permeability change, membrane disruption, and leakage of cellular content. Polymyxin B binds to the lipid A portion of endotoxin and can displace magnesium and calcium from cationic-binding sites [488]. This inactivation has been shown in animal models to prevent the effects of endotoxin [489]. Neither polymyxin B nor colistin is absorbed by the oral route. The serum half-life of polymyxin B is approximately 6 h; the majority of the drug is reabsorbed via the proximal tubules. Colistin is tightly bound to lipid membranes of many organs and is excreted in the urine. Pharmacokinetic studies are difficult to interpret since colistimethate assays do not measure the active drug colistin; one study showed a half-life of 4.2 h. Penetration into cerebrospinal fluid, pleural cavity, lung, and biliary tract is low. Polymyxins are rapidly bactericidal with concentration-dependent kinetics. A postantibiotic effect has been reported against *P. aeruginosa* in patients with cystic fibrosis [490].

The spectrum of polymyxin activity includes *P. aeruginosa* and *A. baumannii*, especially relevant for transplant population. Additionally, rising frequency of MDR *Enterobacteriaceae* and *Stenotrophomonas maltophilia* further enhances their appeal. These bacteria have their LPS molecules bridged and stabilized by divalent cations such as magnesium. Many nosocomial pathogens are inherently resistant to these drugs by virtue of replacement of the divalent cation by a positively charged H1 protein resulting in altered lipid A binding. These include *Providencia* spp., *Proteus* spp., most *Serratia* spp., *B. cepacia*, and *Morganella morganii*. The polymyxins have no activity against GPB. Resistance mechanisms to the polymyxins include overexpression of outer membrane proteins and reduction in the net negative charge of lipid A secondary to substitution of phosphate groups and esterification.

The culture medium can alter susceptibility results since cation concentration can affect the MICs, and the automated microdilution assays may not give reliable information. Comparison of disk diffusion, E-test, and broth microdilution to determine resistance to colistin and polymyxin B were found to be concordant in one analysis [491], and E-test was superior to disk diffusion method for *K. pneumoniae*, especially for isolates with disk zone diameters of 12–13 mm [492].

There are several dosing guidelines for these drugs. Conventional dosing for colistin used in the United States for a 70 kg person is 300 mg of drug base per day or 720 mg of colistimethate or 5 mg/kg colistin base daily with either ideal or actual body weight. For polymyxin B the dose is approximately 2 mg/kg/day given in two divided doses or 15,000–25,000 units/kg/day in two divided doses.

Retrospective toxicity studies showed neurotoxicity between 7% and 27% and nephrotoxicity approaching in 43% of patients [493]. Neurotoxicity has ranged from none to 5% in recent studies. Nephrotoxicity from polymyxin B ranges from 6% to 14% and is higher in patients with preexisting kidney disease and compromised renal function. Kubin et al. [487] performed a retrospective review of acute kidney injury (AKI) in 73 patients in whom polymyxin B was given for at least 3 days. The dose was adjusted by total body weight, and using creatinine clearance a daily dose of 1–1.5 mg/kg/day was given to patients with CrCl <80 mL/min and 2.5–3 mg/kg/day in patients with CrCl >80 mL/min. AKI occurred in 60% of patients with more severe elevations in creatinine constituting injury or renal failure in 33%. At the end of therapy, 49% of patients had AKI. Hospital mortality was not influenced by development of AKI. This study found that obese patients may be at an increased risk for AKI, and concurrent vancomycin therapy might potentiate nephrotoxicity.

At one center, in a new dosing protocol, patients were given a loading dose of 25,000 units/kg of polymyxin B with subsequent doses adjusted for creatinine clearance; the dose for CrCl >80 mL/min was 25,000 units/kg every 24 h [494]. The newer dosing trended in improved microbiological success; however, an increased albeit, reversible renal toxicity was also observed. Optimum dosing for patients with and without renal dysfunction remains uncertain. Yahav et al. reviewed recent studies of colistin and concluded that the drug was administered to sicker patients with carbapenem-resistant bacteria. Overall, nephrotoxicity rates were not higher with colistin in these studies, and colistin-induced nephrotoxicity was reversible in most patients [495].

Use in Transplant Infections

Kalpoe et al. [173] reviewed the mortality associated with carbapenemase-producing *K. pneumonia* in liver transplant

patients. Fourteen patients had carbapenem-resistant isolates with a 30-day mortality of 71%. Ten patients received polymyxin B monotherapy and had 60% mortality rate. Polymyxin was combined with tigecycline in four patients with a 75% mortality and with cefepime and gentamicin in one patient who also died. Tigecycline monotherapy was given in three patients, in whom one patient survived. The patients who survived had surgical site infections and abdominal abscesses. Some in vitro studies have shown synergy between colistin and carbapenems for GNB that were resistant to carbapenems and susceptible to colistin [495]. Inhaled polymyxin has been added to systemic therapy to improve response; however, Kofteridis found that adding aerosolized colistin to intravenous colistin did not improve outcomes in patients with GNB VAP; there were only eight cases of *P. aeruginosa* in this group [496]. Another study compared three patient groups as follows: parenteral colistin, inhaled colistin, and inhaled and parenteral colistin in 20 ICU patients with pneumonia due to MDR *P. aeruginosa*. A clinical response was observed in all patients on inhaled, 40% given parenteral, and 78% in the inhaled-parenteral combined colistin treatment group. However, no patient achieved microbiological eradication, and mortality was lowest in the inhaled group suggesting that inhaled colistin may be useful as adjunctive therapy for the treatment of these daunting lung infections [497].

Fosfomycin

Fosfomycin is an antimicrobial that was first isolated in 1969 and approved in the United States in the form of a sachet containing 5.61 grams of fosfomycin tromethamine. Fosfomycin is a bactericidal agent that inhibits uridine diphosphate-G1cNAc enoyl-pyruvyltransferase, thereby inhibiting bacterial cell wall synthesis. An active bacterial transport system is necessary. Fosfomycin also decreases the adherence of bacteria to epithelial cells of the urinary tract. The original compound has a low bioavailability of 37%; the soluble salt is available for single-dose use with improved oral bioavailability.

Spectrum of Activity

Fosfomycin is approved in the United States for treatment of uncomplicated urinary tract infections due to *E. coli* and *E. faecalis*. The drug has broad in vitro activity against *K. pneumoniae*, *Proteus* spp., *Enterobacter* spp., and *S. marcescens*. *Pseudomonas* is known to develop resistance, and *Acinetobacter* isolates are inherently resistant. Fosfomycin also has activity against *S. pneumoniae*, *S. aureus*, and *S. epidermidis* and lacks anaerobic activity. Falagas et al. report fosfomycin activity against ESBL-producing *E. coli* adding fosfomycin to the list of antibiotics that may be used to treat urinary tract infections due to such pathogens. Falagas review of 17 studies in the treatment of drug-resistant *Enterobacteriaceae* demonstrated a good level of antimicrobial activity, especially against ESBL-producing *E. coli*. Of note, some of the studies involved sites outside the urinary tract such as decubitus ulcers, bloodstream infection, and other unspecified body sites. *E. coli* was the most common isolate, followed by *K. pneumonia* and *Enterobacter* spp. ESBL isolates accounted for 88% of the organisms with 91.3% showing in vitro susceptibility to fosfomycin. Efficacy of oral therapy in lower urinary tract infections was 94% in all studies and ranged between 78.8% and 93%.

An intravenous preparation of fosfomycin is available outside the United States, where it has been used for the treatment of various maladies such as respiratory tract, bone, obstetrical, joint, and bloodstream infections; furthermore, patients with meningitis and typhoid fever have also been treated with parenteral fosfomycin-based regimen [498]. A review of 31 studies had an overall cure rate of 81.2%. The intravenous formulation was well tolerated, and gastrointestinal, skin rash, and phlebitis at the IV site were prominent adverse events. Clinical trials to allow for eventual marketing of the intravenous formulation in the United States are underway. Resistance to fosfomycin has been observed, although the specific mechanisms are varied. Of note, Tullio et al. reported that fosfomycin mitigated depressed phagocytic response of neutrophils isolated from kidney allograft recipient even in the setting of uremia. This restoration of neutrophil functions against ESBL-producing *E. coli* in ex vivo experiments, although intriguing, needs thorough clinical validation.

Use of Fosfomycin in Transplant Patients

Fosfomycin tromethamine appears to have in vitro immunomodulating properties that may be desirable in the transplant population. When used in subinhibitory concentrations, exposure to fosfomycin was shown to induce ex vivo enhancement of depressed phagocytic neutrophil response against ESBL-producing *E.coli* isolated from patients on long-term hemodialysis and from recipients of renal allograft transplantation [499]. Fosfomycin has been used in the renal transplant population to treat urinary tract infections and is considered a therapeutic alternative for MDR GNB infection including graft pyelonephritis [500, 501]. Combination of fosfomycin with sulbactam was tested against eight clinical isolates of carbapenem-resistant *A. baumannii* using checkerboard assays; a synergy was demonstrated in 75% of these isolates. This in vitro

study suggests that combined use of fosfomycin and sulbactam needs further clinical evaluation [502].

Fusidic Acid

Fusidic acid has a unique mechanism of action through binding to elongation factor G (EF-G) which prevents release from the ribosome and inhibition of protein synthesis. The structure is "steroid-like," but the stereochemistry at the ring junctions results in a boat-like structure [503], and the agent has no corticosteroid activity. Fusidic acid has been available in Europe for over 40 years and currently not FDA-approved for use in the United States. The "traditional" spectrum of activity includes MSSA, MRSA, *S. epidermidis*, some beta-hemolytic streptococci, *Corynebacterium* spp., *N. meningitidis*, and most Gram-positive anaerobes. It lacks activity against Gram-negative aerobes and has variable activity against Gram-negative anaerobes. Clinical efficacy has been demonstrated in cSSTIs, osteomyelitis, and other MRSA infections.

Fusidic acid is available by the oral and parenteral routes and is metabolized in the liver by CYP450. Fusidic acid penetrates well into phagocytes and has enhanced antimicrobial activity at low pH [504]. High and sustained serum concentrations are usually achieved. Intravenous preparations have been associated with a high rate of infusion-related phlebitis, and since the oral bioavailability is high, oral route of administration is preferred. Oral fusidic acid has a good safety profile. Kraus et al. reviewed over 1200 citations from the literature worldwide; the most common adverse reactions were gastrointestinal, reversible jaundice, neurologic, hematologic, and cytochrome P450 drug-drug interactions. There is a potential for rhabdomyolysis when given with statins and suggestion that fusidic acid combination may be antagonistic. Concerns about selection of resistance during therapy have contributed to the reluctance to approve this drug in the United States. Resistance is thought to be caused by mutations in the gene coding for EF-G. Chromosomal- or plasmid-mediated mutations, *fus A-E*, have been identified resulting in staphylococcal resistance expressed in vitro MIC ≥2 μg/ml. Resistance is readily acquired when fusidic acid is used as monotherapy and may develop during the course of therapy. The question remains as to whether fusidic acid should be used in combination with other agents.

Jones et al. summarized a fusidic acid (CEM-102) surveillance study (US SENTRY) in the United States in 2008 and 2009 as well as global resistance surveillance data [505]. Fusidic acid $MIC_{50/90}$ was 0.12/0.25 μg/ml against 99.65% of *S. aureus* strains tested. Approximately 53% of these were MRSA that had a trend toward MIC ≥2ug/ml. When compared with oral antibiotics, sulfamethoxazole-trimethoprim inhibited 98.6% of the isolates. Linezolid was eight times less potent than fusidic acid. Fusidic acid was active against 97.6% of MS CNS vs. 90.2% of MR CNS. Fusidic acid resistance was rare, and high-level resistance MIC >32 μg/ml was not seen in the US strains, probably reflecting, in most part, a lack of clinical exposure to this agent in the United States. Jones et al. proposed a staphylococcal breakpoint of ≤1 μg/mL based upon the pharmacodynamics of the drug and low frequency of resistance. Craft et al. published a phase II trial of CEM-102 compared with linezolid in GPB SSTIs using a loading-dose regimen of fusidic acid [506]. Fusidic acid safety, tolerability, and efficacy were comparable to linezolid in this study. Oral fusidic acid is in clinical development in the United States by Cempra Pharmaceuticals as monotherapy with a new dosing regimen. Phase II and III clinical trials are underway. If approved, FA may offer an additional oral agent for treatment of MRSA SSTIs and possibly osteomyelitis.

Fidaxomicin

Discovered in the fermentation broth of an isolate of *Dactylosporangium aurantiacum* subspecies *hamdenensis*, fidaxomicin also known as tiacumicin B and OPT-80 represents the only currently marketed member of the macrocyclic class of antibiotics [507]. Fidaxomicin inhibits bacterial RNA synthesis through blocking the activity of DNA-dependent RNA polymerase via a mechanism distinct from that of the rifamycins and other known inhibitors of RNA polymerase [508]. Specifically, fidaxomicin inhibits melting of the DNA promoter complexes around the start site for transcription through altering the conformation of the DNA in the structure around the complexes [509].

Spectrum of Activity

Fidaxomicin is active in vitro against a number of GPB including *S. aureus* and *E. faecalis*, with no activity demonstrated against most clinically relevant Gram-negative organisms [510]. *Bacteroides* species are not inhibited by fidaxomicin, whereas *C. difficile* is highly sensitive, with a MIC90 of 0.25mcg/mL, and no reports of wild-type isolates with MIC greater than 1mcg/ml have been demonstrated.

Resistance

Reduced susceptibility to fidaxomicin has been identified in one clinical isolate of *Clostridium difficile* resulting from β and β' subunits of RNA polymerase mutation [511]. In vitro studies have determined that serial passage of fidaxomicin may result in a number of single nucleotide polymorphisms

in the *rpoB* and *rpoC* genes encoding RNA polymerase, with the Val1143Asp mutation in the β subunit resulting in reduced susceptibility among the clinical isolates [512].

Adverse Events

Due to negligible absorption from the gastrointestinal tract, it is not expected that oral administration of fidaxomicin would result in serious systemic adverse events [513]. Analysis of the clinical trials leading to marketing approval for fidaxomicin demonstrated no differences in the rates of toxicities experienced by patients receiving fidaxomicin as compared to those receiving the comparator agent such as oral vancomycin [514].

Fidaxomicin in Transplant Patients

CDI is associated with an overall significantly worse outcomes in hospitalized patients undergoing solid organ transplantation [395]. Treatment with vancomycin and/or metronidazole is associated with high rates of CDI recurrences in these severely immunosuppressed patients. Fidaxomicin has been shown in clinical trials to be noninferior when compared with oral vancomycin and favorably associated with a significantly lower rate of early CDI recurrence in the 4 weeks following cessation of therapy follow-up. It must be noted, however, that improved sustained response was not seen in the subgroup of patients with NAP1/B1/027 *C. difficile* strain. There is little data about the incidence of this strain in transplant population. It can be concluded that fidaxomicin is an option for the treatment of CDI in patients with an increased risk for infection recurrence and those with severe CDI [511, 515].

Summary

Infections in transplant recipients are more frequently due to multidrug-resistant organisms such as MRSA, VRE; ESBL and carbapenemase producing GNB. Infections with drug-resistant organisms in patients with severe immune dysfunction pose a serious management challenge, especially in planning empiric and preemptive therapy. Resurgence of old drug like polymyxins and fosfomycin, novel drug combinations, and the much-needed new antimicrobials with innovative mechanism of antimicrobial activity supplemented with structural and mechanistic resilience for evading microbial drug-resistance is the encouragement that current and future research provides. It is essential to recognize the clinical significance of potential drug-drug interactions in this patient population. Prudent antibiotic use is predicted upon careful selection and judicious use of antibiotics for infection prophylaxis, preemptive and empiric therapy, and, most importantly, ongoing surveillance to assess prevalence of causative bacterial pathogens and drug susceptibility profiles in an institution, transplant units, regions of temporary or permanent residence of transplant patients. Furthermore, travel-related exposure to bacteria with unique drug resistance profile; emergence, and distribution of drug resistance among common pathogens forms the core principles for optimized anti-infective treatment approach in caring for the highly susceptible patients undergoing transplantation procedures.

Pharmacokinetics and Pharmacodynamics of Antibiotics in Transplant Patients

51

Kelly E. Schoeppler, Scott W. Mueller, and Gerard R. Barber

Introduction

Infection remains a major cause of morbidity and mortality among solid organ transplant (SOT) and hematopoietic stem cell transplant (HSCT) recipients. Within the first 30 days following organ transplantation, the most frequently encountered sites of bacterial infection are the surgical site, vascular access device, and the lungs. Since the introduction of azathioprine in the 1960s and especially cyclosporine in the mid-1980s, several new potent immunosuppressive manifesting activities through an array of efficient mechanisms have recently arrived to market. While becoming mainstays of immunosuppressive maintenance therapies, they place patients at a markedly increased risk of infection. Challenges placed to clinicians are maintaining a delicate, if not brittle, balance of desirable and sustained immunosuppression while successfully preventing or, if needed, treating acute bacterial or opportunistic infections.

There is a muted response of transplant recipients to infection when compared to the immunocompetent host. Thus, clinicians charged with the management of transplant recipients must seek and closely examine subjective patient findings in concert with the receipt of objective results when available. While serum levels of immunosuppressive agents are available, a definitive marker for true depth of immunosuppression is still not available for clinicians to assess a patient's risk of frequency and severity of infection. Though not within the scope of this chapter, the issue of nosocomial infection among organ donors and donor-derived infections should also be noted.

Presenting further challenge to the maintenance of medications for the more acute issues of immunosuppression and bacterial infection is that organ transplant recipients often take several other medications for comorbidities that may be associated with immunosuppressive drugs. Disease states such as hyperlipidemia, hyperglycemia, hypertension, osteoporosis, and arrhythmia are not infrequent, particularly as organ transplants are increasingly performed in aging populations. Other commonly encountered conditions in this high-risk population such as depression and psychoses can be chronic and particularly challenging to manage with medications [1].

The management of concomitant medical conditions in the transplant recipients often requires the use of a large number of medications, at best constituting a necessary form of polypharmacy. Medication use leading to adverse events is noted to increase the rate of hospitalization and mortality [2, 3] and with strong statistical methodology has been demonstrated to be among the leading causes of adverse events in the hospitalized patient. In Leape's landmark study of 1133 patients sustaining disabling injuries due to medical treatment, the leading causes of operative and nonoperative adverse events were wound infection and drug-related mishaps, respectively [4].

This chapter will focus on antibacterial agents and dosing in special patient populations as well as aerosol and other novel routes of drug administration. Drug-induced immune modulation will also be discussed as will drug-drug interactions, categorized by pharmacokinetic and pharmacodynamic interactions as well as special population parameters within P-glycoprotein and cytochrome P-450 enzyme systems related to the transplant recipient. Consideration of these factors in the presence of potent immunosuppressive agents dictates that close therapeutic

drug monitoring (TDM) be performed. This is especially important as these agents often have narrow therapeutic windows and the risk of infection is strongly influenced by the dose, duration, and sequence of immunosuppressive therapies.

Temporal relationships of the risk of infection and potential etiologic agent have long been noted (see Fig. 51.1), but it is also recognized that changes to therapeutics, such as corticosteroid-sparing immunosuppressive regimens and antimicrobial prophylaxis, have influenced changes to patient presentation and implicated pathogens among SOT recipients [5]. Similar relationships exist among HCST recipients.

The clinician caring for the transplant recipient will also be reminded to maintain a heightened index of suspicion for even the subtlest changes to drug product formulations and new market entries. These may directly or indirectly influence clinical events such as the occurrence of graft rejection.

Stewardship of antimicrobial and immunosuppressive regimens and optimization of the ensuing pharmacokinetic and pharmacodynamic interactions are crucial.

Pharmacokinetics/Pharmacodynamics Primer

Simply, pharmacokinetics is defined by what the body does to a drug molecule. Pharmacokinetic (PK) measures include drug absorption, distribution, metabolism, and excretion (ADME), and these parameters vary based on the chemical properties of the drug. The PK profile, metabolism, and disposition of immunosuppressive medications can be quite complex relying on the cytochrome P450 (CYP450) pathway and adenosine triphosphate binding cassette (ABC) transporters such as P-glycoprotein (P-gp or MDR1) and multidrug resistance-associated protein 2 (MRP2). Both CYP450 enzymes and P-gp are susceptible to enzyme inhibition, competition, and induction by various medications. Conversely, pharmacodynamics (PD) is defined by the effect of a drug on the body. These can be additive or inhibitory dynamic effects on the body, manifesting as therapeutic as well as adverse drug effects [6, 7]. The following indices are important determinants of a drug's PK/PD properties:

- Bioavailability (F): The fraction of drug absorbed into systemic circulation. Bioavailability is determined by the

physiologic properties of the drug and dosage form, as well as the physiologic barriers at the site of absorption.
- Plasma protein binding (PPB): The percentage of circulating drug that is bound to plasma proteins. Only the unbound fraction of drug is able to exert a pharmacodynamic effect;
- Volume of distribution (Vd): A proportionality factor that relates the total amount of drug in the body to the concentration of drug measured in the plasma.
- Maximum concentration (Cmax): The peak concentration a drug achieves after administration.
- Minimum concentration (Cmin): The minimum or trough plasma concentration of a drug.
- Area under the concentration curve (AUC): The area under the plasma drug concentration-time curve, or AUC, reflects the actual total body exposure to drug. It is determined by the total amount of drug administered and the rate of elimination of the drug from the body.
- Clearance (CL): The volume of blood which is completely cleared of drug in a unit of time.
- Half-life ($t_{1/2}$): The amount of time required for the concentration of drug in the plasma to be reduce by 50%.

The minimum inhibitory concentration (MIC) of an antimicrobial is defined as the lowest concentration of the antimicrobial necessary to inhibit bacterial growth during incubation for 24 h in a growth medium. Furthermore, the effectiveness of an antibiotic against a susceptible microbe is typically governed by one of the following pharmacodynamic indices:

- T > MIC—The percentage of the dosage interval in which the concentration of the antimicrobial exceeds the MIC of the organism determines bacterial inhibition. This is also referred to as time-dependent activity in select antimicrobials.
- Cmax:MIC ratio—Bacterial inhibition is related to high concentrations of antimicrobial at the site of action. This is also referred to as concentration-dependent activity in select antimicrobials.
- AUC:MIC ratio—The total amount of drug exposure determines bacterial inhibition. This is a combination of time-dependent and concentration-dependent activity.

Not to be lost among an array of PK/PD characteristics of multiple medications is critical attention to the transplant patient. History is important and a thorough assessment of current patient status even more so. The state of vital organ function can strongly influence the disposition of many medications. Laboratory tests in conjunction with measurement and assessment of vital signs for renal, hepatic, pulmonary, gastrointestinal, and neurologic function should help aid the clinician charged with dosing antimicrobials as well as other medications.

Special Populations

Critical Illness

Despite recent advances leading to improved short-term survival rates in the SOT population, this patient population is at high risk for critical illness. In both the early post-surgery phase and long-term maintenance phase, sepsis and related septic shock are common causes of death [8]. Long-term immunosuppression may modify or mask clinical features of systemic inflammatory response syndrome in patients with sepsis. What is clear is the benefit of early effective antibiotics in SOT recipients with septic shock [9, 10]. The choice of antibiotics used should relate to the local patterns of bacterial susceptibility, patients' clinical presentation, and risk probability of infection, not to mention that patients with severe immune dysfunction are prone to multiple infections that may occur concurrently. Appropriate dosing of antibiotics in critical illness requires knowledge of the pathophysiology of sepsis; understanding of the patient's clinical status and current therapies such as fluid resuscitation status and renal replacement therapy, among others; as well as the PK/PD of the antibiotic being given.

Septic shock initially causes circulatory disruption due to vasodilatation and increased permeability of the microvascular endothelium [11]. Coupled with fluid resuscitation, these factors relate to an increased Vd of antibiotics, particularly hydrophilic antibiotics since the extracellular water compartment expands. Lipophilic antibiotics may be affected but to a lesser magnitude since adipose tissue remains unchanged. Beta-lactams, for example, are generally considered hydrophilic. A brief summary of the hydrophilic and lipophilic tendencies of antibiotics can be found in Table 51.1. A systematic review of beta-lactam pharmacokinetics in critical illness revealed an increased Vd for all studied beta-lactams compared to healthy volunteers [12]. Although this difference may be in part related to increased total body weight, it is important to note that standard renal dose adjustments may not result in effective concentrations of antibiotic after the first dose. Therefore, a full or loading dose should be given prior to dose adjustment for changes in clearance [13, 14].

Increased Vd typically causes a prolonged half-life, and renal dysfunction is common in septic shock; however, some critically ill populations show increased renal blood flow,

Table 51.1 General classification of hydrophilic and lipophilic antibiotics [14, 16]

Hydrophilic	Lipophilic
β-Lactams	Fluoroquinolones (levofloxacin, ciprofloxacin)
Aminoglycosides	Macrolides (azithromycin, clarithromycin)
Glycopeptides (vancomycin)	Lincosamide (clindamycin)
Lipopeptide (daptomycin)	Tetracyclines (including doxycycline, minocycline, tigecycline)
Lipoglycopeptide (telavancin)	Rifamycin (rifampin)
Oxazolidinone (linezolid)	
Polymyxin (colistin)	

and calculations of creatinine clearance may underestimate predicted drug clearance [15]. In the case of time-dependent killing bactericidal agents such as beta-lactams, the percentage of time the drug concentration is above the minimum inhibitory concentration (MIC) of the bacteria is crucial. Target ranges from 40% to 100% of the time above MIC for effective drug dosing and depends upon the beta-lactam drug used [14]. Given the wide therapeutic index of most beta-lactams and lack of available therapeutic drug monitoring, authors' preference is to dose at the higher or more frequent range whenever possible or reasonable to avoid marginally therapeutic underdosing. Continuous and extended infusions of beta-lactams may have benefit as they optimize the pharmacokinetic and pharmacodynamics by virtue of lower peak and higher trough concentrations. At this time, data on clinical outcomes is mixed and lacks rigorous prospective trials. Although intriguing, routine use of continuous or extended infusion beta-lactam antibiotics should be weighed against potential intravenous line access issues, and care should be taken to ensure delays in initial adequate systemic concentrations are not introduced by implementing a protocol for continuous or extended drug infusion.

Aminoglycosides are also considered hydrophilic. Unlike beta-lactams, the bactericidal activity of aminoglycosides is related to peak concentrations such as Cmax:MIC or AUC:MIC ratio. With once-daily dosing, an optimal peak to MIC ratio of 8–10:1 is often targeted [17]. Changes in Vd are again important to consider. Initial doses of 7 mg/kg of gentamicin or tobramycin [18] and 15–20 mg/kg of amikacin are typically recommended for once-daily dosing regimens; however, the patient populations used to validate these dosing regimens often excluded critically ill patients with altered Vd. Furthermore, higher doses of concentration-dependent antibiotics may be required to reach optimum peak concentrations in the critically ill patients [19–21]. Therapeutic drug monitoring is recommended and doses are adjusted to maintain adequate peak concentrations while extending the dosing interval to minimize trough concentrations. Renal toxicity with aminoglycosides is well-described. In an attempt to minimize renal injury, trough concentrations of undetectable or < 1 mg/L for gentamicin and tobramycin or < 5 mg/L for amikacin are recommended, whenever possible [13, 14]. This is especially important in transplant recipients taking concurrent nephrotoxins such as calcineurin inhibitors.

Vancomycin is a cell wall inhibitor, similar to beta-lactam antibiotics, but with a distinctly different binding mechanism. Unlike beta-lactam antibiotics, clinical effectiveness targets for vancomycin relate to an AUC:MIC value >400 [22]. This target is usually attained by using a weight-based dose of 15–20 mg/kg and adjusted frequency for renal function to attain a trough concentration between 15 and 20 mg/L. Because time to a steady-state trough concentration is variable in the critically ill patient and may not be realized for 24–48 h in many patients, a 25–30 mg/kg loading dose can be considered as an initial dose among the critically ill patients undergoing transplantation [22, 23].

Similar themes for the dosing of antibiotics in critically ill patients will be found throughout the literature. Namely, initial aggressive loading doses of intravenous antibiotics are important, and a dosing strategy without available TDM requires a balance between risks of under-treating a severe infection and the potential for drug toxicity. Although dose adjustments of hydrophilic antibiotics in the critically ill often dominate the literature, consideration should be given to all antibiotics to avoid underdosing with initial prescribed regimens when timely administration is of importance. Extracorporeal membrane oxygenation (ECMO) and renal replacement modalities add another layer of complexity. Dosing considerations and recommendations may vary depending on renal replacement machinery, modality, and prescribed utilization. We refer the reader to current reviews discussing dose considerations in continuous renal replacement [24, 25]. Antibiotic removal during ECMO requires further study before recommendations can be made; however, we refer the reader to a review of general dosing considerations [26].

Hematopoietic Stem Cell Transplantation and Neutropenia

HSCT has evolved as a life-saving therapy for many patients with lymphoproliferative disorders, leukemias, and non-malignant disorders including immune deficiencies and bone marrow failure syndrome [27]. Patients requiring HSCT are often at risk of infection prior to receiving their conditioning regimen due to their underlying illness. Further, profound and protracted neutropenia may occur with conditioning. The selection and use of myeloablative and non-myeloablative conditioning regimens given for the preparation for allogeneic or autologous stem cell transplantation are beyond the scope of this chapter. However, it is important to consider

the conditioning regimen, expected engraftment time, use of immunosuppression for graft-versus-host disease after allogeneic transplantation, and complications including oral intestinal mucositis and veno-occlusive disease when selecting antibiotics. For example, drug-drug interactions should be considered when patients are given cyclophosphamide, busulfan, and etoposide as they utilize CYP450 for activation and/or elimination [28]. Methotrexate elimination may be reduced when given with beta-lactam antibiotics; notably penicillin. Other immunosuppressants used in patients with graft-versus-host disease and graft rejection in SOT recipients and their interaction(s) with antibiotics are discussed below. Patient status can often influence the selection of antimicrobial agent and dose as there are important PK/PD considerations in the HSCT and neutropenic populations in general. For example, the development of severe mucositis may preclude the use of oral agents, hepatic veno-occlusive disease may result in severe liver injury leading to decreased elimination of antibiotics metabolized by the liver or excreted through biliary mechanisms, and fluid retention and increased Vd may result in patients with ascites or renal injury. Antibiotics are indicated at the onset of fever and, in some specific populations, for prophylaxis from infection following HSCT conditioning [28].

During the pre-engraftment phase, patients are profoundly neutropenic. Despite a normal or even elevated neutrophil count prior to HSCT or after engraftment, qualitative defects in circulating neutrophils tend to exist. This "functional neutropenia" places the HSCT patient at high risk of infection even before myeloablative therapy is given. Neutropenia also occurs in SOT recipients, although it is less severe and often of brief duration compared with patients undergoing conventional high-risk allogeneic stem cell transplantation. The cause of neutropenia in SOT recipients is multifactorial and mostly attributed to the use of myelosuppressive drugs like azathioprine, mycophenolic acid, tacrolimus, sirolimus, ganciclovir, valganciclovir, antithymocyte globulin, rituximab, and sulfamethoxazole/trimethoprim, among others [28–34]. Peripheral blood neutrophil counts serve as a proxy for the host immune response against bacterial invasion as neutropenic patients are at an increased risk of systemic bacterial infections [29, 35]. Furthermore, in cancer patients with neutropenia, at least one-fifth of those with an absolute neutrophil count (ANC) less than 100 cells/μL may develop bacteremia [28]. As expected, antibiotics are commonly prescribed for such patients for infection prevention and treatment of febrile illnesses, even in the absence of a positive blood culture.

Studies of antimicrobials in HSCT and solid tumor cancer patients with febrile neutropenia have demonstrated significant PK changes for many agents; however, PK changes have not been confirmed in SOT populations with neutropenia. Nonetheless, pertinent antimicrobial PK changes will be reviewed here, as they should be given consideration in all neutropenic patients while identifying the optimal antimicrobial regimen.

Changes in PK indices, as well as a greater variability of these indices, have been demonstrated for many of the beta-lactam antibiotics in patients with febrile neutropenia. In two studies of febrile neutropenic cancer patients compared to healthy volunteers, an increased Vd was observed for both imipenem and meropenem. Imipenem also displayed an increased $t_{1/2}$, whereas the opposite was true for meropenem [36, 37]. A study of ceftazidime showed patients with febrile neutropenia had a reduced AUC and shorter $t_{1/2}$ compared to elderly, healthy subjects [38]. Many studies of the aminoglycosides have shown that these agents have an increased Vd in patients with febrile neutropenia [39–43]. Adequate initial dosing and TDM are essential in order to ensure appropriate aminoglycoside drug concentrations are achieved. Importantly, studies have demonstrated that once-daily aminoglycosides are likely as safe and efficacious as conventional three-times-daily administration in patients with neutropenia [44, 45]. In studies of vancomycin PK, a decreased CL, increased Vd, and slight reduction in AUC were observed in patients with febrile neutropenia [46, 47]. An increase in the variability of these PK parameters was also noted; therefore, careful monitoring of serum trough concentration is warranted. Increased variability along with a small decrease in AUC was also observed in cancer patients with neutropenic fever treated with daptomycin [48, 49]. In a study of compassionate-use linezolid, the PK profile of the drug in neutropenic patients with cancer did not differ significantly from that of the rest of the study population [50]. There is a paucity of data evaluating potential PK changes of fluoroquinolones in patients with neutropenia.

In patients undergoing treatment for hematologic malignancies, HSCT, solid tumors, and SOT, various medication regimens including antimicrobials may be expected to impart some increased risk of neutropenia. However, medication-related neutropenia from non-chemotherapeutic agents is uncommon [51–53]. Trimethoprim/sulfamethoxazole and linezolid are often cited as a potential cause of dose- and duration-related bone marrow suppression although the true incidence remains uncertain [54]. Vancomycin is known to suppress bone marrow function in vitro and observed in vivo [55]. Beta-lactam antibiotics, especially prolonged treatment courses, have been observed to cause leukopenia via an immune-mediated mechanism [51, 56]. Often it is difficult to discern antibiotic-associated myelosuppression from other causes of bone marrow suppression in these complex patients following transplantation. Table 51.2 provides a select list of antibiotics associated with blood cell line disturbances such as neutropenia, thrombocytopenia, or anemia and literature-guided relative risk of such occurrences. It should be noted that antibiotic-associated bone

Table 51.2 Selected antibiotics associated with neutropenia, thrombocytopenia, or anemia [51–53]

Antibiotic	Estimated relative risk of bone marrow suppression	Comment
Trimethoprim/sulfamethoxazole	+++	Potentially all cell line
Beta-lactams	++	Thrombocytopenia and neutropenia
Linezolid	++	Thrombocytopenia and neutropenia
Vancomycin	+/++	Thrombocytopenia and neutropenia
Dapsone	++	Hemolytic anemia with G6PD deficiency, reports of neutropenia and thrombocytopenia
Tetracyclines	+	
Macrolides	0/+	
Clindamycin	0/+	
Fluoroquinolones	0/+	

marrow suppression is relatively uncommon compared with myelotoxicity noted with other classes of medications, and such diagnosis requires a broad differential of possibilities and needs to be considered within the appropriate clinical context.

Elderly

Solid organ transplantation is being performed in an older population with increasing frequency [57]. In general, elderly patients are more likely to have comorbidities managed with multiple medications and subsequently can be subject to a higher risk for adverse drug events when prescribed additional antimicrobial therapy [58]. Because the number of medications most patients are prescribed increases substantially after undergoing SOT, it can be deduced this population of elderly patients is at an even higher risk for adverse drug events. Furthermore, age-related PK/PD changes have been linked with the risk for drug-related toxicity [59]. Anticipating these changes can help avoid or minimize adverse medication outcomes in this special population.

Differences in drug absorption are possible in elderly patients due to reduced gastric acid secretion, weakened peristalsis, and delayed gastric emptying [60–62]. It is unclear if these changes are of clinical significance; they are unlikely to affect a drug's AUC; however, lower Cmax may occur [62]. Vd for lipophilic antimicrobials in elderly patients is typically increased secondary to an increase in adipose tissue and reduced lean body mass compared to younger individuals [63, 64]. Conversely, the Vd for hydrophilic antibiotics will likely be decreased in elderly patients (see Table 51.1). Many elderly patients have a slightly decreased serum albumin concentration and an increased alpha1-acid glycoprotein [62]. While these changes potentially impact PPB and free fraction of highly protein-bound drugs, PPB alterations, however, have not been shown to significantly affect clinical response to antimicrobial agents [65]. Decreased hepatocyte mass and blood flow to the liver contribute to reduced first-pass hepatic metabolism and CL of some drugs [62, 66–68]. Glomerular filtration and tubular function decrease with increasing age, and concentrations of renal drug elimination are subsequently increased, including for several antimicrobial agents. Because muscle mass is often decreased in elderly patients, these patients will frequently present with a normal serum creatinine despite significant renal impairment [69]. Therefore, estimation of creatinine clearance (CrCl) with a predictive equation and clinical judgment is required when determining dosing regimens for renally eliminated antimicrobials in the elderly [70, 71]. The six-variable MDRD equation has been suggested as the most accurate predictor of renal function in this population [62].

Further complicating antimicrobial dosing in the elderly is the fact that elderly patients, especially those with comorbid conditions, are often excluded from clinical trials. Therefore, age-related dose adjustments derived from pharmacokinetic evaluations are not available for a large number of drugs used in this population. Monitoring for signs of clinical improvement or deterioration and drug toxicity and, when available, obtaining serum drug concentrations may assist in guiding dosing strategies among the elderly transplant recipients. The general rule for many classes of medications in the elderly, to start with lower doses and titrate up to an effective dose, should not be applied to antimicrobial therapy. Initial doses should be sufficiently high to rapidly achieve adequate concentrations, especially for antimicrobials dependent upon a high Cmax for efficacy. The subsequent dosage or interval can then be adjusted to maintain serum concentrations comparable to younger patients. In general, the dose should remain unchanged and the interval lengthened for concentration-dependent antimicrobials; conversely, doses can be adjusted for antimicrobials which depend on T > MIC for efficacy.

Cystic Fibrosis

Cystic fibrosis (CF) is the third most common diagnosis category leading to lung transplant in the USA [57]. When infection and inflammation lead to bronchiectasis and, ultimately, end-stage pulmonary disease in patients with CF, lung transplantation offers a survival benefit for most patients [72]. With few exception, the presence of multidrug-resistant pathogens pretransplant is generally not considered a contraindication to lung transplantation [73]. However, in the setting of posttransplant immunosuppression, infections remain

a major source of complications and declining pulmonary graft function following lung transplantation. Additionally, the transplanted lung lacks innervation, resulting in suboptimum cough reflex and adequate clearance of respiratory secretions [74]. Patients with CF undergoing lung transplantation require perioperative antibiotics with a special attention paid to selecting antimicrobials active against the organism(s) the patient may be colonized with or had infectious episodes with prior to transplant. Frequent courses of antibiotics are also likely to be necessary during the posttransplant period. Consideration of antimicrobial PK/PD parameters is paramount for achieving optimum drug concentrations, especially at the infection site(s), and improved drug efficacy to treat often serious and life-threatening infections in this unique patient population.

The extent of drug absorption may be diminished in patients with CF secondary to reduced gastric acid secretion and bile acid malabsorption [75, 76]. While studies in patients with CF have failed to consistently demonstrate a clinically significant decrease in the AUC of orally administered antimicrobials, a reduced Cmax has been observed for some antimicrobial agents [77–82]. There are no PK studies to date which evaluate the impact of CF on the rate and extent of antimicrobial absorption following lung transplantation, although studies of antirejection medications have demonstrated higher oral dosage requirements in the CF population when compared to those without CF [83, 84].

In general, CF patients prior to transplantation have an increased Vd secondary to higher lean muscle mass per kilogram of body weight [85–87]. Hepatic dysfunction is a common complication of CF, but despite this, the CF population appears to have enhanced metabolism of many drugs [88]. Some of the CYP enzymes have demonstrated increased activity in patients with CF such as CYP1A2 and CYP2C8, whereas others like CYP2C9 and CYP3A4 appear to be unaffected [87–91]. The renal clearance of many drugs is also enhanced in patients with CF, although the mechanism for this enhancement is unclear [73, 92, 93].

Data for Vd, CL, $t_{1/2}$, and AUC of antimicrobials in CF patients following lung transplantation is less than adequate [94, 95]. In one retrospective study, tobramycin PK was evaluated in eight patients with CF before and after bilateral lung transplantation [95]. The investigators found no difference in AUC or Vd pretransplant versus posttransplant. CL decreased and $t_{1/2}$ increased from pretransplant values during the immediate postoperative period; however, only a significant difference in $t_{1/2}$ remained in the patients who received tobramycin ≥6 weeks posttransplant. The investigators noted a large interpatient variability in these PK parameters and recommended that they be reexamined during each tobramycin course following lung transplantation.

Taken together, these data suggest that antimicrobial dose requirements in patients with CF may not only differ from non-CF counterparts but may also diverge from pretransplant parameters after patients have undergone lung transplantation. Some potential explanations for these alterations include medication-associated organ dysfunction, drug interactions and changes in fluid, and patients' nutritional status. An individualized approach to antimicrobial dosing is required, one that takes into account the patient's organ function, body composition, and overall severity of illness; TDM should also be utilized when available.

Obesity

Historically, obesity has been considered a relative contraindication for SOT due to increased perioperative morbidity and mortality. While it does appear that obese patients are at an increased risk of surgical site infection, the benefits of transplantation outweigh the risks of surgical complications in many clinical situations among patients with obesity and end-organ disease [96–100]. Moreover, a survival benefit has been demonstrated in obese patients in whom kidney and liver transplants were undertaken compared with similar patients in whom transplantation was deferred due to obesity [101, 102]. Organ transplants are being performed in increasing numbers in such patients, and this trend is likely to continue given the continued rise in the prevalence of obesity nationally [103]. Moreover, the prevalence of obesity after undergoing organ transplantation is also on the rise. Nearly one-third of liver transplant recipients with a normal pretransplant body mass index (BMI) were noted to have BMI in obesity range after undergoing orthotropic liver transplantation [104, 105]. The development of posttransplant obesity has been linked to universal prednisone use and near-universal use of calcineurin inhibitors (CNIs), especially cyclosporine for prevention and treatment of allograft rejection [106, 107]. When treating infections in such patients, consideration for changes in the antimicrobial PK is critical for achieving adequate serum concentrations while minimizing drug toxicity.

Absorption of drugs remains essentially unchanged; however, an increased volume of adipose tissue results in an increased Vd and CL for many antimicrobial agents [108, 109]. The impact of obesity on a drug's Vd will vary based on the characteristics of the drug molecule; for example, hydrophilic molecules are less likely to be distributed into the adipose tissue (Table 51.1). The effect of obesity on hepatic metabolism is largely unknown; obese patients are known to have an increased GFR. This phenomenon has been attributed to the enlarged glomeruli observed in obese versus nonobese patients [110]. In fact, organs from obese kidney donors demonstrate a significantly higher GFR compared to renal grafts harvested from nonobese donors [110]. Estimating CrCl in obese patients presents a challenge to clinicians; transplant

care teams should include experienced PharmDs. CrCl based on total body weight (TBW) in obese patients results in an overestimated renal clearance, whereas ideal body weight (IBW) tends to underestimate CrCl [111, 112]. Adjusted body weight (ABW) appears to closely correlate with CrCl in this population (ABW = IBW + correction factor x [TBW – IBW]). A correction factor of 0.4 is commonly used. The modification of diet in renal disease (MDRD) equation is an attractive option because it does not include body weight as a variable; it should be noted that this formula has not been rigorously tested for drug dose adjustments in obese patients [113]. It is interesting to note that Vd and CL differences have not significantly influenced antimicrobial drug elimination rates, possibly because elimination rate constant (ke) = Vd/Cl, which offset one another. Nonetheless, TDM should be used to help guide therapy in this patient population when possible.

The majority of studies for evaluating vancomycin PK in obese subjects suggest that Vd is increased compared to non-obese patients. It is generally recommended that vancomycin be dosed at 15–20 mg/kg using TBW [114, 115]. Vancomycin CL is also increased in obese patients; TDM of serum vancomycin trough levels should be monitored [114, 115]. For highly hydrophilic drugs, such as the aminoglycosides, it is generally recommended that doses be based on an ABW. For the aminoglycosides, a correction factor of 0.4 is generally recommended [116, 117]. Studies of the fluoroquinolones have produced variable results precluding any specific dosage recommendations; dosing at the higher end of the therapeutic range has been suggested [109]. Beta-lactam antibiotics display hydrophilic properties and have limited distribution into adipose tissue [109]. Nonetheless, higher doses of beta-lactam antibiotics may be required to achieve adequate concentrations, especially in adult transplant patients with extreme obesity. In a study, 2 g of cefazolin was required in obese patients undergoing bariatric surgery to obtain comparable tissue concentrations to 1 g cefazolin dose in nonobese patients [118]. This is reflected in the current antibiotic surgical prophylaxis guidelines as 3 g of cefazolin dose is recommended for patients weighing greater than 120 kg [119]. Authors recommend TBW be used to determine daptomycin dose [120], and for linezolid, IBW can be considered [121–123]. Further studies are required to assess and validate optimum antibiotic dosing in this patient population.

Antibiotic Drug Interactions in Solid Organ Transplantation

Pharmacokinetic Alterations of Calcineurin Inhibitors and Proliferation Signal Inhibitors by Antibiotics

The majority of recognized pharmacokinetic drug interactions with antimicrobial medications in SOT occur with CNIs such as cyclosporine, tacrolimus, and proliferation signal inhibitors (PSIs) like everolimus and sirolimus. This is mainly due to their reliance on CYP450 isoenzymes and transport proteins for clearance and due to TDM is routinely performed for these drugs in transplant recipients. It is important to note that pharmacokinetic alterations via CYP450 and ABC transporters do not only relate to changes in drug clearance, but also impact oral drug bioavailability. Differences in the magnitude of pharmacokinetic alterations due to concomitant use of antibiotic and CNIs or PSIs are a common occurrence in this population with specific treatment requirements. In general, TDM is strongly recommended when patients receiving CNIs or PSIs are initiated on or discontinued from medications with either inhibitory and/or induction effects on CYP3A and/or ABC transporters (such as P-gp) [124, 125]. Tables 51.3 and 51.4 provide a summary of interactions between antibiotics and antirejection agents. It should be noted that inherent variability among patients makes prediction for the extent of these interactions difficult; therefore, close TDM is required. In the event of difficult-to-manage drug-drug interactions, an alternative agent should be used.

Specific interactions requiring empiric dose adjustment are important to recognize. For example, when initiating the CYP3A inhibitors erythromycin or clarithromycin, CNI trough concentrations would be expected to increase 1.6- to sixfold necessitating an empiric dose reduction of 35–50% of the original dose and potentially more based on TDM [126, 127]. Accordingly, dose reductions of 50% for sirolimus and 25% for everolimus should be considered when initiating erythromycin or clarithromycin [128–130]. Once the offending agent is discontinued, dose increases are warranted based on TDM as enzyme and protein inhibition wanes. For the more commonly used azalide, azithromycin, recommendations are less clear. TDM is warranted as reports of increased CNI and, to a lesser extent, PSI concentrations with azithromycin have been reported, but not to the magnitude of the aforementioned macrolides [125, 131–133].

In contrast to enzyme inhibition, the antituberculosis agent rifampin is a potent enzyme inducer responsible for decreasing CNI concentrations by 6- to 15-fold and decreased PSI concentrations by two to fivefold due to reduced bioavailability and heightened enzymatic clearance [134–137]. Whenever possible, an alternative to rifampin should be used as it has been implicated in graft rejection resulting in irreparable graft damage due to subtherapeutic CNI levels. If the combination cannot be avoided, cyclosporine doses may be increased by 1–2 mg/kg/day with three-times-daily dosing and adjusted according to TDM [135]. Specific recommendations for the management of tacrolimus, sirolimus, and everolimus are lacking, but dose adjustments should be expected based on TDM [125]. Rifabutin, a possible substitute for rifampin, may also interact with CNIs and PSIs, albeit to a lesser magnitude [138, 139].

Table 51.3 Definitions of onset of action, magnitude of effect, and relative strength of evidence for immunosuppressant drug interactions [124]

Onset of action	
Rapid	PCK effect is demonstrated within 24 h of co-administration
Delayed	PCK effect will not be demonstrated until the interacting drug is administered for a period of days or weeks
Magnitude of effect	
Major	Effects are life-threatening, capable of permanent damage, or rejection
Moderate	May cause a detriment in clinical status, additional treatment, hospitalization, or extension of stay
Minor	Effects may be mild; consequences may be bothersome or noticeable; additional treatment not required; no sign of effect upon therapeutic outcomes
Relative strength of evidence	
Established	Proven to occur in well-controlled studies Altered pharmacologic effect has been demonstrated in well-controlled trials *OR* PCK effect has been demonstrated in well-controlled human studies. An altered pharmacologic response is expected based upon the magnitude of the kinetic effect, or clinical observations support the occurrence of the interaction
Probable	Very likely, but not proven clinically A PCK interaction has been demonstrated in well-controlled studies. Based on the magnitude of the kinetic changes and the known plasma level-response relationship of the affected drug, an altered pharmacologic response will probably occur *OR* When controlled human experimentation is impractical, well-designed animal experiments confirm an interaction which is suggested by multiple case reports or uncontrolled studies
Suspected	May occur; some good data, but needs further study A PCK interaction has been demonstrated in well-controlled studies Although an altered pharmacologic response might be expected to occur based on the magnitude of the kinetic change, no firm conclusion can be drawn since a plasma level-response relationship has not been established for the affected drug *OR* An altered pharmacologic response has been reported in multiple case reports or repeated uncontrolled clinical studies
Possible	Could occur, but data are very limited Although a PCK interaction has been demonstrated, the kinetic changes are of such magnitude that it is not possible to predict if an altered response will occur *OR* The evidence is divided as to whether an interaction exists *OR* An altered pharmacologic response is suggested by limited data

PCK pharmacokinetic

Noteworthy is the fact that cyclosporine and, to a lesser extent, tacrolimus also inhibit the CYP450 isoenzymes and P-gp. However, there is a paucity of published data implicating elevated antibiotic concentrations due to decreased elimination or increased bioavailability with cyclosporine. Cyclosporine has been shown to increase serum concentrations of tacrolimus, everolimus, and sirolimus when given together. Midazolam and statins eliminated via the liver follow similarly metabolized medications resulting in higher drug exposures, although the significance will vary depending on the therapeutic index of the medication [7, 140, 141].

Pharmacokinetic Alterations of Antimetabolites by Antibiotics

Antibiotic pharmacokinetic interactions have been described for the antimetabolites as well. For example, mycophenolic acid (MPA) has a complex metabolic pathway. Briefly, MPA systemic clearance predominately involves glucuronidation via uridine diphosphate-glucuronosyltransferase (UGT) 1A9 in the liver to its major metabolite, 7-*O*-glucuronide MPA (MPAG). MPAG is a substrate for multidrug resistance-associated protein 2 (MRP2), which is responsible for biliary excretion of MPAG into the intestinal tract. Once in the colon, MPAG is de-glucuronidated by ß-glucuronidase-producing bacteria and reabsorbed as MPA. This enterohepatic recirculation is significant and can account for 10–60% of total MPA exposure, often noted in pharmacokinetic monitoring as a second peak of MPA concentration between 6 and 12 h of mycophenolic mofetil (MMF) administration. In addition, UGT 2B7 is responsible for a minor but active metabolite acyl-glucuronide MPA (AcMPAG). Urinary excretion of glucuronidated metabolites eventually accounts for the ultimate elimination of MPA, where MRP2 may play a role in active tubular secretion [7, 142, 143]. Pharmacokinetic analysis of MPA is assessed by calculating an area under the curve (AUC) profile to account for the total drug exposure and enterohepatic recirculation. Antibiotics such as metronidazole, norfloxacin, and the combination of metronidazole and norfloxacin have

Table 51.4 Documented pharmacokinetic interactions between antibiotic agents with calcineurin inhibitors and proliferation signal inhibitors [125]

Drug	Interaction drug (specific CNI studied)	Effect	Onset	Magnitude	Level of evidence	Management #
CSA/TAC	*Beta-lactams*					
	Cephalosporins					
	Ceftriaxone (CSA)	Increased CSA exposure	Delayed	Moderate	Possible	Monitor CSA/TAC concentrations closely for 1–2 weeks
	Carbapenems					
	Imipenem-cilastatin (CSA)	Increased/decreased CSA exposure	Delayed	Moderate	Possible	Monitor CSA/TAC concentrations closely for 1–2 weeks
	Penicillins					
	Ticarcillin (CSA)	Increased CSA exposure	Delayed	Moderate	Possible	Monitor CSA/TAC concentrations closely for 1–2 weeks
	Nafcillin (CSA)	Decreased CSA exposure	Delayed	Moderate	Possible	Monitor CSA/TAC concentrations closely for 1–2 weeks
	Fluoroquinolones					
	Ciprofloxacin (CSA)	Increased CSA exposure	Delayed	Moderate	Possible	Monitor CSA/TAC concentrations closely for 1–2 weeks; consider alternative fluoroquinolone
	Levofloxacin (CSA, TAC)	Increased CSA/TAC exposure	Delayed	Minimal	Possible	Not clinically significant
	Macrolides/azolides					
	Macrolides					
	Erythromycin (CSA, TAC)	Increase CSA/TAC exposure with subsequent renal, hepatic, and neurologic toxicity	Rapid	Moderate	Probable	Monitor CSA/TAC concentrations closely for 3 weeks and decrease CSA/TAC dose to 50–65% of original dose
	Clarithromycin (CSA, TAC)		Rapid	Moderate	Probable	
	Erythromycin (EVER, SIR)	Increased EVER/SIR exposure	Rapid	Moderate	Established	Reduce dose of SIR to 50% and EVER to 75% of original dose. Monitor SIR/EVER concentrations closely
	Clarithromycin (SIR)	Increased SIR	Rapid	Moderate	Established	Reduce dose of SIR to 50% of original dose. Monitor SIR/EVER concentrations closely
	Azalides					
	Azithromycin (CSA, TAC)	Increased CSA/TAC exposure	Delayed	Moderate	Possible	Monitor CSA/TAC concentrations closely for 1–2 weeks
	Azithromycin (EVER)	Increased EVER exposure	?	Minimal	Possible	Monitor SIR/EVER concentrations closely
	Antianerobic/antiparasitic agents					
	Metronidazole (CSA, TAC)	Increased CSA/TAC exposure	Delayed	Moderate	Possible	Monitor CSA/TAC concentrations closely for 1–2 weeks
	Rifamycins					
	Rifampin (CSA, TAC)	Decreased CSA/TAC exposure	Rapid	Major	Established	Monitor CSA/TAC concentrations closely for 2 weeks; consider use of alternative antimycobacterial agent^, for TAC increase dose accordingly, for CSA increase dose 1–2 mg/kg/day with three times a day dosing
	Rifabutin (CSA, TAC)		Delayed	Moderate	Possible	Monitor CSA/TAC concentration for up to 25 days after beginning rifabutin therapy and after discontinuation
	Rifampin (SIR, EVER)	Decreased SIR/EVER exposure	Rapid	Major	Established	Avoid combination; consider use of alternative antimycobacterial agent^. If unavoidable, monitor SIR/EVER concentrations closely for 1–2 weeks, and adjust dose accordingly
	Sulfonamides/sulfonamide combinations					
	Sulfadimidine/trimethoprim (CSA)	Decreased CSA exposure	Delayed	Major	Possible	Monitor CSA/TAC concentrations closely for the first 4 days
	Sulfadiazine (CSA, TAC)		?	Moderate	Possible	
	Miscellaneous agents					
	Quinupristin/dalfopristin (CSA)	Increased CSA exposure	Delayed	Moderate	Possible	Monitor CSA/TAC concentrations closely for the first 2–3 days; consider linezolid, daptomycin, or telavancin as an alternative
	Chloramphenicol (CSA, TAC)	Increased CSA/TAC exposure	Rapid	Moderate	Suspected	Monitor CSA/TAC concentrations daily for the first week; reduce initial CSA/TAC dose to 75% of original dose
	Clindamycin (CSA)	Reduced CSA exposure	Delayed	Moderate	Possible	Monitor CSA/TAC concentrations closely for the first 4 weeks
	Telithromycin	Increase CSA/TAC exposure	?	Moderate	Possible	Monitor CSA/TAC concentrations closely
	Tigecycline (CSA)	Increased CSA	Rapid	Moderate	Possible	Monitor CSA/TAC concentrations for the first 1–2 days; may need to reduce CSA dose to 50%

Recommendations are based on published literature and varied magnitude of interactions frequently occurs; therefore, individualizing a monitoring plan is always appropriate

been shown to decrease MPA 48-h AUC on average 10, 19, and 33%, respectively. To a similar magnitude, they decrease MPAG 48-h AUC [144]. The disruption of colonic and intestinal Gram-negative aerobic and anaerobic flora that produce ß-glucuronidase likely decreases enterohepatic recirculation leading to reduced drug and metabolite exposure. Similarly, pre-dose or trough MPA levels were significantly reduced from baseline in a group of renal transplant recipients that received either ciprofloxacin or amoxicillin/clavulanic acid on average by 47% between days 3 and 7 of therapy and trended to recover near baseline trough levels after 3 days following discontinuation of the antibiotics [145]. Given the complex pharmacokinetic profile, the utility of a single pre-dose MPA level is questionable, and the extent of reduced MPA AUC is not known, but the proof of an altered pharmacokinetic profile remains. It is likely that other antibiotics with the potential to disrupt the colonic normal flora may reduce enterohepatic recirculation, although this has not been specifically studied.

Rifampin has also been shown to decrease MPA exposure by both increased clearance via UGT induction and possibly inhibition of enterohepatic recirculation. A pharmacokinetic trial assessing the effect of rifampin on MPA concentrations after MMF administration showed a 17.5% reduced average 12-h MPA AUC from the baseline. Metabolite exposure measured by 12-h AUC increased by 34.4 and 193% for MPAG and AcMPAG, respectively [146]. This study showed a much lower magnitude of interaction compared to the reported MPA dose-adjusted 221% increase in 12-h AUC following rifampin discontinuation and a washout period first described by the same investigators [147]. Similarly, in pediatric liver transplant patients, 2 receiving rifampin with MMF had a four- to fivefold higher total clearance of drug from plasma ratio (CL/F) as assessed by 12-h AUC compared to 13 who did not receive rifampin. In this study, target 12-h AUCs were not attained despite dose adjustments [148].

As a whole, literature supports the existence of significant antibiotic-MPA interactions, but with a wide magnitude of variability. Further, MPA TDM is controversial and resource-intensive. At this time, it is unclear how such interactions should be monitored and managed. Broad-spectrum Gram-negative aerobic and anaerobic antimicrobials need judicious use, early de-escalation, or discontinuation when feasible, especially in the SOT recipients. In high-risk individuals, MPA AUCs may be calculated and monitored; however, evidence of improved outcomes with such an approach is currently lacking [7].

Pharmacokinetic Alterations of Corticosteroids by Antibiotics

Prednisone and methylprednisolone are two structurally similar and commonly used synthetic corticosteroids. However, these compounds differ greatly from a pharmacological perspective. Prednisone is an inactive prodrug that must be converted to the active moiety, prednisolone. Methylprednisolone is active but more susceptible to pharmacokinetic drug-drug interactions due to a methyl group at the 6α position. Corticosteroids undergo CYP3A-dependent 6β-hydroxylation which puts them at risk of interactions with other drugs [149]. Corticosteroids have also been shown to change MRP2 and P-gp activity [140]. Despite ubiquitous use in early transplantation and throughout medicine, data describing pharmacokinetic drug interactions with antibiotics are rare. Macrolides have long been considered to be "steroid-sparing" perhaps due to P-gp and CYP3A4 inhibition in addition to their anti-inflammatory effects. In asthmatics, erythromycin was shown to decrease intravenous methylprednisolone clearance by 46% [150]. Similarly, clarithromycin was shown to decrease oral methylprednisolone clearance by 65%. Interestingly, prednisolone pharmacokinetics following oral prednisone was not significantly altered by clarithromycin [151]. Thus, using an equivalent dose of prednisone or prednisolone may obviate the potential interaction with CYP3A4 inhibitors including some azole antifungal agents [125].

Rifampin has been shown to increase cortisol and prednisolone metabolism resulting in therapeutic failure of the anti-inflammatory effect when added to methylprednisolone. Prednisolone AUC was reduced by 66%, clearance increased by more than 200%, and half-life decreased by 40–60% in the presence of rifampin, reported in various clinical scenarios [152]. Although not specifically studied, a similar if not greater pharmacokinetic interaction would be expected with methylprednisolone. A doubling of the prednisolone dose may be needed to retain therapeutic efficacy. This interaction should be avoided, or rifabutin, a less potent enzyme inducer, may be substituted when possible [125, 153].

Pharmacodynamic Interactions of Immunosuppressive Agents with Antibiotics

Pharmacodynamic interactions between CNIs, PSIs, antimetabolites, corticosteroids, and antibiotics may also occur. Due to the nature of these interactions and lack of reporting, the magnitude and incidence frequently go under-recognized. For example, tacrolimus has been reported to prolong the cardiac QT interval in a concentration-dependent manner and has been associated with torsades de pointes, usually when given with other drugs with the potential for QT interval prolongation [154, 155]. It would be expected that antibiotics that also prolong the QT interval would have an additive effect on QT interval aberration. Some of these drugs include, but are not limited to, the antimalarial chloroquine, macrolides, the fluoroquinolones, and trimethoprim/sulfamethoxazole (TMP/

SMX) [156]. Often, these interactions go unrecognized and frequently may be accompanied by the addition of other drugs that have the potential for QT prolongation before a cardiac arrhythmia is noticed. Therefore, the true incidence and clinical significance of such interactions are not known. If the combination is given in a hospital setting, QT monitoring may be employed to assess for severity of cardiac toxicity. However, it is controversial whether monitoring needs to routinely take place. The use of these medications with tacrolimus should be weighed against potential risks and alternatives on a per patient basis. For example, TMP/SMX should not be withheld in transplant patients receiving tacrolimus given the weak evidence and risk of torsades de pointes compared to the benefit for the prevention and treatment of *Pneumocystis jirovecii* pneumonia. In contrast, treatment alternatives to TMP/SMX or linezolid may be considered for cancer patients with severe neutropenia or for those undergoing HSCT if clinical equipoise with an alternative exists to minimize the potential drug-induced myelosuppression.

Similarly, the addition of an aminoglycoside to a CNI may result in a higher incidence of acute kidney injury due to additive nephrotoxic effects. As with most pharmacodynamics interactions, the true prevalence and impact of nephrotoxicity are not well established; however, such interactions with cyclosporine are well-described [157]. This is of particular concern given the increased incidence of resistant Gram-negative bacterial infections and increasing limited treatment options for transplant patients with multidrug-resistant bacteria infections. The use of this combination will primarily be in hospitalized patients; therefore, close monitoring of renal function as well as any needed adjustments to CNI and aminoglycoside concentrations may minimize the potential for toxicity. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided whenever possible with patients being treated with CNI. Renal toxicity due to afferent arterial constriction with CNIs may be potentiated further with repeated NSAID use.

Another example of a potential PD interaction is the use of imipenem/cilastatin with a CNI. Both CNIs and imipenem have been associated with seizures. However, clinical data describing an increased risk of seizure with the often-used combination compared to monotherapy of either drugs is lacking [158]. Nevertheless, whenever using this combination, an assessment of seizure risk should be considered.

In summary, pharmacokinetic interactions with antibiotics and CNIs or PSIs are frequently made apparent by TDM and can be managed by dose adjustments when the interaction is unavoidable. For immunosuppressive agents without readily identifiable target ranges or available TDM, empiric dose adjustments and heightened awareness of monitoring for toxicities and keen assessment of the allograft rejection are the only available strategies that clinicians can use to manage drug interactions with these agents. Further studies are needed to elucidate the role of dose-adjusted AUC monitoring in such patients. Pharmacokinetic interactions with corticosteroids are more often than not ignored and any resultant side effects treated palliatively.

Overlapping drug effects of various immunosuppressive agents such as CNIs, PSIs, antimetabolites, or corticosteroids and antibiotics may indicate a pharmacodynamic interaction. Often dynamic interactions are a result of additive side effects and may lead to unanticipated toxicities. Because of the complexity of the interaction, patient variability, and inability to measure biochemical indicators of the interaction, the true incidence, magnitude, and clinical significance for many PD interactions remain elusive. However, they are important to consider within a clinical context when developing an antimicrobial therapeutic plan for patients undergoing transplantation. Frequently, these potential PD interactions are appropriately managed if considered and carefully monitored without requiring antibiotic substitutions.

Aerosolized Delivery of Antimicrobials

Direct delivery of antibiotics via aerosolization is an appealing method of drug delivery in transplant recipients with tracheobronchial and lung infections. This method of drug delivery avoids delays in drug delivery to the site of infection and also bypasses first-pass metabolism in the liver. Systemic exposure to the drug is minimized, which helps limit systemic drug toxicity. Aerosolized delivery of antibiotics avoids PD drug interactions associated with systemic antibiotic therapy, including the additive nephrotoxicity of aminoglycosides in combinations with the CNIs. Still, this method of drug delivery is associated with significant increases in time for drug administration, cost, and adverse respiratory effects. Furthermore, distribution of inhaled antibiotic in the lungs is not necessarily homogenous; careful consideration of PK factors affecting aerosolized medication delivery is warranted.

The partial size of the molecule delivered via inhalation is the mass aerodynamic diameter (MMAD). The MMAD is important for ensuring delivery to the lower respiratory tract; the ideal MMAD of a particle undergoing aerosolization is 1–5 um [159–161]. Drug particles having MMAD >5 um are more likely to be deposited in the oropharynx and swallowed. Particles with an MMAD <1 um are more likely to be exhaled instead of deposited in the lung [159–162]. Once delivered to the lung, antimicrobials must avoid removal by mucociliary transport in the upper lung or uptake by macrophages in the alveolar region of the lung.

The dissolution rate, which is determined primarily by the lipophilicity of the molecule, is an important factor in this process. A balance between lipophilicity and hydrophilicity is required; while lipophilicity facilitates diffusion across cell membranes to the site of action, it also expedites diffusion out of pulmonary cells into systemic circulation. Conversely, highly hydrophilic compounds may not be absorbed quickly enough to avoid mucociliary clearance and uptake by macrophages [159–162]. The proportion of drug delivered by aerosolization will also differ by the type of nebulizer used. There are three basic types of nebulizers: the jet pneumatic, ultrasonic, and the vibrating mesh (MESH) nebulizer. The jet nebulizer is most common in the hospital setting and there are many different models of the jet nebulizer [162–165]. Although generally considered equivalent, the accuracy of drug delivery, time required for drug delivery, and the amount of drug wasted can vary between jet nebulizer models. Further, the newer breath-actuated and breath-enhanced jet nebulizers, which preferentially deliver medication during inhalation and minimize it during exhalation, improve the speed of medication delivery and reduce medication waste compared to traditional jet nebulizers. Ultrasonic nebulizers lack data regarding antimicrobial delivery; therefore, this nebulizer type is infrequently utilized for this indication. MESH nebulizers use a newer technology, which generates a higher fraction of fine-particles and offers a faster, more efficient method of aerosolization [162, 164]. In general, a lower dose of antimicrobial is required when using a MESH nebulizer compared to jet or ultrasonic nebulizers. The ultrasonic and MESH nebulizers require careful cleaning after each treatment, while jet nebulizers use disposable parts.

A patient's breathing pattern will also impact the deposition of drug particles in the respiratory tract [159, 161, 166]. This consideration is especially important in lung transplant recipients. Clinical studies of single lung transplant recipients have demonstrated that the drug is preferentially delivered to the transplanted, more ventilated, lung [167, 168]. Therefore, aerosolized medication delivery may not result in antimicrobial concentrations in the native lung necessary to eradicate the offending pathogen.

Some systemic absorption will occur following the aerosolized delivery of any drug. Medications gain access to the system circulation through the highly vascularized pulmonary tissue and through intestinal absorption of the swallowed drug. Pharmacokinetic factors determine the extent of the systemic absorption and toxicity following aerosolization of an antimicrobial compound. As mentioned above, a higher degree of lipophilicity equates to a propensity for quick diffusion into systemic circulation through the pulmonary vasculature. Also, the greater the MMAD of an aerosolize particle, the more likely it is to be swallowed and available for intestinal absorption. Once an aerosolized medication is swallowed, the bioavailability of the drug molecule is important for determining systemic exposure [159–162]. A lower bioavailability means less drug is absorbed through the gut into the systemic circulation. Furthermore, the higher the total body CL of a drug, the lower the total systemic drug exposure will be. Therefore, drugs characterized by a low bioavailability and high systemic CL will be less likely to reach high systemic concentrations and potential for systemic drug toxicity.

Aerosolized Delivery of Antimicrobials: Aminoglycosides

The aminoglycosides are highly hydrophilic, polar, compounds that penetrate poorly into lung tissue following intravenous administrations. High serum concentrations are required to ensure adequate drug concentrations at the site of action, thereby increasing the potential for systemic toxicity. Local administration of aminoglycosides via aerosolized delivery is an attractive alternative to intravenous therapy, offering high concentrations at the desired location while reducing systemic exposure.

A preservative-free formulation of tobramycin (TOBI®) was developed to minimize adverse effects associated with inhalation of the molecule. This formulation is the best studied of the aminoglycosides for aerosolized administration, with most clinical data derived from studies in the CF population [169–172]. In 2013, tobramycin inhalation powder (TIP) received FDA approval; the advantage of this powder formulation is the ease of administration via simple inhaler versus a nebulizer. Aerosolized gentamicin and amikacin have also been studied, but these compounds do not have formulations specifically indicated for inhalation [173–176].

Adverse effects commonly associated with aerosolized aminoglycosides include mild, transient voice alteration, wheezing, cough, and dyspnea [177, 178]. Nephrotoxicity from inhaled aminoglycosides has been reported, including several reports involving recipients of SOT [176, 179, 180]. Clinicians should be aware of the potential for systemic adverse effects secondary to aerosolized aminoglycosides in all patients, and especially cognizant of those patients with reduced systemic drug clearance due to renal dysfunction. The potential for development of drug resistance is also a concern; however, clinical trials to date have not demonstrated this to be a significant hindrance to aerosolized therapy [171, 181].

Aerosolized Delivery of Antimicrobials: Colistin

The polymyxin antibiotic colistin causes bacterial cell death by binding and damaging the cell membranes of Gram-negative bacteria, including *Pseudomonas aeruginosa*. Colistimethate sodium and colistin sulfate are the commercially available formulations that are hydrolyzed to colistin in vivo. The use of these agents fell out of favor because of the significant nephrotoxicity and neurotoxicity associated with conventional intravenous administration. Despite these toxicities, interest in colistin has been renewed because it maintained activity against many emerging multidrug-resistant (MDR) Gram-negative bacteria. Furthermore, in an effort to avoid colistin-induced systemic toxicities, the use of aerosolized colistin has been explored. The literature evaluating colistin for hospital acquired pneumonia (HAP) and ventilator associated pneumonia (VAP) is mounting, although much of the published clinical experience to date with aerosolized colistin remains in the CF population [182–186]. Both colistimethate sodium and colistin sulfate can be aerosolized, but neither has been formulated specifically for inhalation.

Bronchospasm following inhalation of either form of colistin is relatively common, although colistimethate sodium appears to be associated with a lower incidence compared to colistin sulfate [187, 188]. When compared to aerosolized tobramycin, aerosolized colistin is associated with an increased incidence of pulmonary adverse effects [189, 190]. Once mixed with a diluent for aerosolization, both colistimethate sodium and colistin sulfate are quickly hydrolyzed to active drug and a metabolite that is toxic to lung tissue [162, 191]. Therefore, these drugs must be administered immediately after reconstitution to minimize adverse effects.

Aerosolized Delivery of Antimicrobials: Aztreonam and Other Beta-Lactams

Aztreonam, a monobactam antipseudomonal antibiotic, has been formulated as a lysine salt specifically for aerosolized administration. Aztreonam lysine (Cayston®) was developed because aerosolization of the intravenous formulation of aztreonam induces airway inflammation. Aztreonam lysine is generally well-tolerated, and the most commonly reported side effects include cough, nasal congestion, and wheezing [192]. Amoxicillin, ceftazidime, and cefotaxime have also been given via the aerosolized route [174, 193, 194]. These treatments were generally well-tolerated, although the small sample sizes of patients evaluated in published reports preclude any conclusions regarding the efficacy or safety of these drugs given via aerosolized route.

Aerosolized Delivery of Antimicrobials: Chronic Suppressive Therapy

Airway colonization with *P. aeruginosa* is linked to an increased risk for bronchiolitis obliterans syndrome (BOS) after lung transplant [195]. Clinical studies in the CF population have demonstrated that chronic suppressive therapy in patients with mild to severe disease severity results in a reduction in the frequency of pulmonary exacerbations, improved FEV1, and/or a reduced requirement for intravenous antipseudomonal antibiotics [169–171, 189, 196–198]. A retrospective, single-center study compared outcomes of lung transplant patients with CF who were prescribed inhaled colistin at one million international units twice daily with posttransplant CF counterpart in whom inhaled colistin was not given. [199]. Groups were stratified based on the presence or absence of bacterial colonization prior to colistin initiation. There were no standardized criteria for colistin initiation in either group. The investigators found that aerosolized colistin was associated with a reduced number of hospitalizations due to infections in the group without previous bacterial colonization; however, this favorable association was not found in patients with prior bacterial colonization. These results suggest a potential role for inhaled colistin as prophylaxis against infection-related hospitalization in CF patients following lung transplantation; additional studies are needed. No published study to date has specifically evaluated the use of inhaled tobramycin or aztreonam in CF patients after undergoing lung transplantation. However, based on data in the pretransplant CF population, it seems reasonable to consider inhaled tobramycin or aztreonam (as well as to inhaled colistin) in patients with chronic, recurring *P. aeruginosa* lung infection after lung transplantation.

Aerosolized Delivery of Antimicrobials for Hospital-Acquired Pneumonia

Due to chronic immunosuppression and impaired host defenses in the lower respiratory tract, transplant recipients are at high risk of hospital acquired pneumonia (HAP), including ventilator associated pneumonia (VAP) [200]. Furthermore, recipients of allograft transplants are at a higher risk of infection due to MDR organism(s) resulting from extensive prior exposure to broad-spectrum antibiotics and underlying immune suppression. The American Thoracic Society and Infectious Diseases Society of America Guidelines now recommend the use of both inhaled and systemic antibiotics in patients with VAP due to certain MDR organisms [200].

Much of the evidence for aerosolized therapy in MDR HAP and VAP is with aerosolized colistin. In observational case reports of patients with MDR organisms, aerosolized

colistin in combination with systemic antibiotics has been associated with increased response rates. One randomized trial demonstrated that the addition of aerosolized colistin to standard therapy conferred a higher likelihood of either confirmed or presumed MDR bacterial eradication, but a beneficial effect on clinical outcome was not demonstrated [188]. In a retrospective multicenter cohort analysis of critically ill patients with MDR Gram-negative pneumonia, an increased clinical cure rate was observed in patients receiving IV colistin plus inhaled colistin versus those who received IV colistin alone [201]. The authors of a recent meta-analysis concluded there was a positive albeit low-quality evidence, demonstrating the addition of aerosolized colistin to systemic antibiotics for VAP is associated with improved outcomes [202].

Although aerosolization of aminoglycosides is an attractive treatment option for patients with HAP for reasons already discussed, there is a paucity of data assessing such practice in a large prospective randomized clinical trial. Small trials have shown that inhaled tobramycin and gentamicin were associated with some positive outcomes in patients with pulmonary infections [178, 202, 203]. In one trial of 37 patients with VAP, intravenous amikacin plus ceftazidime was compared to inhaled amikacin and ceftazidime [193]. Although the trial found no statistically significant differences in clinical outcomes between the groups, the aerosolized group had a numerically higher rate of bacterial eradication and clinical success. Three patients in the intravenous therapy group demonstrated resistance to ceftazidime following treatment initiation compared to no patients with de novo ceftazidime resistant bacteria in the aerosolized group.

Aerosolized Delivery of Antimicrobials for Nontuberculous Mycobacterial Infection

Aerosolized amikacin has been used clinically in combination with other agents for the treatment of nontuberculous mycobacterial infections [175, 204]. Reasons for aerosolized delivery of amikacin in this patient population include pulmonary infections refractory to traditional treatment, drug interactions, and intolerance to oral agents and intravenous amikacin or both. While aerosolized delivery of amikacin was associated with therapeutic success in the aforementioned reports, routine administration of aerosolized amikacin is not recommended due to a relative lack of published data evaluating this practice.

Aerosolized Delivery of Antimicrobials: Other Investigational Therapies for Inhalation

Numerous clinical trials investigating aerosolized antibiotics are currently underway. Fosfomycin, a phosphonic acid antibiotic with a broad spectrum of action, has been formulated in combination with tobramycin for inhalation. In a Phase II trial of 119 patients with CF, fosfomycin plus tobramycin for inhalation (FTI) was compared with placebo in a randomized, double-blinded study following a 28-day course of inhaled aztreonam [205]. Relative improvements in FEV1 achieved during aztreonam therapy were better maintained in patients receiving FTI compared to placebo. The common adverse effects of FTI were cough, dyspnea, fever and wheezing.

Inhaled levofloxacin (Aeroquin™) in a Phase III study did not significantly reduce the time to next pulmonary exacerbation in CF patients when compared with CF patients given placebo [206]. A Phase III study of the new liposomal formulation of amikacin (Arikace™) for the treatment of Nontuberculous mycobacterial (NTM) infection is currently recruiting subjects [207]. A formulation of vancomycin for aerosolization (Aerovanc™) was evaluated in a Phase II trial for Methicillin resistant staphylococcus aureus (MRSA) in CF patients; however, the results of this trial are not available at the time of this publication [208].

Immunomodulation

As previously mentioned, the macrolide antibiotics—including the azalide, azithromycin—have been considered "steroid sparing" in part due to their anti-inflammatory effects. These anti-inflammatory and immunomodulating effects are not surprising given that tacrolimus, sirolimus, and everolimus are non-antibiotic macrolide chemicals. However, the mechanism of immunomodulation for the macrolide antibiotics is less clear and seems to be multifactorial. Several recent reviews of the immunomodulatory properties of macrolide and other antibiotics have been published [209–213], warranting a brief review of the anti-inflammatory and immunomodulatory effects of macrolide, tetracycline, fluoroquinolone, sulfone, and sulfonamide antibiotics. The impact of antibiotics on the hosts' microbiome and subsequent immunomodulation is a rapidly expanding area of research that is beyond the scope of this chapter.

Macrolide Antibiotics

Interest in the anti-inflammatory effects of macrolide antibiotics was ignited with the successful use of erythromycin in the treatment of diffuse panbronchiolitis (DPB), an inflammatory lung disease. Follow-up studies showed both erythromycin and roxithromycin reduced IL-8, IL-1β, and neutrophils in bronchoalveolar fluid of patients with DPB [209, 214]. The clinical effects of macrolides in DPB have been replicated for clarithromycin and azithromycin, and these effects are likely due to similar immunomodulating properties [215].

Since then, macrolides have been extensively researched for their non-antibacterial effects. Although exact mechanisms are not always clear, drug-mediated decrease inflammation through inhibiting proinflammatory cytokines and chemokines, such as IL-1, IL-2, IL-5, IL-6, TNFα, GM-GCSF, and IL-8, and various chemokine ligands, and they may also promote a milieu favoring anti-inflammatory cytokines [209–211, 216]. Studies also suggest macrolides inhibit phagocyte oxidative burst, promote phagocytosis of apoptotic cells by alveolar macrophages, stimulate neutrophil exocytosis, and reduce adhesion molecule I in bronchial epithelial cell, thereby potentially reducing leukocyte adhesion [210, 216]. Overall, macrolide antibiotics have shown anti-inflammatory effects on cytokine production and distinct immunomodulation of neutrophils. A common unifying mechanism for the immunomodulatory effect of macrolide antibiotics on the host immune system is unknown but likely related to high intracellular accumulation. Regardless, the immunomodulatory properties of macrolides are broad, and their use beyond antibiosis has increased considerably.

More recently, a complementary immunomodulatory effect of solithromycin, a late generation fluoroketolide receiving US Food and Drug Administration "Qualified Infectious Disease Product" status, has been investigated in concert with its antibacterial activity. In very late 2016, the drug is awaiting FDA approval to the US market for community-acquired bacterial pneumonia (CABP). An anti-inflammatory effect of solithromycin shows a decreased response of macrophages to produce lipopolysaccharide (LPS)-induced TNFα and IL-8. In a study of 132 adult ambulatory patients presenting with chest radiograph consolidation and having signs and symptoms of CABP, 5 days of oral solithromycin or levofloxacin was compared. The efficacy rates determined by early clinical response (ECR) and overall success at end of treatment and test of cure visits were considered comparable. The investigators attributed the comparable ECR rates of the slow-kill fluoroketolide to the rapidly bactericidal quinolone to solithromycin's immunomodulatory effects [217].

A study of an ovine (sheep) model of intrauterine infection with *Ureaplasma parvum* compared the administration of maternal intravenous azithromycin (AZ) or solithromycin (SOLI) or placebo. At 120-day gestational age (GA), sheep received a single regimen among five distinct regimens which included either IV AZ or SOLI, or placebo or IV + intra-amniotic AZ or SOLI, or placebo. Baby lambs were surgically delivered at 125-day GA. While the amniotic fluid (AF) of all control animals contained culturable *U. parvum*, the AF, lung, and chorioamnion from all AZ- or SOLI-treated animals were culture-negative. Compared to controls, the levels of expression of IL-1β, IL-6, IL-8, and monocyte chemoattractant protein 2 (MCP-2) in fetal skin were significantly decreased in the IV SOLI cohort, and the MCP-1 protein concentration in AF was significantly increased in the IV + IA SOLI cohort. No significant differences in histological inflammation scoring of the lung or chorioamnion were noted among the five active and placebo treatment groups. As intrauterine inflammation is thought to be a major influence to infection-associated preterm birth (PTB), the anti-inflammatory properties of these macrolides may be of value in stunting infections leading to PTB [218].

Tetracycline Antibiotics

Tetracycline antibiotics also exhibit non-antibacterial effects. Most notably is the effect of doxycycline on matrix metalloproteinases (MMPs). Doxycycline is reported to inhibit MMPs to a greater extent than tetracycline or minocycline due to its increased affinity for zinc ions; however, anti-inflammatory effects of both doxycycline and minocycline have been reported [212]. Doxycycline has been studied and shown to be beneficial for gastric ulceration and oxidative stress in rats and ischemia-reperfusion injury in rat hearts by modulating MMP activity [212, 219]. Tetracyclines also scavenge reactive oxygen species, a driver for ischemia-reperfusion injury, which may partially explain its benefit. In addition, minocycline and doxycycline have been shown to have anti-apoptotic effects following global brain ischemia in gerbils. Minocycline, having greater penetration across the blood-brain barrier, has been studied for its neuroprotective anti-apoptotic effects in models of traumatic brain injury, Huntington's disease, and Parkinson's disease. Protective mechanisms are thought to involve reduced caspase-1 and/or caspase-3 expression and inhibition of cytochrome c release from the mitochondria [212, 220]. Finally, doxycycline has been shown to reduce cytokines IL-1α, IL-1β, IL-6, IL-8, and TNFα while increasing IL-10 and IL-12 after human monocytes were challenged with an oral pathogen [221].

Fluoroquinolone Antibiotics

The fluoroquinolone antibiotics have shown conflicting effects on the immune system in vitro ranging from anti-inflammatory to neutral to proinflammatory depending on the experiment methods, cell type, fluoroquinolone, and concentration used. Most in vivo data, however, suggest fluoroquinolone antibiotics modulate the immune system by decreasing proinflammatory cytokines. Ciprofloxacin was shown to reduce TNFα and IL-12 and increase IL-10 during a lipopolysaccharide challenge in mice. Although conflicting data on the immunomodulatory effects of fluoroquinolones exist, the balance of data suggests an anti-inflammatory effect. The mechanism for these actions is still unclear but thought to be possibly mediated by increasing cyclic AMP and acting on cellular transcription factors [213].

Dapsone and Sulfonamides

Compared to newer antibiotics, little data exist evaluating the anti-inflammatory effects of dapsone and sulfonamides, such as sulfamethoxazole. Dapsone has been used to treat urticaria in rare cases [222] and likely has immunomodulatory effects on neutrophils by inhibiting chemotaxis and oxidant production. The exact mechanism is unknown, although dapsone has been shown to inhibit myeloperoxidase [210].

Sulfonamide antibiotics, namely, sulfamethoxazole, used commonly in combination with trimethoprim, inhibit dihydropteroate synthase decreasing tetrahydrofolate synthesis in bacteria. The sulfonamide class of chemicals has a wide range of clinical applications including inflammatory conditions such as Crohn's disease and ulcerative colitis. Sulfamethoxazole's hydroxylamine metabolite has been implicated in inhibiting peripheral blood monocytes in vitro, reducing antibody production, and interfering with T lymphocyte signaling and proliferation [223–225]. Synergistic immunosuppression between tacrolimus and cyclosporine with the hydroxylamine metabolite was shown in mononuclear leukocytes [226].

In summary, a variety of immunomodulating effects from many antibiotics have been reported. Macrolide antibiotics are currently used in respiratory disease partially for their anti-inflammatory properties. The tetracyclines are used in mouthwashes for periodontal diseases and under investigation for various neurologic disorders. The sulfonamides are used for a wide variety of indications outside of antibiosis including inflammatory disorders. With exceptions for macrolides in respiratory diseases, the overall impact of antibiotic immunomodulation antibiotics is largely unknown and requires further research.

Conclusion

Placebo-controlled, pharmacokinetic drug interaction trials are lacking for most commonly used antibiotics. Consequently, evidence supporting suspected, possible, or probable interactions is often presented in the form of case reports and case series-literature. Although currently not well defined, pharmacogenomic factors such as CYP3A, MRP, and P-gp expression may help better predict relevant drug interactions at an individual level and become clinically useful. Advancements within pharmacogenomics beyond our present understanding someday in the near future may result in minimizing the impact of these interactions. For now, among recipients of SOT and HSCT, the drug classes of antimicrobials and immunosuppressives are inextricably woven, each very much contributing to prolonged survival of these patients. The current state of aggressive nosocomial infection, especially regarding virulence and antibiotic resistance characteristics, strenuously support antibiotic optimization principles [227]. Still, whether in the newly transplanted solid organ allograft recipient or the bone marrow transplant recipient long past engraftment, the successful concomitant use of antimicrobials and immunosuppressives demands for clinical vigilance to monitor efficacy and consideration for potential drug interactions and, notably, constant reassessment regarding adverse effects of antimicrobial therapy in this highly susceptible transplant population.

Antifungal Consideration for Transplant Recipients

52

Yanina Dubrovskaya, Man Yee Merl, David S. Perlin, and Amar Safdar

Introduction

Due to recent advances in hematopoietic stem cell and solid organ transplantation (HSCT and SOT, respectively), the disease-free survival among transplant recipients continues to improve. Prolonged immunosuppression, conditioning preparatory chemotherapy, extended duration of pre-HSCT engraftment neutropenia, drug given to suppress adaptive cellular immune response for prevention and treatment of GVHD, and for preservation of visceral allograft predisposes transplant recipients to opportunistic fungal disease. These infections increase morbidity and risk of death among patients undergoing at risk transplantation procedures [1, 2].

Antifungal Classes

Three main classes of antifungal agents are available for systemic prophylaxis and treatment of invasive fungal infections (IFIs). These include polyenes, triazoles, and echinocandins.

Polyenes such as nystatin and amphotericin B (AmB) were the first drugs to be approved for clinical use in the United States; AmB deoxycholate became available for human use in 1957. AmB is a polyene macrolide antibiotic derived from the actinomycete *Streptomyces nodosus*. AmB is approved for the treatment of aspergillosis, cryptococcosis, blastomycosis, systemic candidiasis, coccidioidomycosis, histoplasmosis, and mucormycosis. AmB is named for its amphoteric behavior. It forms relatively soluble salts in basic or acidic aqueous media; however at the physiologic pH, it becomes insoluble in aqueous solutions. AmB is formulated for intravenous (IV) administration as a colloidal suspension by using the bile salt deoxycholate and sodium phosphate buffer. During the 1990s, lipid formulations, amphotericin B lipid complex (Abelcet®, ABLC), amphotericin B colloidal dispersion (Amphotec®, ABCD), and liposomal amphotericin B (AmBisome®, L-AmB) were developed to mitigate nephrotoxicity common with exposure to AmB deoxycholate. ABLC was approved for second-line treatment of IFIs in patients with refractory infections or those who were intolerant to AmB therapy. L-AmB was approved by the Food and Drug Administration (FDA) for empirical therapy in patients with febrile neutropenia, for the treatment of cryptococcal meningitis in human immunodeficiency virus (HIV) patients, for treatment of visceral leishmaniasis, and second-line treatment of aspergillosis, candidiasis, or cryptococcosis refractory to AmB deoxycholate or in patients, in whom renal impairment or unacceptable drug toxicity precluded the use of AmB deoxycholate. Lipid formulations of AmB are generally considered interchangeable with AmB but with considerably improved safety profiles [3–7].

The discovery of azole-based antifungal drugs was a notable step forward given the safety, efficacy, and oral bioavailability of these agents. The azoles are characterized by their core five-member azole ring, which contains two nitrogen (imidazoles) or three nitrogen molecules (triazoles). Triazole-based antifungals include fluconazole, itraconazole, voriconazole, posaconazole, and isavuconazonium sulfate. Favorable safety profile, fungal enzyme-specific target without crossover damage to mammalian cells unlike

AmB make them preferred agents to treat IFIs. The newer triazoles known for their mold-active potency such as voriconazole, posaconazole, and isavuconazonium sulfate are synthetic derivatives of fluconazole and itraconazole with an improved spectrum of activity against filamentous fungi. Fluconazole was approved for treatment of candidiasis, cryptococcal meningitis, and antifungal prophylaxis in patients undergoing HSCT. Voriconazole was licensed in the United States in 2003 as a first-line agent to treat patients with invasive aspergillosis (IA) and invasive candidiasis in the non-neutropenic host and as a second-line therapy for IFIs due to *Scedosporium* and *Fusarium* species. Posaconazole was initially approved in 2006 for IFI prophylaxis in severely immunocompromised patients undergoing HSCT with GVHD and for the treatment of oropharyngeal candidiasis [3, 4, 8–11].

The echinocandin drugs caspofungin, micafungin, and anidulafungin are semisynthetic derivatives of a separate class of antifungals known as pneumocandins. These are large lipopeptide molecules with amphiphilic cyclic hexapeptide and *N*-linked acyl lipid side chain and can only be administered via IV route. The differences in composition of the side chain make each echinocandin structurally unique. Caspofungin acetate was first in this class to become available for clinical use (approved in 2001) as an agent for patients with conventional AmB treatment-refractory IA. This was soon followed by an expanded label indication including empiric therapy for presumed fungal infections in patients with febrile neutropenia and treatment of invasive candidiasis. Subsequently, micafungin and anidulafungin were added. Micafungin was approved by the FDA in 2005 for treatment of invasive candidiasis and prophylaxis of invasive candidiasis in HSCT recipients. Anidulafungin was approved in 2006 for the treatment of invasive candidiasis [3, 4, 12–14].

Mechanism of Action

Polyenes target the fungal cytoplasmic membrane by specific interaction with ergosterol in the fungal cell membrane by creating nonaqueous and aqueous channels. Efflux of potassium through the pores results in the loss of membrane potential and subsequent physiologic collapse and cell death. At low concentrations of AmB, the channels are permeable only to monovalent cations such as potassium. At high concentrations of AmB, the nonaqueous channels interact with cholesterol in the mammalian host cell membrane to form aqueous pores that are permeable to chloride and potassium. This results in increased permeability to H^+/OH^-, intracellular acidification, and subsequent membrane damage. AmB has higher affinity for ergosterol than mammalian cholestrol; ergosterol being the primary sterol constituent of fungal cell membrane. However, binding of AmB to cholesterol in mammalian cells results in drug-induced cellular toxicity as evident in common and often serious adverse events associated with its use. Other potential antifungal mechanisms of polyenes include (a) damage to the fungal cell wall at lower (below minimum inhibitory concentration [MIC]) concentrations, (b) modulation of hosts' immune and inflammatory response, and (c) promoting oxidative damage [3–7].

Azoles exert antifungal action on fungal cell membranes by blocking the biosynthesis of ergosterol. Azole-mediated inhibition of cytochrome P450 (CYP)-dependent 14-α-demethylase (CYP51) interferes with the conversion of lanosterol to ergosterol resulting in accumulation of methyl sterols, which cause disruption of fungal cellular function, impede fungal growth and replication. Inhibition of fungal ergosterol synthesis by triazoles results in cross-inhibition of some CYP-dependent enzymes in humans, an important mechanism for drug toxicity and drug-drug interactions associated with these agents [3, 4, 8–11]. The azole compounds exhibit varying degree of affinities for CYP-dependent 14-α-demethylase, which in return reflect upon their differential antifungal activity, adverse events, and extent of drug-drug interaction [15].

Echinocandins act through the inhibition of glucan synthase, an enzyme responsible for synthesis of β-1,3-D-glucan, which is an integral component of fungal cell wall. Decreased β-(1,3)-D-glucan cell wall content results in cell dysmorphia, weakened cell wall due to loss of cell integrity promoting cell lysis. Because mammalian cells do not contain glucan synthase or a cell wall, the echinocandins do not affect the integrity of human cells. The genes that encode β-(1,3)-D-glucan synthase complex are *FKS1*, *FKS2*, and *FKS3*, although *FKS3* is expressed at a very low level. Transcription of fungal cell wall proteins in some yeasts like *Candida glabrata* is regulated by *FKS2* and dependent on the enzyme calcineurin, whereas *FKS1*-linked proteins are regulated by fungal cell turnover [16].

Spectrum of Activity

AmB is a broad-spectrum antifungal agent, with activity against many clinically relevant yeasts and molds**.** It has demonstrated clinical activity against nearly all *Candida* species except certain isolates of *Candida lusitaniae, Candida guilliermondii*, and many strains of *Candida auris.* AmB is active against dimorphic fungi such as *Blastomyces*, *Histoplasma, Coccidioides*, and *Cryptococcus* spp. It is also active against filamentous molds, such as *Aspergillus* spp. and organisms associated with mucormycosis among other rare molds.

Important limitation of AmB coverage includes *Aspergillus terreus*, *Scedosporium apiospermum*, *Fusarium* spp., *Paecilomyces* spp., *Sporothrix schenckii,* and mostly

pan-drug-resistant *Scedosporium prolificans* [3–7, 17]. Azoles are active against *Candida* spp., dimorphic endemic fungi, and *C. neoformans*. Among non-*albicans Candida* spp., azoles have variable dose-dependent activity against *C. glabrata.* Fluconazole is not active against *C. krusei, C. auris*, and filamentous fungi, whereas itraconazole has activity against *Aspergillus* spp. and some rarer molds. Voriconazole has activity against *Aspergillus* and *Fusarium* spp.; posaconazole and isavuconazonium sulfate is active against *Aspergillus, Fusarium*, most *Zygomycetes* species among other rarer molds [3, 4, 8–11, 17].

Echinocandins are broadly active against all *Candida* spp. including isolates resistant to other antifungal agents. Echinocandins have reduced in vitro activity against isolates of *C. parapsilosis* and *C. guilliermondii*, but this lesser activity does not appear to correlate with clinical treatment failure. These agents are not active against *C. neoformans*, *Fusarium*, and most *Zygomycetes* spp. In addition, *A. lentulus* is an emerging *Aspergillus* species associated with IA in patients undergoing allogeneic HSCT, heart, kidney, and liver allograft transplantation; this organism tends to be resistant to echinocandins [3, 4, 12–14, 17].

Resistance

Mechanisms of antifungal resistance are either primary or secondary and are related to intrinsic or acquired fungal characteristics [18]. Intrinsic resistance is defined as resistance to all or almost all isolates of a species to a antifungal drug, which does not involve an acquired resistance often seen following exposure to such a drug. Primary resistance occurs in organisms that have not been exposed to a specific antimicrobial agent in clinical practice. It is a significant factor contributing drug resistance among patients with invasive fungal disease resulting in a selection of inherently less susceptible fungal species. In contrast, secondary or acquired drug resistance arises after treatment with an antimicrobial agent; this is less prevalent and alludes to de novo mechanism(s) that confer reduced susceptibility for an organism, to which it was previously susceptible[19].

Poor therapeutic response to polyenes is generally relegated to inherently resistant molds such as *A. lentulus*, *A. terreus*, *Pseudallescheria boydii, Scedosporium apiospermum*, *Scedosporium prolificans*, *Paecilomyces lilanicus*, and *Fusarium* spp. and to some yeasts with varying degree of susceptibility such as *C. lusitaniae* and *C. auris***.** Mutation in genes involved in ergosterol biosynthesis pathway have the abilty to foist lack of susceptibility to AmB in such fungal strains, whereas, molecular mechanism(s) involved in inherent resistance remain elusive for a variety of fungal pathogens [19]. Secondary resistance to AmB is rare, even in patients with clinical failure to AmB; in contrast, resistant mutants may be selected in vitro experiments after exposure to AmB [20]. Prior exposure to azoles, such as itraconazole that acts by lowering fungal cell membrane sterol concentration, may unwittingly confer subsequent reduced susceptibility to polyenes [21]. Acquired resistance to AmB has been most extensively evaluated in yeasts and is associated with mutations in sterol biosynthesis genes like *ERG1*, *ERG2*, *ERG3*, *ERG4, ERG6*, and *ERG11*. For example, mutations in *erg3* encoding for C-5 sterol desaturase lead to qualitative and quantitative alterations of membrane lipids and an absence of ergosterol [22]. It should be noted that deletion of *erg3* genes in *A. fumigatus* did not change AmB susceptibility despite such mutants exhibited a marked alteration of cell membrane sterol composition including reduced ergosterol content [23]. This may reflect a more complex biosynthesis pathway for sterols in *Aspergillus* spp. Finally, *A. terreus* compared with *A. fumigatus* exhibits high catalase production, which has been suggested to undermine AmB-associated oxidative fungal damage, thereby resulting in ineffective drug-induced cell death [24].

The molecular mechanisms responsible for triazole resistance are common to most yeasts and molds [25, 26]. Three major mechanisms have been elucidated in recent years. First, mutations in the drug target, CYP450 14-α-demethylase, encoded by e*rg11* among yeasts and c*yp51A* among the filamentous fungi, alter the apparent drug-binding domain [27, 28]. Second, overexpression of drug efflux transporters belonging to the adenosine triphosphate (ATP) binding cassette (ABC) and major facilitator system (MFS) classes reduces the intracellular steady-state drug levels [29]. Finally, azole resistance resulting from upregulation of demethylation target [25]. The evolution of drug resistance in susceptible yeast involves either a single-step mechanism or a progressive accumulation of mutations resulting in changes in target site affinity and induction of various drug efflux transporters or both. Many of these mechanisms are induced by changes in major transcriptional regulators such as Tac1, Pdr1, which are influenced by gain-of-function mutations and changes in copy number due to genomic modifications resulting in loss of heterozygosity and isochromosome formation [30–32]. This multifactorial basis of azole resistance in clinical isolates is widely observed [25, 33, 34]. For molds like *A. fumigatus*, target site modification is the principal mechanism of clinical resistance. Mutations in *cyp51A* gene result in structural alteration to the enzyme, which in turn inhibit binding to the drugs. Prominent mutational hotspots confirmed to cause multiazole resistance that have been characterized at amino acid positions Gly54, Met220, and Leu 98 [35, 36]. Other mutations in the *cyp51A* gene have been reported, and additional resistance mechanisms are postulated [35]. In Europe, nearly all resistance is due to tandem repeat mutations in the promoter region of *cyp51A* along with specific mutations in the coding region

with the mechanisms TR34/L98H, TR46/Y121F/T289A [37, 38]. These prominent resistant isolates have been observed globally in more than 22 countries [39] and appear to arise as consequence of azole use in the agricultural industry and are selected out as primary resistance [40]. This specific resistance mechanism has rarely been observed in patients with fungal infections, in whom resistance develops during antifungal therapy. Azole resistance to *cyp51A* mutations is a growing phenomenon worldwide, and its magnitude may be overestimated, as chronic *Aspergillus* infection is often cryptic and can only be detected through molecular techniques [41, 42]. Overexpression of ABC and MFS drug transporters is a common mechanism in *Candida* species, but their role in *Aspergillus* is still not clear [43, 44]. Finally, in a small percentage of fungal isolates, the mechanism of triazole resistance remains uncertain.

Echinocandin resistance in *C. albicans* and most other *Candida* spp. occurs in two highly conserved "hotspot" regions of *FKS1* [45–48]. These limited regions encompass residues Phe641-Pro649 and Arg1361. In *C. glabrata*, the comparable mutations are found in either *FKS1* or *FKS2* [46, 49]. Mutations in *FKS* genes induce elevated MIC values 0.5–2 logs and reduce the sensitivity of glucan synthase IC_{50} or K_i to drug by 50- to 3000-fold [45, 49, 50]. Most clinical breakthrough infections were observed due to *C. albicans* and *C. glabrata*, which are the two common *Candida* spp. associated with yeast invasive disease in the immunocompromised patients. For *C. albicans*, amino acid changes at Ser645 (S645P, F, Y) are the most abundant and cause the most pronounced resistance phenotype; other substitutions at F641, L642, T643, L644, A645, L646, R647, and D648 account for remaining resistance [48–53]. In *C. glabrata* mutations, conferring resistance occurs in both *FKS1* and *FKS2*. S663P in *FKS2* is the most prominent amino acid substitution in more than half of the cases [49, 52]. Other substitutions in *FKS2* include F569S, F559V, Y, L664R, D666G, E, and P667T in hotspot 2, W1375L. In *C. glabrata*, some isolates contain nonsense mutation in either *FKS1* or *FKS2* and a *fks* mutation in the corresponding allele [46, 49]. Not all *FKS* mutations confer the same strong resistance phenotype and are less likely to result in breakthrough disease. On the basis of MIC testing of clinical isolates, pharmacokinetic-pharmacodynamic (PK-PD) studies, and kinetic inhibition of glucan synthase, an order for strength of resistance associated with substitutions at *fks* residues was proposed: S645, F641> > L642, T643, L644, L646, R647, and D648 > P649 [51]. In PK-PD studies involving Fks1-Ser645 substitutions, micafungin even in high doses was insufficient to elicit an antifungal response, suggesting that conventional dose therapy with micafungin would not be effective in treating infections due to such organisms [54]. However, yeast's behavior with the most prominent *FKS2* mutation Fks2p-S663F unlike *FKS1* mutant, Fks1p-S629P, in *C. glabrata* has responded to elevated drug dosing [53]. Furthermore, *C. glabrata* strains harboring the mutation Fks2p-P667T and Fks2p-D666F also differentially responded in a dose-dependent fashion to the three echinocandin drugs [54]. Drug-response relationships for high MIC mutant *Candida* strains may provide an approach to stratify resistance and assess dosing solutions to overcome potential lack of clinical response to therapy without the need to change drug class [55].

Toxicities

Systemic toxicity with AmB is well known. Nephrotoxicity is associated with dose-dependent reduction in glomerular filtration rate. Other effects on renal function include potassium, magnesium, and bicarbonate wasting and decreased erythropoietin production. Azotemia caused by AmB is often worse in patients taking other nephrotoxic drugs. Presence of hypotension, renal allograft transplantation, and preexisting chronic kidney disease increases the probability for AmB drug-induced azotemia. In infusion-related reactions such as fever, chills, rigors, tachypnea, and worsened hypoxemia in patients with preexisting cardiac or pulmonary disease. It is important to note that infusion-related adverse events tend to improve in severity as treatment with AmB is continued [3–5, 56]. The infusion toxicities are most prominent with AmB deoxycholate, whereas AmB lipid formulations are better tolerated [6, 7, 57]. Renal preservation was comparable for ABLC and L-AmB either given as prophylaxis or for treatment of invasive fungal disease [57].

Generally, azoles are well-tolerated drugs. Fluconazole has an excellent safety profile. Most adverse effects associated with fluconazole are minor and usually gastrointestinal in nature. Fluconazole carries modest risk of QTc (corrected QT interval)-interval prolongation rarely resulting in torsades de pointes. Elevation of hepatic transaminase levels is seldom seen even in patients treated with high-dose fluconazole given for an extended duration. These events typically occur in patients with a higher susceptibility for such events. Reversible alopecia is not uncommon with fluconazole [3, 4, 9, 58].

Posaconazole is associated with mild to moderate gastrointestinal symptoms including altered taste and reduced appetite; mild nausea is not uncommon in transplant patients receiving posaconazole. Liver toxicity is however, a serious concern with this agent, especially in the transplant population, and often due to concurrent use of other agents with hepatotoxicity risk profile [3, 4, 11]. Two unique adverse events were noted with voriconazole use: (1) dose-related reversible disturbance of vision or photopsia that may present as photophobia, changes in color vision, increased or decreased visual acuity and light perception, or blurred vision and (2) cutaneous phototoxicity. Visual disturbances are usually mild and

transient and abate as treatment is continued beyond first week. Similarly, cutaneous phototoxicity is reversible after discontinuation of therapy. An elevation in serum transaminases levels, skin rash reported in nearly 8% of patients, and visual hallucinations in up to 4% of patients receiving voriconazole therapy have been reported. The cyclodextrin vehicle in IV formulation of voriconazole can accumulate in patients with insufficient renal clearance [3, 4, 10].

Itraconazole carries less favorable toxicity profile among the azole-based drugs. A negative inotropic effect that may precipitate congestive heart failure is a unique cardiotoxicity associated with itraconazole. The US federal registration and labeling guideline recommends avoidance of itraconazole in patients with heart failure. Oral itraconazole solution contains a cyclodextrin carrier which can cause gastrointestinal toxicity such as nausea, vomiting, diarrhea, and abdominal pain; these adverse events, if severe, may necessitate discontinuation of therapy. Like other azoles, itraconazole use may result in hepatic toxicity ranging from mild, transient elevations of hepatic enzymes to rare cases of life-threatening liver failure [3, 4, 8]. Close monitoring of liver function is recommended with all members of the azole-based drugs, especially in the at risk transplant population.

Overall, the echinocandin class has the most favorable safety profile. Echinocandin may infrequently lead to hepatic dysfunction, whereas, acute liver failure is an exceedingly rare complication. In clinical trials, all three currently licensed echinocandins show a comparable increase in liver enzymes, when compared with patients treated with polyene or triazole drugs. Monitoring liver enzymes is recommended during echinocandin therapy. A histamine-mediated, infusion-related reaction was seen in some patients; slowing the rate of infusion and pre-infusion antihistamines are effective [3, 4, 12–14].

Clinical Efficacy

Primary Antifungal Prophylaxis in HSCT Recipients

Primary antifungal prophylaxis with fluconazole has become the standard for patients undergoing HSCT since the early 1990s. The studies compared fluconazole with placebo or oral nonabsorbable agents and demonstrated significant 8–14% reduction in the cases of proven IFIs among patients following transplantation [16, 59–64]. Furthermore, fewer IFI-related deaths in fluconazole prophylaxis arm was encouraging [16, 60–62, 64, 65]. A significant reduction in overall mortality and probability of death up to 3 months after stem cell transplantation was an important finding (31 vs. 52 deaths in fluconazole and placebo groups, respectively [p = 0.004]) [16, 60]. The limitations for the prophylaxis studies are reflected in the variability among (a) the distribution of autologous vs. allogeneic HSCT recipients, (b) duration of antifungal prophylaxis after transplantation, and (c) dose of fluconazole used [16, 60–62, 64, 65]. In addition, breakthrough IFIs with *C. glabrata*, *C. krusei*, *Aspergillus* spp., and mucormycosis have occurred in patients given fluconazole prophylaxis [16, 60–62, 64]. Old age, concurrent use of antibacterial chemoprophylaxis, cytarabine plus anthracycline-based chemotherapy, and high *Candida* colonization index were identified as independent risk factors for fluconazole failure [64].

Routine use of recombinant myeloid growth factors, a decline in conventional myeloablative preparatory transplant conditioning regimens have favorably shortened the duration of pre-engraftment neutropenia. In addition, selective and less toxic conditioning regimens such as non-myeloablative stem cell transplantation and lower risk of orointestinal mucosal disruption have also favorably reduced invasive candidiasis risk during early transplant period. Despite these important improvements, risk for invasive mold infections continue to remain a serious concern for high-risk allogeneic HSCT recipients. The incidence of mold infection including IA in autologous stem cell transplant recipients is low, with a few following exceptions: (1) heavily pretreated patients with multiple myeloma and (2) those with fludarabine therapy for lymphoproliferative disorders [65].

The current National Comprehensive Cancer Network (NCCN) guidelines on prevention and treatment of cancer-related infections recommend fluconazole 400 mg daily among other antifungal agents for antifungal prophylaxis in autologous HSCT recipients until engraftment; for allogeneic HSCT recipients, it is recommended that prophylaxis should be continued for a minimum of 75 days after transplantation [66]. Lack of protection against infections caused by *C. krusei* and *Aspergillus* with fluconazole prophylaxis is important to note. Mold-active drug prophylaxis should be considered based on the assessment of patients' risk profile; furthermore taking into account the regional and local rates for such infections including seasonal variability for IFIs, where applicable [16]. Prophylaxis with a mold-active triazole drug like voriconazole or posaconazole is considered in select patients in whom treatment of acute or chronic GVHD requires accelerated immunosuppression. These drugs are also considered in patients undergoing high-risk transplant procedures with an anticipated delay in restitution of myeloid hematopoiesis. Anti-mold secondary prophylaxis is routinely introduced for patients with a history of successfully treated IFI prior to HSCT procedure.

Voriconazole has extended spectrum of activity against medically important yeasts and filamentous fungi such as *Aspergillus* spp. and most black molds. In high-risk HSCT

patients, voriconazole prophylaxis is an appealing alternative to fluconazole. A randomized, double-blind study compared voriconazole 200 mg twice daily with fluconazole 400 mg once daily given for first 100 days after transplantation. Patients underwent assessment of serum galactomannan twice weekly for 60 days, then weekly until day 100; empiric antifungal therapy was therefore given for individuals with probable breakthrough IFI. Patients with prior systemic candidiasis in 2 months and mold IFIs in 4 months prior were excluded from participation in this study. There was no significant difference in the incidence of IFIs or fungus-free survival [67]. However, in patients with acute myeloid leukemia (AML) who underwent allogeneic HSCT, fewer IFIs (8.5 vs. 21%; $p = 0.04$) and improved fungus-free survival in voriconazole vs. fluconazole prophylaxis group was encouraging (78% vs. 61%, respectively; $p = 0.04$). There was no difference in overall survival in any of the subgroups including patients with AML [67]. Based on this data, specific patients such as those with AML undergoing allogeneic HSCT, in whom the risk of IA and invasive candidiasis due to fluconazole nonsusceptible organisms is high, may be suitable candidates for prophylaxis with voriconazole.

Micafungin is another agent recommended for prophylaxis in patients undergoing autologous or allogeneic HSCT. The multi-institutional, randomized trial included 882 adult and pediatric autologous or allogeneic HSCT recipients who were given 50 mg of micafungin ($n = 425$) or 400 mg of fluconazole ($n = 457$) once daily and continued through stem cell engraftment. Successful prophylaxis was defined as the absence of suspected, proven, or probable IFIs through the end of therapy and no evidence of proven or probable IFIs 4 weeks after prophylaxis was completed. The overall efficacy of micafungin was 80% vs. 73.5% in fluconazole group ($p = 0.03$). In patients given micafungin prophylaxis, a trend toward lower rates of aspergillosis was also encouraging. There was no difference in mortality between the two groups. Breakthrough infections in this study included four cases of candidemia and one case of probable aspergillosis in the micafungin group, whereas two cases of candidemia and seven cases of aspergillosis (four proven, three probable) in the HSCT recipients given fluconazole prophylaxis. A major limitation of this study was the short duration of prophylaxis (until engraftment), which did not allow assessment of efficacy of micafungin prophylaxis in patients at continued risk for IFI during other at risk postengraftment period that coincide with acute GVHD [16, 68–70]. A small prospective, randomized, open-labeled trial included 104 HSCT recipients given antifungal prophylaxis with 150 mg daily micafungin compared with 400 mg a day of fluconazole. There were no differences in the rate of breakthrough IFI in this small study [68, 70]. The duration of prophylaxis in this study was 5 days after engraftment or 42 days after HSCT. Currently, micafungin 50 mg daily is approved in the United States for prophylaxis in patients undergoing HSCT [13].

In stem cell transplant recipients with severe GVHD, an expanded antifungal coverage against mold infections is desirable. The role of posaconazole was assessed in a trial involving 600 patients, and the overall frequency of breakthrough IFIs within 16 weeks of randomization was 5.3% in posaconazole group given 600 mg in three divided doses vs. 9% in patients who were given 400 mg fluconazole daily ($p = 0.07$). Furthermore, frequency of proven or probable aspergillosis in posaconazole treatment cohort was 2.3% compared with 7% noted in patients, in whom fluconazole prophylaxis was given ($p = 0.006$). The rate of breakthrough invasive candidiasis was not significantly different between the two groups. The overall mortality in patients given posaconazole and fluconazole prophylaxis was 25% and 28%, respectively [16, 71].

The newer antifungal agents such as voriconazole, micafungin, posaconazole and isavuconazonium sulfate (presently only approved for the treatment of invasive aspergillosis and invasive mucormycosis) have made prophylactic itraconazole use obsolete due to higher rates of adverse events and drug-drug interactions [65, 66, 72, 73]. Efficacy and safety of voriconazole and itraconazole was evaluated in 234 patients undergoing allogeneic HSCT. In this study, the primary composite endpoints were success of prophylaxis, ability to tolerate study drug for more than 100 days, and survival past 180 days after HSCT without proven or probable IFI. Superiority of voriconazole in the composite primary endpoint was that patients given voriconazole prophylaxis were able to tolerate prophylaxis for 100 plus days with minimal treatment interruption [73]. Based on the toxicity profile of AmB deoxycholate, its use for antifungal prophylaxis in transplant patients is very limited.

Selection of antifungal agent for primary prophylaxis in transplant population should include the following considerations: (a) identify the type of HSCT procedure that portends greater risk for IFI such as T cell-depleted grafts, cord blood stem cell grafts, and mismatched allografts; (b) identify patients for high IFI vulnerability like heavily treated individuals with recurrent or treatment-refractory hematologic malignancy, high yeast colonization index, and evolving understating in disruptions in hosts' microbiota and various genetic polymorphisms in innate and adaptive immune pathways that may eccentuate post-transplant proclivity for fungal infections; the last two parameters are not routinely monitored. In addition, drug-related factors such as (1) oral bioavailability, (2) spectrum of antifungal activity, (3) voids in the antifungal coverage such as voriconazole's lack of efficacy against agents of human mucormycosis, (4) safety and tolerability, and (5) importantly, potential for drug-drug interaction. The optimum duration of antifungal prophylaxis in HSCT recipients is not certain; most experts surmise that antifungal prophylaxis be continued beyond

pre-engraftment neutropenic period [66]. A gathering consensus is for prophylaxis to be continued through the period(s) of moderate to severe GVHD. Since death in HSCT recipients in most cases, is cumulation of a number of factors, both infectious (i.e., CMV, IFIs, bacterial sepsis) and noninfections (i.e., GVHD, cancer recurrence, graft failure) complications, it is, therefore, perhaps unwise to assess efficacy of IFI prophylaxis on the impact on overall mortality in this highly vulnerable complex population.

Primary Antifungal Prophylaxis in SOT Recipients

Among SOT population, recipients of orthotopic liver transplantation (OLT) are at an increase risk for locally invasive or systemic yeasts infections, whereas those undergoing lung and heart-lung transplantation have higher susceptibility for invasive mold disease [74–77]. Risk factors for invasive candidiasis in OLT recipients include (1) retransplantation, (2) serum creatinine >2.0 mg/dL, (3) choledochojejunostomy, (4) intraoperative use of >40 units of blood products, (5) prolonged intraoperative time > 1 h, and (6) demonstration of fungal colonization 2 days prior and 3 days following transplant surgery [77, 78]. In a randomized, placebo-controlled trial, fluconazole 400 mg given daily for 70 days after transplant surgery was associated with fungal infection rate of 6% compared with 23% in no prophylaxis group ($p < 0.001$). A significantly lower IFI-related deaths in patients given fluconazole prophylaxis compared with no antifungal prophylaxis were encouraging (2% vs. 13%, respectively; $p = 0.003$); however, the overall mortality was similar in both groups [76].

In a retrospective review of 445 consecutive pancreas transplant recipients, overall rate of intra-abdominal fungal infections (IAFIs) was 9.2%. In patients who received fluconazole 400 mg daily for 7 days after transplantation had 6% vs. 10% IAFIs in patients without prophylaxis. Donor age was noted as a significant risk factor. However, it was important to note that 1-year graft survival rate in recipients with IAFI was 17%, compared with 65% in patients without such infections ($p = 0.0001$) [79].

In a prospective review of 19 small bowel transplant recipients, 28% had at least 1 episode of fungal infections during the 524 days post-transplant follow-up [80]. There are no randomized trials of antifungal prophylaxis in this at risk visceral allograft group. According to Clinical Practice Guideline for the Management of Candidiasis, 200–400 mg (3–6 mg/kg) fluconazole for 7–14 days is recommended as postoperative prophylaxis for liver transplant recipients who have at least two key risk factors, whereas prophylaxis is recommended for all patients undergoing pancreas and small bowel transplantation surgery [81]. The risk of invasive candidiasis in kidney, heart, and lung transplant recipients is low and has significantly declined over the past 25 years [81, 82]. A detailed review on SOT antifungal prophylaxis is provided elsewhere in this volume.

Treatment of IFIs in HSCT and SOT

Despite the standard use of antifungal prophylaxis in patients undergoing HSCT and SOT, IFIs continue to be a significant cause of morbidity and mortality. Transplant-Associated Infection Surveillance Network (TRANSNET) is a network of 23 US transplant centers performing HSCT and SOT, or both. TRANSNET reported 983 proven (56%) and probable (44%) IFIs in 875 HSCT recipients between 2001 and 2006. IA was common (43%), followed by invasive candidiasis (28%), zygomycosis (8%), and invasive *Fusarium* spp. infection (3%). The incidence of IFIs was nearly 8% in the recipients of mismatched-related and matched-unrelated allogeneic HSCT; for matched-related allogeneic SCT, the incidence was marginally lower (5.8%), and as expected, IFI complication was reported in only 1% of patients undergoing autologous stem cell transplantation. Overall 1-year survival after infections was 6% for patients with fusariosis, 25% for aspergillosis, 28% for zygomycosis, and 34% for transplant recipients with invasive candidiasis [83]. This database received reports of 1,208 proven (42%) and probable (58%) IFIs among 1,063 SOT recipients during the same period. Invasive candidiasis was common (53%), followed by aspergillosis (19%), cryptococcosis (8%), non-*Aspergillus* molds (8%), endemic fungi (5%), and zygomycosis (2%). The 12-month cumulative incidence of first IFI was 12% for small bowel, 9% in lung, 5% in liver, 4% in heart, 3% in pancreas, and 1% in recipients of renal allograft transplantation. The 1-year survival after the diagnosis of IA was 59%; 61% for non-*Aspergillus* mold infections, 66% in patients with invasive candidiasis, and 73% among SOT recipients with cryptococcal infection [84].

fluconazole prophylaxis in patients undergoing HSCT has resulted in a noteworthy decline in cases of invasive candidiasis. The widespread use of systemic antifungal agent given for infection prevention, as expected, has influenced epidemiology of *Candida* spp. infection as drug-resistant or inherently nonsusceptible yeast stains and species become more common in clinical practice. It is important to recognize that IA is the most common fungal infection in HSCT recipients, whereas locally invasive or systemic candidiasis is more frequently encountered in patients undergoing SOT.

In this section, we discuss the current literature support for primary and salvage therapy for primary and breakthrough invasive candidiasis, IA, zygomycosis, and other non-*Aspergillus* mold infections.

Invasive Candidiasis

A randomized study comparing IV fluconazole 400 mg daily with AmB deoxycholate for the treatment of candidemia in non-neutropenic patients found both regimens were comparable [85]. Therefore, fluconazole and AmB were considered as standard-of-care treatment for candidemia in patients with intact peripheral blood neutrophil counts. Clinical efficacy and safety of echinocandins including caspofungin, micafungin, and anidulafungin as the initial treatment for invasive candidiasis has been established in four randomized multicenter trials. The first trial compared caspofungin 70 mg dose followed by 50 mg daily dose vs. AmB given (0.6–1.0 mg/kg daily) in 224 patients, which also included 14 patients with severe neutropenia and 7 SOT recipients. Successful outcomes following caspofungin and AmB therapy were 73 vs. 62%, respectively (95% confidence interval [CI]; −0.7–26.0) [86]. A double-blind, randomized, multinational trial included 531 patients with invasive candidiasis given either micafungin 100 mg daily or L-AmB given 3 mg/kg daily [87]. In this study, 62 patients had neutropenia and 32 had undergone SOT. Micafungin was as effective as L-AmB, resulting in nearly 90% successful outcome in either group. Anidulafungin 200 mg followed by 100 mg daily dose was compared with 800 mg of fluconazole followed by 400 mg daily for treatment of invasive candidiasis in a double-blind, noninferiority trial [88]. The study included 12 SOT recipients. Efficacy analysis in 245 patients showed anidulafungin therapy was associated with higher response rates of 76% vs. 60% in patients given fluconazole (95% CI; 3.9–27.0). Another large multicenter trial assessed efficacy and safety of micafungin vs. caspofungin for the treatment of invasive candidiasis [89]. The results of these trials consistently have shown superior efficacy and safety of echinocandins for the treatment of invasive candidiasis. There is insufficient clinical data to favor one echinocandin over the another. It is worth pointing out that HSCT and SOT recipients are underrepresented in these trials. Breakthrough infections in patients receiving azoles are most likely due to fluconazole-resistant *Candida* spp., especially *C. glabrata* and *C. krusei*; echinocandins or L-AmB as first-line therapy in patients undergoing hematopoietic or visceral allograft transplantation is strongly recommended.

In the 2016 Infectious Diseases Society of America (IDSA) guidelines for the treatment of candidiasis, an echinocandin is recommended as initial therapy in (a) patients with neutropenia, (b) critically ill patients, (c) those with recent triazole drug exposure, or (d) patients with suspected or proven *C. glabrata* and *C. krusei* infection [90]. If an organism is identified as fluconazole-susceptible and patient is hemodynamically stable and no longer neutropenic, with sterile blood cultures, and has no prior exposure to azole prophylaxis, in such situations treatment with fluconazole at 6–12 mg/kg daily may be considered. NCCN and IDSA do not recommend using AmB products routinely for candidemia, patients with *Candida* spp. meningitis or endocarditis being an exception [66, 81]. Patients who fail to respond to echinocandins or those intolerant to these agents, treatment with L-AmB may thereupon commenced. There is no clinical trial-based experience for voriconazole use as first-line treatment in neutropenic patients with invasive candidiasis, it is often used as transition to oral therapy or given as second-line agent.

Most *C. glabrata* and *C. krusei* clinical isolates retain susceptibility to the mold-active triazoles like voriconazole, posaconazole and isavuconazonium sulfate [91]. The recommended duration of treatment for patients with uncomplicated candidemia is 2 weeks after the first sterile blood culture and resolution of signs and symptoms associated with these infections [81]. In patients with *Candida* retinal or other ophthalmic involvement, treatment is given for an extended duration. Those with candidemia associated with an infected intravascular devise, infected devices should be removed expeditiously. In patients with persistent neutropenia and candidemia without secondary complication, treatment may also be discontinued after 2 weeks of therapy.

Invasive Aspergillosis

For decades, AmB deoxycholate was the only treatment option for patients with IA. Voriconazole has replaced amphotericin as the first-line drug for the treatment of IA. The open-label, multicenter randomized trial in severely immunocompromised patients included 67 HSCT and 14 SOT recipients with probable or proven IA who were randomized to receive either voriconazole 6 mg/kg two doses followed by 4 mg/kg twice daily (n = 144) or AmB deoxycholate given as 1 to 1.5 mg/kg daily dose (n = 133) [92]. Twelve weeks after treatment commenced, voriconazole resulted in a significantly higher rate of complete and partial response compared with patients treated with AmB deoxycholate (53% vs. 32%, respectively; 95% CI, 10.4–32.9). Additionally, treatment with voriconazole also resulted in improved survival after 12 weeks of therapy (71% vs. 58% in patients given AmB deoxycholate; hazard ratio = 0.59; 95% CI, 0.40–0.88). In 67 HSCT recipients, 32% had a response to voriconazole compared with a dismal response of 13% in patients treated with AmB deoxycholate. In a retrospective study of 192 patients, 137 with proven and 55 with probable central nervous system (CNS) aspergillosis, 48% responded to treatment with voriconazole [93].

L-AmB is an alternative option for initial therapy in patients with IA. The AmBiLoad trial was a double-blind dose comparison trial of L-AmB 3 or 10 mg/kg/day given for the first 2 weeks, followed by 3 mg/kg daily maintenance dose as primary treatment of IFI [94]. Of 201 patients with confirmed

invasive mold infection, 107 patients received the lower dose and 94 patients received 10 mg/kg daily dose. IA accounted for 97% of all IFIs in this study. Severe neutropenia was noted in 73% of patients at the start of therapy. The trial included 35 HSCT patients, and one patient after SOT. No significant difference in efficacy between the two groups was an unexpected finding. A 50% response in patients initially given low dose vs. 46% in those treated with 10 mg/kg dose during the first 2 weeks along with an improved survival at 12 weeks favored patients initially given 3 mg/kg dose (72% vs. 59% in high-dose treatment group; 95% CI, −0.2−26%). These results demonstrated efficacy of L-AmB 3 mg/kg daily dose, whereas no benefit could be seen in patients given initial 2 weeks of high-dose L-AmB therapy. L-AmB has been used as an alternative agent for the treatment of IA in transplant patients intolerant to voriconazole or those with concerns for drug toxicity and potential drug-drug interactions.

The optimum therapy for breakthrough IA in patients receiving mold-active prophylaxis is not clear. A switch in the class of antifungals is suggested, and for patients with treatment of refractory IA, salvage combination therapy may be entertained, albeit, stellar prospective large cohort data to support such combination antifungal drug treatment regimens is currently lacking.

Posaconazole has not been evaluated for primary therapy of IA. It was effective as salvage therapy given 800 mg daily in three to four divided doses for patients with IA and underlying hematologic malignancies, HSCT, and SOT [95–97]. In Europe, posaconazole is approved as salvage therapy for IA and other IFIs refractory to standard antifungal agents. In the United States, posaconazole is approved as prophylaxis for IA in high-risk patient.

Isavuconazonium sulfate is the newest triazole mold-active drug to be introduced for clinical use. A phase III, double-blind, global comparative study in 527 adults assessed safety and efficacy of isavuconazonium sulfate 372 mg prodrug, which is equivalent to 200 mg isavuconazole given three times daily for first 2 days followed by 372 mg prodrug taken once daily compared with standard IA dose voriconazole therapy. The primary efficacy endpoint was all-cause mortality after the first dose through 42 days after the treatment commenced. Safety was assessed in patients who received even a single dose of the study drugs. All-cause mortality was 19% and 20% in patients given isavuconazole or voriconazole, respectively. Drug-related adverse events were 42% in patients treated with isavuconazole compared with 60% in the voriconazole treatment group ($p < 0.001$). It is important to note that patients given isavuconazole had significantly lower hepatobiliary dysfunction, 9% vs. 16% in voriconazole treatment arm ($p = 0.016$). Similarly, eye disorders, 15% vs. 27% ($p = 0.002$), and skin and skin structure disorders, 33% vs. 42% ($p = 0.037$), favored isavuconazole vs. voriconazole, respectively [98]. This drug may be utilized as an alternative first-line therapy for transplant patients with IA, with a potential benefit in significantly less ocular and hepatotoxicity.

Caspofungin 70 mg single dose followed by 50 mg daily was evaluated as first-line IA therapy in patients with hematologic malignancy, autologous and allogeneic HSCT [99, 100]. The results from these two noncomparative trials showed a modest complete or partial response assessed as 12 week survival was 33% and 50–53%. Caspofungin was evaluated in 90 patients with IA who were refractory to or intolerant of amphotericin products or triazoles and showed success rate of 45% [101]. Caspofungin is approved by FDA as salvage therapy in patients with IA. A noncomparative study for micafungin alone or in combination with other antifungal agents as primary or salvage therapy for IA in HSCT recipient did not permit definitive conclusion regarding drug efficacy and clinical utility [102, 103].

A potential synergist antifungal effect of echinocandin in combination with a triazole agent was observed in vitro experiments [104]. The rationale is that echinocandins target the fungal cell wall, which is distinct from the polyenes and azoles that target the fungal cell membrane. The clinical database is limited, combination antifungal therapy may be considered with due caution in management of difficult-to-treat IA, especially in severely immunosuppressed transplant patients with a greater risk of failure to conventional single drug antifungal therapy. Its role remains to be formally defined by prospective, randomized comparative studies. A retrospective study reported an improved 3-month survival of 78% in SOT recipients treated with voriconazole plus caspofungin compared with voriconazole alone as salvage therapy for IA [103]. Combination of voriconazole plus caspofungin as primary therapy for IA also showed potential promise in SOT recipients in a prospective observational study [104].

Both NCCN and the 2008/2016 [105] IDSA guidelines for treatment of IA recommend IV or oral voriconazole as first-line therapy in patients with IA [66, 106]. A combination of antifungal drugs from different classes other than initial regimen or an additional antifungal agent to current therapy may be used as salvage therapy. Patients who have responded to initial IV therapy and are clinically stable may be switched to appropriate oral agents. The duration of therapy for IA is defined by the resolution of all clinical and radiographic features associated with IA; in patients with persistent immune defect(s), a secondary suppressive antifungal therapy is often needed to prevent infection recurrence.

Zygomycosis

Zygomycosis is now referred as mucormycosis. Mucormycosis typically manifests as invasive sino-orbital and pulmonary disease [107]. Voriconazole and echinocandins have no activity

against the agents of mucormycosis. Mucormycosis is an uncommon infection even in the severely immunosuppressed transplant recipients. It may become marginally more prominent in patient presenting with sino-orbital or intracranial fungal disease, patients who may develop voriconazole-breakthrough IFIs, and patients with heavy metal overload conditions. There are no randomized studies to assess selection of ideal therapy for patients with this rare fungal disease. Most data regarding therapy is in patients with poorly controlled diabetes mellitus with or without ketoacidosis. High-dose lipid AmB preparations such as L-AmB or ABLC (5 mg/kg/day) are considered treatment of choice. Surgical debridement of necrotic devitalized tissue should be approached with a sense of urgency, when feasible, aggressive surgical debridement forms the cornerstone of comprehensive care for patients with this life-threatening fungal disease [107]. Posaconazole and isavuconazole show in vitro activity against the agents of mucormycosis. Posaconazole was given as 800 mg divided daily dose with a mixed result as salvage therapy in patients of AmB refractory disease or patients who were intolerant to AmB formulations [108, 109]. Rates of treatment success including partial or complete response or disease stabilization were between 60% and 80%. Posaconazole has also been used for prolonged infection suppression after an initial response with amphotericin and surgical debridement [66].

In a single-arm open-label trial (VITAL study), adult patients from 34 centers worldwide with rare mold disease including mucormycosis between 2008 and 2013 were given isavuconazole 200 mg three times daily for six doses, followed by 200 mg daily until infection resolved, or treatment failed, or for 180 days or more after treatment commenced. The primary endpoint was complete or partial response, which was regarded as treatment success; or treatment failure in patients with stable or progressive disease. In 37 patients with mucormycosis, isavuconazole was given for a median of 84 days and ranged between 2 and 882 days. Forty-two days after treatment began, 54% of patients had a partial or complete response, and in 43% disease became stable, whereas only one patient exhibited progression of fungal disease. Crude all-cause mortality was 33% after 42 days of isavuconazole therapy comparable to 39% in AmB-treated matched controls [110].

Free iron availability in fungal microenvironment supplements mucormycete growth and plays a fundamental role in the disease pathogenesis. Conventional iron chelators such as deferoxamine when given to patients with iron overload conditions promote iron ion-rich environment in which, agents of mucormycosis flourish and thrive. Whereas, the new-generation chelating agents like deferiprone and deferasirox reduce the concentration of free iron ions, thereby creating a nutritionally truncated milieu that impedes fungal growth and propagation. Iron chelation with deferasirox had encouraging results in experimental mucormycosis models. In a small phase II study, however, patients with mucormycosis treated with deferasirox plus L-AmB had a higher mortality rate at 90 days. Population imbalances may have contributed to this unexpected result. However, at present adjunctive deferasirox therapy for mucormycosis cannot be recommended [111, 112].

Other Invasive Mold Diseases

Fusarium spp. and *Scedosporium* spp. are uncommon causes of IFIs in the transplant population. However, these infections are on a gradual rise among all cause IFIs in certain geographic regions. These pathogens are associated with life-threatening disease that often fails to respond to conventional antifungal drug therapy [112, 113]. Therapy for invasive fusariosis generally involves drugs like voriconazole, posaconazole, and isavuconazole and lipid formulations of AmB [115–118]. *Scedosporium* species are resistant to AmB, although itraconazole, voriconazole, posaconazole, and isovuconazole retains activity against clinical *Scedosporium* isolates [118, 119].

Cryptococcus spp. infection typically manifest as CNS or lung infection, with proclivity for disseminated infection. The first-line therapy for cryptococcal meningoencephalitis is the combination of liposomal L-AmB (3–4 mg/kg/day) or ABLC (5 mg/kg/day) plus flucytosine (100 mg/kg/day orally in four divided doses) for the first 2 weeks, followed by fluconazole (400–800 mg, 4–6 mg/kg/day) for 8 weeks, then 200–400 mg/day orally fluconazole for another 6–12 months for secondary infection suppression. If flucytosine is not available, consider L-AmB or ABLC for at least 4 to 6 weeks of induction therapy L-AmB (6 mg/kg/day) might be considered in patients with relapsed infection or infection associated with high fungal burden. For mild-to-moderate pulmonary cryptococcosis, fluconazole 400 mg daily is given for 6–12 months. Patients with severe lung disease should be treated as those with CNS infection. For cryptococcemia or disseminated disease, consider fluconazole 400 mg or 6 mg/kg daily dose for 6–12 months [120].

Summary

Selection of antifungal agent for prophylaxis or treatment of IFIs in transplant recipients should be based on criteria outlined in this chapter. Status of hosts' immune response, local fungal epidemiology, drug pharmacology, spectrum of antifungal activity, drug toxicity, and importantly, potential for drug-drug interaction should all play an important part in such decision making. Management of IFIs requires optimization of immune function, which in most high-risk allograft transplant recipients remains unattainable. To abrogate this critical limitation, a number of ancillary immune boosting

measures are currently under consideration including the evolving understanding of potential immune modulatory effects of the antifungal drugs. In the future, this may be an additional feature to consider in the selection of best possible, pathogen-targeted drug regimen for the highly vulnerable patients undergoing lifesaving transplantation procedures.

Immunomodulatory Properties of Antifungal Agents on Immune Functions of the Host

53

Maria Simitsopoulou and Emmanuel Roilides

Introduction

During the past two to three decades, an increasing incidence of invasive fungal diseases among immunocompromised patients has been witnessed [1, 2]. The rising number of patients undergoing allogeneic hematopoietic stem cell transplantation and solid organ allograft transplantation receiving immunosuppressive drug regimens is in part responsible for this epidemiologic trend. The overall immunosuppressed status of these patients makes them highly susceptible to viral, bacterial, fungal, and protozoal opportunistic pathogens [3]. Fungi are a significant cause of morbidity and mortality in patients undergoing allogeneic graft transplantation [4, 5]. While *Candida* and *Aspergillus* species are the cause for most of the post-transplant invasive fungal diseases, a number of other less frequent pathogens, such as Zygomycetes, *Fusarium*, and *Scedosporium* species may sporadically cause serious disease [5–8].

These recent epidemiologic trends coupled with emergence and spread of drug-resistant fungal pathogens, i.e., multidrug-resistant *Candida* spp. like *Candida auris;* azole and polyene-resistant *Aspergillus* spp. such as *Aspergillus terreus* [9, 10]. Furthermore, antifungal drug toxicity, and drug-drug interaction have foster interest in exploring pharmacodynamic properties of antifungal drugs with emphasis on the potential immune modifying aspect on host-fungus interplay.

In this chapter the main in vitro and in vivo immunomodulatory effects of antifungal drugs on phagocytic cells in response to fungal stimulation with reference to their interaction with phagocyte functions is presented. When applicable, the underlying mechanism(s) and potential clinical relevance of such antifungal effects are given.

Host-Fungal Pathogen Interplay

The innate immune system is based not only on barrier and chemical defense mechanisms to combat infection, but also on various immune cells that recognize invading pathogens and activate a series of antimicrobial immune responses. Upon fungal invasion, ciliated respiratory epithelium and gastrointestinal and vaginal mucosa secrete antimicrobial compounds to neutralize or kill invading organisms. Similarly, resident or recruited phagocytic macrophages, polymorphonuclear leukocytes (PMNs), or dendritic cells (DCs), the cellular components of innate immunity, play a central role in cytokine production and T-cell-mediated immunity.

Phagocytic cells recognize fungal particles through specific cell-surface pattern recognition receptors (PRRs), leading to the activation of phagocytosis, production of inflammatory molecules for the recruitment of additional Th1 and Th2 cell adaptive immune response, and production of microbicidal products. Pathogen detection involves recognition of conserved pathogen-associated molecular patterns (PAMPs), either secreted by or located on the surface of fungal particles, by the well-known Toll-like receptors (TLRs) like dectin-1, dectin-2, mannose receptors (MR), dendritic cell-specific ICAM3-grabbing non-integrin (DC-SIGN), and the nucleotide-binding domain and leucine-rich repeat containing (NLR) family of cytosolic receptors that mediate both inflammatory and cell death pathways [11, 12]. Most TLRs transduce the signal received from the surface to the nucleus via a signaling pathway that depends on the adaptor myeloid differentiation factor 88 (MyD88) and its downstream mediators interleukin-receptor-associated kinase 4 (IRAK-4) and tumor necrosis factor receptor-associated factor 6 (TRAF-6) that activate nuclear factor (NF)-κB in

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_53

order for the appropriate cellular responses needed to be initiated [13–15]. The final effector response profile in the target cell depends on the cell type. For example, activation of TLR2 or dectin-1 in macrophages results in the production of several pro-inflammatory cytokines and chemokines, such as IL-1α/β, IL-6, TNF-α, IL-8, and RANTES, that initiate a protective immune response against fungal invasion. Upregulation of epithelial TLR4 is involved in mediating a secondary protective effect against *Candida albicans* invasion in the presence of PMNs [16]. Recognition of *Aspergillus fumigatus* and activation of PMNs occur through the involvement of other TLRs. Signaling through TLR2 promotes the oxidative fungicidal pathway of PMNs with the participation of pro-inflammatory cytokines and results in killing fungal microconidia. TLR4 signaling on the other hand, is essential for the induction of nonoxidative mechanisms mediated by the release of PMN azurophilic granule constituents and IL-10 upregulation, important for fungal hyphal damage. Both pathways are affected to various degrees by TLR3, TLR5, TLR6, TLR7, TLR8, and TLR9 signaling [17]. As PMNs are important for pathogen elimination in the early stages of fungal invasion, an excessive release of toxic reactive species may also result in tissue injury and SIRS vs. sepsis like syndrome. Therefore, PMNs through TLR cross talk mount a robust antifungal response which, however, is tightly regulated in order to balance between protection and inflammation. The specificity of immune host response is dictated not only by the different PAMP structures present in the fungal cell wall, but also by the complex interactions between the PRR pathways demonstrated in a number of studies [18].

Fungal conidia are damaged through a phagocytic process effected primarily by the incoming mononuclear cells (MNCs) or resident tissue macrophages; by comparison, hyphae are damaged through the extracellular release of fungicidal products of the oxidative burst and nonoxidative mechanisms of PMNs. During the oxidative burst, phagocytic cells generate reactive oxygen species (ROS), such as superoxide anion, hydrogen peroxide, and nitrogen intermediates; this microbicidal system employed primarily by PMNs is catalyzed by the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, a multisubunit enzyme complex embedded in the plasma membrane of the cells. Patients with chronic granulomatous disease (CGD), in which superoxide anion is not produced due to mutations in the NADPH oxidase, these patients are predisposed to severe systemic bacterial and fungal infections. Despite the absence of ROS production, the CGD neutrophil phagosome is able to kill significant microbial load by microbicidal molecules that are independent of the respiratory burst [19]. The oxygen-independent system, which relies on the microbicidal properties of proteases, cationic peptides, defensins, lactoferrin, or lysozyme stored in azurophilic granules, is essential for the optimal antifungal activity of phagocytes [20]. Myeloperoxidase (MPO), a granular enzyme released into the phagosome, catalyzes the conversion of superoxide into several reactive oxygen molecules such as hypochlorous acid, chloramines, hydroxyl radicals, and singlet oxygen. A study conducted with MPO−/− and X-linked CGD mice demonstrated that both MPO and NADPH oxidase are equally important for host defense against a large fungal inoculum [21]. Recently, PMN extracellular traps (NETs) consisting of decondensed chromatin and antimicrobial proteins released from dying PMNs have also been added to the protective mechanisms employed by the host against fungal invaders [22, 23].

While PMNs and macrophages are important effectors of innate immunity involved in the immediate killing of pathogens, DCs by being potent antigen-presenting cells needed for T-cell activation via appropriate signals are regarded as the principle communication between the innate and adaptive immune responses. Depending on the fungal morphotype ingested by DCs, different downstream signaling programs are activated: conidial ingestion leads to the production of pro-inflammatory cytokines and activation of protective Th1-cell responses; in contrast, hyphal ingestion results in production of IL-4 and/or IL-10 and activation of Th2/T_{reg} cells [24–26].

Antifungal Drug-Induced Effects on Host-Fungus Interplay

The main antifungal agents currently used for treatment of invasive fungal diseases belong to the following three categories: (1) polyenes represented by deoxycholate and lipid formulations of amphotericin B; (2) azoles most importantly fluconazole, voriconazole, posaconazole and isavuconazonium sulfate; and (3) echinocandins class consists of caspofungin, micafungin, and anidulafungin. Amphotericin B binds to ergosterol in the fungal cell membrane forming transmembrane channels, through which intracellular molecules leak out; azoles act by inhibiting synthesis of ergosterol; whereas echinocandins are cell-wall active drugs inhibiting 1,3-β-D-glucan synthesis. Members of each category exert various modulatory effects on host-pathogen interactions. In addition, certain antibacterial agents have interactions with antifungals and hosts' cytokine response.

In the phagocyte-fungus-antifungal drug interplay, drugs may directly interact with the immune effector cells through cell receptors, leading to altered antifungal activities. Following cellular uptake and intracellular accumulation, antifungals may modify immune responses by release of pro- or anti-inflammatory cytokines and influence production of reactive oxygen species or affect enzymatic pathways, such products are shown to possess antifungal properties [27–29]. In addition, antifungal agents at subinhibitory concentrations may indirectly affect phagocyte activities by alteration of fungal morphology, resulting in increased pathogen susceptibility to phagocyte actions, and by acting upon the fun-

gal organisms either by fungistatic or fungicidal effect reduce fungal burden, thereby providing time for host to mount a robust and durable antifungal response needed to eradicate the invading pathogen, while keeping excessive unconstrained inflammation in check. Modulation of phagocyte behavior has also been observed after priming of phagocytes with cytokines, increasing the intracellular antifungal effect of drugs [30, 31].

The following drug-fungus or drug-host or drug-fungus-host interactions are described in the following parts of the chapter as:

1. Drug-phagocyte communication through cellular receptors
2. Antifungal drug-induced cytokine and chemokine expression profiles in human phagocytes
3. Modulation of phagocytes' activity by antifungal agents
4. Modulation of phagocytes' activity by the combined effect of cytokines and antifungal agents

Immunomodulatory Effects of Amphotericin B Formulations

During the past several years, studies have suggested that antifungal agents may alter phagocytes' immune responses against fungi by affecting specific PRRs. Amphotericin B is a broad-spectrum polyene antifungal agent. Deoxycholate compound is the oldest amphotericin B formulation and remains among the most useful agents against invasive fungal diseases especially in resource-limited countries. Its use is wide, despite the infusion-related reactions and risk for dose-dependent nephrotoxicity; the drug induced kidney injury is postulated to originate from a potent pro-inflammatory response by innate immune cells elicited by its affinity for cholesterol binding in mammalian cell membrane[32]. Two complementary studies have demonstrated that amphotericin B is probably perceived as a PAMP by CD14, TLR1, and TLR2 receptors, which are coactivated through a reorganization of lipid raft proteins in the microdomains of cell membrane serving as centers for assembly of signaling molecules, which promotes secretion of pro-inflammatory cytokines and chemokines [33, 34] (Table 53.1). A detailed investigation of the intracellular signaling induced by amphotericin B in a monocytic cell line has shown that pro-inflammatory cytokine production is mediated by B-cell progenitor tyrosine kinase (Btk), phospholipase C (PLC), protein kinase C (PKC), cellular tyrosine kinase (c-Src), and NF-κB signaling molecules [35]. These studies provide a molecular basis for the recognized inflammatory adverse effects associated with amphotericin B in patients and identify potential targets for agents that could minimize such effects.

Table 53.1 Effects of antifungal agents on pattern recognition receptors of phagocytes

Antifungal agent	Recognition receptors	Fungus studied
Fluconazole	Up-regulation of TLR9 in PMNs	*C. albicans*
Voriconazole	Up-regulation of TLR2, 4, 9 in PMNs	*A. fumigatus*
	Up-regulation of TLR2 in MNCs	*A. fumigatus*
Deoxycholate amphotericin B	Up-regulation of TLR1, TLR2, CD14 in MNCs	*A. fumigatus*
Liposomal Amphotercin B	Up-regulation of TLR4 in PMNs	*A. fumigatus, C. albicans*
Caspofungin	Up-regulation of TLR2, 4, 9, in PMNs dectin-1 in MNCs, PMNs	*A. fumigatus, C. albicans A. fumigatus*

Lipid formulations of amphotericin B were developed in order to avoid or minimize toxicity and contribute to the overall improvement of therapeutic index. Exposure of murine and human PMNs to *A. fumigatus* in the presence of liposomal amphotericin B (LAMB) involves different TLR-activation pathways as compared to deoxycholate amphotericin B (DAMB). While DAMB activates the oxidative antifungal response leading to an increased pro-inflammatory state through TLR2 signal transduction, LAMB by diverting signaling from TLR2 to TLR4, induces more IL-10 and less TNF-α or superoxide anion production in PMNs stimulated with *A. fumigatus* conidia (Table 53.1). In addition, LAMB augments the conidiocidal activity of both murine and human PMNs suggesting that it either has an immunomodulatory role on PMN antifungal functions or increases conidial susceptibility to PMN conidiocidal activity altering fungal membrane [36] (Table 53.2).

As stated above, infusion-related adverse drug reactions observed in patients treated with amphotericin B are associated with the ability of DAMB to induce the release of pro-inflammatory cytokines after activation of immune cells via TLRs and CD14 with the subsequent activation of MyD88 and NF-κB signal transducer molecules. In an attempt to understand the molecular mechanisms by which lipid amphotericin B formulations induce a specific gene expression profile as compared to DAMB, studies using human MNCs have identified a number of immune molecules that are induced and released following exposure to different amphotericin B formulations [37–45] or after challenge with *A. fumigatus* hyphae [46, 47] (Table 53.3). These studies indicated that DAMB and amphotericin B colloidal dispersion (ABCD) upregulate gene expression and production of pro-inflammatory cytokines and chemokines. By comparison, LAMB and ABLC generally downregulate or do not affect gene expression of pro-inflammatory cytokines and chemokines, which may explain the relatively lower frequency of adverse infusion-related reactions of these agents reported in clinical trials.

Table 53.2 Effects of antifungal agents on the antifungal activities of phagocytes

Immunomodulatory agent	Phagocyte function	Fungus/animal model studied
FLC	Moderate anticonidial activity in PMNs	*C. albicans*
FLC + G-CSF	Enhanced survival	Disseminated candidiasis
FLC + sIL-4R or FLC + rIL-12	Synergistic effect on survival	*C. albicans*; immunosuppressed murine model
VRC	Unaffected anticonidial activity in PMNs	*C. albicans*
VRC	Drug- and time-dependent anticonidial activity in MNCs	*Candida* spp.
VRC	Additive antihyphal activity in PMNs	*R. microsporus*
VRC + GM-CSF or G-CSF	Increased anticandidal activity in MNCs and PMNs	*Candida* spp., *Cryptococcus neoformans*
VRC + GM-CSF	No effect on antihyphal activity in MNCs; increased antihyphal activity in PMNs	*A. fumigatus*
PSC	Modest efficacy	*R. microsporus*; immunosuppressed murine model
PSC + GM-CSF	Increased hyphal damage	*S. prolificans*; ex vivo
PSC + G-CSF	Modest survival or antagonistic effect	*A. fumigatus*, *R. microsporus*; immunosuppressed murine model
DAMB	Increased anticonidial activity in MNCs	*A. fumigatus*, *C. albicans*
DAMB	Increased antihyphal activity in MNCs, PMNs	*A. fumigatus*, *F. solani*
DAMB	Reduction in fungal load, induction of Th1 immune response	disseminated aspergillosis
DAMB + sIL-4R or rIL-12	Synergistic effect on survival	*C. albicans*; immunosuppressed murine model
DAMB + IFN-γ	Additive inhibitory effect	*C. neoformans*
LAMB	Increased antihyphal activity in MNCs, PMNs	*A. fumigatus*, *F. solani*
ABLC	Increased antihyphal activity in MNCs, PMNs	*A. fumigatus*, *F. solani*
ABLC	Additive antihyphal activity in PMNs	*S. prolificans*, *S. apiospermum*
ABCD	Increased antihyphal activity in MNCs, PMNs	*A. fumigatus*, *F. solani*
CAS	Increased intracellular killing; unaffected phagocytosis	*C. albicans*
CAS	Augmented antihyphal activity in PMNs	*A. fumigatus*
CAS + GM-CSF	Increased anticandidal activity	*C. glabrata*
MICA	Augmented antihyphal activity in PMNs, MNCs	*A. fumigatus*
AND	Increased intracellular killing, unaffected phagocytosis	*C. albicans*
AND	Additive antifungal activity in PMNs	*C. parapsilosis* biofilms
AND	Additive antifungal activity in MNCs	*C. albicans* biofilms
AND	Augmented antihyphal activity in PMNs	*A. fumigatus*
CIP + AMB	Synergistic anticonidial activity in PMNs	*A. fumigatus*

FLC fluconazole, *VRC* voriconazole, *PSC* posaconazole, *DAMB* deoxycholate amphotericin B, *LAMB* liposomal amphotericin B, *ABLC* amphotericin B lipid complex, *ABCD* amphotericin B colloidal dispersion, *CAS* caspofungin, *MICA* micafungin, *AND* anidulafungin, *AMB* amphotericin B, *CIP* ciprofloxacin, *G-CSF* granulocyte colony stimulating factor, *sIL4R* soluble IL-4 receptor, *rIL12* recombinant IL-12, *GM-CSF* granulocyte macrophage colony stimulating factor, *IFN-g* interferon gamma

Table 53.3 Effects of antifungal agents on phagocytes' immune gene expression

Antifungal agents	MNCs function	Fungal morphotype
Voriconazole	Down-regulation of TNF-α Pro-inflammatory response	*A. fumigatus* conidia *A. fumigatus* hyphae
Deoxycholate amphotericin B	Pro-inflammatory response, signal transduction, cell differentiation, complement activation	*A. fumigatus* hyphae
Amphotericin B colloidal dispersion Liposomal amphotericin B	Substantial pro-inflammatory cytokine release Decreased Th1 immune response	*A. fumigatus* hyphae *A. fumigatus* hyphae
Amphotericin B lipid complex	Decreased Th1 immune response	*A. fumigatus* hyphae
Caspofungin	Up-regulation of TNF-α Down-regulation of TNF-α	*A. fumigatus* hyphae *A. fumigatus* conidia
Micafungin	Up-regulation of TNF-α Down-regulation of TNF-α	*A. fumigatus* hyphae *A. fumigatus* conidia

VRC voriconazole, *DAMB* deoxycholate amphotericin B, *LAMB* liposomal amphotericin B, *ABLC* amphotericin B lipid complex, *ABCD* amphotericin B colloidal dispersion, *CAS* caspofungin, *MICA* micafungin

Membrane cation channel formation measured in model cholesterol-containing large unilamellar vesicles showed that only DAMB and ABCD induce significant ion currents, providing an additional rationale for the different cytokine-mediated adverse effects observed with amphotericin B formulations [40]. Moreover, these studies demonstrated that DAMB and lipid formulations affect gene expression and release of IL-1β, IL-1Ra, MCP-1, MIP-1β, and TNF-α variably, which may further modulate host response to invasive fungal infections.

Microarray studies have expanded the previous observations on the effects of amphotericin B formulations in MNCs and identified new immunomodulatory proteins that are responsive to amphotericin B. In particular, DAMB induces the expression of IL-1α and the chemokines IL-8, MIP-1α, the signal transduction proteins nuclear factor of κ light polypeptide gene enhancer in B-cell inhibitor α (NFKBIA), COX2, and G6PD. The ability of IL-8 and MIP-1α to recruit MNCs and PMNs could mediate the pulmonary toxicity occasionally observed with amphotericin B formulations. COX2 regulates prostaglandin production and release believed to mediate fever and chills observed during amphotericin B administration. G6PD has a key role in the production of NADPH, which is required for the respiratory burst in PMNs; therefore, upregulation of G6PD could explain the stimulatory effects the drug has on PMNs [44].

Another microarray study evaluated the effects of DAMB and ABLC on gene expression of immune molecules by MNCs exposed to *A. fumigatus* hyphae; considerably fewer genes associated with inflammatory and chemotactic activity were induced in MNCs exposed to the combination treatments of *A. fumigatus*-DAMB or *A. fumigatus*-ABLC as compared to each component alone, suggesting that both antifungal agents act by damaging *Aspergillus* hyphae rather than by activating phagocytes for cell recruitment and enhancement of antihyphal activity [47].

The potential impact that antifungal agents, primarily directed against fungal organisms, could also have on modifying immune cell functions through intracellular drug accumulation was readily recognized. This occurred after initial observations on the influence of amphotericin B to augment the fungicidal activity of human MNCs against ingested *C. albicans* and *A. fumigatus* conidia [48, 49]. Similar enhancement of killing was demonstrated to occur with fluconazole, voriconazole, caspofungin, and anidulafungin on phagocytized *C. albicans*, *Candida glabrata*, and *Candida krusei* [50–55]. Results of these studies indicate the impact of drug accumulation and on intracellular antifungal activity.

Amphotericin B has direct antifungal activity against *Cryptococcus neoformans*, and it also possesses an immunomodulating activity by augmenting the anticryptococcal response of murine peritoneal macrophages via upregulation of nitric oxide synthesis mediated by either TNF-α or IL-1 [56]. Furthermore, DAMB and lipid amphotericin B formulations enhance fungicidal activity of human or rabbit phagocytes against hyphae or conidia of *A. fumigatus* and *Fusarium solani*. This upregulatory activity of amphotericin B formulations is associated with supplement production of H_2O_2 and H_2O_2-dependent intracellular intermediates [57–59] (Table 53.2). In addition, while LAMB exhibits synergistic activity with PMNs in inducing hyphal damage to *Rhizopus microsporus*, ABLC has synergistic or additive activity with PMNs against all three Zygomycetes tested, *Rhizopus oryzae*, *Rhizopus microsporus*, and *Absidia corymbifera* [60]. Similarly, both LAMB and ABLC interacted with phagocytes and produced additive antifungal activity against *A. fumigatus* and *Scedosporium* spp. selectively [61, 62] (Table 53.2). The mechanism(s) underlying these combinational activities may be related to the structure of the compounds and their molecular interaction with the fungal organisms. The ribbon-like structure of ABLC may have more hydrolysis sites exposed to the action of fungal or host cell-derived phospholipases than the lipid bilayer structure of LAMB, thus amphotericin B could be released more readily and in greater amounts from ABLC than from LAMB [63].

Immunomodulatory Effects of Azoles

Among azoles, voriconazole and fluconazole have been shown to interact with phagocytes through TLR receptors in response to *A. fumigatus* or *C. albicans* as stimuli [64, 65]. Specifically, voriconazole enhances pro-inflammatory phagocyte programs by signaling an upregulation of TLR2, this effect is mediated by NF-κB activation and nuclear translocation, resulting in increased MNC fungicidal activity following challenge with *A. fumigatus* hyphae [64]. In addition, interaction of voriconazole or fluconazole with PMNs stimulated with *A. fumigatus* or *C. albicans* induces upregulation of TLR9 receptor, whereas caspofungin induces PMNs to increase expression of TLR2 in response to *A. fumigatus* and TLR4 and TLR9 following *C. albicans* exposure [65] (Table 53.1). These findings indicate that host response to antifungal agents are mediated through different PRRs elicited via fungal stimuli.

Reduction of TNF-α mRNA expression was observed upon evaluation of the immunomodulatory effects of amphotericin B, voriconazole, and micafungin on human MNCs stimulated with *A. fumigatus* conidia [66]. A hypothesis provided is that intracellular accumulation of these drugs may have influenced conidial metabolism, which in turn changed fungal-cell interactions causing a reduced TNF-α production. In contrast, incubation of voriconazole with MNCs in the presence of *A. fumigatus* hyphae upregulates inflammation-related genes such as IFN-γ, IL-1R1, and TNF-α potentially leading to a more efficient host resistance to *A. fumigatus* [64] (Table 53.3).

Immunomodulatory Effects of Echinocandins

Echinocandins modify dectin-1-dependent inflammatory response against *A. fumigatus* through modulation of the surface β-glucan content. The immune modulating effects of

β-glucans, a major fungal cell wall component, are attributed to the ability to bind PRRs including dectin-1 receptor. This receptor, primarily expressed by PMNs, macrophages, and DCs, mediate activation of various cellular functions from fungal binding, uptake, and fungal neutralization to cytokine and chemokine production [67, 68].

Preincubating *A. fumigatus* conidia with subinhibitory concentrations of caspofungin results in diminished TNF-α and CXCL2 release by macrophages; this molecular response is associated with diminished dectin-1 signaling, reflecting the minimal amounts of dectin-1 molecules present on the surface of conidia. In contrast, caspofungin or micafungin-treated *A. fumigatus* hyphae trigger enhanced inflammatory response, which is also highly associated with increased dectin-1 signaling [69] (Table 53.3). A complementary study [70] has confirmed that exposure to subinhibitory concentrations of caspofungin increases β-glucan exposure on the surface of *A. fumigatus*, *A. terreus*, *Fusarium solanii*, *F. oxysporum*, and *Scedosporium apiospermum* and augments PMN antihyphal activity. Similarly, in an in vivo animal model of disseminated candidiasis, subtherapeutic doses of caspofungin administered to mice resulted in exposure of the pro-inflammatory β-glucan epitope and augmentation of binding to dectin-1, leading to activation of innate immunity. In this study, direct measurement of morphotype-specific β-glucan exposure in mouse tissues during infection has shown that caspofungin causes hyphal-specific exposure of β-glucans with very few yeast-form cells to have exposed β-glucan molecules on their surface. These findings suggest that, during the normal course of infection, echinocandin-mediated unmasking and fungicidal activities are filament-biased. Such morphotype bias may be due to intrinsic structural differences between hyphal and yeast walls [71–73]. Of note, a recent report demonstrated that caspofungin-treated *C. albicans* is able to suppress ROS production in phagocytes, suggesting that suppression of ROS is independent of β-glucan exposure. Since phagocyte-generated ROS have microbicidal activity against many pathogenic microorganisms, suppression of ROS production may represent an evasion mechanism for *Candida* blastoconidia to escape phagocytic killing [74].

Modulation of phagocyte functions seems to be drug-specific as well as time- and organism-dependent. In particular, caspofungin significantly influences oxidative burst metabolism and improves intracellular killing rates of *C. albicans*, but has no effect on phagocytosis. Caspofungin used in clinically relevant concentrations synergizes with PMNs for intracellular killing of ingested *C. albicans* blastoconidia, providing indirect evidence of the drug's ability to pass through the cell membrane and remain in a biologically active form to clear intracellular proliferating *C. albicans* blastoconidia [75].

Infectious complications in renal transplant recipients, especially in the early post-transplant period, are mainly due to *C. albicans* [5]. A study evaluating the immunomodulating influence of caspofungin on PMNs isolated from such patients, in response to *C. albicans* echinocandin exerted antifungal activity by interacting with both the PMNs and the yeast. The drug interacted with the PMNs by entering cells and killing proliferating blastoconidia, and it also unmasked a virulence factor on *C. albicans* outer cell wall, rendering the fungus susceptible to PMNs lytic mechanisms [76].

Furthermore, when *A. fumigatus* hyphae are generated in the presence of sub-MIC values of micafungin and they are subsequently cultured with PMNs or MNCs, their metabolic activity is inhibited by >80% or > 60%, respectively. These findings support the hypothesis that the greater efficacy of micafungin could be due to the combined effect of phagocytic cells and antimold activity [77]. Similarly, anidulafungin was noted to significantly improve intracellular killing rates of *C. albicans* after 2 h of incubation [51] (Table 53.2). The encouraging data on the immunomodulating properties of echinocandins and particularly caspofungin come to reinforce their favorable pharmacodynamic and pharmacokinetic characteristics and clinical efficacy, supporting their use as empiric treatment in high-risk populations with impaired immune functions [78–80].

Candida, the most frequent pathogen isolated in bloodstream infections, form biofilm , a characteristic that increasesits disease causing potential and morbidity, especially among immunocompromised patients [81–83]. Biofilms are formed after single *Candida* cells attach to a suitable substrate i.e., vascular or urinary catheters, stents, pacemakers, or artificial joints; they then proliferate and grow into microcolonies forming well-organized cellular communities held together by pseudohyphae and a carbohydrate-rich extracellular matrix. Biofilms show increased resistance to antifungals compared to their planktonically grown forms and can withstand hosts' antifungal immune response [84–86]. In vitro biofilm models designed to evaluate MNC-mediated phagocytosis show that immune cells are unable to inhibit *C. albicans* to form biofilm and respond to the fungal form by differentially expressing several pro- and anti-inflammatory cytokines [87]. Although activities [this 'activity'] of voriconazole in combination with human MNCs have shown indifferent results in suppressing the metabolic activity of *C. albicans* within biofilms, the combined treatment of anidulafungin with MNCs have demonstrated additive interactions against the biofilm forms [88]. Similarly, anidulafungin in combination with PMNs also exert additive activity against *C. parapsilosis* biofilms [89].

Immunomodulatory Effects of Antibacterial Agents on Antifungal Activity

Immunocompromised patients are at high risk for *Candida* and *Aspergillus* infections, but they are also at high risk for bacterial infections. For this reason, antibacterial and antifungal agents may be administered simultaneously for pre-

vention and treatement of an established infection. Fluoroquinolones, such as ciprofloxacin, moxifloxacin, or levofloxacin, when combined with antifungal agents show improved antifungal effect. In drug combination studies, where fluoroquinolones were combined with amphotericin B, voriconazole, or caspofungin, a synergistic pharmacodynamic interaction was observed against *C. albicans* and for *A. fumigatus* resulting in alterated growth inhibitory activity. Fluoroquinolones, by binding to fungal topoisomerases, may interfere with DNA replication and inhibit fungal proliferation; since fluoroquinolones are unable to gain intracellular access due to lack of fungal cell membrane permeability, it has been hypothesized that antifungal agents may increase intracellular concentrations of fluoroquinolones [90, 91]. More importantly, the effectiveness of the combined action of ciprofloxacin and amphotericin B in modulating the antifungal activity of PMNs against *A. fumigatus* has recently been shown, suggesting that both antimicrobial agents exert a beneficial effect on the oxidative mechanisms of PMNs thereby optimizing antifungal effect [92].

Modulation of Phagocytes' Activity by the Combined Effect of Cytokines and Antifungal Agents

Indirect modulation of phagocyte behavior was demonstrated after pretreatment with cytokines and exposure to antifungal drugs. In vitro and in vivo preclinical studies of the combined effect of cytokines with antifungal agents on the antifungal activity of phagocytes have promised a better outcome for combined drug-cytokine therapy in treating life-threatening invasive fungal disease. Activation of phagocytes with granulocyte-macrophage colony-stimulating factor (GM-CSF) or IFN-γ enhances the intracellular anticandidal activity of voriconazole against fluconazole-resistant *Candida* spp. or *C. neoformans* [52, 93]. Caspofungin and the voriconazole-caspofungin combination enhances activity of GM-CSF-primed monocytes in both time- and dose-dependent manner [53]. In another in vitro study G-CSF- or GM-CSF-activated PMNs were shown to enhance collaboration with voriconazole against *A. fumigatus* hyphae [94] (Table 53.2). Pretreatment of murine macrophages with IFN-γ and subsequent amphotericin B exposure was able to activate the synthesis of nitrogen reactive intermediates inhibiting replication of ingested *C. neoformans* [95]. Most in vivo studies using hematopoietic growth factors or recombinant interleukins as adjunctive agents in antifungal therapy have reported either a beneficial response [96–99] or no significant difference [100, 101] (Table 53.2) in the survival of infected mice.

An important issue raised by these experimental models of invasive fungal infections is the impact of the host predisposing factors on the outcome of combined therapies with antifungal agents and cytokines. Early in infection, neutralization of the protective Th1 pro-inflammatory cytokines like IFN-γ, TNF-α, or IL-12 leads to the development of Th2 rather than Th1 cellular response, which promotes progressive fungal disease, whereas neutralization of IL-4 and IL-10 upregulates the desirable Th1 rather than Th2 response [102, 103]. In immunocompetent mice with lethal disseminated candidiasis, treatment with amphotericin B or fluconazole is associated with Th1 immune response. Leukopenic or neutropenic mice respond differently to the therapeutic efficacy of antifungal agents combined with cytokines. In particular, the efficacy of combined therapy with soluble IL-4 receptor and amphotericin B is higher in leukopenic than in neutropenic mice, whereas coadministration of recombinant IL-12 and fluconazole is higher in neutropenic than in leukopenic mice. The synergistic effect of the combination treatments is retained in immunocompromised mice [97]. Corticosteroids, another major predisposing factor for invasive fungal infections, maintain the number of dysfunctional PMNs, which are unable to restrict fungal growth; administration of G-CSF to corticosteroid-treated mice with disseminated aspergillosis contributes to the development of progressive disease by increasing the number of dysfunctional PMNs and antagonizing the therapeutic effect of posaconazole [100]. These data indicate that the host immune reactivity influences the efficacy of antifungal drugs given in combination with certain cytokines. The immune modulatory role that combined treatment of antifungal agents and cytokines play in promoting defenses against fungal pathogens; preclinical and limited clinical data for adjunct combination therapy with antifungals is periodically reviewed and perhaps such combination regimens may improve antifungal activity of neutrophils and monocytes/macrophages as well as upregulate protective T-helper type 1 adaptive immune response, however at present, such combinations are not routinely recommneded in the management of IFIs even in severely immunosuppressed patients undergoing allogeneic transplantation [104–109].

Conclusions

In addition to their capacity to affect the development and proliferation of fungi, antifungal agents directly interact with the hosts' immune system. Immunomodulatory effects of antifungals include alteration of phagocytosis, augmentation of oxidative and nonoxidative mechanisms of first line immune defense cells, chemotaxis, and pro-inflammatory or anti-inflammatory cytokine production.

DAMB interacts with CD14, TLR1, and TLR2 receptors, inducing a MyD88-dependent intracellular signaling cascade that culminates in the activation of NF-κB transcription factor and the subsequent upregulation of pro-inflammatory cytokines and chemokines. By diverting signaling from

TLR2 to TLR4, LAMB augments antifungal activity of phagocytes while attenuating the pro-inflammatory effects observed with DAMB. Similarly, ABLC downregulates the pro-inflammatory response and increases the antihyphal activity of phagocytes, whereas ABCD shows similar gene expression and antifungal profiles noted with DAMB. These observations offer a putative molecular basis for optimization of LAMB/ABLC therapeutic efficacy for invasive fungal diseases as opposed to the cytokine-mediated adverse effects in response to DAMB/ABCD drug formulations.

Among azoles, voriconazole interact with TLR2, TLR4, or TLR9 thereby enhancing pro-inflammatory programs of phagocytes and augment their antifungal activity, a feature that is maintained after activation of phagocytes with GM-CSF or G-CSF. In contrast, fluconazole by interacting with TLR9 induces a moderate antifungal phagocytic activity; however, pretreatment of immune cells with G-CSF and subsequent exposure to fluconazole appears to synergistically effect in confronting fungal infections.

Among echinocandins, the immunomodulatory role of caspofungin was mediated via cross talk between TLR2, TLR4, TLR9, and dectin 1 receptor leading to the induction of Th1 pro-inflammatory program in activation of antifungal host defense. Similarly, anidulafungin and micafungin have a favorable effect on intracellular killing, especially for yeasts in biofilm. Antibacterial agents, such as ciprofloxacin, when combined with amphotericin B exert a positive effect on the oxidative antifungal mechanisms of phagocytes.

Considerable information has been accumulated on immunomodulatory properties of antifungal agents on hosts' immune response, there is still much to be deciphered regarding the potential interference between pathogen-targeting drugs and the phagocytic effector cell response, especially among allograft transplant recipients. Powerful new technology platforms for data acquisition and processing are urgently needed to perform genome-wide association studies comparing various treatment regimens in the context of antifungal-host-pathogen interaction. Presently, limited clinical data exist to conclude clinical feasibility and potential benefit from immunomodulatory therapy. The possible synergistic role of new antifungal agents on hosts' cytokines response offers an opportunity to optimize treatment for life-threatening fungal disease in the at risk transplant population.

Disclosure of Potential Conflict of Interest None of the authors of this manuscript have potential conflict of interest.

Antiviral Consideration for Transplantation Including Drug Resistance

54

Sunwen Chou and Nell S. Lurain

Introduction

Antiviral therapy is routinely used in transplant recipients for the prevention and treatment of herpesvirus infections and influenza, as well as treatment of chronic viral hepatitis and HIV. In addition, therapy is often considered for respiratory, gastrointestinal, and disseminated viral syndromes, for which in many cases no FDA-approved treatments are currently available. Where proven therapy is available for acute viral infections, a good outcome requires prompt treatment facilitated by rapid molecular viral diagnostic testing.

Active post-transplant viral infections arise from preexisting latent and persistent infections in the recipient and/or donor, and from nosocomial or community sources reflecting current epidemiology. Assessment of the timing and probabilities of these sources of infection enables a preventive or prophylactic antiviral approach that is more likely to be successful than the treatment of viral disease that has caused end-organ damage.

Host factors strongly influence the selection, duration, and expected outcome of antiviral treatment. Critical factors include prior host immunity to the infecting virus and the extent of post-transplant immunosuppression. Approved uses and benefits of antiviral treatment that are based on clinical trials in normal hosts or other patient populations do not necessarily apply to transplant recipients, leaving many unresolved questions on optimal use of current antivirals.

Natural history and treatment responsiveness of acute and chronic infections may depend on baseline genetic differences of infecting strains of viruses such as herpes simplex, influenza, and hepatitis C. Prolonged exposure to antiviral drugs may lead to the selection of drug-resistant mutants and a need for laboratory confirmation and/or alternative treatment.

Antiviral drug development requires multiple testing stages to evaluate potential benefits for various indications and patient populations, in relation to toxicity, pharmacological complexity, and cost. At each stage, candidate compounds are eliminated, or controlled trials may not be done. It is important to refrain from a presumption of efficacy based on promising preliminary uncontrolled findings. Case reports are problematic because the outcome of viral infection is highly dependent on host defenses. Favorable individual outcomes coincidental with unproven treatments may lead to complicated and costly recommended practices that should not be mistaken as evidence-based treatments.

In this chapter, we review antiviral drug therapy other than for HIV infection from the standpoint of mechanisms of action, clinical applications, and antiviral drug resistance. Recommendations for antiviral therapy of specific conditions and patient subsets are discussed in chapters dealing with the individual viruses.

Herpesvirus Antivirals

Several licensed herpesvirus antiviral drugs (see Table 54.1) are available, which target the viral DNA polymerase that is essential for viral replication. Herpesvirus genomes encode many other important gene products that are attractive targets for antiviral therapy. Issues of toxicity and emerging antiviral resistance associated with the longstanding approved drugs have led to clinical trials of promising experimental compounds.

Table 54.1 Antiviral agents approved for therapy of herpesviruses (mid-2017)

Antiviral agent (abbreviation)	Structure and mechanism of action	Therapeutic uses and doses (see important cautions)[a]	Adverse effects	Resistance mechanisms
Acyclovir (ACV)	Acyclic guanosine nucleoside analog. Inactive until converted to monophosphate by viral thymidine kinase and then converted to triphosphate by cellular kinases. ACV triphosphate inhibits viral DNA polymerase; obligate DNA chain terminator when incorporated into growing DNA strands	Treatment of active disease: Mucocutaneous (oral, genital, skin) HSV infection PO, 400 mg 3×/day IV, 5 mg/kg every 8 h Visceral and disseminated HSV infection IV, 10 mg/kg every 8 h VZV infection: localized zoster PO, 800 mg 5×/day (VACV or FCV preferred) IV, 5 mg/kg every 8 h VZV infection, primary or disseminated IV, 10 mg/kg every 8 h Prevention of HSV and VZV reactivation PO, 400–800 mg 2×/day (not needed if receiving GCV or VGCV for CMV)	Nephrotoxicity: crystalluria with rapid IV infusion or renal dysfunction Neurotoxicity: headache, encephalopathy, seizures with drug accumulation resulting from high doses and/or renal dysfunction	Viral thymidine kinase mutations resulting in deficient, altered or partial activity; DNA polymerase mutations less common Cross-resistance with penciclovir and ganciclovir expected because resistant mutants are usually thymidine kinase deficient
Valacyclovir (VACV)	L-valyl ester prodrug of ACV. Metabolically converted to ACV in intestinal and liver cells and then same action as acyclovir	Treatment of active disease: Mucocutaneous HSV infection PO, 1000 mg 2×/day VZV infection: localized zoster PO, 1000 mg 3×/day Prevention of HSV and VZV reactivation PO, 500 mg 2×/day (not needed if receiving GCV or VGCV for CMV)	Same as ACV; GI[b] Thrombotic angiopathy at high doses (8 g/day) in AIDS	Same as ACV
Famciclovir (FCV)	Diacetyl ester prodrug of penciclovir (PCV), an acyclic guanosine analog. PCV is phosphorylated by viral thymidine kinase and cellular enzymes, as with acyclovir. PCV triphosphate inhibits DNA polymerase although not obligate DNA chain terminator	Treatment of active disease: Mucocutaneous HSV infection PO, 500 mg 2×/day VZV infection: localized zoster PO, 500 mg 3×/day Prevention of HSV and VZV reactivation PO, 500 mg 2×/day (if not receiving CMV prophylaxis; see below)	Headache, GI[b]	Thymidine kinase mutation more common than DNA polymerase mutations. Cross-resistance with ACV expected
Ganciclovir (GCV)	Acyclic guanosine nucleoside analog. Converted to monophosphate by viral kinase (HSV TK, CMV UL97), then to triphosphate by cellular kinases. GCV triphosphate inhibits viral DNA polymerase although not obligate DNA chain terminator	Treatment of active CMV disease: IV 5 mg/kg every 12 h Preemptive treatment of CMV reactivation: IV 5 mg/kg every 12 h Prophylaxis of CMV infection: IV 5 mg/kg per day Oral ganciclovir no longer marketed	Bone marrow suppression: Granulocytopenia, anemia, thrombocytopenia, GI[b] Avoid coadministration of GCV with imipenem-cilastatin; may cause seizures	Mutations in UL97 kinase, commonly M460V/I, H520Q, C592G, A594V, L595S, and C603W. Others mostly at codons 590–607 Less common DNA polymerase mutations, usually confer cross-resistance to CDV and less often to FOS

Table 54.1 (continued)

Antiviral agent (abbreviation)	Structure and mechanism of action	Therapeutic uses and doses (see important cautions)[a]	Adverse effects	Resistance mechanisms
Valganciclovir (VGCV)	L-valyl ester prodrug of GCV. Metabolically converted to GCV in intestinal and liver cells. Then same antiviral action as GCV	Treatment of mild-moderate CMV disease: PO 900 mg 2×/day Preemptive treatment of CMV reactivation: PO 900 mg 2×/day Prophylaxis of CMV infection: PO 900 mg per day for 100–200 days after solid organ transplantation (see text)	Same as GCV; GI[b]	Same as GCV
Foscarnet (FOS)	Trisodium phosphonoformate; pyrophosphate analog. Noncompetitive inhibitor of DNA polymerase pyrophosphate binding site	Treatment of tissue-invasive CMV disease when intolerant, resistant or refractory to GCV; IV, 90 mg/kg over 1.5–2 h every 12 h with prehydration; can be reduced to 90 mg/kg daily for maintenance therapy Treatment of ACV-resistant VZV disease: same dose as above Treatment of ACV-resistant HSV disease IV 40 mg/kg over 1 h every 8 or 12 h	Nephrotoxicity (25%), metabolic and electrolyte abnormalities, seizures; fluid load from saline prehydration. Must carefully monitor and replete multiple electrolytes as needed Avoid other nephrotoxic drugs	DNA polymerase mutations For CMV, some low-grade cross-resistance with GCV, rarely CDV For HSV and VZV, some cross-resistance with ACV
Cidofovir (CDV)	Cytosine monophosphate nucleotide analog. Phosphorylated by cellular kinases to cidofovir diphosphate (nucleoside triphosphate analog). Viral kinase not needed for antiviral activity	Treatment of CMV, HSV or VZV disease when intolerant, resistant, or refractory to GCV and FOS: IV, 5 mg/kg 1×/week for 2 weeks, then 5 mg/kg every 2 weeks, with saline pre- and post-hydration and oral probenecid 2 g, 3 h before dose, then 1 g 2 and 8 h after dose Treatment of disseminated adenovirus infection (same dosing)	Nephrotoxicity (25%); monitor closely and stop CDV if present Probenecid-related toxicity: GI[b], rash, drug interactions (e.g., decreased GCV renal clearance) Avoid other nephrotoxic drugs	DNA polymerase mutations For CMV, cross-resistance with GCV, rarely with FOS

[a]Recommended uses for adult transplant recipients with normal renal function. Doses of all drugs must be adjusted for renal function. Many of the listed uses are not FDA-approved; see text. See package insert for FDA-approved indications and doses. Abbreviations: *IV* intravenously, *PO* orally
[b]GI (gastrointestinal) symptoms include diarrhea, nausea, and vomiting

Acyclovir, Valacyclovir, Penciclovir, and Famciclovir

All of these drugs are structurally related guanosine nucleoside analogs that are selectively phosphorylated by a viral kinase during conversion to the active triphosphate form that inhibits the viral DNA polymerase (see Table 54.1). Valacyclovir is an oral prodrug of acyclovir, and famciclovir is the oral prodrug of penciclovir.

Acyclovir is active against herpes simplex (HSV-1 and HSV-2) and varicella-zoster (VZV) viruses, which all encode a thymidine kinase (TK) that phosphorylates acyclovir. Acyclovir is not a good substrate for the Epstein-Barr virus (EBV) TK [1]. However, EBV and cytomegalovirus (CMV) encode other kinases (BGLF4 and UL97, respectively), which can phosphorylate acyclovir to some extent [1, 2].

Traditionally, the drug concentration required to reduce viral growth by 50% (EC50) in a cell culture plaque reduc-

tion assay is used to assess HSV, VZV, and CMV susceptibility in vitro. Acyclovir is most active in vitro against HSV-1 (EC50 about 1 μM) and HSV-2 (EC50 about 2 μM), and VZV and EBV are less susceptible with EC50 about 4–6 μM [1], while CMV is relatively resistant with EC50 ≥40 μM [2]. The in vitro activity of penciclovir against herpesviruses is comparable to acyclovir. Penciclovir is more effectively phosphorylated in HSV-infected cells than is acyclovir, and the triphosphate persists within infected cells longer than acyclovir triphosphate, but the latter is a more potent inhibitor of the viral DNA polymerase than penciclovir triphosphate [3].

Pharmacology

Acyclovir is available for intravenous (IV) use, with peak plasma concentrations of 30–60 μM and elimination half-life by renal secretion and glomerular filtration of about 3 h [4]. Dose adjustment is required for impaired renal function. CSF levels of acyclovir are about 25% of plasma levels [5]. The oral bioavailability of acyclovir is poor (15–20%), but low cost and adequate achievable plasma concentrations (3–7 μM) resulted in widespread use for less severe HSV and VZV disease (Table 54.1) before the advent of generic valacyclovir.

The acyclovir prodrug valacyclovir has much better bioavailability [6] and achieves circulating levels comparable to IV therapy, which is useful for the prophylaxis and treatment of mild to moderate HSV and VZV disease (Table 54.1). Penciclovir itself is marketed only as a topical cream, but its oral prodrug famciclovir has bioavailability and therapeutic indications similar to valacyclovir.

Acyclovir, valacyclovir, and famciclovir are relatively well tolerated, with lack of bone marrow toxicity being a significant advantage. Problems may arise when high doses are used, infused too quickly, or where renal impairment is present. Good hydration and monitoring for renal function are essential during high-dose IV therapy. Excessive acyclovir doses may cause crystalluria and encephalopathy. Very high oral doses of valacyclovir (8 grams per day) have been associated with thrombotic microangiopathy and hemolytic uremic syndrome and should be avoided [7].

Clinical Indications

The routine use of acyclovir in transplantation is for the prevention of mucocutaneous HSV disease and herpes zoster (Table 54.1). For hematopoietic cell transplantation, current guidelines [8, 9] recommend acyclovir or valacyclovir prophylaxis for HSV and VZV starting at the beginning of conditioning therapy and continuing until engraftment or until mucositis resolves, usually about 1 month of prophylaxis. Prophylaxis can be extended beyond the early post-transplant period in patients with a history of recurrent symptomatic disease. Adequate doses are suggested to reduce the incidence of incomplete suppression and drug resistance, including recommendation for twice daily dosing of valacyclovir. Analogous recommendations apply in solid organ transplantation: if ganciclovir or valganciclovir is not being used to prevent CMV disease, acyclovir-based prophylaxis may be given for at least 1 month [10, 11].

Active post-transplant HSV and VZV infection can be treated with IV acyclovir (Table 54.1). Although oral acyclovir, valacyclovir, and famciclovir are not specifically FDA-approved for these indications in transplant recipients, they are widely used for less severe infections [10, 11]. Disseminated or visceral disease in transplant recipients should be treated with IV acyclovir until progressive disease has resolved, and then considered for conversion to oral therapy for several additional weeks. HSV encephalitis is rare in the transplant population, but disseminated HSV infection may present as pneumonia, severe hepatitis, and gastrointestinal disease and requires timely diagnosis to enable prompt initiation of IV acyclovir. Despite controlled clinical trials demonstrating a benefit of acyclovir or valacyclovir prophylaxis in reducing post-transplant CMV disease [12], ganciclovir and valganciclovir are currently preferred, as discussed below.

Drug Resistance Mechanisms

In over 90% of cases, HSV or VZV resistance to acyclovir results from a mutation in the TK gene [13, 14]. Because this gene is nonessential for viral replication, any mutation that prevents the translation of a functional kinase can confer resistance to both acyclovir and famciclovir. Frameshift mutations at homopolymer tracts (3–7 repeats of the same nucleotide) in the TK gene, resulting in a truncated molecule, are collectively the most common genetic basis for drug resistance in HSV and VZV. Premature stop mutations are also relatively frequent in VZV. Mutations causing single amino acid substitutions, clustering in the adenosine triphosphate (ATP) and nucleoside binding domains, can result in a functionally deficient kinase or one with decreased affinity for the antiviral nucleoside analog [13, 15]. The latter class of mutations may confer resistance to a specific drug, but acyclovir and famciclovir cross-resistance is the rule for TK mutants [16]. TK-defective HSV strains have been reported to be less pathogenic or less neurovirulent in animal models [17] but in clinical practice progressive disease due to acyclovir-resistant HSV is well described [13].

Mutations in the viral DNA polymerase gene (*pol*) can also confer resistance to nucleoside analogs and have the potential for cross-resistance to other drugs with the same target [18], but are far less common than TK mutations after acyclovir treatment. HSV *pol* mutations conferring acyclovir resistance have been mapped to conserved functional domains in herpesviruses DNA polymerases, with clustering in the palm and finger structure domains for both HSV and VZV [13, 18]. Available data suggest that such mutations frequently confer acyclovir-foscarnet cross-resistance.

Ganciclovir and Valganciclovir

Ganciclovir is structurally related to acyclovir and is also initially phosphorylated by a viral kinase, but unlike acyclovir its triphosphate is not an obligate chain terminator. Valganciclovir is the oral prodrug (Table 54.1). CMV does not encode a thymidine kinase, but the CMV UL97 protein kinase incidentally phosphorylates ganciclovir. Ganciclovir has much greater in vitro potency against CMV than acyclovir and is FDA-approved solely for this virus [19], although it has strong in vitro activity against HSV-1, HSV-2, and VZV as well [20].

Pharmacology

Ganciclovir is available for IV use (Table 54.1), with expected peak plasma concentrations of 30–40 μM and elimination half-life of about 3.5 hours primarily by renal clearance. After monophosphorylation by a virally encoded kinase and then by cellular enzymes, the resulting intracellular ganciclovir triphosphate has a prolonged half-life estimated at >24 h [21]. This probably accounts for the slower resumption of CMV growth after removal of ganciclovir from culture media, in comparison with some other CMV antivirals [22]. Oral ganciclovir has poor bioavailability [23] and is no longer marketed despite FDA approval for prevention of CMV disease in transplantation and AIDS. Valganciclovir has better oral bioavailability of about 60% and is the preferred oral formulation. Ganciclovir and valganciclovir toxicity manifests primarily as bone marrow suppression, which can become dose limiting [24, 25]. Granulocyte colony-stimulating factors may help with marrow recovery.

Clinical Indications

The introduction of ganciclovir did little to alter the fatal outcome of advanced CMV pneumonia [26]. Thus, the prevention of serious CMV disease became the main antiviral goal in transplant recipients. Two approaches to prevention were formulated: early identification of CMV viremia prior to end-organ disease by regular monitoring, followed by prompt "preemptive" treatment; or antiviral prophylaxis for planned durations after transplantation. Clinical trials showed that either approach using IV or oral ganciclovir was effective, more so than acyclovir-based regimens [12, 27].

Randomized clinical trials resulted in the current FDA-approved indications for valganciclovir in transplantation (Table 54.1). A trial of 100 days of valganciclovir vs. oral ganciclovir in high-risk solid organ recipients (mainly liver and kidney) showed comparable efficacy at preventing CMV disease when assessed at 6 and 12 months post-transplant [28]. FDA approval of valganciclovir was withheld for liver transplant recipients because of a higher incidence of invasive CMV disease, but valganciclovir therapy for this recipient subset is widely used and recommended [29]. Another trial concluded that valganciclovir prophylaxis for 200 days was superior to 100 days in preventing CMV disease at 12 months in high-risk kidney recipients [30], resulting in FDA approval for extended prophylaxis in this patient subset.

For treatment of overt CMV disease, ranging from an undifferentiated febrile syndrome to invasive disease such as colitis or pneumonia, IV ganciclovir remains a standard option. A controlled trial showed noninferiority of oral valganciclovir when compared to IV ganciclovir for the treatment of nonthreatening CMV disease in solid organ recipients [31], but this use of valganciclovir is not FDA-approved. Duration of therapy is dependent on clinical response but is typically several weeks followed by oral maintenance therapy until viremia is cleared.

Drug Resistance Mechanisms

Over 90% of ganciclovir-resistant clinical isolates contain a mutation in the UL97 kinase gene [32]. The most relevant mutations reduce the phosphorylation of ganciclovir while preserving biologically important UL97 kinase activity and near-normal viral growth. One of seven UL97 amino acid substitutions (Table 54.1) is found in about 80% of ganciclovir-resistant clinical isolates [32]. These substitutions generally confer five- to tenfold increases in ganciclovir EC50, except for C592G which confers only a threefold increase. In the UL97 codon range 590–607, less common sequence variants include point mutations and in-frame codon deletions, which confer degrees of ganciclovir resistance ranging from none to 15-fold [33].

Many CMV DNA polymerase (UL54 *pol*) mutations found in clinical specimens have been analyzed for their drug resistance phenotype [32, 34]. Such mutations may confer resistance to one or more of the currently approved CMV drugs ganciclovir, foscarnet and cidofovir, and in the case of ganciclovir may combine with a preexisting UL97 mutation to increase the overall level of drug resistance several fold. Rarely, ganciclovir may select for a *pol* resistance mutation before a UL97 mutation is detected. In general, ganciclovir and cidofovir dual resistance without foscarnet cross-resistance results from mutation in the exonuclease domains or codon 987 in the thumb domain.

Foscarnet

Foscarnet is trisodium phosphonoformate, a pyrophosphate analog, which inhibits the viral DNA polymerase by interfering with the release of pyrophosphate from the incoming nucleotide during DNA replication. The antiviral spectrum of foscarnet in vitro includes all herpesviruses, HIV, and hepatitis B virus [35], but it is FDA-approved only for treatment of HSV and CMV.

Pharmacology

Foscarnet is available as a solution containing 24 mg/mL for IV use [35]. To reduce toxicity, saline prehydration of up to a liter is recommended. Foscarnet is not further metabolized but is renally excreted by glomerular filtration and secretion, and is significantly deposited in bone. Variable uptake in bone may explain the great variation in plasma pharmacokinetics of foscarnet, with peak concentrations expected around 500 μM and a plasma elimination half-life of about 4.5 h. There is a prolonged phase of slow clearance of accumulated drug from bone.

Foscarnet therapy is frequently limited by nephrotoxicity and metabolic disturbances, such as hypocalcemia, hypophosphatemia, hypomagnesemia, and hypokalemia, all of which can become symptomatic (including tetany, seizures, and arrhythmias) and always require close monitoring and electrolyte repletion as needed. The infusion rate must be controlled to avoid acute impact on electrolyte concentrations. The need for prolonged IV infusions and access devices complicates treatment planning. The fluid and salt load of the saline prehydration may be poorly tolerated. Concentration of foscarnet in the urine may cause uroepithelial cytotoxicity and genital ulceration.

Clinical Indications

For treatment of overt CMV disease, FDA approval of foscarnet remains limited to retinitis, because there have been no controlled treatment trials for other tissue-invasive disease. There are, however, case series on the use of foscarnet especially in stem cell transplant recipients to avoid the dose-limiting hematologic toxicity of ganciclovir [36], and for treatment of ganciclovir-resistant infection [37]. Overall data suggest similar virologic efficacy as ganciclovir, but with a different set of major toxicities as outlined above. Comparison of 14 days of preemptive therapy with IV ganciclovir or foscarnet after allogeneic stem cell transplantation [38] showed similar efficacy in preventing CMV disease, with the expected toxicities for each drug.

Foscarnet is FDA-approved for treatment of acyclovir-resistant mucocutaneous HSV infection in immunocompromised hosts [13]. Although unapproved, this indication is in practice extended to the treatment of acyclovir-resistant herpes zoster.

Drug Resistance Mechanisms

Foscarnet resistance mutations in HSV, VZV, and CMV are clustered in the palm and finger structure domains of their corresponding DNA polymerases [13, 18, 32]. However, some mutations map to locations well outside these domains. Acyclovir and foscarnet cross-resistance of HSV and VZV may result from mutations that cluster in the same polymerase domains for both drugs [13]. CMV foscarnet resistance mutations may show variable low-grade or borderline ganciclovir and/or cidofovir cross-resistance. A few specific mutations such as A834P or deletion of codons 981–982 confer moderate triple drug resistance. The level of ganciclovir or foscarnet resistance conferred by CMV *pol* mutations is usually in the two- to fivefold range [32].

Cidofovir

Cidofovir is an acyclic nucleoside phosphonate nucleotide analog. It does not require initial phosphorylation by a viral kinase. Instead, cellular enzymes convert cidofovir to its active diphosphate form, which is a nonobligate DNA chain terminator. Cidofovir was FDA-approved in 1996 for treatment of CMV retinitis in AIDS. This narrow approved usage is in contrast with its wide in vitro antiviral spectrum which includes herpesviruses, adenoviruses, poxviruses, and even papovaviruses that do not encode their own DNA polymerase [39]. Cidofovir has good in vitro potency against HSV, VZV, and CMV.

Pharmacology

The specified cidofovir dosing protocol (see Table 54.1) includes extensive pre- and post-hydration and three doses of probenecid in an attempt to reduce nephrotoxicity. Cidofovir is renally cleared and renal function must be closely monitored both to guide dosing and to discontinue use for deteriorated renal function or proteinuria. The medication is given at long intervals, in part to avoid the rapid development of nephrotoxicity, and because the cidofovir diphosphate has a long intracellular half-life. In clinical trials, about a quarter of subjects developed nephrotoxicity, a similar fraction as foscarnet therapy despite the use of hydration and probenecid [40]. Ophthalmologists using cidofovir as systemic or intravitreal therapy have reported uveitis and intraocular hypotony as distinctive complications [41]. Intolerance of cidofovir therapy may also result from adverse reactions to the significant saline hydration and probenecid that accompanies each dose.

Clinical Indications

No controlled trials have established the efficacy of cidofovir for treating any tissue-invasive CMV disease in the transplant setting, whether as initial therapy or for salvage. In the stem cell transplant population, a retrospective series was collected of cidofovir use as salvage or preemptive therapy for CMV disease [40]. Such uncontrolled studies carry a risk of reporting bias. As salvage therapy, there was apparent benefit in 9 of 16 cases of CMV pneumonia, and the efficacy of cidofovir as preemptive therapy was estimated at about 65%. Nephrotoxicity was noted in 26% and was persistent in more than half of the cases where it occurred. Cidofovir is generally regarded as a third line treatment for resistant or

refractory CMV disease in transplant populations. Efficacy is poorly documented, with both optimistic reports and those indicating only a transient virologic benefit followed by emergence of cidofovir resistance.

An orally bioavailable lipid conjugate of cidofovir, hexadecyloxypropyl-cidofovir or brincidofovir (CMX001), has undergone clinical trial. Nephrotoxicity is reduced with this formulation because cidofovir is not concentrated in renal tubular cells [42]. The in vitro antiviral potency of brincidofovir is orders of magnitude greater than the parent compound, but this did not allow a corresponding decrease in the prophylactic dose in a Phase II dose ranging trial in stem cell recipients [43]. At the selected dose, severe diarrhea and associated increased mortality caused the failure of a Phase III CMV prophylaxis trial in stem cell recipients (clinicaltrials.gov NCT01769170). Use of brincidofovir may possibly be revisited if an improved risk-benefit profile is established by use of new formulations or careful selection of treatment candidates.

There is interest in the antiviral activity of cidofovir against adenoviruses and polyomaviruses (BK, JC), which are significant pathogens in transplant recipients [39]. Use of cidofovir has been suggested for adenovirus infections in allogeneic stem cell transplantation [44]. More recently, 9 of 13 subjects with adenovirus disease appeared to have a virologic response to brincidofovir [45]. An expanded access protocol (clinicaltrials.gov NCT02596997) was registered in late 2015 to provide brincidofovir for treatment of serious adenovirus infection or disease.

Drug Resistance Mechanisms

Mutations conferring drug resistance to cidofovir in the CMV DNA polymerase gene are clustered in the exonuclease and thumb domains [32], and cross-resistance with ganciclovir is expected. In some cases, a relatively large increase in cidofovir EC50 (10–20-fold) is conferred by these mutations. There is little information on resistance mutations of HSV and VZV that develop after cidofovir treatment.

Incidence and Clinical Diagnosis of Herpesvirus Drug Resistance

The risk of drug resistance increases with the duration and intensity of active viral replication while under treatment. Contributory host factors include severe immunosuppression and lack of preexisting immunity. Resistance usually emerges after weeks to months of drug exposure, and is suspected when there is active viral replication or progressive disease despite adequate antiviral drug delivery.

The prevalence of acyclovir- and penciclovir-resistant HSV isolates among immunocompetent populations is generally <1% [13, 14, 17], except that those repeatedly treated for herpes keratitis may have a higher frequency of acyclovir resistance, reported at 6.4% [46]. In immunocompromised transplant recipients, prevalence of acyclovir-resistant HSV can reach 7–10% and higher in allogeneic marrow recipients [17, 47]. Limited data appear similar for VZV [48].

CMV-seronegative recipients of a CMV-seropositive transplanted solid organ (D+/R-subset) are at the highest risk of drug resistance because of prolonged prophylaxis or therapy for post-transplant primary CMV infection and disease [32]. Incidence of ganciclovir resistance in this subset is 5–12% and higher among lung recipients. Transplant recipients who have profound and prolonged T-cell depletion resulting from anti-CD52 alemtuzumab therapy, are also a high-risk population. Drug-resistant CMV disease is associated with increased morbidity and mortality, probably reflecting underlying conditions that predisposed the host to the development of resistant virus [49].

In high-risk populations, treated subjects should be monitored regularly for a virologic and clinical response. Rising plasma viral loads or progressive disease after more than 2 weeks of full treatment doses may be an early indicator of emerging drug resistance. The rapidity of development of resistance depends on the intensity of viral replication while under treatment, but is rarely detectable until after at least 6 weeks and usually a few months of drug exposure.

An unsatisfactory response to antiviral therapy may result from adverse host factors, inadequate drug potency at tissue sites of infection, or development of antiviral drug resistance. Laboratory confirmation of drug resistance is desirable to evaluate alternative therapeutic options.

For HSV, phenotypic testing of a patient's viral isolate against drug in cell culture to determine an EC50 value is recommended, because HSV grows easily and rapidly [13], whereas slow growth makes this assay less feasible for VZV. Genotypic assays for HSV and VZV involve polymerase chain reaction (PCR) amplification and sequencing of the viral TK and *pol* genes. TK deficiency can be inferred, if a TK frameshift or stop mutation is detected, but uncertainty can arise from the many uncharacterized TK and *pol* amino acid substitutions in HSV [13]. VZV has fewer TK sequence polymorphisms and strong clustering of *pol* mutations, which may facilitate interpretation [13, 15, 18]. TK deficient strains can be expected to be highly resistant to acyclovir while *pol* mutants would typically show more moderate resistance [15].

CMV drug resistance testing relies mainly on genotypic assays of viral sequences directly amplified from clinical specimens, usually the same plasma specimens used for viral load determinations. It is inadvisable to attempt genotyping on plasma loads of less than 1000 genome copies/mL because of the risk of nonrepresentative PCR amplification [50]. Assays are available from academic and commercial reference laboratories.

Interpretation of the results is straightforward if a known UL97 or *pol* resistance mutation is reported [32]. Uncharacterized UL54 *pol* sequence variants can be difficult to interpret because of significant baseline sequence polymorphisms, mostly outside conserved functional domains and technical artifacts that can arise during genotypic testing [51]. Newly recognized mutations can be tested for relevance to drug resistance after transferring them into baseline laboratory CMV strains. This recombinant phenotyping procedure is too slow to resolve a current diagnostic uncertainty [32].

Management of Herpesvirus Drug Resistance

Clinical guidelines have been developed that take into account a lack of prospective data to address the natural history of drug-resistant infection, the efficacy of alternative therapy, and criteria for their use [13, 29]. Proposed management algorithms require individual interpretation, given the great variability in host factors and prior antiviral drug exposure. At the outset, it is important to improve host antiviral defenses as much as possible, such as by minimizing immunosuppressive therapy. Another concern is for adequate antiviral drug delivery, including dosage, formulation, duration, and patient adherence.

The urgency with which antiviral treatment must be switched depends on the severity of the current infection as judged by measured viral loads and symptomatic disease. Severe disease in a seriously immunocompromised host may warrant empiric foscarnet therapy. Otherwise, full doses of IV acyclovir for HSV or VZV infection, or higher doses of IV ganciclovir for CMV infection, up to 10 mg/kg twice daily in patients with normal renal function can be continued, pending genotypic testing; high-dose ganciclovir is not FDA-approved [13, 29].

For confirmed acyclovir-resistant HSV or VZV, foscarnet is the main alternative therapy because resistance usually results from TK mutations [13]. However, acyclovir-foscarnet cross-resistance is typical for the uncommon *pol* mutants of HSV and VZV that may emerge [18]. In these instances, cidofovir may be an option [13].

Full- or high-dose IV ganciclovir may retain meaningful anti-CMV activity in the presence of mutations that confer lower-grade resistance to ganciclovir [33]. Foscarnet is the usual alternative therapy for ganciclovir-resistant CMV as it has less cross-resistance than cidofovir. Cidofovir should not be chosen for ganciclovir-resistant CMV infection without genotypic testing for a *pol* mutation conferring cross-resistance. Even if one is not detected, there is concern that undetected resistant *pol* mutant subpopulations may emerge relatively rapidly [52].

Other Herpesvirus Antivirals

Antiviral compounds that do not target the viral DNA polymerase are being developed with objectives of oral bioavailability, improved safety profile and lack of cross-resistance with existing drugs. The potential benefit of combination therapy directed at multiple viral targets is appealing in immunocompromised hosts.

Pritelivir and Amenamevir

Pritelivir and amenamevir are orally dosed helicase/primase inhibitors. They target enzymes other than DNA polymerase that are essential for viral DNA replication [53, 54]. The in vitro spectrum of activity of pritelivir includes HSV-1 and HSV-2, while amenamevir is active against HSV and VZV. A Phase II study showed amenamevir and valacyclovir to have similar efficacy in treating episodes of genital herpes [55]. Pritelivir has undergone two Phase II trials for suppression of recurrent HSV-2 in normal hosts. When compared with placebo, daily or weekly doses of pritelivir for 4 weeks reduced the incidence and quantity of genital lesions and HSV shedding [56]. In a crossover trial, pritelivir 100 mg daily was superior to valacyclovir 500 mg daily as measured by HSV detection in frequently sampled genital swabs [57]. After clinical trials were placed on hold pending review of primate toxicity data, a new trial was listed in 2017 to compare pritelivir with foscarnet for the treatment of acyclovir-resistant mucocutaneous herpes simplex infections in immunocompromised adults (clinicaltrials.gov NCT03073967). Mutations in the HSV helicase gene UL5 and to a lesser extent in the primase gene UL52 have been described that confer pritelivir and amenamevir cross-resistance, including high-level resistance conferred by UL5 K356N (HSV-1 codon numbering) with retained in vitro viral growth fitness [58, 59]. As expected, no pritelivir resistance was observed after short-term, 4-week exposure to pritelivir for prevention of genital herpes [60].

Maribavir

Maribavir is a benzimidazole L-riboside CMV UL97 kinase inhibitor [61] that has good anti-CMV activity in vitro depending on cell culture conditions [62]. CMV replication is greatly reduced but not entirely prevented in the absence of the UL97 kinase. After early studies showing low host toxicity and indications of antiviral efficacy, two randomized Phase III clinical trials of low-dose oral maribavir at 100 mg twice daily failed as prophylaxis for CMV reactivation after stem cell [63] or liver transplantation [64]. Open-

label use of higher doses suggested a possible benefit as salvage therapy for refractory or resistant CMV disease [65] but resulted in the first documented instance of maribavir resistance in a clinical CMV isolate [66]. Additional Phase II trials were conducted in 2012 through 2015 to explore the use of maribavir as treatment of CMV viremia without end-organ disease (EudraCT 2010-024247-32) or for salvage treatment of resistant or refractory disease. Preliminary data suggested that oral doses ranging from 400 to 1200 mg twice daily all showed anti-CMV activity (clinicaltrials.gov NCT01611974), and corresponding Phase III trials were launched (clinicaltrials.gov NCT02927067 and NCT02931539). Major maribavir resistance mutations map to the UL97 kinase target, commonly T409 M and H411Y/N located at the ATP binding domain that is the presumed site of competitive binding of maribavir [67]. These specific mutations increase the maribavir EC50 by ~80-fold (T409 M) or 9- to −12-fold (H411 mutants) without significant ganciclovir cross-resistance. Unusual UL97 p-loop mutations, for example, at codon 342, can confer dual ganciclovir-maribavir resistance without knocking out biological kinase activity [68]. Diverse UL27 gene mutations confer low-grade maribavir resistance probably by modulating cell cycle conditions to compensate partially for the effects of UL97 kinase inhibition [69, 70].

Letermovir

Letermovir is an orally bioavailable CMV terminase inhibitor [71] with potent in vitro antiviral potency (low nanomolar EC50). The terminase complex includes components encoded by CMV genes UL56, UL89, and UL51 [72] and performs essential functions including cleavage of replicated viral DNA into unit length genomes and their translocation across the portal protein (UL104) into newly formed viral capsids. Phase II and III clinical trials for prophylaxis of CMV infection in stem cell transplant recipients were successful [73] (clinicaltrials.gov NCT02137772), and letermovir was FDA-approved for this indication in late 2017. Lack of hematologic toxicity is a distinct advantage over ganciclovir or valganciclovir, and is expected to be most useful in the period immediately following stem cell transplantation, as studied in the clinical trials. There are insufficient data to assess the efficacy of letermovir as therapy for active CMV disease, including cases resistant or refractory to treatment with standard DNA polymerase inhibitors. CMV UL56 gene mutants are readily selected in cell culture to confer letermovir resistance [74, 75], but no meaningful clinical correlation yet exists. In a letermovir prophylaxis trial, UL56 amino acid substitution V236M emerged to confer ~40-fold increased letermovir EC50 [76]. Amino acid substitutions at the C325 residue of UL56 confer absolute letermovir resistance in vitro and are a locus of interest for diagnostic testing. Cross-resistance with DNA polymerase inhibitors or maribavir is not expected given the different antiviral drug targets.

Antivirals for RNA Respiratory Viruses

Influenza, parainfluenza, respiratory syncytial virus (RSV), and other RNA viruses cause diffuse pneumonias often resulting in respiratory failure and death, especially in hematopoietic cell and lung transplant recipients. The role of antiviral therapy in reducing mortality and lung damage has not been proven by controlled trials, leaving many controversies regarding the proper application of available therapies (Table 54.2). Approved antiviral drugs include the neuraminidase inhibitors (NAIs) oseltamivir, peramivir, and zanamivir for influenza A and B, M2 ion channel blockers amantadine and rimantadine for influenza A only, and ribavirin, which is FDA-approved for aerosol use only in pediatric RSV infection. When considering antiviral therapy for these infections, attention should simultaneously be paid to infection control measures to prevent nosocomial spread, pending diagnostic confirmation.

Oseltamivir, Peramivir, and Zanamivir

Influenza types A and B are major human pathogens. Subtypes within type A are grouped by the antigenicity of the hemagglutinin (H) and neuraminidase (N) proteins. Currently circulating influenza A strains are subtypes H3N2 and to a lesser extent H1N1 2009 pandemic strain, with occasional human cases related to avian influenza strains H5, H7, and H9. Neuraminidase cleaves the sialic acid containing cell surface receptor that binds viral hemagglutinin, thus enabling the release of newly formed virions from infected cells. Oseltamivir and zanamivir are sialic acid analog neuraminidase inhibitors (NAIs) initially marketed in 1999 [77], with the former modified for oral bioavailability and the latter delivered by inhalation. Peramivir is an intravenously administered transition-state analog NAI approved by the FDA in 2014. Influenza A and B neuraminidases are susceptible to inhibition as long as they have not developed resistance mutations, although there may be strain variation in the degree of susceptibility.

Pharmacology

Oseltamivir phosphate in oral capsules is metabolized by hepatic esterases to the active drug oseltamivir carboxylate (Table 54.2) that has a bioavailability of at least 75% and plasma elimination half-life of 6–10 h. It is renally cleared and the dosing interval is doubled for creatinine clearance <30 mL/min. The drug is generally well toler-

Table 54.2 Antiviral agents approved for respiratory viral infections (2017)

Antiviral agent	Structure and mechanism of action	Therapeutic use[a]	Route and adult dose[b]	Side effects Adverse interactions	Resistance
Oseltamivir	Ethyl ester prodrug converted in liver to a cyclohexene carboxylic acid derivative Sialic acid analog competitive neuraminidase (NA) inhibitor targeting release of virus particles from host cells	Influenza A and B: treatment and prophylaxis Prompt initiation needed for best outcome. Some benefit possible with delayed treatment Pandemic 2009 H1N1 flu A: most strains initially susceptible. May become resistant after drug exposure and transmission Seasonal H1N1 (2008) flu A: almost all strains resistant	Oral Treatment: Standard dose: 75 mg 2×/day for 5 days, longer if severely ill Prophylaxis: 75 mg/day for at least 10 days (until 1 week after last case during influenza outbreaks in health care facilities; 10 days after household exposure) Not approved for age <1 year	GI[c], headache, rare neuropsychiatric symptoms	Most common NA mutations[d] some are cross-resistant to zanamivir (*) *H1N1*: H275Y *pH1/N1*: N294S, H275Y, E119V*, I222V, *H3N2*: N294S, R292K*, E119V/I, I222V *H5N1*: N294S, H275Y *Influenza B*: R152K*, D198N*, R371K*
Peramivir	Cyclopentane carboxylic acid derivative Transition state analog NA inhibitor	Influenza A and B	Intravenous infusion Treatment: 18 years and older One 600 mg dose by infusion for 15–30 minutes	GI[c], hypersensitivity	NA mutations[d] with some cross-resistance to oseltamivir (*) *H1N1*: H275Y *H3N2*: R292K*, *Influenza B*: R152K*, H275Y HA mutation K189E
Zanamivir	Dihydropyran carboxylic acid derivative Sialic acid analog NA inhibitor	Influenza A and B: treatment and prophylaxis Marketed as powder for inhalation. Intravenous form is experimental	Powder for inhalation: Treatment: 10 mg (2 puffs) 2 times/day for 5 days Not approved for age < 7 year Prophylaxis: 10 mg/day for durations as described for oseltamivir Not approved for age < 5 year or with underlying lung disease	Allergic reactions oropharyngeal or facial Cough, nasal and throat discomfort, bronchospasm GI[c], headache	NA mutations[d] with occasional cross-resistance to oseltamivir (*) *H1N1*: E119G, E119V*, Q136K *H3N2*: R292K*, Q136K, D151A/D *H5N1*: E119G, D198G *Influenza B*: R152K, D198N*, R371K*
Amantadine	1-aminoadamantane Blocks viral M2 protein, prevents internalization and uncoating of virus	Influenza A: treatment and prophylaxis (susceptible strains only) No activity against influenza B	Oral Treatment: 200 mg/day for 3–5 days Prophylaxis: 200 mg/day for 2–4 week	GI[c], CNS symptoms[e] Avoid use with anticholinergics and antihistamines	M2 mutations at residues 26, 27, 30, 31, 34, most commonly S31 N H3N2 and pandemic H1N1 > 90% resistant Cross-resistance to rimantadine
Rimantadine	(*RS*)-1-(1-adamantyl) ethanamine Mechanism same as amantadine	Same as amantadine	Oral Treatment: 100 mg 2 times/day for 7 days	Side effects similar to amantadine but less severe	M2 mutations at residues 26, 27, 30, 31, 34 Cross-resistance to amantadine

Table 54.2 (continued)

Antiviral agent	Structure and mechanism of action	Therapeutic use[a]	Route and adult dose[b]	Side effects Adverse interactions	Resistance
Ribavirin	1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide Single antiviral mechanism not established Proposed mechanisms: 1. Depletion of guanosine triphosphate by inhibition of inosine monophosphate dehydrogenase 2. Inhibition of viral polymerase or induction of error-prone replication 3. Inhibition of RNA capping 4. Immunomodulatory or cell signaling effects	Respiratory syncytial virus (RSV) No FDA-approved indications in adult respiratory viral infections Treatment: lower respiratory tract infection Preventive treatment: to reduce lower respiratory tract extension of nasopharyngeal infection detected by PCR Ribavirin also proposed for parainfluenza, influenza (as adjunct), metapneumovirus	Inhaled aerosol 20 mg/mL: Treatment of RSV: 6 g by aerosol over 18 h/day for 7 days using a small particle aerosol generator and face mask ± intravenous immunoglobulin or palivizumab Oral: Efficacy in respiratory viral infections is not established but suggested by case series Intravenous: Request through FDA emergency investigational new drug program	Inhaled form: Bronchospasm, respiratory distress, cough Oral form: Hemolytic anemia, neutropenia, thrombocytopenia, GI[c], headache, insomnia, asthenia Intravenous form: Hemolytic anemia	No resistance mutations characterized for RSV

[a]Recommended usage may differ from FDA-approved indications and doses
[b]Dosage information as suggested for normal adults. See full dosing information provided in package insert
[c]GI (gastrointestinal) symptoms include nausea and vomiting (diarrhea less often)
[d]N2 numbering system used for mutations except H275Y
[e]CNS (central nervous system) symptoms include confusion, difficulty concentrating, dizziness, hallucinations, and seizures

ated, with adverse effects limited to nausea and vomiting [78], but controversially associated neuropsychiatric events have been described mainly in children and from Japan [79].

Peramivir is intravenously administered as a single 600 mg dose adjusted for renal function since it has a prolonged duration of neuraminidase inhibitory activity [80]. Reported adverse effects were infrequent, including diarrhea and hypersensitivity reactions.

Zanamivir is administered as a powder for inhalation (Table 54.2) and is not approved for use in young children or patients with underlying chronic lung disease. Less than 20% of the inhaled drug reaches the lung, but the high local concentrations may be an advantage [77]. The drug is renally cleared but no dose adjustment is needed for renal failure given the low systemic bioavailability.

Clinical Applications

Because influenza genotypes evolve in unpredictable ways, efficacy of antiviral drugs against prevailing influenza strains will vary over time. Early and preventive use of antiviral therapy is much more effective than trying to resolve an established viral pneumonia. This may require presumptive treatment pending diagnostic testing.

Oseltamivir, peramivir, and zanamivir are FDA-approved for treatment of influenza A and B within 48 h of onset of symptoms, preferably sooner. Under these conditions, healthy adults and children with laboratory-confirmed influenza are shown to have a 1–2-day reduction in symptoms with any of the three NAIs and a little more if treatment is started within 12 h [77, 78]. Although delayed treatment beyond 48 h is unlikely to be statistically effective in normal hosts [81], treatment is recommended in transplant recipients regardless of duration of illness when diagnosed, because of the greater likelihood of prolonged viral replication and severe disease [82, 83]. Depending on clinical response and severity of illness, extension of treatment beyond the FDA-approved 5-day course may be warranted. No controlled studies have shown a mortality benefit from antiviral treatment of influenza, but low-confidence observational studies taken together appear to support a meaningful impact of oseltamivir on mortality if treated within 48 h and possibly later [81]. Comparison of oseltamivir and IV peramivir treatment showed similar outcomes in hospitalized adults with seasonal influenza [84].

As prophylaxis, oseltamivir, and zanamivir are recommended for use as shown in Table 54.2, in conjunction with vaccination [8]. Effectiveness has been shown when started

within 2 days of exposure to symptomatic influenza [85] or within 36 h of exposure for zanamivir [86], with reduction in incidence of symptomatic infection of about 80% in institutional and household contacts. Heightened surveillance of acute illness and prompt initiation of therapy has been proposed to address the concern for selection of resistant viruses during prophylaxis [83].

Drug Resistance

Drug resistance is a major determinant of the utility of NAIs against circulating influenza strains. Because information changes rapidly, updated information is regularly posted to the CDC web site (http://www.cdc.gov/flu). As an example of evolving trends, the presently circulating seasonal H3N2 influenza A strain is generally susceptible to oseltamivir, while the seasonal H1N1 influenza A prevalent in 2008 became almost 100% resistant, leading to a recommendation not to use this drug [82]. In 2009, a pandemic strain of H1N1 influenza A susceptible to oseltamivir rapidly displaced the previous H1N1 strain, thus making the drug again widely suitable for presumptive therapy and prophylaxis.

Neuraminidase mutations conferring drug resistance may involve residues that form a framework for the enzyme or catalytic residues that contact sialic acid substrates [87]. The most common mutation H275Y, or H274Y in N2 nomenclature, detected in H1N1 and H5N1 strains is a framework mutation, which confers high-level oseltamivir and peramivir resistance but retains susceptibility to zanamivir. Depending on the genetic context, this mutation may have little adverse effect on viral growth and can easily be transmitted without continued drug exposure, as shown by the 2008 seasonal H1N1 strains. H3N2 influenza A strains tend to develop the framework mutation E119V and a variety of catalytic mutations such as R292K. Zanamivir resistance characteristically involves the framework mutation E119G which confers low-grade cross-resistance to oseltamivir. Resistance to zanamivir is so far less common than resistance to oseltamivir. Phenotypic determination of influenza drug resistance can be performed in cell culture or by enzymatic assays, with significant interassay variability, or more practically by genotypic assays which should test for the range of reported mutations (Table 54.2) rather than just the signature mutations such as H275Y [87].

Amantadine and Rimantadine

These adamantanes act by blocking the function of the M2 ion channel involved in viral uncoating and ribonucleoprotein release for nuclear entry and initiation of replication. This antiviral mechanism is valid only for influenza A because influenza B does not have the same M2 protein. Unfortunately M2 mutations, typically S31 N, can easily develop with little growth penalty, enabling the worldwide spread of resistant influenza A, to the point of making this drug class therapeutically ineffective [88]. The last prevalent strain for which amantadine susceptibility was observed was the 2008 seasonal H1N1 strain. The drugs were administered orally for influenza A prophylaxis and early therapy, with cautions for neurologic side effects (Table 54.2).

Ribavirin

Ribavirin is FDA-approved for oral use as adjunctive therapy for hepatitis C virus (HCV) and aerosol use for severe pediatric RSV bronchiolitis. Its use in transplant recipients is controversial, because the typical inhalation mode of delivery is not FDA-approved, insufficiently evidence-based, and involves extraordinary costs and logistical complexity [89, 90]. Evidence for efficacy of oral or intravenous ribavirin for respiratory viral infections is inconclusive at best.

No single antiviral mechanism of action has been established for ribavirin. It is a carboxamide triazole riboside, which can be considered a synthetic nucleoside analog that is converted to a triphosphate by cellular enzymes. Several mechanisms of action have been proposed [91] (see Table 54.2). The claimed spectrum of antiviral activity of ribavirin is very broad, covering many RNA viruses and some DNA viruses such as adenovirus and poxviruses [91]. Ribavirin is often mentioned as a potential off-label unproven treatment for various life-threatening infections including viral pneumonias and hemorrhagic fevers [92].

Pharmacology

Ribavirin is supplied as a powder for use in making a 20 mg/mL aqueous solution to be delivered using a small particle aerosol generator (SPAG-2 device) (Table 54.2). The substance is teratogenic usually interpreted as requiring a negative pressure ventilated isolation room, and that it may precipitate in ventilator tubing or airways causing mechanical obstruction and respiratory deterioration. Patients may object to the prolonged attachment of a mask. Symptoms include cough, respiratory distress, bronchospasm, or claustrophobia. The delivered dose is unpredictable but systemic toxicity is not expected.

As an oral formulation ribavirin is available as generic capsules and tablets. Oral bioavailability is about 60%, and increases with a high fat meal. For HCV, dosing is weight based, ranging from 800 to 1400 mg total per day; no standard has been set for respiratory viruses. The plasma half-life varies from 79 to 170 h, but ribavirin persists for much longer in other body compartments [93]. It is not protein bound and does not inhibit CYP450 enzymes. Drug interactions prominently include nucleoside antiretroviral drugs, in particular didanosine and zidovudine [94], and azathioprine.

It is renally cleared (61%) and dose adjustments or discontinuation are indicated in patients with renal dysfunction. Hemolytic anemia is the major serious adverse effect; others are as listed in Table 54.2. An IV form of ribavirin has limited availability through an FDA emergency investigational drug protocol [92]. Hemolytic anemia appears to be the main adverse effect of this formulation as well.

Clinical Applications

Aerosol ribavirin for treatment of severe pediatric RSV bronchiolitis was initially supported by controlled trials reporting beneficial effects such as reduction of ventilatory support and hospitalization in normal infants requiring mechanical ventilation [95]. No mortality benefit has been proven in any controlled trial. The reported benefits have been strongly disputed, including negative results in a subsequent controlled trial [96]. In a 2006 guideline [97], the American Academy of Pediatrics suggested that ribavirin might be considered for use in highly selected situations involving severe disease and risk factors for it, but the 2014 updated guideline [98] makes no mention of ribavirin use under any circumstances.

Among hematopoietic cell recipients, lymphopenia is a strong predictor for RSV morbidity and mortality [99]. RSV infection in this population frequently progresses to lower respiratory tract disease and death. The majority of observational studies support a benefit of aerosolized ribavirin treatment in preventing these outcomes, but evidence is of poor quality [90, 100]. An attempted prospective clinical trial was terminated without definitive results because of slow patient accrual [101].

Given the inconclusive data, transplant programs have tended to develop their own clinical protocols, which may involve early use of aerosol ribavirin in an attempt to prevent progression of RSV upper respiratory infection in higher-risk patient subsets such as those with lymphopenia or receiving anti-lymphocyte regimens, or to improve outcomes of established lower respiratory tract disease. Because of the high cost and complexity of aerosol ribavirin administration, use of oral or IV ribavirin as an alternative has been reported, with weak evidence for apparently favorable outcomes [90, 102, 103]. Additional benefit has been attributed to the administration of nonspecific or specific RSV antibody (IVIG or palivizumab) [90], which may be included in institutional protocols for lower respiratory tract disease despite weak data supporting their routine use.

Use of ribavirin to treat other respiratory viral infections such as parainfluenza and metapneumovirus is based on insufficient observational data [104–106]. A review of FDA emergency drug requests for IV ribavirin showed adenovirus to be the most commonly targeted virus, accounting for 55% of all requests, followed by RSV, parainfluenza, influenza, hantavirus, measles (SSPE), and rabies. The reported outcomes were variable [92]. For example, a controlled trial showed no benefit in hantavirus pulmonary syndrome, and published cases of adenovirus infection treated with IV ribavirin had a 63% overall mortality rate [92].

Drug Resistance

No resistance mutations have been described for RSV to support the existence of a specific antiviral drug target for ribavirin despite its tendency to increase the viral mutation rate [107].

Presatovir (GS-5806)

Presatovir (GS-5806) is a small molecule inhibitor of RSV acting on the viral fusion process involved in entry into host cells [102]. It is active against a variety of RSV subtype A and B isolates in vitro, has low cellular cytotoxicity, and is undergoing Phase II clinical trials in lung and hematopoietic cell transplant recipients and in hospitalized adults. Treatment emergent mutations in the RSV F gene such as F140L and T400I have been identified in human subjects treated with 1–3 doses of presatovir, which confer >200-fold increases in EC50 [108].

Hepatitis C Virus Antivirals

Direct-acting small molecule drugs with specific antiviral targets disrupted old treatment paradigms based on interferon and ribavirin and now enable the successful treatment of chronic HCV infection in the vast majority of cases after 8–24 weeks of combination therapy [109]. Clearance of circulating HCV RNA at 12 or 24 weeks after completion of therapy is defined as a sustained virologic response (SVR, SVR12, or SVR24), with nearly all cases of SVR12 achieving SVR24 and essentially a virologic cure [110], thus halting the progression of HCV disease [111], although prior liver damage and its sequelae including hepatocellular carcinoma may persist. The goal of early cure of chronic HCV infection before evidence of liver damage should eventually displace the historical practice of prioritizing patients according to disease severity for receiving older, poorly tolerated therapeutic regimens of dubious efficacy. At present, the high cost of newer treatments is limiting universal access to therapy. In this rapidly evolving field, a joint society (IDSA-AASLD) online resource (http://www.hcvguidelines.org) is available for continuously updated authoritative guidance on treating HCV infection.

HCV therapy (Table 54.3) [112–122] currently involves three antiviral targets, the NS3/NS4A protease, the NS5A accessory protein, and the NS5B viral polymerase. Used in combination the drugs are highly effective in those not previously treated for HCV, with SVR rates routinely exceeding

[a]References for resistance substitutions [112–122]

90% [109] (Table 54.4). Some approved regimens require the addition of ribavirin to improve response rates, but with significant ribavirin adverse effects. Further drug development is aimed at optimizing therapy for all genotypes without use of ribavirin, reducing adverse effects and drug interactions, and improving efficacy in difficult situations such as cirrhosis, immune compromise, or failure of prior therapy. Combination therapy directed at multiple viral targets is needed to achieve satisfactory response rates. As with HIV therapy, fixed combinations as tested in clinical trials are offered for treatment convenience but limit the flexibility to use nonstandard combinations for special situations.

HCV NS3/4A Protease Inhibitors

The prototype compounds telaprevir and boceprevir [123, 124], were approved in 2011 for treatment of HCV genotype 1 in combination with Peg-IFN/ribavirin, but were discontinued shortly thereafter because of limited efficacy, unfavorable adverse effects and drug interaction profiles. They have been superseded by newer protease inhibitors including paritaprevir, grazoprevir, glecaprevir, and voxilaprevir (Tables 54.3 and 54.4). Drug interactions with post-transplant immunosuppressive therapy remain an important consideration for use of this drug class. The severe skin rash associated with telaprevir has been less problematic for the newer compounds, which are generally well tolerated, except that no protease inhibitors are approved for use in decompensated cirrhosis (Table 54.4). Although the prototype protease inhibitors were mainly active against genotype 1 (1b more than1a), newer compounds are active against multiple genotypes, which simplifies the formulation of pangenotypic treatment regimens (Table 54.4).

Resistance to earlier generation protease inhibitors developed readily, with NS3 amino acid substitutions typically at codons V36, Y56, Q80, R155, A156, and D168 (Table 54.3) combining to confer high-grade resistance and cross-resistance [112, 121]. Amino acid substitutions conferring drug resistance are found as baseline polymorphisms at

Table 54.4 Approved direct-acting antiviral combinations for HCV therapy (2018)

Trade name (pharmaceutical company)	Components[a]	Approved indications for genotypes[b]		Common adverse reactions
Epclusa (Gilead)	Sofosbuvir Velpatasvir	GT1,2,3,4,5,6:	< C[c], C, or DC[d] + RBV (12 week)	Headache, fatigue +ribavirin: see Table 54.2
Harvoni (Gilead)	Sofosbuvir Ledipasvir	GT1: GT4,5,6: GT1: GT1,4:	< C (12 week), C (24 week) < C or C (12 week) DC (12 week + RBV) Liver Transplant <C or C (12 week + RBV)	Headache, fatigue, asthenia
Vosevi (Gilead)	Sofosbuvir Velpatasvir Voxilaprevir	GT1,2,3,4,5,6:	< C or C (12 week)	Headache, fatigue, diarrhea, nausea
Viekira Pak (Abbvie)	Ombitasvir Paritaprevir Ritonavir Dasabuvir	GT1a: GT1a: GT1b:	< C 12 week + RBV C 24 week + RBV < C or C 12 week	Nausea, pruritus, insomnia +ribavirin: see Table 54.2
Zepatier (Merck)	Elbasvir Grazoprevir	GT1,4:	< DC, 12 week GT1a with baseline NS5A polymorphisms, retreatment cases may need RBV and 16 week	Headache, fatigue, nausea +ribavirin: see Table 54.2
Mavyret (Abbvie)	Glecaprevir Pibrentasvir	GT1,2,3,4,5,6:	< C (8 week), C (12 week) Avoid if previously treated with HCV protease inhibitors	Headache, fatigue
Sovaldi (Gilead) Daklinza (BMS)	Sofosbuvir Daclatasvir +Ribavirin	GT1,3: GT1,3:	< C (12 week), or < DC (GT1, 12 week) DC or Liver Tx (12 week with RBV)	Headache, fatigue +ribavirin: see Table 54.2

[a]Dosage for combinations is 1 tablet once daily except for the following: Technvie 2 tablets once daily; Viekira Pak 2 tablets containing ombitasvir/paritaprevir/ritonavir once daily plus 1 tablet dasabuvir twice daily
[b]*GT* genotype, *RBV* ribavirin
[c]*C* cirrhosis, compensated (Child-Pugh class A), *<C* non-cirrhotic
[d]*DC* decompensated cirrhosis (Child-Pugh class B or C), *< DC* non-cirrhotic or compensated cirrhosis

varying frequency across genotypes and geographical regions, an important factor affecting treatment responses [112, 120, 121]. For example, the common baseline HCV genotype 1a polymorphism Q80K reduces susceptibility to simeprevir and combines with the easily selected substitution R155K to confer high-grade resistance associated with a lower SVR rate reported in some clinical trials [118, 120, 125]. Thus, simeprevir was not recommended for treatment of genotype 1a when Q80K is present at baseline [126], and its marketing has since been discontinued. NS3 resistance mutations usually fade or disappear after inhibitor therapy is withdrawn, but the mutations may be archived to affect responses to retreatment [127]. However, newer protease inhibitors have been successful in salvage regimens. Voxilaprevir added to a previously approved combination of sofosbuvir and velpatasvir enabled the successful salvage therapy of those who failed prior direct-acting antiviral therapy [128], as did a combination of glecaprevir and the NS5A inhibitor pibrentasvir [129].

HCV NS5A Inhibitors

The viral NS5A gene product is involved in viral replication and assembly and interacts with the NS5B polymerase and cellular proteins [130]. In general, NS5A inhibitors add few adverse effects and have important roles as part of 2- or 3-drug combinations (Table 54.4). The currently approved drugs ledispasvir, daclatasvir, ombitasvir, velpatasvir, pibrentasvir and elbasvir tend to be potent against multiple genotypes. However, viral genetic changes present at baseline or readily selected after drug exposure can confer high-grade resistance and cross-resistance to other NS5A inhibitors, the same weakness reported for protease inhibitors (Table 54.3). Commonly involved NS5A codons include 28, 30–32, 58, and 93 [112, 120, 121]. For example, NS5A substitution Y93H, as a baseline polymorphism or drug-selected variant, factors in high-grade resistance to almost all of the NS5A inhibitors listed above, producing a >100-fold increase in EC50. Pibrentasvir, a newer NS5A inhibitor, also selected for Y93H in vitro, but the mutation conferred only low-grade resistance (< ten-fold EC50 increase) [131]. Unlike NS3 resistance mutations, NS5A mutations may persist long after treatment is withdrawn [120].

HCV NS5B Inhibitors

HCV NS5B inhibitors target the RNA-dependent RNA polymerase and may be categorized as nucleoside/nucleotide or non-nucleoside [132]. The nucleotide phosphoramidate prodrug

sofosbuvir shows high potency against most genotypes, but less for genotype 3 [109]. It is a key component of several effective multi-drug treatment regimens in combination with ledipasvir, daclatasvir, or velpatasvir and voxilaprevir [109] (Table 54.4). Sofosbuvir is well tolerated in combination therapies, but caution is required for those with renal failure or taking interacting cardiac medications. Lack of interaction with cyclosporine and tacrolimus is an advantage. For those with severe renal impairment, alternative regimens should be selected such as elbasvir-grazoprevir or glecaprevir-pibrentasvir. Sofosbuvir has a relatively high barrier to resistance; resistant mutants selected after drug exposure such as S282T have low growth fitness [132]. Non-nucleoside NS5B inhibitors tend to have a more restricted genotype range, lower potency, and lower barrier to resistance. An example is dasabuvir, with activity limited to genotype 1 (with ribavirin added for genotype 1a), but it has achieved high SVR rates in combination with ombitasvir and ritonavir-boosted paritaprevir [133–135], including in liver transplant recipients [136]. NS5B amino acid substitutions such as C316Y confer high-grade dasabuvir resistance resulting in 1000-fold or more increased EC50, but S556G, which confers ~30-fold increased EC50 for genotype 1a, was more commonly encountered in treated individuals [116].

Drug Resistance Testing

Drug resistance testing is expected to have a limited role in the management of HCV therapy as potent pangenotypic regimens with a better barrier to resistance become available, because high rates of SVR have been achieved even in treatment-experienced subjects. Diagnostic HCV genotyping technology is not well standardized for the representative amplification and accurate detection of mutations in the specimen being tested [120]. Deep sequencing approaches may enable the detection of smaller subpopulations (<15%) of mutant sequences than conventional Sanger sequencing, but has no proven added benefit in optimization of therapy [120]. If reliable diagnostic genotyping services are available, it is appropriate to screen for baseline mutations or polymorphisms that may affect response to drugs under consideration, for example, NS3 Q80K for simeprevir or NS5A amino acid substitutions at codons listed above for elbasvir [120, 126]. Findings may influence decisions on selection and duration of therapy and use of ribavirin. Resistance testing may have a larger role when evaluating retreatment regimens in those who have failed prior therapy.

Hepatitis B Antivirals

The virion of HBV contains a small partially double-stranded circular 3.2 kb DNA genome, which becomes a covalently closed circular (cccDNA) molecule in the infected cell [137]. Replication of the genome occurs through an RNA intermediate and is carried out by a virus-encoded reverse transcriptase. This enzyme is the target of HBV-specific antiviral drugs as well as some HIV-1 reverse transcriptase inhibitors. These drugs are approved for chronic hepatitis B (CHB) infection. Antiviral therapy is unable to eliminate the cccDNA, which persists indefinitely in the nucleus of infected cells and serves as the template for viral rebound when therapy is terminated. Consequently, there are ongoing drug-screening efforts to identify molecules that inhibit production of cccDNA [138].

Drugs approved for CHB antiviral therapy fall into 2 classes: (1) standard and pegylated IFN-α2; and (2) four available nucleoside/nucleotide analog (NA) reverse transcriptase inhibitors, counting tenofovir as one drug with two formulations (Table 54.5). Therapeutic algorithms are based on HBe antigen (positive or negative), HBV DNA levels, and status of liver disease [139, 140]. The goal of HBV antiviral therapy is durable suppression of viral replication and decreased risk of cirrhosis, liver decompensation, and hepatocellular carcinoma [139]. In contrast to HCV, indefinite NA maintenance therapy may be needed to prevent relapse in those patients who have not cleared hepatitis B surface antigen (HBsAg), thus favoring regimens that minimize the emergence of drug resistance. Entecavir and tenofovir disoproxil fumarate (TDF) or tenofovir alafenamide (TAF) are preferred drugs because of a higher genetic barrier to resistance. In those receiving liver transplants for HBV-related liver failure, antiviral treatment may be given prior to transplantation to suppress circulating viral loads, followed by use of hepatitis B immunoglobulin (HBIG) and antivirals post-transplant. This strategy was initially proven successful using lamivudine and later improved by use of entecavir or tenofovir instead, to the extent that HBIG use can be reduced or eliminated [141].

Pegylated Interferon

Peg-IFN-α2 therapy offers the possibility of a durable virologic response with no antiviral resistance, but many do not respond optimally [140]. Given the significant adverse effects that limit its use in those with advanced disease, comorbidities and post-transplant immunosuppressive therapy, patient selection is important. Additional factors to consider are age, transaminase levels, HBV genotype, levels of HBV DNA, and HBsAg [139, 140]. Peg-IFN has been studied in combination with lamivudine, but the superiority of the combination over Peg-IFN alone has not been demonstrated [142].

Lamivudine

Lamivudine was initially developed for HIV-1 and was the first NA to be approved for treatment of CHB, a major

Table 54.5 Antiviral agents approved for HBV therapy (2018)

Antiviral agent	Structure and mechanism of action	Therapeutic uses and doses[a]	Adverse effects	Resistance
Adefovir dipovoxil	Diester prodrug of adenosine monophosphate analog requires intracellular enzymatic activation Inhibition of HBV reverse transcriptase (RT). Viral DNA chain terminator	Chronic HBV > age 12 Oral administration: 10 mg, 1×/day	Nephrotoxicity, asthenia, gastrointestinal symptoms, lactic acidosis and severe hepatomegaly with steatosis, exacerbation of hepatitis on discontinuation of therapy	Reverse transcriptase (RT): N236 T, A181T/V Intermediate genetic barrier to resistance
Entecavir	Guanosine analog Inhibition of 3 functions of HBV RT DNA: priming, negative strand reverse transcription, positive strand synthesis. Non-obligate chain terminator	Chronic HBV in adults with evidence of active viral replication Oral administration Treatment naïve: 0.5 mg 1×/day Previous exposure to lamivudine or telbivudine or decompensated disease: 1 mg 1×/day	Mild GI[b] and CNS[c] symptoms, acute, lactic acidosis and severe hepatomegaly with steatosis, exacerbation of hepatitis on discontinuation of therapy	RT: M204V/I with or without L180M, V173L, L80I, T184G, S202I, M250V (multiple mutations required for high-level resistance) High genetic barrier to resistance
Lamivudine	Dideoxycytidine analog DNA chain terminator, Inhibition of HBV RT polymerization	Chronic HBV in adults with evidence of active viral replication Oral administration: 100 mg once/day	Minimal toxicity. Lactic acidosis, severe hepatomegaly with steatosis, acute exacerbation of hepatitis with termination of therapy	RT: M204V/I,L180M, V173L, L80M, A181T/V cross-resistance to adefovir, entecavir, and telbivudine Low genetic barrier to resistance
Pegylated interferon 2a (PEG-IFN2a)	Covalent conjugate of IFN-α 2a and branched polyethylene glycol (PEG) chains; molecular mass 60,000 Da Binds to cell receptors, induces innate immune response, stimulates IFN response genes, and inhibits viral replication in infected cells. Broad biological effects on uninfected cells	Chronic HBV Subcutaneous injection: 180 μg/week	Fever, myalgia, headache, fatigue, neuropsychiatric disorders[d]	Unknown
Interferon alpha 2b	Unconjugated IFN-α 2b molecular mass 19,271 Da Mechanism same as PEG-IFN-α	Chronic HBV Subcutaneous or intramuscular injection 10 million IU 3×/week for 16 weeks	Fever, headache, chills, myalgia neuropsychiatric disorders[d]	Unknown
Tenofovir disoproxil fumarate (TDF)	Diester prodrug of acyclic analog of adenosine monophosphate Competitive inhibitor of adenosine triphosphate, DNA chain terminator	Treatment of chronic HBV Oral administration 300 mg 1×/day	GI[b] and CNS[c] symptoms, nephrotoxicity, reduced bone density, lactic acidosis, severe hepatomegaly with steatosis, acute exacerbation of hepatitis with termination of therapy	No TDF-specific mutations identified Reduced susceptibility to ADV, LdT, and 3TC-resistant isolates (A181V/T, N236T, M204I/V) High genetic barrier to resistance
Tenofovir alafenamide fumarate (TAF)	Phosphonamidate prodrug of tenofovir. Acyclic analog of adenosine monophosphate Competitive inhibitor of adenosine triphosphate, DNA chain terminator	Treatment of chronic HBV Oral administration 25 mg (one tablet) 1×/day	GI[b], headache, cough, fatigue, back pain, lactic acidosis, severe hepatomegaly with steatosis, acute exacerbation of hepatitis with termination of therapy Lower reduction of bone density compared to TDF	No TAF-specific mutations identified High genetic barrier to resistance

[a]Dosage information includes only most common applications. See full dosing information provided by pharmaceutical company package insert
[b]GI (gastrointestinal) symptoms include diarrhea, nausea, and vomiting
[c]CNS (central nervous system) symptoms include confusion, difficulty concentrating, dizziness, hallucinations, and seizures
[d]Neuropsychiatric disorders include suicide, depression, and self-injury

advance in therapy at the time. Although lamivudine has been shown to decrease the rate of development of fibrosis as well as the incidence of HCC [143], HBV antiviral resistance develops in 65% of cases after 5 years and is associated with clinical relapse [144]. Thus, it is no longer a preferred treatment. The characteristic amino acid substitution M204V/I that develops in the YMDD motif of the HBV DNA polymerase confers very-high-level lamivudine resistance (>10,000-fold increased IC50) and is followed by the development of L180M that increases viral fitness [145].

Adefovir Dipovoxil

Adefovir is administered as a prodrug that is converted intracellularly to the active adefovir diphosphate. Adefovir treatment resulted in biochemical and histologic improvement in patients with HBeAg-negative CHB with sustained treatment, but evidence of resistance mutations were identified in 6% at 3 years and 29% after 5 years of therapy [146]. Because of the intermediate genetic barrier to resistance, adefovir is not a preferred drug for long-term therapy. Adefovir resistance mutations differ from those of lamivudine and mainly involve polymerase amino acid substitutions A181V and N236T [146].

Telbivudine

Telbivudine is a thymidine nucleoside analog and a stronger inhibitor of HBV than lamivudine but likewise has a low genetic barrier to resistance. It selects for amino acid substitution M204I (YMDD motif), which also confers cross-resistance to lamivudine [147]. While it performed better than lamivudine [148] or adefovir [149] in comparison trials of CHB treatment, telbivudine was withdrawn from marketing after 2016. Telbivudine cannot be combined with Peg-IFN because of increased risk of neuropathy [150].

Entecavir

Entecavir undergoes intracellular anabolism to the active deoxyguanosine triphosphate analog, which has a 3′-hydroxyl group that makes it a nonobligate chain terminator of HBV DNA synthesis. It inhibits three polymerase functions: priming, reverse transcription, and second-strand synthesis [151]. Entecavir has a relatively high genetic barrier for drug resistance, requiring multiple mutations that reduce viral fitness. Selection of DNA polymerase substitution M204V ± L180M from previous lamivudine therapy facilitates entecavir resistance through additional substitutions T184G/L, S202G, and M250V [152], but the reported rate of resistance after entecavir therapy is only 1.2% after 5 years [151]. It remains a first-line agent for CHB antiviral therapy, although tenofovir-based therapy would be a better option in those previously exposed to lamivudine or telbivudine [139].

Tenofovir Disoproxil Fumarate (TDF)

This prodrug undergoes intracellular hydrolysis followed by phosphorylation to an adenosine triphosphate analog. It has become a first-line drug for CHB therapy, because it has a high genetic barrier to resistance and potent antiviral activity [139, 140]. TDF resistance has not been observed after up to 8 years of therapy [153]. TDF therapy is generally well tolerated but requires periodic monitoring for renal toxicity. TDF is also available as a combined formulation (Truvada) with the nucleoside analog emtricitabine, which has anti-HBV activity similar to lamivudine [154]. This combined formulation has been investigated for treatment of CHB, but did not perform any better than TDF alone in patients with lamivudine-resistant infection [155]. Emtricitabine monotherapy is not recommended, because it has the same low genetic barrier to resistance and resistance profile (M204V/I with or without L180M) as lamivudine [156].

Tenofovir Alafenamide (TAF)

Tenofovir alafenamide (TAF) was approved for treatment of CHB in 2016. This alternative prodrug formulation of tenofovir achieves equally effective intracellular levels of the active tenofovir diphosphate at much lower doses of 300 mg for TDF vs. 25 mg for TAF and lower plasma tenofovir levels with less consequent toxicity [157]. In a comparison trial, TAF was non-inferior to TDF for the treatment of CHB, with fewer adverse changes in bone mineral density and renal function detected in the TAF group [158, 159]. TAF may be preferable to TDF in older subjects and those with renal function impairment or bone mineral disorders [139].

Summary

A basic principle of antiviral therapy in immunosuppressed hosts is to anticipate and screen for infections that can be prevented or treated early before irreversible damage from invasive disease. For herpesviruses, guanosine nucleoside analogs acyclovir and ganciclovir, selectively activated by viral kinases and ultimately targeting the viral DNA polymerase, have long been preferred antivirals. Orally bioavailable prodrugs valacyclovir, famciclovir, and valganciclovir greatly simplify outpatient management and are suitable for mild to moderate disease and extended prophylactic use.

Acyclovir and related prodrugs have a superior safety profile for use in herpes simplex and varicella-zoster infections, but are insufficiently active against cytomegalovirus, for which ganciclovir and valganciclovir are used instead, with monitoring for bone marrow suppression. Long-term use with incomplete viral suppression may select for drug resistance mutations, typically in the viral kinase gene that initially phosphorylates these drugs. Foscarnet and cidofovir are alternative herpesvirus treatments that evade drug resistance resulting from kinase mutations, but viral DNA polymerase mutations can confer cross-resistance. They are available for intravenous use only and have significant dose-limiting toxicity. Orally bioavailable drugs with alternative viral targets are being introduced for cytomegalovirus infection, such as the terminase inhibitor letermovir.

Neuraminidase inhibitors available for oral, intravenous, and inhalation use are the current treatments of choice for influenza infections. Optimum benefit requires early diagnosis and presumptive treatment or post-exposure prophylaxis, whereas it is difficult to show a mortality benefit of antiviral therapy for any viral pneumonia that has caused respiratory failure. Ribavirin in aerosolized or systemic form has been proposed for treatment of respiratory syncytial virus with a lesser evidence base and lack of clarity in balance of risks and benefits.

Hepatitis C virus is a leading cause of liver failure requiring transplantation. The complexity and toxicity of previous interferon and ribavirin regimens for this virus required careful evaluation of treatment indications and risks, but newer direct-acting antivirals targeting the protease and viral replication proteins offer far higher cure rates with shorter combination regimens applicable to a wider range of viral genotypes and disease states. Therapeutic options are being further improved with potent, pangenotypic, ribavirin-free regimens that can be applied to populations with historically lower treatment response rates.

Treatment of chronic hepatitis B is primarily directed at the viral DNA polymerase (reverse transcriptase). Current antivirals such as tenofovir offer good potency and adequately high genetic barrier to the development of drug resistance, but are unable to clear the covalently closed circular form of viral DNA responsible for viral persistence. Strategies to overcome this limitation are in development.

55 Pharmacokinetics and Pharmacodynamics of Antiviral Drugs in Special Population

Marco R. Scipione and John Papadopoulos

Introduction

Viral infections are a serious public health concern and can contribute significantly to patients' morbidity and mortality. It is estimated that there are 350 million people worldwide who are carriers of the hepatitis B virus (HBV) and 17,000 new cases per year of hepatitis C (HCV) are identified [1]. Herpes viruses remain a threat with an estimated 50% seroprevalence of herpes simplex virus type-1 (HSV-1) and 20% seroprevalence of HSV-2 among adults in the United States [2]. Influenza is also a global health problem with thousands of deaths each year and specifically 18,500 confirmed deaths worldwide from the 2009 influenza A H1N1 pandemic alone [3, 4]. It is imperative that clinicians have an intimate knowledge of any medication used in their practice and a working knowledge base of pharmacokinetics (PK) and pharmacodynamics (PD) is especially true in the discipline of infectious diseases. This chapter will review in detail the pharmacokinetic and pharmacodynamic parameters of antiviral agents utilized to treat selected viral infections in the immunosuppressed transplant population.

Anti-herpes Virus Agents

Acyclovir

Mechanism of Action and Resistance

Acyclovir is a synthetic purine nucleoside analogue with in vitro and in vivo inhibitory activity against herpes simplex virus type 1 (HSV-1), herpes simplex virus type 2 (HSV-2), and varicella zoster virus (VZV) [5]. Acyclovir competitively inhibits viral DNA polymerase, incorporates and terminates the growing viral DNA chain, and inactivates viral DNA polymerase only after it has been phosphorylated by the enzyme thymidine kinase (TK) encoded by HSV and VZV. This enzyme converts acyclovir into acyclovir monophosphate, which is then further converted into diphosphate by a cellular guanylate kinase and finally into a triphosphate, which exerts its antiviral activity [6]. Resistance to acyclovir is due to mutations on the UL23 gene that encodes the TK enzyme, or the UL30 gene that encodes for viral DNA polymerase [2]. Approximately 95% of clinical isolates with acyclovir resistance have a UL23 gene mutation. Mutations in the UL30 gene are less common in clinical isolates [2]. The concentration of acyclovir needed to inhibit viral plaques by 50% in vitro is 0.01 μg/mL to 2.7 μg/mL for HSV-1 and 0.01 μg/mL to 4.4 μg/mL for HSV-2. The concentration of acyclovir needed for inhibition of VZV in vitro is 0.17 μg/mL to 26 μg/mL [7].

Pharmacokinetics

Plasma protein binding of acyclovir ranges from 9% to 33% with an average plasma elimination half-life ($t_{1/2}$) of 2.5–3.3 h after oral administration [8, 9] (Table 55.1). The bioavailability of acyclovir is low, with only 10–20% bioavailability after administration of enteral acyclovir, and proportional increases in dose do not provide proportional increases in plasma acyclovir concentrations [7]. Peak plasma concentrations (C_{max}) at steady state after multiple doses of oral acyclovir are approximately 0.83 μg/mL after 200 mg, 1.21 μg/mL after 400 mg, and 1.61 μg/mL after 800 mg [9]. The C_{max} after intravenous (IV) administration of acyclovir 5 mg/kg every 8 hours is 9.8 μg/mL, and the trough concentration (C_{min}) is 0.7 μg/mL [9, 10]. After 10 mg/kg every 8 h of IV acyclovir, the C_{max} is 20.7 μg/mL, and the C_{min} is 2.3 μg/mL [9, 10]. Food does not affect the rate or extent of oral acyclovir absorption. Plasma elimination $t_{1/2}$ and total body clearance (Cl_{total}) are dependent on renal function, and Cl_{total} is markedly reduced in anuric patients [10, 11]. Renal excretion is the major route of elimination and is dependent on

active tubular secretion [10, 12]. As a result, the dose of acyclovir should be adjusted based on renal function. Acyclovir concentrations are decreased by 60% after a 6-h hemodialysis (HD) period, and less than 10% of acyclovir is removed during peritoneal dialysis [13, 14].

Acyclovir is extensively distributed in a wide variety of tissues and body fluids. After administration of IV acyclovir, the level in cerebral spinal fluid (CSF) is approximately 50% of plasma concentration; however, one study estimated the penetration ratio which ranges from 13% to 52% of plasma, with a mean value of 31% [10, 15]. The concentration of acyclovir in aqueous humor is 3.26 μmol/L [16]. Concentrations in amniotic fluid of 1.3 μg/mL are higher than corresponding maternal plasma concentrations of 0.2 μg/mL at the time of labor in pregnant women taking acyclovir three times daily [17]. There is minimal systemic absorption seen after application of topical acyclovir 5% cream or ointment on intact skin [18].

Pharmacokinetics in Pediatric Patients

The pharmacokinetics of acyclovir in pediatric patients is similar to adults, with a $t_{1/2}$ of 2.6 h after oral administration of acyclovir and a bioavailability of 12% [19]. The peak concentrations after IV acyclovir doses of 250 mg/m^2 and 500 mg/m^2 in children are 10 μg/mL and 21 μg/mL, respectively [10]. In neonates the $t_{1/2}$ of acyclovir is 3.8 h, and the C_{max} is 30 μg/mL after a 5 mg/kg dose, 61 μg/mL after a 10 mg/kg dose, and 86 μg/mL after a 15 mg/kg dose [20].

Dosing and Drug Interactions

The dose of IV acyclovir for the treatment of HSV encephalitis or VZV in immunocompromised hosts is 10–15 mg/kg given every 8 h (Table 55.2). The dose of oral acyclovir depends on the indication with 400 mg every 8 h recommended for treatment of the first episode of genital HSV or 400 mg five times daily if the patient is immunocompromised. For VZV, the oral dose of acyclovir is 800 mg five times daily. Acyclovir concentrations are increased when used in combination with probenecid due to decreased renal tubular secretion (Table 55.3). Combination of acyclovir and zidovudine may cause lethargy (Table 55.4).

Valacyclovir

Mechanism of Action and Resistance

Valacyclovir is the L-valyl ester of acyclovir which is rapidly converted to acyclovir and L-valine by first-pass metabolism [21]. Plasma concentrations of unconverted valacyclovir are low and undetectable 3 h after oral administration [22]. Valacyclovir plasma concentrations are 0.5 μg/mL, 0.4 μg/mL, and 0.8 μg/mL after a single administration of 1000 mg of valacyclovir in patients with hepatic dysfunction, renal dysfunction, and health volunteers, respectively [23, 24]. Once valacyclovir is converted to acyclovir, it undergoes the same phosphorylation to triphosphate as acyclovir to exert its antiviral activity [6]. As valacyclovir is rapidly converted to acyclovir, aforementioned mechanisms of drug resistance remain identical.

Pharmacokinetics

The absolute bioavailability of acyclovir after administration of valacyclovir is approximately 55% after a 1000 mg dose (Table 55.1). Similar to oral acyclovir, increases in acyclovir C_{max} and area under the curve (AUC) after single and multiple doses of valacyclovir are not proportional to increases in dose. The C_{max} is 3.3 μg/mL and the AUC is 11.6 μg*h/mL after a single dose of 500 mg of valacyclovir compared to a C_{max} and AUC of 5.7 μg/mL and 19.5 μg*h/mL, respectively, after a single dose of 1000 mg of valacyclovir [25]. Plasma protein binding of valacyclovir ranges from 14% to 18%.

Forty-one percent of acyclovir is recovered in urine after a single dose of 1000 mg of valacyclovir. In patients with end-stage renal disease, the acyclovir $t_{1/2}$ increases from 2 to 3 h to approximately 14 h after administration of valacyclovir [24]. In patients undergoing hemodialysis (HD), approximately 33% of acyclovir gets removed during a 4-h dialysis session [26]. Since valacyclovir needs to get converted to acyclovir by first-pass intestinal or hepatic metabolism, there is a concern that patients with moderate to severe liver disease may not have adequate conversion to acyclovir after administration of valacyclovir [27]. However, the rate and not the extent of conversion of valacyclovir to acyclovir is reduced, and the $t_{1/2}$ is not affected [28].

Distribution of acyclovir after administration of valacyclovir is similar to the distribution seen after administration of IV or oral acyclovir. After administration of 1000 mg of valacyclovir every 8-h regimen, the concentration of acyclovir in CSF is 2.5 μmol/L at 2 h and 2.3 μmol/L at 8 hours [29]. In patients with normal renal function the AUC in CSF to AUC in serum ratio is approximately 19% after administration of 1000 mg of valacyclovir every 8 h and 25% after administration of 2000 mg of valacyclovir every 6 h [29, 30].

Pharmacokinetics in Pediatric Patients

The pharmacokinetics of acyclovir has been evaluated in pediatric patients after administration of valacyclovir oral suspension. The C_{max} and AUC are 7.0 μg/mL and 27.6 μg*h/mL in children 1–2 months old, 5.2 μg/mL and 17.7 μg*h/mL in children 3–5 months old, 4.9 μg/mL and 14.1 μg*h/mL in children 6–11 months, and 4.7 μg/mL and 15.3 μg*h/mL in children 12–23 months after doses of 25 mg/kg of valacyclovir [31]. In children 2–5 years old who received 20 mg/kg of valacyclovir, the C_{max} and AUC were 3.8 μg/mL and 10.1 μg*h/mL; and in children 6–11 years, the C_{max} and AUC were 4.7 μg/mL and 13.1 μg*h/mL [31].

Table 55.2 Dose of antiviral agents for treatment of herpes viruses

Virus	Agent	Route	Usual adult dosage	Duration
Herpes simplex virus (HSV)				
Genital first episode	Acyclovir	IV	5 mg/kg q8h[a,b]	5 days[c]
		PO	400 mg q8h[a,d]	7–10 days[e]
		PO	200 mg five times daily[a,d,f]	7–10 days
		Topical	Apply q3h (6 times per day)	7 days
	Valacyclovir	PO	1000 mg q12h[a,d,g]	7–10 days[e]
	Famciclovir	PO	250 mg q8h[a,f]	7–10 days
		PO	500 mg q12h[a]	5–14 days
Genital recurrent episode	Acyclovir	PO	800 mg q8h[a,b]	2 days
		PO	400 mg q8h[a,b]	5 days[e]
		PO	200 mg five times daily[a]	5 days
	Valacyclovir	PO	500 mg q12h[a,b,f]	3 days
		PO	1000 mg q24h[a,b,f]	5 days
		PO	1000 mg q12h[a,b,g]	7–10 days
	Famciclovir	PO	125 mg q12h[a,b]	5 days
		PO	500 mg × 1 followed by 250 mg q12h[a,b]	2 days
		PO	1000 mg q12h[a,b]	1 day
Genital suppression	Acyclovir	PO	400 mg q12h[a]	12 months
		PO	200 mg q8h[a,f]	12 months
	Valacyclovir	PO	500 mg q24h[a,h]	12 months
		PO	1000 mg q24h[a,i]	12 months
		PO	250 mg q12h[a]	12 months
		PO	500 mg q12h[a]	12 months
Encephalitis	Acyclovir	IV	10–15 mg/kg q8h[a]	14–21 days
Mucocutaneous in immunocompromised patients	Acyclovir	IV	5–10 mg/kg q8h[a,j]	7–14 days
		PO	400 mg five times daily[a]	7–14 days
	Valacyclovir	PO	500 mg q12h[a]	7–10 days
		PO	1000 mg q12h[a]	7–10 days
	Famciclovir	PO	500 mg q12h[a]	7–10 days
	Foscarnet	IV	40 mg q8h[a]	14–21 days
		IV	60 mg q12h[a]	14–21 days
Orolabial	Acyclovir	PO	400 mg q8h[a]	5–10 days
		Topical	Apply five times daily	4 days
	Valacyclovir	PO	2000 mg q12h[a]	1 day
	Famciclovir	PO	500 mg q12h[a]	5–10 days
		PO	1500 mg × 1	1 day
	Penciclovir	Topical	Apply q2h while awake	4 days
Varicella zoster virus (VZV)				
Herpes zoster (shingles) in normal host	Acyclovir	PO	800 mg five times daily[a]	7–10 days
	Valacyclovir	PO	1000 mg q8h[a]	7 days
	Famciclovir	PO	500 mg q8h[a]	7 days
Herpes zoster (shingles) in immunocompromised host	Acyclovir	IV	10 mg/kg q8h[a,c]	7–10 days
		PO	800 mg five times daily[a,k]	7–10 days
	Valacyclovir	PO	1000 mg q8h[a,k]	7–10 days
	Famciclovir	PO	500 mg q8h[a,k]	7 days
Cytomegalovirus (CMV)				
Retinitis	Ganciclovir	IV	5 mg/kg q12h[a] (induction)	21 days
		IV	5 mg/kg q24h[a] (maintenance)	
	Valganciclovir	PO	900 mg q12h[a] (induction)	21 days
		PO	900 mg q24h[a] (maintenance)	
	Cidofovir	IV	5 mg/kg once weekly × 2 then 5 mg/kg every other week	
	Foscarnet	IV	60 mg/kg q8h[a] Or 90 mg/kg q12h[a] (induction)	21 days
		Iv	90–120 mg/kg q24h[a,l] (maintenance)	

Table 55.2 (continued)

[a]Dose adjustment required for renal insufficiency
[b]Start within 24 h of onset of symptoms
[c]Therapy may be completed with oral acyclovir for a total of 10 days
[d]Start within 48 h of onset of symptoms
[e]Duration for patients with HIV should be 5–14 days
[f]Do not use for immunocompromised patients or patients with HIV
[g]Dose of 1000 mg PO q12h should be used for treatment of all initial and recurrent episodes in patients with HIV
[h]If <10 episodes per year
[i]If ≥10 episodes per year
[j]Acyclovir 10 mg/kg should be reserved for progressive infections
[k]Oral therapy should only be used in patients with an acute localized dermatome
[l]Chronic suppression may be necessary with valganciclovir 900 mg PO q24h

Table 55.3 Pharmacokinetic drug-drug interactions with antiviral agents

Dosing and Drug Interactions

The dose of valacyclovir for treatment of the first episode of HSV is 1000 mg every 12 h and 500 mg every 12 h for any recurrent episodes (Table 55.2). The dose of valacyclovir is 1000 mg every 8 h for the treatment of VZV. Similar to acyclovir, valacyclovir concentrations are increased when used concurrently with probenecid, and the combination of valacyclovir and zidovudine may cause lethargy (Table 55.3).

Table 55.4 Pharmacodynamic drug-drug interactions with antiviral agents

	Increased pharmacodynamics (drug effect)
Acyclovir	Interferon Additive antiviral effect Zidovudine May cause lethargy
Adefovir	Aminoglycosides, amphotericin, cyclosporine, tacrolimus, vancomycin Increased nephrotoxicity Ribavirin Increased hepatotoxicity
Amantadine	Anticholinergic agents Additive anticholinergic effects May prolong the QT interval Use with caution with other agents that prolong the QT interval
Boceprevir	
Cidofovir	Aminoglycosides, amphotericin B, foscarnet, pentamidine Increased nephrotoxicity
Entecavir	Ribavirin Increased hepatotoxicity
Famciclovir	

Ganciclovir

Mechanism of Action and Resistance

Ganciclovir is an acyclic nucleoside analogue of 2′-deoxyguanosine that inhibits replication of cytomegalovirus (CMV), HSV, and VZV [32]. In order to exhibit its antiviral activity, ganciclovir similar to acyclovir must be phosphorylated. The phosphorylation unlike acyclovir does not depend on viral TK; in fact it is mediated via CMV-encoded (UL97 gene) protein kinase homologue [32]. After conversion to ganciclovir monophosphate, it is converted to di- and triphos-

Table 55.4 (continued)

	Increased pharmacodynamics (drug effect)
Foscarnet	May prolong the QT interval Use with caution with other agents that prolong the QT interval Can cause significant electrolyte disturbances (hypokalemia, hypocalcemia, hypomagnesemia, hypophosphatemia) Use with caution with aminoglycosides, amphotericin B, diuretics, and pentamidine Aminoglycosides, amphotericin B, cidofovir, pentamidine Increased nephrotoxicity
Ganciclovir	Azathioprine, cyclosporine, didanosine, zidovudine Increased hematological toxicity Ganciclovir may antagonize the effect of didanosine and zidovudine against HIV Aminoglycosides, amphotericin B, cidofovir, foscarnet, pentamidine Increased nephrotoxicity Imipenem-cilastatin Increased seizure risk

phate forms by cellular kinases. Ganciclovir triphosphate concentrations are 100-fold greater in CMV-infected cells than uninfected cells [33]. Ganciclovir triphosphate inhibits viral DNA synthesis by competitive inhibition of viral DNA polymerases and incorporation into viral DNA, resulting in slowing of viral DNA elongation [33]. Resistance to ganciclovir is commonly a result of a mutation in the UL97 gene; mutation in DNA polymerase is a less common mechanism of viral drug resistance [34]. The 0.1–1.6 μg/mL ganciclovir concentration leads to inhibit 50% of viral plaques in cell line CMV cultures [32].

Pharmacokinetics

After administration of 5 mg/kg IV ganciclovir, the C_{max} ranges from 8.0 to 9.0 μg/mL, and the AUC ranges from 22.1 to 26.8 μg*h/mL [35] (Table 55.1). The bioavailability of oral ganciclovir is only 5–8%, with a C_{max} of 1.2 μg/mL and AUC of 15.4 μg*h/L [35]. Intravenous ganciclovir exhibits linear pharmacokinetics up to 5 mg/kg and oral ganciclovir exhibits linear pharmacokinetics up to 4000 mg/day [36]. Protein binding of ganciclovir is only 1–2%, and the average $t_{1/2}$ is 3.5 h following IV administration and 3–7 h following oral administration [37, 38]. The volume of distribution (V_d) of IV ganciclovir is 0.7 L/kg. Ganciclovir is also available as a 0.15% ophthalmic gel and 4.5 mg intraocular implant for treatment of CMV retinitis. The estimated daily dose of ganciclovir that is obtained after administration of the 0.15% ophthalmic gel is 0.04% and 0.1% of the oral and IV doses, respectively, limiting the systemic exposure [39]. After insertion of the intraocular implant, the release rate of ganciclovir and the mean vitreous ganciclovir level are 1.4 μg/h and 4.1 μg/mL, respectively [40].

The renal clearance (Cl_{renal}) of ganciclovir is 3.2 mL/min/kg, which accounts for 91% of Cl_{total} in patients with normal renal function [41, 42]. The major route of elimination of ganciclovir is unchanged drug by glomerular filtration and active renal tubular secretion. The $t_{1/2}$ of ganciclovir increases from 3.6 h in patients with normal renal function to 11.5 h in patients with renal insufficiency after receiving 5 mg/kg of IV ganciclovir [43]. In patients undergoing HD, plasma concentrations of ganciclovir are reduced by approximately 50% [43]. The concentration obtained in CSF 3.5 hours after administration of IV ganciclovir 2.5 mg/kg is 0.7 μg/mL, while the serum concentration is 2.2 μg/mL [44].

Pharmacokinetics in Pediatric Patients

The C_{max} after IV doses of 4 mg/kg or 6 mg/kg of ganciclovir are 5.5 μg/mL and 7.0 μg/mL in neonates aged 2–49 days, respectively [45, 46]. The $t_{1/2}$ is 2.4 h for both dosing regimens. In pediatric patients aged 6 months to 17 years, the C_{max} is 6.6 μg/mL after doses of 5 mg/kg IV ganciclovir [47].

Dosing and Drug Interactions

The dose of IV ganciclovir for the treatment of CMV retinitis is 5 mg/kg every 12 h for 14–21 days followed by 5 mg/kg every 24 h (Table 55.2). Oral ganciclovir should not be used for the treatment of CMV due to poor bioavailability. Ganciclovir concentrations increase with concurrent probenecid use (Table 55.3). Hematological toxicities may be increased when ganciclovir is used in combination with azathioprine, cyclosporine, didanosine, or zidovudine. Ganciclovir may antagonize the effects of didanosine and zidovudine against HSV. Caution should be used when ganciclovir is combined with aminoglycosides, amphotericin B, cidofovir, foscarnet,

or pentamidine due to the increased risk of nephrotoxicity (Table 55.4). The combination of ganciclovir and imipenem-cilastatin may increase the risk of seizures.

Valganciclovir

Mechanism of Action and Resistance

Valganciclovir is the L-valyl ester of ganciclovir and exists as a mixture of two diastereomers, which are rapidly converted to ganciclovir by intestinal and hepatic esterases [33, 48]. Plasma concentrations of unconverted valganciclovir are low with an AUC of 1% and C_{max} of 3% of ganciclovir [49]. Once valganciclovir is converted to ganciclovir, it is phosphorylated by the same mechanism in order to inhibit viral DNA synthesis [33, 48].

Pharmacokinetics

The bioavailability of ganciclovir after administration of 900 mg once daily of enteral valganciclovir in healthy subjects was 59%, which is significantly higher than the 5% bioavailability after administration of oral ganciclovir [50–52] (Table 55.1). The time to C_{max} after administration of oral valganciclovir is 1–2 h [51]. The ganciclovir AUC increases by 30% and the C_{max} increases by 14% when valganciclovir is administered with a high fat meal; however, there is no change in the time to C_{max} [49]. The $t_{1/2}$ of valganciclovir and IV ganciclovir is 4 h and 3.8 h, respectively [38, 49]. Similarly, AUC for oral valganciclovir and IV ganciclovir are comparable (24.8 μg*h/mL vs. 26.5 μg*h/mL), although valganciclovir C_{max} is 30% lower compared to IV ganciclovir (6.1 μg/mL vs. 9.0 μg/mL) [35, 51]. The pharmacokinetics of ganciclovir after administration of oral valganciclovir has been evaluated in solid organ transplant patients. The AUC, C_{max}, and $t_{1/2}$ of ganciclovir after administration of valganciclovir are similar regardless of type of solid organ transplantation including heart, liver, and kidney organ graft transplants [53].

Valganciclovir is mainly eliminated by renal excretion as ganciclovir through glomerular filtration and active tubular secretions. The elimination $t_{1/2}$ is increased and Cl_{total} of ganciclovir is reduced following administration of valganciclovir in patients with renal impairment. The $t_{1/2}$ of ganciclovir increases from 4.9 h in patients with creatinine clearance (CrCl) 51–70 mL/min to 22 h and 68 h in patients with CrCl 11 to 20 mL/min and ≤10 mL/min, respectively [54]. Hemodialysis reduces plasma concentrations of ganciclovir by 50% following valganciclovir administration [54].

Pharmacokinetics in Pediatric Patients

The bioavailability of ganciclovir after administration of oral valganciclovir is slightly lower in children at 42–54% compared to adults at 60%, and clearance is related to body surface area and renal function [53, 55, 56]. A lower C_{min} may be seen in younger children with mean age of 4.5 years compared to older children with a mean age of 11 years [56, 57]. The pharmacokinetics of oral valganciclovir was compared to IV ganciclovir in neonates >7 days to 3 months of age with congenital CMV infection of the CNS. After 6 weeks of therapy with 14–20 mg/kg twice-daily oral valganciclovir solution, the $AUC_{0–12h}$ was 27.4 μg*h/mL which is similar to the $AUC_{0–12h}$ of 25.4 μg*h/mL achieved from 5 mg/kg of IV ganciclovir [55, 58].

Dosing and Drug Interactions

The dose of valganciclovir for the treatment of CMV retinitis is 900 mg every 12 h for 21 days followed by 900 mg every 24 h (Table 55.2). Drug interactions with valganciclovir are the same as those seen with ganciclovir (Table 55.3).

Foscarnet

Mechanism of Action and Resistance

Foscarnet is an organic analogue of inorganic pyrophosphate that inhibits replication of herpes virus by selective inhibition at the pyrophosphate binding site on virus-specific DNA polymerases at concentrations that do not affect cellular DNA polymerases [59]. Unlike acyclovir, valacyclovir, ganciclovir, or valganciclovir, foscarnet does not require phosphorylation by TK or other kinases such as UL97. As a result, foscarnet has activity against HSV, VZV, and CMV including TK deficient mutants and CMV UL97 mutants [59]. Foscarnet resistance has been identified and is a result of single base substitutions in conserved and nonconserved regions of the DNA polymerase [2]. Some of these isolates can retain susceptibility to acyclovir; however, mutants with alterations in both TK and DNA polymerase would result in resistance to both acyclovir and foscarnet [2]. The concentrations of foscarnet needed to inhibit viral plaques in cell line cultures were 0.4 μmol/mL to 3.5 μmol/L for HSV-1 and 0.6 μmol/L to 22 μmol/L for HSV-2. The concentration of foscarnet needed for inhibition of VZV in cultures was 0.4 μmol/L, and for CMV inhibition it was 0.3 μmol/L [59].

Pharmacokinetics

The pharmacokinetics of foscarnet has been established during induction therapy in AIDS patients with CMV retinitis (Table 55.1). After administration of 60 mg/kg IV q8h, the C_{max} is 589 μmol/L, and C_{min} is 114 μmol/L at steady state [60, 61]. The V_d is 0.31 to 0.74 L/kg and the plasma $t_{1/2}$ is 4 h [62–64]. After administration of 90 mg/kg IV every 12 h, the C_{max} and C_{min} are 623 μmol/L and 63 μmol/L, respectively, while the V_d is 0.52 L/kg with a plasma $t_{1/2}$ of 3 hours and Cl_{total} of 7.0 L/h [62–64]. A total of 14–17% of foscarnet is protein bound. Although not approved in the United States, foscarnet has been given as an intravitreal injection for treatment of acute retinal necrosis [65–67].

The Cl_{total} of foscarnet is 6.2 L/h, with 78–86% of this agent cleared via renal elimination [62–64]. The clearance of foscarnet is significantly reduced with reduced renal function and the elimination $t_{1/2}$ increases by ten-fold [68]. As a result of the reduced clearance, the $t_{1/2}$ of foscarnet increases from 2 hours in patients with a mean CrCl of 108 mL/min to 3.4 h in patients with a mean CrCl of 68 mL/min to 13 and 25 h in patients with a mean CrCl of 34 mL/min and 20 mL/min, respectively [68]. It is mportant to note that foscarnet terminal $t_{1/2}$ based on urinary excretion is 88 h, which is significantly higher than the plasma $t_{1/2}$, and this possibly in part reflects release of foscarnet from the bone [62, 64, 68].

Dosing and Drug Interactions

The dose of foscarnet for the treatment of CMV is 60 mg/kg every 8 h followed by 90–120 mg/kg every 24 h (Table 55.2). An alternative dosing regimen of 90 mg/kg every 12 hours has also been used. Chronic suppression with oral valganciclovir may still be necessary. As foscarnet may prolong the QT interval, caution should be taken when it is used with other agents that may also prolong the QT interval (Table 55.4). Caution should be used when foscarnet is used with aminoglycosides, amphotericin B, diuretics, and pentamidine due to the risk of significant electrolyte abnormalities including hypokalemia, hypocalcemia, hypomagnesemia, and hypophosphatemia. There is also an increased risk of nephrotoxicity when foscarnet is used concurrently with aminoglycosides, amphotericin B, cidofovir, or pentamidine.

Cidofovir

Mechanism of Action and Resistance

Cidofovir is a nucleoside analogue, which suppresses viral replication by selective inhibition of viral DNA synthesis. Cidofovir must be phosphorylated by cellular enzymes to cidofovir diphosphate, which is the active intracellular metabolite. Incorporation of cidofovir into the growing viral DNA chain results in reductions in viral DNA synthesis [69]. Cidofovir is active against HSV, VZV, and CMV, including acyclovir and ganciclovir resistant isolates, as cidofovir does not require activation by TK or UL97 [34]. Mutations in DNA polymerase can cause resistance to cidofovir. Almost all DNA polymerase mutations that confer ganciclovir resistance will also confer cidofovir resistance [34]. Ganciclovir-resistant isolates due to mutations in UL97 genes retain susceptibility to cidofovir [69]. The concentrations of cidofovir needed to inhibit viral plaques by 50% in cell cultures were 12.7–31.7 μmol/L for HSV-1 and HSV-2. The concentrations of cidofovir needed for inhibition of VZV and CMV were 0.79 μmol/L and 0.5 μmol/L to 2.8 μmol/L, respectively [70].

Pharmacokinetics

Pharmacokinetics of cidofovir has been evaluated in patients who received cidofovir with or without probenecid in HIV-infected patients. Less than 6% of cidofovir is protein bound [71]. Probenecid competitively inhibits the renal tubular secretion of cidofovir, reducing the Cl_{renal} to a level consistent with glomerular filtration [72]. In patients who receive cidofovir without probenecid, the C_{max} and AUC are 7.3 μg/mL and 20 μg*h/mL after 3 mg/kg and 11.5 μg/mL and 28.3 μg*h/mL after 5 mg/kg dose [71]. After administration of 5 mg/kg of IV cidofovir without probenecid, the V_d is 556 L/kg, the Cl_{total} is 177 mL/h/kg, and the Cl_{renal} is 149 mL/h/kg, which is greater than glomerular filtration [71]. When probenecid is administered along with cidofovir, the C_{max} and AUC increase to 9.8 μg/mL and 25.7 μg*h/mL after 3 mg/kg and 19.6 μg/mL and 40.8 μg*h/mL after 5 mg/kg [69, 72]. The V_d decreases to 388 L/kg, and the Cl_{total} decreases to 138 mL/h/kg, and the Cl_{renal} is reduced to 96 mL/h/kg, which is consistent with glomerular filtration [72].

In patients with normal renal function, 80–100% of the cidofovir dose is recovered unchanged in the urine within 24 h [71]. Approximately 70 to 85% of the cidofovir dose is excreted unchanged in the urine when it is administered with probenecid [69]. Cidofovir's renal tubular secretion and renal clearance decrease proportionally to glomerular filtration CrCl [73]. Hemodialysis reduces serum cidofovir levels by 75% [73]. Due to therapy-related renal failure, cidofovir bladder irrigation has been used for treatment of polyomavirus-associated hemorrhagic cystitis; however, there is only limited data on its use in this situation [74]. Topical cidofovir gel has been used successfully for the treatment of cutaneous acyclovir- and foscarnet-resistant herpes virus; however, there is limited information regarding the pharmacokinetics of this dosage form [75]. As there is no commercially available product, topical cidofovir must be prepared using specific compounding instructions [75]. Topical eye drops with cidofovir have also been used for the treatment of viral conjunctivitis [76].

Dosing and Drug Interactions

The dose of cidofovir for the treatment of CMV is 5 mg/kg once weekly for two doses followed by 5 mg/kg every other week (Table 55.2). There is a potential for increased nephrotoxicity when cidofovir is used concurrently with aminoglycosides, amphotericin B, foscarnet, and pentamidine (Table 55.4).

Famciclovir

Mechanism of Action and Resistance

Famciclovir is the diacetyl 6-deoxy analogue of the active antiviral agent penciclovir. After oral administration, famciclovir

is rapidly converted to penciclovir, along with other inactive metabolites including 6-deoxy penciclovir (5%), monoacetylated penciclovir (<0.5%), and 6-deoxy-monoacetylated penciclovir (<0.5%) by aldehyde oxidase with little to no famciclovir detected [77]. Similar to acyclovir, penciclovir undergoes phosphorylation to the active form penciclovir triphosphate [77]. Resistance to penciclovir is due to mutations in the UL23 gene, encoding the TK enzyme, with cross-resistance noted between penciclovir and acyclovir [2]. The concentration of penciclovir needed to inhibit viral plaques by 50% in vitro was 0.6 μg/mL to 0.8 μg/mL for HSV-1 and 2.2 μg/mL to 2.4 μg/mL for HSV-2 [78].

Pharmacokinetics

The bioavailability of penciclovir after administration of 500 mg of oral famciclovir is 77% [79] (Table 55.1). Unlike acyclovir and valacyclovir, penciclovir concentrations are proportionally increased with increasing doses of famciclovir. The C_{max} and AUC of penciclovir are 1.6 mg/L and 4.3 mg*h/L after a single dose of 250 mg famciclovir, and the C_{max} and AUC increase to 3.3 mg/L and 9.3 mg*h/L, respectively, after a single dose of 500 mg. After a single dose of 750 mg famciclovir, the C_{max} of penciclovir is 5.1 mg/L and the AUC is 14.1 mg*h/L [79]. Plasma protein binding of penciclovir is <20%, and the V_d is 1.5 L/kg in healthy males after a single IV dose of penciclovir [80]. The $t_{1/2}$ of penciclovir is approximately 2 h in healthy male volunteers after oral administration of famciclovir [79–81]. Famciclovir is not available as a topical preparation; however, there is a topical penciclovir 1% cream that is commercially available for the treatment of herpes labialis [82].

Approximately 94% of penciclovir is recovered in the urine over 24 hours with 83% of the dose recovered in the first 6 hours after administration of IV penciclovir [83]. After administration with 500 mg of oral famciclovir, 73% of the dose is recovered in the urine with penciclovir and 6-deoxy penciclovir accounting for 82% and 7%, respectively [81]. Only 27% of the administered dose of famciclovir is recovered in the feces [79]. Clearance of penciclovir after administration of famciclovir is via renal elimination with active tubular secretion, a contributing factor [79, 81]. The clearance of penciclovir decreases linearly with declining renal function [81]. The $t_{1/2}$ of penciclovir increases from 2.2 h in patients with no renal impairment to 2.5 h, 3.9 h, and 9.9 h in patients with mild (CrCl 60 to 80 mL/min), moderate (CrCl 30 to 59 mL/min), and severe (CrCl 5 to 29 mL/min) renal impairment, respectively [81].

Patients with mild to moderate hepatic impairment have no effect on the AUC of penciclovir following 500 mg of famciclovir dose, although the C_{max} was reduced by 43% and the time to C_{max} was increased by 0.75 h [84]. The pharmacokinetics of penciclovir after administration of famciclovir has not been studied in patients with severe hepatic impairment.

Dosing and Drug Interactions

The treatment dose for HSV of famciclovir is 250 mg every 8 h for the first episode and 125 mg every 8 h for any recurrent episodes (Table 55.2). In immunocompromised patients with HSV the dose of famciclovir is 500 mg every 12 h and the dose for treatment of VZV is 500 mg every 8 h. Concentrations of famciclovir will increase with concurrent use of probenecid due to decreased renal tubular secretion (Table 55.3).

Anti-influenza Agents

Amantadine

Mechanism of Action and Resistance

Amantadine is a symmetric tricyclic amine that inhibits the replication of influenza A virus isolates and has very little to no activity against influenza B [85]. Amantadine prevents the release of viral nucleic acid into the host cell by interfering with the function of the transmembrane domain of the viral M2 protein [86, 87]. Amantadine resistance has limited its use, as resistance can emerge after 2–4 days of treatment due to an amino acid substitution in the M2 protein [88, 89].

Pharmacokinetics

Amantadine is well absorbed. Oral bioavailability, which is 86–92%, and C_{max} are directly related to doses up to 200 mg/day (Table 55.5). In subjects given doses above 200 mg/day, greater increases in C_{max} may occur [85]. An N-acetylated metabolite accounts for 5–15% of the administered dose found in urine. Following 200 mg dose of amantadine, plasma acetylamantadine accounted for 80% of the concurrent amantadine plasma concentration in 5 healthy volunteers, while 7 volunteers did not have any acetylamantadine detected [85]. The C_{max} of amantadine is 0.29 μg/mL, and the time to C_{max} is 1–12 h with a $t_{1/2}$ of 10–45 h [85, 90]. Amantadine Cl_{plasma} is 7–22 L/h and the V_d is 3–12 L/kg and amantadine is 67% plasma protein bound [85, 90, 91].

Amantadine is primarily excreted unchanged in the urine by glomerular filtration and tubular secretion. The Cl_{plasma} is reduced and $t_{1/2}$ and plasma concentrations are increased in elderly patients compared to young adults [85, 92]. These changes could be a result of a decrease in renal function. The Cl_{plasma} of amantadine is reduced and the $t_{1/2}$ increase by 2 to 3 times when CrCl <40 m L/min/1.73m^2 [90]. The $t_{1/2}$ increases

to 8 days and amantadine is not removed in anuric patients receiving HD with less than 5% removed during a 4-h HD session [90]. After a single 200 mg dose, the maximum nasal mucus concentrations of amantadine after 1, 4, and 8 h were 0.15 μg/g, 0.28 μg/g, and 0.39 μg/g with a C_{max} of 0.42 μg/g, which is 31%, 59%, 95%, and 71% of the plasma concentrations, respectively [92].

Dosing and Drug Interactions

The dose of amantadine for the treatment of influenza A is 100 mg every 12 h for 5 days (Table 55.6). Amantadine should not be used for the treatment of influenza B. Amantadine levels increase when used concurrently with quinidine, quinine, triamterene, or trimethoprim due to decreased renal tubular secretion (Table 55.3). Caution should be taken when amantadine is used with anticholinergic agents due to additive anticholinergic effects (Table 55.4). Furthermore, amantadine should be used with caution when given with agents that prolong the QT interval.

Rimantadine

Mechanism of Action and Resistance

Rimantadine is a symmetric tricyclic amine that inhibits the replication of influenza A virus isolates and has very little to no activity against influenza B [93, 94]. The mechanism of action is similar to amantadine as it prevents the release of viral nucleic acid in the host cell by interfering with the function of the transmembrane domain of the viral M2 protein [88, 89].

Pharmacokinetics

Approximately 90% of a rimantadine dose is absorbed, the C_{max} after a single 100 mg dose of rimantadine is 0.074 μg/mL, and the time to C_{max} is 6 h [95] (Table 55.5). The $t_{1/2}$ after a single dose ranges from 25 to 37 h [95]. In elderly patients aged 71–79 years old, the $t_{1/2}$ is 32 h [95]. Similar to $t_{1/2}$ the AUC also increases by 20–30% in elderly patients.

Rimantadine is metabolized in the liver and only 25% is excreted in the urine as unchanged drug [95]. There are no

Table 55.6 Dose of antiviral agents for treatment of respiratory viruses

Virus	Agent	Route	Usual adult dosage	Duration
Influenza A	Rimantadine	PO	100 mg q12h[a]	7 days[b]
	Amantadine	PO	100 mg q12h[a,c]	5 days[b]
	Oseltamivir	PO	75 mg q12h[a,d]	5 days[b]
	Zanamivir	Oral inhalation	10 mg q12h[e]	5 days[b]
Influenza B	Oseltamivir	PO	75 mg q12h[a,d]	5 days[b]
	Zanamivir	Oral inhalation	10 mg q12h[e]	5 days[b]
Respiratory syncytial virus or human metapneumovirus	Ribavirin	Inhalation	6 g/day[f]	7–10 days

[a]Dose adjustment required for renal insufficiency
[b]Duration prophylaxis for influenza should be continued for at least 10 days following known exposure
[c]Amantadine 200 mg PO q24h can also be used for influenza A
[d]Oseltamivir 75 mg PO q24h for 10 days should be used for prophylaxis of influenza A or B virus
[e]Zanamivir 10 mg inhaled orally q24h for 10 days should be used for prophylaxis of influenza A or B virus
[f]Should be given as 2 g over 2–3 h every 8 h or 6 g over 18 h continuously. Must be administered via Small Particle Aerosol Generator-2 (SPAG-2)

differences in C_{max}, C_{min}, and AUC in patients with normal renal function compared to patients with mild to moderate renal insufficiency (CrCl 30–80 mL/min). However, there is an increase in C_{max} by 75%, C_{min} by 82%, and AUC by 81% in patients with severe renal impairment (CrCl 5–29 mL/min) [95]. In HD patients the $t_{1/2}$ increases by 1.6-fold, and there is a 40% decrease in clearance after a single 200 mg oral dose [95]. Nasal fluid concentrations of rimantadine are 1.5 times higher than plasma concentrations [95].

Dosing and Drug Interactions

The dose of rimantadine for the treatment of influenza A is 100 mg every 12 hours for 5 days (Table 55.6). Rimantadine should not be used for the treatment of influenza B. There are no significant drug-drug interactions with rimantadine (Table 55.3).

Oseltamivir

Mechanism of Action and Resistance

Oseltamivir is an ethyl ester prodrug that requires ester hydrolysis to convert it to the active form, oseltamivir carboxylate, which inhibits influenza virus neuraminidase affecting the release of viral particles [96]. Oseltamivir is absorbed from the GI tract and is converted by hepatic esterases to oseltamivir carboxylate, with less than 5% remaining as oseltamivir [97]. Approximately 75% of the oral dose is found as oseltamivir carboxylate in the systemic circulation [97, 98]. Reduced susceptibility of influenza virus to oseltamivir carboxylate may be due to amino acid substitutions in viral neuraminidase and/or hemagglutinin [99, 100]. Substitutions in hemagglutinin amino acids may reduce viral dependency on neuraminidase activity but do not confer resistance to oseltamivir on their own [99, 101]. Cross-resistance has been observed between zanamivir and oseltamivir; however, some oseltamivir resistance-associated substitutions do not reduce susceptibility to zanamivir [102–105]. There has not been a single amino acid substitution that confers cross-resistance between neuraminidase inhibitors and the M2 ion channel inhibitors, although two separate substitutions may be present in a single virus [101].

Pharmacokinetics

Following multiple doses of oseltamivir 75 mg twice daily, the C_{max} and $AUC_{0–12}$ of oseltamivir are 65 ng/mL and 112 ng*h/mL, and the C_{max} and $AUC_{0–12}$ of oseltamivir carboxylate are 348 ng/mL and 2719 ng*h/mL [97] (Table 55.5). The V_d at steady state of oseltamivir carboxylate following IV administration is 23 to 26 L, and the protein binding is only 3% [97, 98]. The protein binding of oseltamivir is 42%. Approximately 90% of oseltamivir is converted to oseltamivir carboxylate. The $t_{1/2}$ of oseltamivir is 1–3 h, and the $t_{1/2}$ of oseltamivir carboxylate is 6–10 h [96, 97, 106].

Almost all (>99%) of oseltamivir carboxylate is eliminated unchanged in the urine [97]. Oseltamivir carboxylate is removed via renal tubular secretion as well as glomerular filtration [97]. As elimination of oseltamivir carboxylate is via renal clearance, the exposure of oseltamivir carboxylate is inversely proportional to declining renal function. The C_{max} of oseltamivir carboxylate is 494 μg/L in patients with normal renal function (CrCl >90 mL/min) compared to 4052 μg/L in patients with a CrCl <30 mL/min after receiving oseltamivir 100 mg every 12 h. The $AUC_{0–12}$ of oseltamivir carboxylate also increases from 4187 μg*h/L to 43,086 μg*h/L [97]. In patients undergoing HD the C_{max} for oseltamivir carboxylate is 943 ng/mL after a single dose and 1120 ng/mL after repeated doses [107]. Oseltamivir carboxylate exposure is not different in patients with mild to moderate hepatic impairment [98, 108].

Pharmacokinetics in Pediatric Patients

Pediatric patients clear oseltamivir and oseltamivir carboxylate faster than adults, resulting in lower drug exposure [109]. The Cl_{total} of oseltamivir carboxylate decreases linearly with increasing age up to 12 years. The pharmacokinetics of oseltamivir carboxylate in children >12 years old is similar to adults [109].

Dosing and Drug Interactions

The dose of oseltamivir for the treatment of influenza A or B is 75 mg every 12 h and the dose for prophylaxis is 75 mg every 24 h (Table 55.6). Oseltamivir levels may be increased if used with probenecid due to decreased renal tubular secretion (Table 55.3).

Zanamivir

Mechanism of Action and Resistance

Zanamivir is an orally inhaled inhibitor of influenza virus neuraminidase that affects the release of viral particles [110]. Reduced susceptibility in cell culture to zanamivir is associated with mutations that result in amino acid changes in the viral neuraminidase, viral hemagglutinin, or both [101]. Cross-resistance has been observed between some zanamivir-resistant and oseltamivir-resistant influenza viruses [101]. The Q136K zanamivir resistance-associated substitution observed in N1 neuraminidase confers resistance to zanamivir but not oseltamivir [101].

Pharmacokinetics

After inhalation, approximately 13% of the dose is deposited in the lungs and 78% in the oropharynx [111] (Table 55.5). The C_{max} in serum occurs within 2 h after an inhaled dose of zanamivir [112]. Zanamivir has limited protein binding of <10%, and 90% of the drug is excreted unchanged in the urine after intravenous administration, whereas only 4% of the dose is recovered in the urine after intranasal administration [112]. The $t_{1/2}$ of zanamivir after inhalation is 3.6 h [112].

Pharmacokinetics in Pediatric Patients

Serum zanamivir concentrations in pediatric patients ≤5 years of age was similar to adults after administration of inhaled zanamivir 10 mg (183 ng*h/L vs. 194 ng*h/L, respectively) [113].

Dosing and Drug Interactions

The dose of zanamivir for the treatment of influenza A or B is 10 mg via inhaler every 12 h and the dose for prophylaxis is 10 mg via inhaler every 24 h (Table 55.6). There are no significant drug-drug interactions with zanamivir (Table 55.3).

Anti-hepatitis Virus Agents

Adefovir Dipivoxil

Mechanism of Action and Resistance

Adefovir is an acyclic nucleotide analogue of adenosine monophosphate. Once phosphorylated by cellular kinases to the active metabolite, adefovir diphosphate, it inhibits *Hepatitis B virus* (HBV) DNA polymerase and reverse transcriptase, by competing with deoxyadenosine triphosphate causing DNA chain termination after incorporation into viral DNA [114]. Adefovir dipivoxil is a prodrug and is rapidly converted to the active agent adefovir. Amino acid substitutions rtN236T and rtA181T/V are the primary mutations that are associated with adefovir resistance causing a two- to ninefold decrease in susceptibility to adefovir [115–118]. Adefovir resistance-associated substitution rtA181V is also associated with decreased susceptibility to lamivudine [116].

Pharmacokinetics

The bioavailability of adefovir after administration of adefovir dipivoxil is 59% [114]. The C_{max} of adefovir is 18 to 19 ng/mL after a single oral dose of 10 mg of adefovir dipivoxil, and the time to C_{max} is 2 h [114, 119] (Table 55.7). The AUC of adefovir is 204 ng*h/mL and the $t_{1/2}$ is 7.1–7.5 h [114, 119]. The plasma protein binding of adefovir is <4%. The V_d at steady state is 392 mL/kg after IV administration of 1 mg/kg/day of adefovir and 352 mL/kg after 3 mg/kg/day [114].

Adefovir is excreted by glomerular filtration and active renal tubular secretion; 40–45% of the adefovir dipivoxil dose was recovered as adefovir in the urine 24 h after administration [114, 119, 120]. In patients who receive 10 mg/day of adefovir dipivoxil suspension with a CrCl 50–79 mL/min, the C_{max} is 34 ng/mL and the AUC is 361 ng*h/mL at 48 weeks [121]. In patients with CrCl 20–49 mL/min who receive 5 mg/day, the C_{max} is 20 ng/mL and the AUC is 277 ng*h/mL at 48 weeks [121]. For patients undergoing HD who receive 1 mg × 1 followed by 0.5 mg three times weekly, the C_{max} is 10 ng/mL at week 12 and the AUC is 213 ng*h/mL. Plasma concentrations of adefovir decrease by 70–90% after HD [121].

Pharmacokinetics in Pediatric Patients

The pharmacokinetics of adefovir dipivoxil has been evaluated in pediatric patients with chronic hepatitis B [122]. In children aged 2–6 years, the C_{max} and AUC were 15 ng/mL and 105 ng*h/mL, respectively, following 0.14 mg/kg of adefovir dipivoxil dose. The C_{max} and AUC were 27 ng/mL and 224 ng*h/mL, respectively following 0.3 mg/kg of adefovir dipivoxil. In children aged 7–11 years who receive 0.14 mg/kg dose, the C_{max} was 14 ng/mL, and the AUC was 129 ng*h/mL compared to 33 ng/mL and 292 ng*h/mL for children who receive 0.3 mg/kg, respectively. For adolescents aged 12–17 years who were given 10 mg dose, the C_{max} was 23 ng/mL, and the AUC was 237 ng*h/mL and was similar to parameters noted in adults [122].

Dosing and Drug Interactions

The dose of adefovir for the treatment of chronic HBV is 10 mg every 24 h (Table 55.8). The use of ibuprofen with adefovir may increase the bioavailability of adefovir (Table 55.3). The combination of adefovir and ribavirin may increase the risk of hepatotoxicity and the use of adefovir with aminoglycosides, amphotericin B, cyclosporine, tacrolimus, or vancomycin may enhance the risk for nephrotoxicity (Table 55.4).

Table 55.8 Dose of antiviral agents for treatment of hepatitis viruses

Virus	Agent	Route	Usual adult dosage	Duration
Chronic hepatitis C	Telaprevir[a,b]	PO	750 mg q8h[c]	12 weeks[d]
	Boceprevir[a,b]	PO	800 mg q8h	Based on virologic response[e]
	Ribavirin	PO	800–1400 mg/day in 2 divided doses[f,g,h]	48 weeks[i]
		PO	800–1200 mg/day in 2 divided doses[f,g,j,k]	48 weeks[i]
	Peg-interferon-alfa-2a	SQ	180 μg weekly[f,l]	48 weeks[i]
	Peg-interferon-alfa-2b	SQ	1.5 μg weekly[f,l]	48 weeks[i]
Chronic hepatitis B	Adefovir dipivoxil	PO	10 mg q24h[f]	
	Entecavir	PO	0.5–1 mg q24h[f,m]	
	Lamivudine	PO	100 mg q24h[f]	
	Tenofovir	PO	300 mg q24h[f]	

[a]Telaprevir and boceprevir should only be used in patients infected with Hepatitis C Virus genotype-1
[b]Should always be used in combination with peg-interferon-alfa and ribavirin
[c]No data is available regarding use in renal insufficiency
[d]Continued treatment with peg-interferon-alfa and ribavirin is based on clinical response. The three-drug regimen should be discontinued at week 4 or 12 if viral RNA levels are ≥1000 international units/mL. Peg-interferon-alfa and ribavirin should be discontinued if viral RNA levels are detectable at week 24
[e]Boceprevir should be added to peg-interferon-alfa and ribavirin after 4 weeks of treatment. The three-drug regimen should be discontinued at week 12 if viral RNA levels ≥100 international units/mL or at week 24 if confirmed detectable viral-RNA levels
[f]Dose adjustment required for renal insufficiency
[g]Should be used in combination with interferon-alfa ± boceprevir or telaprevir
[h]Rebetol® dose is based on weight and is approved for use in combination with peg-interferon-alfa-2b for patients following prior treatment failure in compensated liver disease
[i]Duration of therapy should be 24 weeks for patients infected with HCV-genotype-2 or -3
[j]Copegus® should be used in combination with peg-interferon-alfa-2a for interferon-alfa naïve patients with compensated liver disease
[k]Ribavirin dose should be 1000–1200mg/day for HCV-genotype-1 or -4, and 800mg/day for HCV-genotype-2
[l]Should be used in combination with ribavirin +/- boceprevir or telaprevir
[m]Entecavir 1mg PO q24h should be used for lamivudine-refractory or -resistant HCV or for patients with decompensated liver disease

Entecavir

Mechanism of Action and Resistance

Entecavir is a guanine nucleoside analogue with activity against HBV reverse transcriptase. Entecavir must be phosphorylated to the active triphosphate form, which competes with the natural substrate deoxyguanosine triphosphate to functionally inhibit base priming, reverse transcription of the negative strand from the pregenomic messenger RNA, and synthesis of the positive strand of HBV DNA [123–125]. Entecavir is also a weak inhibitor of cellular DNA polymerases and mitochondrial DNA polymerase [123–125]. There is a slight reduction in entecavir susceptibility observed for lamivudine-resistant strains [126]. A reduction in entecavir susceptibility is seen in the presence of rtM204I/V substitutions with or without rtL180M. Additional substitutions at rt184, rtS202, and rtM250, or a combination of these may also reduce susceptibility to entecavir [127].

Pharmacokinetics

The C_{max} of entecavir at steady state is 4.2 ng/mL following a 0.5 mg dose and 8.2 ng/mL after a 1 mg dose [128, 129] (Table 55.7). The C_{max} occurs between 0.5 and 1.5 h after the dose [129]. The C_{max} and AUC at steady state increase proportionally to the dose. Administration of entecavir with a high fat containing meal or a light meal causes a delay in absorption, a decrease in C_{max} of 45%, and a decrease in AUC of 20% [129]. Protein binding of entecavir is 13%, and the apparent V_d is in excess of total body water [129]. The terminal $t_{1/2}$ of entecavir is approximately 128–149 h [128, 129].

Entecavir is primarily cleared by the kidneys; 62–73% of unchanged drug was recovered in urine [129]. Entecavir undergoes both glomerular filtration and net tubular secretion [128]. The C_{max} of entecavir increases to 10.4 ng/mL in patients with CrCl 50–80 mL/min, 15.3 ng/mL in patients with CrCl of <30 mL/min, and 15.4 ng/mL in patients undergoing HD [128]. The pharmacokinetics of entecavir is similar in patients with normal hepatic function compared to patients with moderate or severe hepatic dysfunction [129].

Dosing and Drug Interactions

The dose of entecavir for the treatment of chronic HBV is 0.5 mg every 24 h (Table 55.8). Entecavir 1 mg every 24 h should be used for patients with lamivudine resistant or refractory HBV infection or those with hepatic decompensation. The use of entecavir and ribavirin may increase the risk of hepatotoxicity (Table 55.4).

Lamivudine

Mechanism of Action and Resistance

Lamivudine is a synthetic nucleoside analogue, which is phosphorylated to its active 5′-triphosphate metabolite, lamivudine triphosphate [130]. The monophosphate form is incorporated into viral DNA by HBV reverse transcriptase that results in DNA chain termination. Lamivudine triphosphate also inhibits the RNA- and DNA-dependent DNA polymerase activities of HIV-1 reverse transcriptase [130]. Lamivudine resistance results from M204 V/I substitution in the viral reverse transcriptase [131]. HBV containing lamivudine resistance-associated substitutions may still retain susceptibility to adefovir dipivoxil; however, such viral strains may have a 30-fold reduced susceptibility to entecavir [131]. The substitution rtA181T will also result in decreased response to entecavir [131]. Entecavir-resistance HBV exhibit 1000-fold reduced susceptibility to lamivudine [131].

Pharmacokinetics

Lamivudine is rapidly absorbed after oral administration with a C_{max} in HBV infected patients of 1.3 μg/mL following a single dose of 100 mg [132] (Table 55.7). The time to C_{max} occurs between 0.5 and 2 hours after the dose is administered [132]. The AUC following a single 100 mg dose of lamivudine is 4.3 μg*h/mL, and the AUC at steady state following repeated doses is 4.7 μg*h/mL [132]. There is no difference in AUC in fasting or fed states, although C_{max} may be lower. The bioavailability of lamivudine is 86% after a dose of 150 mg tablet and 87% after 10 mg/mL oral solution with a $t_{1/2}$ of approximately 5 hours [133, 134]. Plasma protein binding is <36%, and the V_d after IV administration of lamivudine in HIV patients is 1.3 L/kg, which suggests that it distributes widely into extravascular space [132, 133]. Five to ten percent of a 300 mg dose of lamivudine is excreted as a trans-sulfoxide metabolite in the urine [132]. The serum concentration of the trans-sulfoxide metabolite has not been measured [132].

Lamivudine is eliminated in the urine as unchanged drug by active cationic secretion Cl_{renal} accounting for 71% of total drug clearance [135]. Compared to patients with normal renal function, patients with moderate to severe renal impairment have 4- to 13-fold increases in AUC and a 1.2- to 1.8-fold longer half-life [132, 135]. A 4-hour HD session does not affect the overall exposure of lamivudine due to the large V_d even though 50% of lamivudine is extracted from plasma [132, 136]. The pharmacokinetic parameters of lamivudine are not significantly altered by reduced hepatic function. After a single dose of 300 mg of lamivudine, the C_{max} is 2.6 μg/mL in patients with normal hepatic function compared to 2.9 μg/mL in patients with moderate hepatic impairment and 3.1 μg/mL patients with severe hepatic impairment. The AUC is also similar between patients with normal hepatic function (11.8 μg*h/mL) and moderate (11.4 μg*h/mL) to severe (12.8 μg*h/mL) hepatic impairment [137].

Pharmacokinetics in Pediatric Patients

In neonates, the median $t_{1/2}$ of lamivudine is 6 h, the C_{max} is 1969 μg/L, and the AUC is 16,883 μg*h/L when a dose of 4 mg/kg every 12 h is administered for 1 week [138]. In infants and adolescents, lamivudine is rapidly absorbed with a time to C_{max} of 0.5 to 1 h. The C_{max} and AUC of lamivudine are proportional to the dose for patients aged 2–12 years; however, the absolute bioavailability is reduced by 59% [132, 139]. The mean AUC in patients <12 years old receiving 4 mg/kg is 5056 μg*h/L, which is roughly half of the adult dose [132, 139].

Dosing and Drug Interactions

The dose of lamivudine for the treatment of chronic HBV is 100 mg every 24 h (Table 55.6). Use of trimethoprim with lamivudine may increase the levels of lamivudine due to decreased renal tubular secretions (Table 55.3). Lamivudine given along with ribavirin may increase the risk for hepatotoxicity (Table 55.4).

Tenofovir Disoproxil Fumarate

Mechanism of Action and Resistance

Tenofovir disoproxil fumarate (TDF) is an acyclic nucleoside phosphate diester analogue of adenosine monophosphate. TDF requires initial diester hydrolysis for conversion to tenofovir and subsequent phosphorylation by cellular enzymes to form tenofovir diphosphate [140]. Tenofovir diphosphate inhibits the activity of HBV reverse transcriptase by competing with the natural substrate deoxyadenosine 5′-triphosphate and incorporates into DNA causing chain termination [141]. Tenofovir has demonstrated the highest barrier to resistance in clinical studies [142, 143]. Tenofovir has been shown to be effective in patients with lamivudine resistance and in patients with an incomplete response to adefovir, but not necessarily in all patients with adefovir resistance [142, 144].

Pharmacokinetics

The oral bioavailability of tenofovir in fasting patients was 25%, and the C_{max} after a single dose in HIV-1 infected individuals was 0.2 μg/mL to 0.3 μg/mL, which is reached in 1 h, and the AUC is 2.3–2.5 μg*h/mL [141, 145, 146] (Table 55.7). Protein binding of tenofovir is 7% and the V_d at steady state is 1.3 L/kg [141]. After a single oral dose, the $t_{1/2}$ of tenofovir was 17 h, whereas intracellular half-life was 95 hours [147]. Administration of TDF with a high-fat meal increases oral bioavailability, and AUC and C_{max} are

increased by 40% and 14%, respectively. Albeit, administration of light meal has not affected the bioavailability of the drug [141, 145].

Approximately 70–80% of the tenofovir dose is recovered unchanged in the urine within 72 h after IV administration [148]. Tenofovir is eliminated via a combination of glomerular filtration and active tubular secretion [141]. After a single dose of 300 mg of TDF, the C_{max} is 0.34 μg/mL in patients with CrCl ≥80 mL/min, 0.33 μg/mL in patients with CrCl 50–80 mL/min, 0.37 μg/mL in patients with CrCl 30–49 mL/min, and 0.60 μg/mL in patients with CrCl 12–29 mL/min [146]. The AUC is 2.2 μg*h/mL in patients CrCl >80 mL/min compared to 3.1 μg*h/mL in patients with CrCl of 50–80 mL/min, 6.0 μg*h/mL in patients with CrCl 30–49 mL/min, and 15.9 μg*h/mL in patients with CrCl 12–29 mL/min [146]. Approximately 10% of tenofovir is removed during a 4-hour HD session following a single 300 mg dose of TDF [149]. There are no differences in tenofovir pharmacokinetics in patients with moderate or severe hepatic impairment [146, 149].

Pharmacokinetics in Pediatric Patients

Tenofovir exposure in pediatric patients aged 2–18 is similar to adult patients with a C_{max} of 0.27 μg/mL and an AUC of 2.2 μg*h/mL [150].

Dosing and Drug Interactions

The dose of TDF for the treatment of HBV is 300 mg every 24 h (Table 55.8). Tenofovir is an inhibitor of CYP 450 1A2; therefore, tenofovir will decrease the hepatic metabolism of theophylline and zidovudine causing increased concentrations of these agents (Table 55.3). Tenofovir is also an inducer of p-glycoprotein (P-gp), which may thereby increase dabigatran and linagliptin elimination.

Telaprevir

Mechanism of Action and Resistance

Telaprevir is an inhibitor of the hepatitis C Virus (HCV) NS3/4A serine protease, necessary for the proteolytic cleavage of the HCV-encoded polyprotein into mature forms of the NS4A, NS4B, NS5A, and NS5B proteins and essential for viral replication. In a biochemical assay, telaprevir inhibits the proteolytic activity of the recombinant HCV NS3 protease domain [151]. Resistance to telaprevir is due to genetic changes in the RNA that codes for the amino acid residues of the NS3/NS4A protease active site [152–154]. In treatment naïve patients, high levels of HCV variants conferring telaprevir resistance were uncommon. However, resistance may develop in patients undergoing treatment, although the incidence is low in patients receiving combination therapy with ribavirin and peg-interferon-alfa [152, 155, 156].

Pharmacokinetics

The pharmacokinetic properties of telaprevir have been evaluated in healthy adult individuals and in patients with chronic HCV infection (Table 55.7). After multiple doses of telaprevir (750 mg every 8 h) in combination with peg-interferon-alfa and ribavirin in treatment-naïve subjects with genotype 1 with chronic HCV infection, the C_{max} is 4036–4523 ng/mL, C_{min} is 2476 to 2624 ng/mL, and the AUC is 80,420 to 85,890 ng*h/mL [157, 158]. Telaprevir is absorbed from the small intestine, there is no evidence of absorption in the colon [151, 158]. Plasma C_{max} after a single oral dose were generally achieved after 4–5 h. Exposure to telaprevir is higher during coadministration with peg-interferon-alfa and ribavirin compared with telaprevir given alone [151]. The AUC of telaprevir increases by 237% when it was administered with a standard fat meal compared to fasting conditions [151, 159]. When telaprevir is administered with a low-fat meal, the AUC increases by 117% compared to 330% with a meal high in fat content [151, 159]. Protein binding of telaprevir was 59–76% and it binds primarily to alpha 1-acid glycoprotein and albumin. Protein binding was concentration dependent, decreasing with higher telaprevir concentrations [151, 159]. The V_d after oral administration of telaprevir was 252 L [151, 159]. The $t_{1/2}$ after a 750 mg single oral dose ranged from 4.0 to 4.7 h and at steady state, the $t_{1/2}$ was 9 to 11 h [151, 159]. Telaprevir is extensively metabolized in the liver with multiple active and inactive metabolites detected in feces, plasma, and urine. Cytochrome p450 3A4 (CYP3A4) is responsible for telaprevir metabolism; however, non-CYP-mediated metabolism may play a role after multiple doses. Telaprevir is also a substrate of P-glycoprotein (P-gp) [151, 159].

Approximately 82% of telaprevir is recovered within 96 h in feces and only 1% in urine after a single 750 mg dose. Unchanged drug accounts for 32% of the recovered dose, while 19% is the R-diastereomer [151, 159]. The AUC of telaprevir decreases by 46% in HCV-negative patients with moderate hepatic impairment (Child-Pugh Class B) compared to healthy patients. In patients with mild hepatic impairment (Child-Pugh Class A), the AUC is only reduced by 15% in HCV-negative subjects [151, 159]. Patients with cirrhosis have similar pharmacokinetic parameters compared to those without cirrhosis in whom telaprevir was used in combination with peg-interferon-alfa and ribavirin. Compared with healthy adults, in patients with CrCl of <30 mL/min, C_{max} and AUC increased by 3% and 21%, respectively, after a single 750 mg telaprevir dose [151, 159].

Dosing and Drug Interactions

The dose of telaprevir for the treatment of HCV is 750 mg every 8 h in combination with peg-interferon-alfa and ribavirin (Table 55.8). Telaprevir is a substrate of CYP450 3A4; therefore, concurrent use with CYP450 3A4 inhibitors, such as amiodarone and voriconazole, will result in

increased telaprevir levels (Table 55.3). A reduced telaprevir concentration may occur when given with CYP450 3A4 inducers, such as carbamazepine, efavirenz, rifampin, and phenytoin. Telaprevir is also an inhibitor of CYP450 3A4 and p-glycoprotein; therefore the use of telaprevir with substrates of either enzymes will cause increased concentrations of those substrates due to reduced hepatic metabolism.

Boceprevir

Mechanism of Action and Resistance

Boceprevir is an inhibitor of the HCV NS3/4A protease that is necessary for the proteolytic cleavage of the HCV encoded polyprotein into mature forms [160, 161]. Boceprevir forms a covalent, yet reversible bond to the NS3 protease active serine site to inhibit viral replication in HCV-infected cells [160, 161]. Monotherapy with NS3/4 protease inhibitors results in rapid selection of resistant viral strains [162, 163]. The activity of boceprevir against the HCV NS3/4A protease or genotype 1b is reduced by amino acid substitutions in the NS3 protease domain [162, 164]. Patients who filed to respond to boceprevir therapy are more likely to have boceprevir-resistant mutants at the end of treatment [162]. Treatment-emergent NS3 amino acid substitutions detected in boceprevir-treated subjects, in whom SVR was not achieved, demonstrate a reduced activity of other HCV NS3/4A protease inhibitors [162, 165, 166].

Pharmacokinetics

Boceprevir capsules contain a 1:1 mixture of two diastereomers, which change to a 2:1 ratio, favoring the active diastereomer in plasma. Boceprevir demonstrates linear pharmacokinetics and the oral bioavailability is 26–34% in animals [167] (Table 55.7). After a single dose of boceprevir 400 mg, the C_{max} and AUC are 557 ng/mL and 2020 ng*h/mL in healthy subjects [168]. After receiving 400 mg every 8 h for 7 days, the AUC and C_{max} of boceprevir in HCV-positive patients were 1990 ng*h/mL and 523 ng/mL, respectively [169]. In subjects who receive monotherapy with 800 mg every 8 h, the AUC was 5408 ng*h/mL, and the C_{max} was 1723 ng/mL [162]. The time to C_{max} after oral administration was 2 h; AUC, C_{max}, and C_{min} all increase in a less-than-dose-proportional manner, indicating decreased absorption at higher dose concentrations [162, 167]. The AUC of boceprevir when administered as 800 mg every 8 h is 65% higher when it is given with food compared to given in a fasting state [162]. However, there is no difference whether it is given with a high or low fat meal [162]. The V_d at steady state was 772 L and 75% protein binding after a single dose [167]. The $t_{1/2}$ of boceprevir is approximately 3 h with a Cl_{total} of 161 L/h [162].

The primary mechanism of metabolism of boceprevir is through the aldo-keto reductase (AKR)-mediated pathway, which produces inactive metabolites [162, 168, 170]. Boceprevir also undergoes oxidative metabolism mediated by CYP3A4/5, although this is to a lesser extent [161, 168, 169]. Approximately 79% of the boceprevir dose is excreted in feces compared to only 9% in urine [162]. The mean AUC of the active diastereomer of boceprevir is 2050 ng*h/mL and 2690 ng*h/mL in subjects with moderate (Child-Pugh 7–9) and severe (Child-Pugh 10–12) hepatic impairment compared to 2020 ng*h/mL in normal patients following a single 400 mg dose of boceprevir [168]. Subjects with mild hepatic impairment have similar active diastereomer exposure as subjects with normal hepatic function. The mean AUC of boceprevir is 10% lower in subjects undergoing HD relative to subjects with normal renal function after a single dose of 800 mg of boceprevir [168]. Hemodialysis removes less than 1% of the boceprevir dose.

Dosing and Drug Interactions

The dose of boceprevir for the treatment of HCV is 800 mg every 8 h in combination with peg-interferon-alfa and ribavirin (Table 55.8). Boceprevir is a substrate of CYP450 3A4 therefore concurrent use with CYP450 3A4 inhibitors will cause an increase in boceprevir levels and concurrent use with CYP450 3A4 inducers will result in decrease boceprevir concentration (Table 55.3). Boceprevir is a strong inhibitor of CYP450 3A4, and concomitant boceprevir use with amiodarone, cyclosporine, simvastatin, tacrolimus, voriconazole, and warfarin will reduce their hepatic metabolism and potentially lead to toxic drug concentration unless appropriate dose adjustment has been undertaken. Boceprevir is also an inhibitor of p-glycoprotein, causing increases in digoxin and rivaroxaban concentrations.

Ribavirin

Mechanism of Action and Resistance

Ribavirin has direct antiviral activity in tissue culture against many RNA viruses, and increases the frequency of genomic mutation among several RNA viruses. Ribavirin triphosphate inhibits HCV polymerase in a biochemical reaction; the precise mechanism that confers antiviral activity of ribavirin is not known [171–173]. The combination of peg-interferon-alfa-2a and ribavirin is more effective at inhibiting HCV RNA replication than either agent alone [171]. Several studies have suggested that ribavirin has immunomodulatory effects, and HCV-specific T-cell responses have been observed in patients on combination therapy with interferon; however, this effect may be due to the reduction in viral load [171, 174]. Evidence of immunomodulation by ribavirin acting synergistically with interferon is lacking, but the loss of infected HCV cells by

immune-mediated damage is thought to underlie the second phase decline in HCV RNA following interferon use [171, 175–177]. Ribavirin has been shown to enhance this second phase decline, suggesting that it also has an immunomodulatory effect [171, 176, 178]. It is suggested that the faster decline in HCV RNA with combination therapy may be related to ribavirin-induced restoration of hosts' immune response and perhaps independent of concurrent interferon use [171, 177]. This suggests that ribavirin may garner hosts' anti-HCV immune response; however, mechanism and immune pathways to support this hypothesis remain evasive [171].

Pharmacokinetics

After a single dose of 600 mg of ribavirin, the C_{max} and AUC were 782 ng/mL and 13,400 ng*h/mL, respectively, and time to C_{max} was 1.7 h [171, 179, 180] (Table 55.7). The $t_{1/2}$ after a single oral dose of ribavirin was 120–170 h and ribavirin tends to accumulate, therefore the C_{max} is higher after multiple doses [171]. Following multiple 600 mg twice-daily doses of ribavirin, C_{max} was 3677 ng/mL, a fivefold increase compared to single-dose therapy [171, 180]. The AUC after multiple doses also increased to 227,867 ng*h/mL, and the terminal $t_{1/2}$ was higher (274–298 h) [171, 173]. The absolute bioavailability of ribavirin after oral administration was 64% [171, 181]. When a single dose of ribavirin was given with a meal high in fat content the time to C_{max} was extended. The $AUC_{0\text{-}192h}$ and C_{max} increased by 42%, and 66%, respectively, when given with a high fat meal compared to fasting state [182]. Administration of ribavirin with antacids caused a 14% reduction in the AUC after a single dose [182]. Ribavirin is not a substrate of CYP450 enzymes, and the exact mechanism of elimination and metabolism is not known [171].

Ribavirin is also available as an aerosol for inhalation for treatment of respiratory syncytial virus (RSV) and human metapneumovirus (hMNV) [183]. After administration of aerosolized ribavirin by facemask for 2.5 h three times daily, the plasma concentrations ranged from 0.44 to 1.55 μmol/L after 3 days of therapy. When administered by facemask or mist tent for 20 h each day, the plasma concentration ranged from 1.5 to 14.3 μmol/L after 5 days of therapy [184].

The clearance of ribavirin is reduced in subjects with CrCl of ≤50 mL/min, including those undergoing HD. The clearance is reduced by approximately 30% compared to subjects with normal renal function. In patients with end-stage kidney disease on HD who were given a 200 mg daily dose, the ribavirin exposure was 20% lower compared to patients with normal renal function who received standard ribavirin dose [182]. Approximately 50% of plasma ribavirin is removed by HD; however, the plasma exposure should not change with HD because of the large V_d of ribavirin [182]. Hepatic dysfunction (Child-Pugh A, B, or C) has no effect on ribavirin AUC when compared to patients with intact liver function [171, 179].

Pharmacokinetics in Pediatric Patients

The pharmacokinetics of ribavirin is similar in adults and pediatric patients. The C_{max} and AUC were 3275 ng/mL and 29,774 ng*h/mL, respectively, after 15 mg/kg daily dose given in two divided doses [185]. The 2-h time to C_{max} was also similar [185].

Dosing and Drug Interactions

The dose of ribavirin for the treatment of HCV ranges from 1000 to 1200 mg daily given in combination with peg-interferon-alfa (Table 55.8). The dose of ribavirin for treatment of RSV is 6 g per day administered via a Small Particle Aerosol Generator-2 (SPAG-2) nebulizer. The use of oral ribavirin with adefovir, lamivudine, or entecavir may increase the risk of hepatotoxicity (Table 55.4).

Interferon

Mechanism of Action and Resistance

Interferons exert a vast array of biological functions, including development of innate immunity, and cellular and humoral adaptive immune responses, as well as exhibiting direct antiviral activity [186]. Interferons bind to high-affinity receptors on the surface of virus-infected cells, which activate an intracellular signal transduction pathway that results in rapid activation of gene transcription for proteins that inhibit viral protein translation and RNAases leading to inhibit of viral replication [187–189]. In addition to the direct antiviral effect, interferons cause an upregulation of major histocompatibility complex (MHC) class-I and class-II molecules; an increase in IL-10, IL-12, and TNF-α production; and activation of dendritic cells [190–194].

Pharmacokinetics

After subcutaneously administered, approximately 80% of the interferon-alfa dose is absorbed [195] (Table 55.7). The C_{max} occurs after 1–8 h, followed by a measureable concentration for 4–24 h after administration [195]. The V_d of interferon-alfa is 12–40 L with a terminal $t_{1/2}$ of 4–16 h [195]. Wide fluctuations in serum concentrations of interferon-alfa have been observed, which may result in impaired suppression of viral replication [196]. The development of pegylated interferon (peg-interferon) has greatly improved the poor pharmacokinetic profile of nonpegylated conventional interferon, delaying its clearance and allowing it to be given less frequently while ensuring effective concentrations [196].

The V_d for peg-interferon-alfa-2a was 4–16 L, and it distributes primarily in the blood and interstitial fluid resulting in high concentrations in the liver [196]. A single dose of peg-interferon-alfa-2a produces a C_{max} of 14.2 mg/L in a mean duration of 78 h [197]. After administration of multiple doses of peg-interferon-alfa-2a to patients with chronic

HCV infection, the C_{max} was 25.6 mg/L in a mean duration of 45 h [197]. Peg-interferon-alfa-2a has a low peak to trough ratio indicating less fluctuation in the serum concentration of the drug during the weekly dosing interval. Peg-interferon-alfa-2a is cleared by both the kidney and the liver; due to its large size, the pharmacokinetics of the drug is unaffected in patients with renal failure [197].

Peg-interferon-alfa-2b has a smaller polymer attached causing it to have a slightly different pharmacokinetic profile to peg-interferon-alfa-2a. Peg-interferon-alfa-2b reaches a C_{max} after 15–44 h, which is sustained for 48–72 h after the dose [196]. Peg-interferon-alfa-2b had a V_d of 0.99 L/kg [187]. The absorption $t_{1/2}$ of peg-interferon-alfa-2b was 4–5 h compared to 50 h for peg-interferon-alfa-2a [187]. Free interferon-alfa-2b is released from the pegylated form soon after administration and undergoes renal excretion, whereas interferon-alfa-2a does not get released and the pegylated form interacts with cell surface receptors. The C_{max} and AUC of peg-interferon-alfa-2b increases in a dose-related manner and week 48, and C_{min} is threefold higher than C_{min} observed at week 4 [198]. Renal elimination accounts for 30% of the clearance of peg-interferon-alfa-2b [198].

Pharmacokinetics in Pediatric Patients

The clearance of peg-interferon-alfa-2a in children is nearly fourfold lower compared to the clearance reported in adults, although the steady-state trough levels in children with a body surface area (BSA)-adjusted dosing are similar to trough levels observed in adults given 180 μg fixed dosing [199]. Time to reach the steady state in children is approximately 12 weeks, whereas in adults, steady state is reached within 5–8 weeks. In children receiving the BSA-adjusted dose, the AUC during the dosing interval is 25–70% higher than that observed in adults receiving 180 μg fixed dosing [199].

Dosing and Drug Interactions

The dose of peg-interferon-alfa-2a for the treatment of HCV in adults is 180 μg subcutaneously once weekly in combination with ribavirin, while the dose for peg-interferon-alfa-2b is 1.5 μg/kg subcutaneously once weekly in combination with ribavirin (Table 55.8). The use of interferon-alfa with aldesleukin can cause increased myocardial and renal toxicity (Table 55.4). Interferon-alfa is an inhibitor of CYP450 1A2; therefore, the concentrations of theophylline and zidovudine will increase due to reduced hepatic metabolism, when used concurrently with interferon-alfa (Table 55.3).

Summary

Intense research has led to introduction of a number of new agents available to treat infections caused by major viral pathogens among the highly susceptible patients undergoing hematopoietic stem cell and solid organ transplantation. Clinicians caring for such patients face ongoing challenge in selection of the best drug therapy of various viral illness. The understanding and application of pharmacokinetics and pharmacodynamics principles may improve selection of appropriate agent or regimens, dose optimization, minimization for potential drug-drug interaction, and avoidance of drug toxicity when possible in the vulnerable transplant population.

Antimycobacterial Consideration in Transplantation Including Drug Non-susceptibility and Resistance: Tuberculosis and Nontuberculous Mycobacterial Disease

Julie V. Philley and David E. Griffith

Introduction

The increasing availability and success of solid organ transplant (SOT) programs are an unequivocal success story for contemporary medicine and for the thousands of patients who receive SOT. A large part of that success is due to potent immunosuppressive drugs that prevent the body from rejecting transplanted organs. The highly desirable effect of immunosuppression is unfortunately accompanied by the predictable and inevitable risk of infection as a consequence of immunosuppression. Tuberculosis (TB) and nontbuerculous mycobacteria (NTM) are two important infections that can occur in this setting. Tuberculosis is an especially important concern because of its public health implications. Additionally, because of the increasingly international background of SOT participants, donors, and recipients, the risk of drug-resistant TB is also increasingly apparent. In this chapter we will discuss the mechanisms of mycobacterial drug resistance, the epidemiology of drug-resistant mycobacteria, the clinical presentation of mycobacterial disease in SOT recipients, the treatment options for drug-resistant mycobacterial pathogens, and the strategies for avoiding drug-resistant mycobacterial infection. Because of the overarching public health importance of TB as well as the greater risk for TB in SOT versus NTM infection, the emphasis of this chapter will be on TB.

Mechanisms of Mycobacterial Drug Resistance

Resistance to antituberculous drugs occurs during selective multiplication of drug-resistant mycobacteria which spontaneously emerge in any population of *M. tuberculosis*. These resistant mutants are able to proliferate and replace the wild-type strains most frequently when there are a suboptimal number of effective companion medications. For instance, organisms with spontaneous mutations in the rpoβ gene conferring rifamycin resistance can flourish if rifampin is used as monotherapy with elimination of the rifamycin susceptible organisms. This phenomenon is the basis for the well-known admonishment that TB patients should never be treated with a single antituberculosis drug or with inadequate companion drugs to protect against the emergence of drug-resistant organisms. Molecular epidemiology indicates that multidrug-resistant TB (MDR-TB) strains arise by sequential accumulation of resistance mutations for individual drugs as a consequence of inadequate or inappropriate TB medication regimens [1]. In that context, it is noteworthy that clinically apparent drug-resistant TB did not exist until antituberculosis drugs were introduced with subsequent selection of the naturally occurring resistant strains. Resistance is not linked between classes of antituberculous drugs. Drug resistance which develops during or after a course of treatment has been called "acquired drug resistance" (the name that will be used in this chapter) but is also now referred to as "resistance among previously treated cases" by the World Health Organization (WHO) [2]. Similarly, drug resistance which develops when there is no history of TB treatment has been labeled as "primary drug resistance" but is now also called "resistance among new cases" [2]. For *Mycobacterium tuberculosis* isolates, there is generally good and predictable correlation between in vitro susceptibility results and in vivo response to the antimycobacterial agents. There are potent bactericidal agents for treating TB so that drugs can be tested individually in patients over short time periods, not long

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_56

enough to result in acquired mutational resistance, which allows reasonable assurance that in vitro findings will translate into in vivo results.

Multidrug-resistant TB (MDR-TB), caused by strains resistant to at least isoniazid and rifampin [2], is difficult to treat effectively and requires medications that are expensive, toxic, and less effective than first-line antituberculosis therapy [2]. Extensively drug-resistant TB (XDR-TB) is defined as TB resistant to isoniazid, rifampin, second-line injectable drug (kanamycin, amikacin, or capreomycin), and any fluoroquinolone [2]. MDR- and XDR-TB strains are resistant to the most potent antituberculous medications that are predictably associated with successful outcomes.

The origins of drug resistance for NTM are more complicated and include both innate and acquired drug resistance mechanisms. For *Mycobacterium avium* complex (MAC), the only antibiotics that show a correlation between in vitro MIC and in vivo response are clarithromycin, azithromycin, and amikacin [3, 4]. This observed concordance between in vitro susceptibility and in vivo response has a genetic correlate with the development of 23S rRNA gene mutations for macrolide resistance and 16S rRNA gene mutations for amikacin resistance [3, 4]. In this regard, MAC behaves like TB so that acquired mutational resistance to macrolides and to amikacin can occur if these drugs are used improperly [4, 5]. This correlation has not been established for any other agents used for treating MAC which means that the in vitro MICs for drugs like ethambutol, the rifamycins, and the fluoroquinolones do not help guide therapeutic choices [3]. For instance, ethambutol appears to be a critically important agent for protecting against the emergence of acquired mutational macrolide resistance regardless of the in vitro MIC, while there is no apparent role for fluoroquinolones in the therapy of MAC regardless of the MIC [5]. It is assumed that innate resistance factors, independent of the MIC of the drug for that organism, govern the response of MAC to these antibiotics [6].

For *M. abscessus* subsp. *abscessus*, it is even more complicated. *Mycobacterium abscessus* subsp. *abscessus* has an active inducible macrolide resistance gene or erm gene [7]. Because of the erm gene, these isolates may appear macrolide susceptible with low macrolide MICs on initial in vitro testing, but with macrolide exposure, the MICs increase to resistant levels. This is perhaps the best described type of innate mycobacterial drug resistance. Innate resistance likely accounts for the majority of in vivo drug resistance seen with many NTM. The *erm* gene is probably just the tip of the NTM drug resistance iceberg. To add a further complicating factor, some *M. abscessus* isolates have an *erm* gene mutation that inactivates the *erm* gene rendering the isolate macrolide susceptible [8]. In this circumstance, if a macrolide is used inappropriately, the isolates can still develop acquired mutational macrolide resistance (23S rRNA gene).

Preventing the emergence of drug-resistant TB and NTM isolates is paramount and requires familiarity with the individual mycobacterial organisms and their sometimes unpredictable behavior. It remains critically important to have adequate laboratory services in transplant recipients for adequate drug susceptibility testing and to identify molecular mechanisms of resistance.

Tuberculosis

Solid organ transplant recipients are at a 36- to 74-fold higher risk of developing TB risk of developing infection with *Mycobacterium tuberculosis* compared with the general population [9–16]. Infection may come from the transplant donor and recipient or be community acquired. Posttransplant TB has been reported to be more common in lung recipients than in liver transplant patients although the variation may depend on the local incidence of infection rather than the organ transplanted [17, 18]. The incidence of posttransplant TB varies greatly depending on the local prevalence of TB infection ranging from 1% in Germany to 13.7% in India [12, 13]. Studies in the United States and Europe suggest that 0.35–6.6% of SOT recipients develop TB and 4% of those cases are donor derived [13]. Most patients develop TB infection in the first year post transplantation, but a bimodal distribution has also been observed, with the incidence of TB at a peak 2 years after SOT [12].

While the majority of SOT patients develop pulmonary TB, the risk of disseminated infection and death due to TB is higher in transplant recipients than in the general population [12–16]. The high incidence of disseminated infections is up to tenfold greater than in immunocompetent TB patients [12–14]. Tuberculosis mortality in SOT recipients is variable but ranges from 9.5 to 17% [12–16]. Because of the nonspecific clinical manifestations of extrapulmonary and disseminated MAC which is also associated with a lack of clearly diagnostic symptoms, the diagnosis may be problematic and elusive [12–14]. The delayed diagnosis results in a delayed therapeutic intervention with attendant excess morbidity and mortality.

The majority of posttransplant TB cases occur secondary to reactivation in recipients with unrecognized or untreated latent TB infection (LTBI) although transmission of TB through the allograft can also occur [12–16]. One study reported that 20–25% of all TB diagnosed post transplantation was in people who had positive TST before transplantation [15]. Donor-derived TB is often unrecognized especially in areas of low TB prevalence contributing to significant morbidity and mortality [12–14]. Global travel and immigration have resulted in an increasingly diverse transplant donor population in lower-incidence countries, while organ transplantation has increased in some of the higher-inci-

dence regions, both factors affecting the overall incidence of donor-derived TB and the risk for drug-resistant TB. The United States is among the nations with the lowest rates of TB, approximately 3 cases per 100,000 population, with the majority of cases occurring in individuals born outside the United States [19]. Thus in the United States, it is more likely that donor-derived TB may be associated with a donor who is foreign born or has lived for significant period of time in TB-endemic countries. In several of the reported SOT, TB transmission events, the donor was born in an area of high TB endemicity; in most cases the transmitted TB could be typed to a strain from the area where the donor was born [17, 18].

Epidemiology

Because of the increasing impact of international patients on SOT as well as TB epidemiology in the United States, it is absolutely essential to understand global TB trends in general and global trends for drug-resistant TB in particular. Global TB rates declined at the slow pace of 1.5% from 2014 to 2015. Based on a limited number of countries reporting longitudinal TB drug resistance data, the WHO concludes that during that time period, there was a slight trend for an increase in MDR-TB cases as a proportion of all TB cases in the reporting countries [2]. The estimates for the number of incident rifampin-resistant (RR-TB), MDR-TB and XDR-TB, cases increased to a combined total of 580,000 [2]. The inclusion of rifampin-resistant cases is the result of increasing the use of GeneXpert technology in the developing world which identifies TB isolates with rpoβ mutations and is frequently an indication of MDR-TB isolates [2].

The prognosis for MDR-TB and XDR-TB worldwide is very poor. In 2015 a total of 125,000 (20%) of the estimated 580,000 patients with MDR-/RR-TB were enrolled in treatment [2]. The treatment success rate in the 2013 cohort (cured or completed therapy) was only 52%. Patients with XDR-TB who started on treatment in 2013 had successful completion of therapy (28%), death (27%), and treatment failure (21%) or were lost to follow-up (23%) [2].

Overall, the percentage of MDR-TB cases in the United States decreased slightly from 1.4% (96 cases) in 2013 to 1.3% (91 cases) in 2014 [19]. Of the total number of reported MDR-TB cases, the proportion occurring among foreign-born persons increased from 31% (149 of 484) in 1993 to 88% (80 of 91) in 2014 [19]. There were no reported cases of XDR-TB in 2014 [19].

Knowing the country of origin for SOT donors and recipients is an essential information for determining the risk of drug-resistant TB. Of the estimated 580,000 cases of MDR-/RR-TB that emerged in 2015, over 45% were in India (130,000), the People's Republic of China (70,000), and the Russian Federation (60,000) [2]. Other countries with large numbers of cases include Indonesia (32,000), Nigeria (29,000), Pakistan (26,000), Ukraine (20,000), and South Africa (20,000) [2]. The top 30 countries with the highest number of TB cases accounted for nearly 90% of MDR-/RR-TB [2]. These countries are primarily in sub-Saharan Africa, Southeast Asia, and Eastern Europe. The estimated percentage of new MDR-/RR-TB cases for the 30 high-burden countries was 4.3% for new cases and 22% for previously treated cases [2].

Diagnosis of LTBI and Active TB

All potential transplant donors and recipients should be screened for LTBI and active TB. The sometimes precipitous nature of organ availability precludes rigorous evaluation of some donors, but an effort must be made to assess the risk of LTBI or active TB despite often rapidly evolving circumstances as with deceased donors. When there is adequate time, a deliberate and thorough evaluation should be undertaken. While current screening and diagnostic modalities were designed primarily to identify cases of LTBI, it is, of course, essential that screening protocols identify donors with unrecognized active TB, to facilitate diagnosis and management of TB and improve transplantation outcome.

The current method for donor screening for both latent and active TB includes history and symptom assessment (prior TB exposures, history of active TB, travel or residence in endemic regions, history of pneumonia, fever, weight loss, and past tuberculin skin test results), physical examination (cachexia or lymphadenopathy), cultures, and thoracic imaging. For living donors, the tuberculin skin test (TST) or interferon-gamma release assay (IGRA) screening should also be used. Cultures may be helpful when active TB is suspected although cultures can take up to 6 weeks before turning positive and thus may occur post transplantation. Nucleic acid amplification tests (NAAT) will identify *Mycobacterium tuberculosis* in clinical specimens with active infection and should be obtained routinely from sputum of pulmonary TB suspects.

The major risk factors for likelihood of TB infection in the United States are recent TB exposure and prior residence in a country with high TB endemicity. Once infected, patients undergoing immunosuppression following SOT are at very high risk for progression from LTBI to active TB. It is also clear that treatment of LTBI among high-risk groups reduces the risk of progression from LTBI to active tuberculosis [19].

The currently FDA-approved screening methods for LTBI in the United States include the tuberculin skin test (TST) and the IGRA and QuantiFERON-TB gold in-tube (QFT-GIT) assay and T-SPOT.TB test (T-SPOT). None of these tests are definitive for diagnosing LTBI, and none of these

tests differentiate active from latent TB. As many as 10–25% of people with active TB do not react to TST with 5 mm or greater of induration, and patients with disseminated TB have a false-negative test rate of approximately 50% [20].

IGRAs are primarily a reflection of CD4 T-cell immune response to mycobacterial antigens manifested by the clonal expansion of antigens specific T cells. Effector memory T cells respond to subsequent antigen exposure which is characterized by the release of cytokines, including interferon gamma, and further cellular expansion. IGRA reflect the presence of these antigen-specific memory T cells. Currently there are two commercially available IGRA platforms that measure interferon-gamma release in response to *M. tuberculosis*-specific antigens. The QuantiFERON-TB gold in-tube (QFT-GIT) assay and T-spot. TB test (T-spot). The QFT measures interferon-gamma plasma concentration using an enzyme-linked immunoabsorbant assay (ELISA), while the T-spot assay enumerates T cells releasing interferon gamma using an enzyme-linked immunospot assay.

The IGRAs offer advantages over the TST for several reasons. Importantly, they require only one patient encounter to perform the test. The IGRAs also eliminate the need for technical skill required for TST placement and the subjectivity associated with manual reading of the TST. A main strength of the IGRAs is that they are not influenced by BCG vaccination and therefore have increased specificity compared with a TST in BCG-vaccinated patients due to the use of highly specific antigens that were derived from *Mycobacterium tuberculosis* which are absent in all strains of BCG and most NTM [20]. Thus a specific T-cell response toward those antigens is a more specific marker for true *M. tuberculosis* infection and then a TST response toward purified protein derivative (PPD). In people from TB-endemic areas where BCG vaccination is common, IGRAs have clear advantages over TST because of increased specificity of the results. This is an especially important performance characteristic of the IGRAs in the United States with the preponderance of TB including resistant TB, occurring in BCG-vaccinated patients born out outside of the United States. Problems associated with the IGRAs include indeterminate/invalid IGRA responses, poor reproducibility of IGRA results (especially in low-risk populations), and frequent discordance between the IGRAs and the TST [20].

Studies have compared the TST and IGRAs in immunocompromised patients [20–27]. Both diagnostic tests have diminished sensitivity in this setting, but data suggest that IGRAs are at least as sensitive as TST in the setting of HIV infection [26, 27]. Studies have been done comparing IGRAs with TST in populations that are heterogeneous with respect to the type of underlying immunocompromised [20–27]. These studies demonstrate significant discordance between TST an IGRA results. Overall it does not appear that there are sufficient data to recommend a preference for either a TST or an IGRA as the first-line diagnostic test in individuals likely to be infected with TB or have a high risk of progression to TB disease, such as organ transplant patients receiving immunosuppressive drugs to prevent allograft rejection [20]. The exception is for patients who have had BCG vaccination where the IGRA is clearly preferred to the TST. Both TST and IGRAs are less sensitive in the diagnosis of new TB exposure after solid organ transplant.

While TST is not feasible in deceased donor site due to the delay in development of a reaction, IGRA testing in deceased donors is possible [12]. In a deceased donor, it is important to assess whether antigen-presenting cells and T cells are functional enough to produce an appropriate immune response. Therefore, an advantage of IGRAs in the deceased donor setting is that specific stimulation reactions are accompanied both by a negative control that allows assessment of nonspecific background reactivity and also by a mitogen stimulus that is used as a positive control to assess general T-cell responsiveness. This may allow for interpretable results. Unfortunately, there are no data on the clinical utility or test performance of IGRAs in the deceased donor population. It is also unknown whether brain death may impact the performance of the assays.

Another issue about testing for LTBI in the deceased donor population is that the donor may be from a potentially low-risk population. Positive tests in a low-risk population may represent a false-positive result rather than a true latent TB infection [20]. Donors with an indeterminate or positive IGRA should not be excluded from donation although they should be carefully screened for active disease. In these cases it may be advantageous to procure tissue and blood for additional testing.

The epidemiologic history is more reliable compared with currently available tests for living donors who are generally healthy but may be from an area of high TB prevalence or have received BCG vaccine. Either IGRA or TST is routinely recommended to screen for LTBI in living donors with the exception of BCG-vaccinated individuals who should be tested with an IGRA. For living kidney and liver donors, transplant can often be delayed until a full evaluation of possible latent or active TB is performed. Although there are no formal studies of TST or IGRAs in the living donor population, test characteristics in living donors should be similar to those of healthy adults.

There is no specific guidance for patients with a severe immunocompromised state such as those who have undergone SOT who undergo both TST and IGRA. Some experts recommend that if either test is positive, then treatment for presumed LTBI would be appropriate regardless of the BCG status of the patient if the patient is from a country highly endemic for TB.

Treatment of LTBI

It is absolutely essential to exclude the presence of active TB disease in any patient with a positive TST or IGRA, either donor or recipient. The initiation of LTBI therapy in a patient with active disease would likely result in the development of drug-resistant TB.

There are several approved and effective treatment regimens for LTBI. The treatment regimen supported by the most experience and evidence of efficacy is INH monotherapy administered for at least 9 months [28]. Isoniazid LTBI therapy is effective for preventing active TB in both pre- and post-renal transplant recipients even in TB-endemic areas [29]. Isoniazid is also effective for preventing reactivation TB in liver transplant patients [30]. The problems with this regimen include the long duration of treatment and the risk for hepatic toxicity [28]. For patients who are awaiting transplant, there may not be adequate time to complete 9 months of INH therapy prior to the transplant. A recent meta-analysis of INH in renal transplant patients reported that the risk of developing liver dysfunction among those who received TB prophylaxis was 59% higher than those who received no chemoprophylaxis [29]. However, most reported instances of liver dysfunction were mild and reversible and did not warrant discontinuation of treatment. Liver transplant recipients present a high risk of hepatotoxicity with INH therapy including the need for emergency transplantation [31]. Other investigators have not reported increased hepatotoxicity associated with INH in the liver transplant population [32–35]. Clinicians may still be reluctant to use this approach for patients with impending hepatic failure who are waiting for liver transplantation or for patients who have recently received a liver transplant. The advantage of this regimen is the relatively low risk for significant drug-drug interactions with immunosuppressive agents to prevent allograft rejection compared to rifamycins. Specifically the interaction between INH with calcineurin inhibitors is limited [36] (see Table 56.1).

The second regimen involves rifampin monotherapy for 4 months [20]. The major problem with this regimen is the drug-drug interactions that are encountered with multiple immunosuppressive agents because of the stimulation by rifampin of hepatic cytochrome P450 enzymes (CYP3A4) that increase metabolism of the antirejection drugs [36]. When rifamycins are used, levels of immunosuppressive drugs should be closely monitored, and the dose of calcineurin inhibitors, mTOR, and corticosteroids should be increased. The advantages of rifampin in this setting are shorter duration of therapy and decreased risk of hepatic toxicity than with INH although the risk of hepatotoxicity is not completely avoided. The 5-month difference in regimen duration may allow some patients awaiting transplantation to complete LTBI therapy before transplantation. The use of rifamycins in the treatment of active TB is discussed below.

The challenges and benefits of LTBI therapy in SOT patients was recently reported in a study of 189 SOT patients with LTBI who were initially prescribed isoniazid (73%), rifampin (12.7%), or another regimen (14.3%) [37]. Adequate LTBI therapy occurred in 122 (64.5%). Patients who were liver transplant candidates or recipients were less likely to complete therapy than nonliver transplant patients as were patients treated in the posttransplant phase. Liver enzyme elevation led to discontinuation of therapy more often in liver transplant candidates and recipients and posttransplant treatment. After a mean follow-up of 4.9 year/patient, there were no cases of active TB.

A third and more recent approach involves 12 weekly doses of INH and rifapentine [38–40] given by directly observed therapy. The major problems with this approach are the potential for hepatic toxicity with isoniazid and the potential for drug-drug interactions with rifapentine, although the stimulation of hepatic cytochrome P450 enzymes with rifa-

Table 56.1 Mycobacterial disease and transplant drug-drug interactions

Drug and mechanism	Cyclosporin drug levels available	Mycophenolate	Sirolimus drug levels available	Tacrolimus drug levels available	Prednisone

Aminoglycosides	Possible additive or synergistic risk of renal impairment			Possible additive or synergistic risk of renal impairment	

[a]*NS* no significant interaction

pentine may be somewhat less than with rifampin. This regimen has been shown to be associated with fewer instances of hepatic toxicity than INH alone in both HIV seropositive and seronegative populations [38–40]. A major advantage of this approach is the relatively rapid completion of therapy for LTBI (3 months vs. 4 months for rifampin and 9 months for INH) and a demonstrably improved completion rate compared with INH. Because of the short duration and association with improved treatment completion, this regimen appears to be superior to the alternative regimens.

As discussed in detail in the section on multidrug-resistant TB (MDR-TB), fluoroquinolone monotherapy is another choice [41]. An advantage of this approach is the relative safety of fluoroquinolones from a hepatic perspective. The major drawback to this regimen is the lack of conclusive data demonstrating its efficacy in the setting of either drug-susceptible or drug-resistant TB. In patients exposed to drug-resistant TB isolates, there is also the risk of developing fluoroquinolone resistance if there is occult active disease, which could transform a patient with MDR-TB into one with XDR-TB.

From the risk/benefit perspective related to TB, any patient with LTBI should receive therapy. Each patient must be assessed individually so that the best and most appropriate LTBI regimen can be chosen.

A major concern for treating LTBI and active TB is the drug-drug interactions that may occur between the antimycobacterial medications, especially the rifamycins, and the immunosuppressive antirejection agents. The following discussion about these interactions is pertinent to both LTBI and active TB therapy.

Significant drug-drug interactions can occur with antimycobacterial medications and most immunosuppressive agents used to deter allograft rejection (Table 56.2). The rifamycins

Table 56.2 Recommended treatment regimens for TB and NTM

Organism and resistance	Recommended regimen	Extent/duration of therapy
No first-line drug resistance	RIF 10 mg/kg daily INH 5 mg/kg daily PZA 20–25 mg/kg daily initial 2 months)	6–9 months
INH resistance	RIF 10 mg/kg daily EMB 15 mg/kg daily PZA, 20–25 mg/kg daily	Rifampin + at least two other drugs, 6–9 months Extensive Add LEVO 1000–1500 mg daily or Amikacin *or* capreomycin 15 mg/kg 5×/week
RIF Resistance	EMB 15 mg/kg daily PZA, 20–25 mg/kg daily LEVO, 750–1000 mg daily[b] Amikacin *or* capreomycin 15 mg/kg 5×/week	Amikacin or capreomycin, 5×/week until culture conversion and then 3×/week for at least 6 months Oral drugs for 18 months Extensive Amikacin or capreomycin, 5×/week for 6 months and then 3×/week for 6–12 months Oral drugs for 18–24 months
MDR-TB INH RIF Rifabutin	Amikacin *or* capreomycin 15 mg/kg 5×/week LEVO, 750–1000 mg daily[b] PZA, 20–25 mg/kg daily EMB, 15 mg/kg daily Ethionamide, 500–750 mg daily B_6, 100 mg daily	Primary or limited Amikacin or capreomycin, 5×/week for 4–6 months and then 3×/week for 6–12 months Oral drugs for 18–24 months Extensive Amikacin or capreomycin, 5×/week for 4–6 months and then 3×/week until culture negative for 12 months Oral drugs for 24 months PAS or cycloserine may be added
XDR-TB		
INH RIF Rifabutin Kanamycin and/or amikacin and/or capreomycin Ofloxacin ±Others	Use any new fluoroquinolone that is sensitive Use any injectable that may be active Any first-line drug available Linezolid, 600 mg daily Ethionamide if available PAS, 6–8 g daily Cycloserine, 500–750 mg daily Other third-line drugs if needed to have at least five drugs available[b]	Primary or limited Amikacin (capreomycin or kanamycin), if available, 5×/week for 6 months and then 3×/week until culture negative for 12 months Include linezolid for entire 24 months Oral drugs, at least four or five, for 24 months Extensive Amikacin (capreomycin or kanamycin), if available, 5×/week for 6 months and then 3×/week until culture negative for 12 months Include linezolid for entire 24 months Oral drugs, at least four or five, for 24 months
MAC[c] Macrolide susceptible	Azithromycin 250 mg/day or clarithromycin 500 mg BID EMB 15 mg/kg daily RIF 10 mg/kg daily	Extensive, cavitary, or severe Amikacin, 5×/week for 6 months and then 3×/week until culture negative for 12 months

Table 56.2 (continued)

Organism and resistance	Recommended regimen	Extent/duration of therapy
MAC Macrolide resistant	EMB 15 mg/kg daily RBT 150–300 mg daily Amikacin, 5×/week for 6 months and then 3×/week until culture negative for 12 months	Extensive or severe disease, consider: Clofazimine 100 mg daily Linezolid 300–600 mg/daily Bedaquiline
M. abscessus subsp. *abscessus*	Amikacin, 5×/week for 6 months and then 3×/week until culture negative for 12 months Tigecycline 25–50 mg daily Cefoxitin 3–4 mg twice daily Imipenem 500–1000 mg twice daily Clofazimine 100 mg daily	

[a]Treatment should always be in consultation with an expert in management of MDR-TB, XDR-TB, macrolide-resistant MAC, or *M. abscessus* subsp. *abscessus*. Extensive disease consists of extensive infiltrates, cavities, or pulmonary destruction
[b]We usually prefer LEVO (with a dosage of at least 750 mg daily), but patients with decreased renal failure or those with possible resistance to LEVO should receive moxifloxacin (see text)
[c]Mycobacterium avium complex

are the major concern, but isoniazid also has the potential to alter the pharmacokinetics of several agents as well. The interactions between the antituberculosis drugs and the anti-rejection immunosuppressive drugs is mediated primarily through the hepatic cytochrome P450 enzyme system (CYP3A4) with either stimulation (rifamycins) or inhibition (isoniazid) of the hepatic enzymes resulting in either decreased or increased serum drug levels, respectively. Among the rifamycins, rifampin is the most potent cytochrome P450 enzyme stimulant followed by rifapentine and then rifabutin. It is important to remember that the rifamycins, especially rifampin, are the best and most effective drugs for treating TB disease. If a rifamycin is not included in a TB treatment regimen, the shortest duration of therapy becomes 12 months with likely exposure to more hepatotoxic drugs such as INH. Maintaining rifamycins in a TB treatment regimen is a very high priority, and abandoning rifamycins in a post SOT patient should only be done as a last resort. The rifamycins are generally less important for the treatment of NTM pathogens, with the exception of *M. kansasii*. Mycophenolate levels are significantly reduced in the presence of rifampin [36]. Isoniazid does not apparently have a significant effect on mycophenolate metabolism. Cyclosporin is metabolized by hepatic cytochrome P450 enzymes, and stimulation of these enzymes by rifampin significantly increases metabolism and clearance of cyclosporin with subsequent decrease in cyclosporin serum concentrations. Inhibition of the cytochrome P450 enzymes by INH diminishes metabolism and clearance of cyclosporin with subsequent increase in serum cyclosporin concentrations and the potential for cyclosporin toxicity. Similarly clarithromycin can increase serum cyclosporin concentrations. The rifamycins also increase the metabolism of tacrolimus and sirolimus through stimulation of cytochrome P450 enzymes. The effect of INH is not as clear as with cyclosporin. Clarithromycin also decreases the metabolism and clearance of the drugs and increases the serum concentration with the potential for nephrotoxicity. The rifamycins also increase prednisone metabolism but do not have a significant effect on Imuran metabolism. Serum levels are available for mycophenolate, cyclosporin, tacrolimus, and sirolimus which may be helpful for guiding therapy with concomitant use of a rifamycin.

Diagnosis of Active TB

Although primary pulmonary TB can be a presenting illness in the recipient, fever of unknown origin, sepsis, and organ dysfunction are more typical of transmission from non-pulmonary organs or in a donor site with disseminated disease at the time of donation. About one third to one half of all active TB cases after transplantation are disseminated or occur at extrapulmonary sites, compared to about 15% of cases in immunocompetent persons [12–14]. Any SOT patient with unexplained pulmonary densities should be suspected of having active TB. Any SOT patient with unexplained fever or evidence of multi-organ involvement should be suspected of having active TB. False-negative TST and IGRA results may occur with miliary or disseminated disease [19, 42]. Therefore, neither IGRA nor TST should be relied upon to exclude active TB disease.

Clinicians should be aware of the risk of donor-derived reactivation and an occult infection and when clinically indicated test for disease in the allograft and elsewhere, using cultures, NAAT, radiology, pathology, and clinical acumen, maintaining a low threshold to diagnose this disease clinically. In several transmission events, appropriate cultures for TB were collected but became positively well after the transplants had occurred [12].

Early recognition of risk factors for drug resistance is important. Drug resistance should be suspected in those who were

born or lived in countries with a high rate of drug resistance, were exposed to a person with drug resistance, or have a history of prior TB treatment, TB treatment failure, or if treatment was not directly observed, the regimen was inadequate, medication supply was inconsistent, or there was poor adherence.

For any AFB smear- or culture-positive specimen from an SOT donor or recipient, a GeneXpert® analysis should be requested. The GeneXpert utilizes both an NAAT for determining the presence of *M. tuberculosis* and is a screening test for rifampin resistance by evaluating the presence of rpoβ mutations that confer rifampin resistance [20, 43]. Pretest preparation of samples with this technology is minimal, and the results are available within hours. The sensitivity and specificity of the GeneXpert for detecting rifampin-resistant *M. tuberculosis* isolates from AFB smear-positive respiratory specimens are >95% [20, 43]. As previously noted, the presence of rifampin resistance is strongly associated with MDR-TB especially in high-incidence countries. In the setting of SOT, a positive smear or culture specimen must be evaluated by GeneXpert to screen for rifampin resistance. Standard in vitro susceptibility testing is also always mandatory because both false-positive and false-negative results can occur with GeneXpert, although rare. In most instances of discordant GeneXpert and phenotypic drug susceptibility results, the GeneXpert result is most predictive of treatment response [20].

If a specimen appears rifampin resistant by GeneXpert, it should be referred to the Centers for Disease Control and Prevention (CDC) for molecular detection of drug resistance (MDDR) which analyzes mutations that are associated with resistance to other antimycobacterial agents [44]. For drugs other than rifampin, MDDR is approximately 80–85% sensitive depending on the drug in question [45]. Results are typically available within 48 h after receipt of the specimen by the CDC. Standard phenotypic in vitro drug susceptibility testing is always necessary for confirmation of results, again because of the potential for false-positive or false-negative MDDR results.

The two major concerns for treating active mycobacterial disease after transplantation are the immunosuppression necessary to avoid allograft rejection which may hinder effective treatment response and the drug-drug interactions that may occur between the antimycobacterial medications, especially the rifamycins, and the immunosuppressive agents. The first concern is a strong argument for inclusion of rifamycins in the treatment regimen of SOT TB patients. The use of rifampin with multiple antirejection medications can increase the risk of acute rejection [46, 47]. Conversely, a study evaluating the impact of rifampin-based anti-TB regimens found that neither rejection rate nor mortality after TB differed between those treated with and without rifampin [48]. Another study also demonstrated similar graft rejection and mortality between rifampin-containing and levofloxacin-containing groups [49]. Additionally few rejections were reported in SOT recipients with TB treated with rifampin [50, 51]. Given the importance of rifampin in the treatment of TB, some experts prefer the use of rifampin for SOT with TB with at least twofold to fivefold increase of doses of calcineurin inhibitors and close monitoring of their serum levels [52, 53].

Examples of TB treatment regimens based on in vitro drug susceptibility results are given in Table 56.1. The importance of rapid identification of drug-resistant *M. tuberculosis* disease cannot be overstated. Because of the risks of treatment failure posed by the extreme immunosuppression following SOT, the risks for allograft rejection posed by drug-drug interactions between immunosuppressive drugs (Table 56.2), and the risks for drug toxicity posed by the antimycobacterial drugs and TB drug, especially second-line TB drug, empiric TB therapy is extremely difficult and fraught with potential pitfalls.

Treatment for MDR-TB should be guided by an expert in the management of MDR-TB and should preferably begin with six but not fewer than four new drugs with proven susceptibility, two of which should be bactericidal [2, 54]. A standard approach is to (a) use any first-line drugs to which the isolate remains susceptible; (b) add a second-line injectable drug (SLID) such as streptomycin, kanamycin, amikacin, and capreomycin unless the patient has specific contraindications to the use of these drugs such as over age 60, baseline chronic kidney disease, baseline hearing loss, young children, or persons with decreased body mass (an SLID is recommended for 8 months of treatment, unless contraindicated; this period defines the intensive phase); (c) add a fluoroquinolone (high-dose levofloxacin or moxifloxacin); and (d) choose additional remaining drugs to bring the number of drugs in the regimen to at least five, preferably six, if all susceptibility tests are not yet available. Initial consideration should be given to linezolid and high-dose PZA. The remaining drugs should be chosen from the weaker second-line oral agents such as ethionamide, cycloserine, clofazimine, and PAS. In interactions with transplant rejections, medications must be considered, adjusted, and monitored through the treatment course. The recent WHO guidelines allow for extension of the intensive phase when treatment response has been slow, when there is extensive pulmonary or extrapulmonary TB disease, and when patients have failed prior treatment for MDR-TB [2]. At least three, preferably four, effective medications are recommended in the continuation phase of therapy. This phase is extended 12 months past the initial phase for a total duration of therapy of 20 months in most patients. However, in patients with extensive cavitary disease, longer therapy, i.e., at least 12 months of the injectable after conversion of cultures to negative and 24–26 months of treatment with the oral regimen, is likely to be needed to decrease the incidence of relapse [2, 54].

Short Course MDR-TB Treatment Regimens

Standardized short-course treatment regimens, lasting 12 months or less, are a new treatment option recommended by the 2016 WHO Guidelines for any patient with MDR-TB who has not previously been treated with second-line TB drugs for greater than 1 month and whose *M. tuberculosis* isolate is proven or thought likely to be susceptible to all medications in the regimen [2]. The isolate should be shown to be susceptible to at least the fluoroquinolones and SLID agents prior to starting the regimen.

The WHO short-course regimen is standardized and divided into two phases. The initial intensive phase is 4 months (which can be extended to 6 months if sputum conversion is slow) and includes high-dose gatifloxacin (or moxifloxacin), kanamycin, ethionamide (or prothionamide), clofazimine, high-dose INH, PZA, and ethambutol. This is followed by the 5-month-long continuation phase of treatment which includes high-dose gatifloxacin (or moxifloxacin), clofazimine, PZA, and ethambutol. The applicability of this approach for SOT recipients is unknown and as with any MDR-TB treatment regimen should only be undertaken with consultation from experts.

Just as treatment for MDR-TB is largely based on expert opinion and observational studies, so is treatment for XDR-TB. Treatment is even more difficult, as there is less information available to guide providers. It is essential to have both first- and second-line drug susceptibility tests, including tests for all injectable agents, ethionamide, and a newer-generation fluoroquinolone in order to maximize the therapeutic regimen. Treatment should be guided by an expert in the management of MDR- and XDR-TB.

Treatment of XDR-TB is based on the same principles as is the treatment of MDR-TB [2]. The treatment regimen is built the same way. It is especially important to include any first-line drug to which the isolate remains susceptible. An injectable should always be used if any is identified as effective. Testing should be done against each SLID, kanamycin, amikacin, and capreomycin, as inclusion of an injectable to which the isolate is susceptible will improve treatment outcomes. If susceptibility to levofloxacin or moxifloxacin is determined, one of these should be used. Additional second- and third-line drugs should be added to bring the number of drugs in the regimen to at least six. Usually, treatment with both the injectable and the oral drug regimen should be longer and more aggressive than for MDR-TB, although definite guidelines do not exist [2].

Treatment regimens for MDR- and XDR-TB include drugs with significant toxicity [2, 54, 55]. Patients should be warned to expect some adverse effects but encouraged that once they complete treatment, most drug-related side effects and toxicities will resolve. Suggestions for monitoring TB medication toxicity are provided in Table 56.3.

Table 56.3 Commonly used antimycobacterial drugs: toxicity, side effects, and monitoring

Drug	Side effects, toxicity[a,b]	Drug monitoring
Rifampin, rifapentine	Orange staining of body fluids, GI discomfort, flu-like symptoms, hepatotoxicity, renal failure, hemolytic anemia, thrombocytopenia	Baseline and monthly liver enzymes, bilirubin, creatinine, CBC
Rifabutin	Leukopenia, thrombocytopenia, skin discoloration, hepatotoxicity, arthralgias, anterior uveitis	Baseline and monthly liver enzymes and bilirubin, CBC Drug interactions
Isoniazid (INH)	Hepatitis, peripheral neuropathy, optic neuritis, arthralgias, drug-induced lupus	Clinical monitoring for hepatotoxicity is essential. Baseline and monthly liver enzymes and bilirubin
Ethambutol	Retrobulbar neuritis, visual acuity and color vision loss, peripheral neuropathy	Baseline and monthly visual acuity and color vision checks
PZA	Hepatotoxicity, arthralgias, photosensitivity, nausea, abdominal discomfort, gout	Baseline and monthly liver enzymes and bilirubin. Baseline uric acid then as dictated by symptoms
Amikacin, streptomycin	Nephrotoxicity, ototoxicity, vestibular toxicity, electrolyte imbalances (hypokalemia, hypocalcemia, hypomagnesemia)	Baseline and monthly creatinine, electrolytes, magnesium, calcium Baseline and monthly audiometry and vestibular exams
Levofloxacin, moxifloxacin	Nausea, headache, dizziness, insomnia, arthralgia, tendonitis, rarely tendon rupture, QTc prolongation	Symptomatic monitoring No routine laboratory monitoring recommended
Linezolid	Myelosuppression, diarrhea, nausea, optic and peripheral neuropathy	Symptomatic monitoring Baseline and monthly CBC, visual acuity, and color vision testing
Clofazimine	Discoloration of skin, nausea, photosensitivity, GI bleeding, and bowel obstruction	Symptomatic monitoring No routine laboratory, monitoring recommended
Cefoxitin	Abdominal discomfort, leukopenia	Baseline and monthly CBC
Imipenem	Diarrhea, nausea, vomiting, seizure	Symptomatic monitoring
Tigecycline	Nausea and vomiting	Symptomatic monitoring No routine laboratory monitoring
Clarithromycin	Diarrhea, nausea, abnormal taste, abdominal pain, hepatotoxicity, hearing loss	Symptomatic monitoring No routine laboratory monitoring is recommended

[a]All drugs used for treating mycobacterial infections have the potential for causing hypersensitivity reactions
[b]All drugs require clinical monitoring on at least a monthly basis

Medications Recommended for MDR-TB

Injectable agents include streptomycin, amikacin, and kanamycin, which are aminoglycosides, and the closely related polypeptide capreomycin act at the 30S ribosome to inhibit protein synthesis [54]. Adverse events include ototoxicity, nephrotoxicity, and rare neuromuscular blockade. Aminoglycoside and capreomycin use may be complicated by reductions in serum calcium, magnesium, and potassium [54, 55]. Cross resistance is not seen between streptomycin and amikacin, so unless patients have had prior treatment with either kanamycin or amikacin, these isolates are generally sensitive to amikacin. Isolates which are kanamycin resistant are usually resistant to amikacin (Table 56.4).

Fluoroquinolones including ciprofloxacin, ofloxacin, levofloxacin, and moxifloxacin are bactericidal against both extracellular rapidly multiplying bacteria and intracellular nonmultiplying bacteria [56–59]. They inhibit bacterial DNA gyrase, an enzyme that is essential for the maintenance of DNA supercoils, which are needed for chromosomal replication [54]. The fluoroquinolones penetrate well into tissues (alveolar macrophages), respiratory secretions, and body fluids, with concentrations equal to or higher than those in serum. Central nervous system (CNS) penetration is good, allowing these drugs to be used for tuberculous meningitis [54]. Despite the absence of prospective clinical trials using fluoroquinolones for MDR-TB, because of considerable experience with levofloxacin and moxifloxacin, they are regarded as critical to good treatment outcomes [2, 54].

Fluoroquinolone resistance develops as a two-step process, and higher serum levels protect against selection of mutants [60, 61]. Resistance to fluoroquinolones develops rapidly when they are used as monotherapy [60]. Single-fluoroquinolone prescriptions for community-acquired pneumonia in a Canadian study were not associated with development of resistant *M. tuberculosis*, whereas multiple-fluoroquinolone prescriptions were [61]. Cross resistance within the class of fluoroquinolones was previously felt to be complete. Recent anecdotal experience noted ofloxacin resistance but retained in vitro susceptibility to the newer agents [54]. Toxicity with the fluoroquinolone class of drugs most commonly is reported as gastrointestinal upset such as nausea and bloating. Myalgia is relatively common, and, rarely, tendon rupture has been reported [54]. Prolongation of the QT interval has been noted in patients taking moxifloxacin, but a detrimental clinical impact of that observation has not been demonstrated.

Most reports note that 20–30% or more of MDR-TB isolates retain sensitivity to rifabutin [62]. Rifabutin is bactericidal, with an MIC for TB less than or equal to 2 μg/ml regarded as susceptible. Although peak serum levels are 1 μg/ml, the drug has excellent activity and penetrates into polymorphonuclear leukocytes, lymphocytes, and macrophages. Tissue levels are significantly higher than serum levels. In the lungs, tissue levels are five to ten times higher than

Table 56.4 Key recommendations

It is imperative to test potential transplant recipient and donors for LTBI as early in the process as possible. That means testing potential SOT candidates for LTBI as soon as the possibility of SOT is considered, hopefully well before the patient is put on a transplant list.
The TST or IGRA are acceptable tests for screening for LTBI. In the case of discrepant results, any positivity (unless related to a documented BCG vaccination) should be considered for treatment of LTBI.
Prior to the initiation of LTBI therapy, it is imperative to exclude active TB.
It is imperative to treat LTBI in potential transplant recipient site and donors as expeditiously as possible, preferably completing that therapy prior to transplantation but if necessary, continuing therapy posttransplant.
Options for treating LTBI include INH for 9 months, rifampin for 4 months, and INH/rifapentine for 3 months. The optimal regimen for each patient must be determined individually.
It is imperative to assess carefully the risk of both LTBI and active TB in deceased donors especially those from areas of high TB endemicity.
Patients who are posttransplant must be assessed very carefully for active TB prior to initiation of LTBI therapy. Mycobacterial disease, especially TB, should be suspected in posttransplant patients with unexplained fever or evidence of disease dissemination. In the presence of active TB, LTBI therapy could result in the development of acquired drug resistance.
Cultures and NAAT from suspected sites of TB diseases are necessary for confirming the diagnosis.
Invasive techniques such as bronchoscopy with transbronchial biopsy for pulmonary disease or direct sampling from an extrapulmonary site of involvement should be performed if routine evaluation is not diagnostic.
For severe forms of TB or disseminated TB, the use of a rifamycin (rifampin or rifabutin) should be considered.
When rifamycins are used, levels of immunosuppressive drugs should be closely monitored, and the dose of calcineurin inhibitors, mTOR, and corticosteroids should be increased.
Treatment of drug-resistant TB, including multidrug-resistant TB (MDR-TB), should be managed by an expert in TB treatment.
Diagnosis of NTM pulmonary disease requires fulfilling four criteria, (a) a compatible clinical presentation, (b) radiographic abnormalities consistent with NTM disease, (c) exclusion of other diagnoses, and (d) isolation of a pathogenic NTM species from sputum (at least two positive cultures), bronchoalveolar lavage, or tissue biopsy (one positive culture).
Diagnosis of extrapulmonary disease requires isolation of a pathogenic NTM from a normally sterile body site such as blood, cerebrospinal fluid, or other sterile fluids.
Treatment of NTM disease should be managed by an expert in NTM treatment.

in plasma [54]. Patients whose *M. tuberculosis* isolates are rifampin resistant but rifabutin susceptible should receive rifabutin as part of their MDR-TB treatment regimen [2].

Ethionamide is structurally similar to isoniazid and also appears to inhibit cell wall mycolic acid synthesis [54]. The drug is bactericidal, well absorbed orally, and widely distributed. The most frequent adverse effect is gastrointestinal intolerance, including nausea, epigastric pain, and metallic taste. Significant hepatitis occurs in about 4.3% of patients, but transient abnormalities in liver tests are more common. Hypothyroidism develops in a significant number of patients treated with ethionamide.

Cycloserine is bacteriostatic for mycobacteria, acting to inhibit cell wall synthesis [54]. It is rapidly absorbed after oral administration and is widely distributed. The most common side effects pertain to the CNS seizures, psychosis, mania, depression, other emotional disturbances, and drowsiness. Neurotoxicity appears to be dose dependent and is rarely seen if serum drug levels remain below 30 μg/ml.

Clofazimine is a riminophenazine dye compound used to treat *Mycobacterium leprae* with activity against TB [54]. The mechanism of action is unknown but may involve DNA binding. Concentrated in macrophages, clofazimine has proven effective in a murine TB model. Generally well tolerated except for occasional gastrointestinal complaints, the most frequent patient concern is reversible skin darkening due to drug deposition.

Linezolid is an oxazolidinone antibacterial agent that blocks ribosomal protein synthesis. It acts by binding to the 50S bacterial ribosomal subunit, which prevents formation of the initiation complex for protein synthesis [54]. The drug has good in vitro activity against *Mycobacterium tuberculosis*, with modest early bactericidal activity and minimal extended bactericidal activity during days 2–7 [63].

In observational studies linezolid in multidrug regimens has been associated with improved outcomes in patients with MDR- and XDR-TB even when added to a chronically failing regimen as salvage therapy [63–68]. The dosage of linezolid for bacterial infections is 600 mg twice daily, but most studies have used 600 mg once daily for treatment of TB, in an effort to limit toxicity and cost. Serum drug levels are sufficiently above the MIC with this dosage [67].

Unfortunately, administration of 600 mg daily has not shown significant reduction in toxicity [65–67]. More recently, good outcomes with less frequent and severe toxicity have been reported for small series of patients treated with linezolid at 300 mg daily [66]. Most reports show frequent serious adverse events occur in a significant proportion of patients treated with linezolid and may lead to discontinuation of the drug. These reactions, which are caused by inhibition of mitochondrial protein synthesis, include myelosuppression, peripheral and optic neuropathy, and lactic acidosis [69–72]. Peripheral neuropathy has been especially concerning, as it may persist after stopping treatment [72]. Toxicity is related to duration of therapy. Hematological toxicity may occur in the first weeks to months of therapy, but neurologic toxicity usually occurs after 3–4 months. Lactic acidosis occurs during the initial weeks of therapy [72]. Linezolid is associated with the serotonin syndrome in up to 25% of patients given selective serotonin reuptake inhibitors or other medications that increase serotonin concentrations in the CNS [72]. Patients should also be counseled to avoid foods, dietary supplements, and beverages high in tyramine. The toxicity of linezolid is significant, and patients must be monitored carefully and the risks and benefits repeatedly reviewed and discussed with the patients [73].

Treatment of Latent Infection Possibly Due to MDR-TB

All persons identified as MDR-TB contacts are at risk and should be quickly evaluated for latent infection and active disease. The optimal management of established LTBI is a matter of debate. No regimen has been proved unequivocally effective, and it is unlikely that a definitive study will be done to guide management. Those who are tuberculin skin test positive are close contacts of an MDR-TB case, have no history of a previously positive tuberculin test, and can be considered for treatment of latent MDR-TB. Most clinicians agree that LTBI treatment should be offered to tuberculin skin test-positive, immunosuppressed individuals with documented exposure to MDR-TB. If assessment indicates the likelihood of exposure to drug-susceptible TB, isoniazid therapy may be preferred.

The selection of agents should be guided by the susceptibility profile of the index case. One possible regimen is a combination of pyrazinamide (25–30 mg daily) and ethambutol (15–25 mg daily). If fluoroquinolone susceptibility is documented, a regimen that combines ofloxacin (800 mg), levofloxacin (750 mg), or moxifloxacin (400 mg) daily with pyrazinamide might be used. A pyrazinamide-fluoroquinolone combination appears to result in enhanced activity within the macrophage [74]. The pyrazinamide-based regimens have been associated with high levels of hepatotoxicity [75]. A fluoroquinolone also can be combined with ethambutol. There is preliminary data that suggests fluoroquinolone administration alone prevents early disease progression in patients with LTBI who are contacts to MDR-TB patients [41]. The fluoroquinolones are also relatively nontoxic to the liver. Some experts recommend fluoroquinolone monotherapy, although emergence of fluoroquinolone resistance is a concern. LTBI treatment with fluoroquinolone is usually prescribed for 6–12 months (see above).

Nevertheless, it is important to monitor all persons with presumed latent MDR-TB for at least 2 years following the

exposure. Periodic assessments should include clinical exams and chest radiographs every 3 months for persons with HIV or other immunosuppressing illness and every 6 months for all others [54].

Nontuberculous Mycobacteria

The pathophysiology of nontuberculous mycobacterial lung disease is not well-known, and specifically it is not known if there is a latent infection stage similar to that of *Mycobacterium tuberculosis*. There are no tests similar to the TST and IGRAs to evaluate the possibility of latent nontuberculous mycobacterial infection. Therefore, there is no possibility of screening for latent nontuberculous mycobacterial infection in SOT donors or recipients. The diagnosis of nontuberculous mycobacterial disease can only be made on the basis of positive cultures and by clinical history. There are no surrogate markers of infection or disease. A positive culture from biopsy is usually adequate for diagnosis of nontuberculous mycobacterial infection, but diagnoses of nontuberculous mycobacterial lung disease are more difficult due to the possibility of respiratory specimen contamination by NTM.

In contrast to MTB, DST for NTM remains controversial and problematic providing less reliable therapeutic guidance. For many species such as the *Mycobacterium avium* complex (MAC), the correlation between in vitro DST results and in vivo response to antimycobacterial medications remains inconsistent and unpredictable. An important example is MAC where the only antimicrobial agents for which a correlation between in vitro DST for MAC and clinical response has been demonstrated in controlled clinical trials are the macrolides (clarithromycin and azithromycin) and amikacin.

This frustrating phenomenon is due to multiple factors unrelated to resistance factors not tested by DST and MICs. Natural resistance to antimicrobial drugs is conferred by a variety of mechanisms that interfere with uptake of the drug, enable it biotransformation in the cell, or decrease the affinity with the drug target. The most frustrating aspect of these natural drug resistance mechanisms is that they are generally not reflected in the in vitro MIC of specific drugs utilized for treatment of NTM. Natural drug resistance likely determines a large part of the multidrug resistance that is commonplace in NTM. This multidrug resistance, in turn, is a likely explanation of the limited efficacy of current treatment regimens for NTM disease. Testing the susceptibility of individual clinical isolates is of limited value for drugs to which natural resistance occurs. Ultimately, for most drugs used for treating NTM pathogens, there is no clear correlation between in vitro activity and the outcome of treatment, in vivo.

In contrast to MTB, DST of NTM should be performed on the initial isolate only for clinically significant isolates that exhibit variability in susceptibility to clinically useful antimicrobial agents and/or significant risk of acquired mutational resistance to one or more of these agents. For slowly growing NTM such as MAC, DST should be performed using a broth-based method, either macrodilution or microdilution.

Molecular analysis of MAC isolates that have developed resistance to macrolides in vitro has shown that these isolates have acquired a point mutation for the 23S rRNA gene. DST is indicated for clinically significant MAC isolates from patients on prior macrolide therapy, isolates who develop bacteremia while on macrolide prophylaxis, and isolates from patients who relapse while on macrolide therapy or initial isolates to establish baseline values. DST should be repeated after 3 months of treatment for patients with disseminated disease and after 6 months of treatment for patients with pulmonary disease if the patient shows either no clinical improvement or clinical deterioration while on therapy.

Other important NTM species that exhibit poor correlation between in vitro susceptibility and in vivo response to therapy include *M. xenopi*, *M. malmoense*, *M. marinum* and *M. szulgai*, and *M. simiae*.

M. kansasii is a clinically significant slowly growing mycobacterium which can cause disease resembling TB. For *M. kansasii*, the MICs for rifampin, INH, and ethambutol for untreated strains fall within a narrow range, and routine susceptibility testing is generally not needed. Treatment failure can occur and is invariably associated with resistance to rifampin. Given that treatment failure is associated with rifampin resistance and drug treatment histories are generally unavailable, susceptibility to the single drug rifampin is the only one currently recommended for primary testing. Susceptibility testing should be repeated for patients who fail initial therapy or remain AFB culture positive after 3 months of therapy. For secondary drug testing of isolates resistant to rifampin, a total of eight drugs could be tested including macrolides and fluoroquinolones.

For rapidly growing mycobacteria, broth microdilution testing of pathogenic RGM requires skill acquired through experience with the test method and knowledge of the expected susceptibility patterns of different species. Therefore, in general, for laboratories that encounter these organisms infrequently, referring those isolates for which susceptibility testing is indicated to an established reference laboratory is recommended. Susceptibility testing is indicated for any RGM that is considered clinically significant. These organisms may cause pulmonary disease, but they also may be recovered as a contaminant so that not all RGM recovered from sputum is clinically significant. Isolates recovered in low numbers from only one of multiple sputum specimens are not likely to cause disease and therefore do not warrant susceptibility testing. Agents that should be

tested against the RGM are amikacin, cefoxitin, ciprofloxacin, clarithromycin, doxycycline, imipenem, sulfamethoxazole, and tobramycin. Other drugs that should be considered include linezolid, tigecycline, and moxifloxacin.

While macrolides have traditionally been used in this role, recent studies have questioned the importance of macrolides in the treatment of *Mycobacterium abscessus* subsp. *abscessus* as the organism contains the erm(41) gene [76]. This is an inducible gene so that when the organism is incubated in the presence of clarithromycin, induction occurs and the organism rapidly acquires macrolide resistance. In contrast, *M. massiliense* has a nonfunctional copy of the gene, so macrolide resistance is not induced in the presence of clarithromycin. Patients infected with *M. massiliense* are more likely to improve clinically, radiographically, and bacteriologically with macrolide-based therapy than those with *M. abscessus* [77]. Limited data suggest that azithromycin may be more effective against *M. abscessus* than clarithromycin [78].

Species identification discriminating between *M. abscessus* and *M. massiliense* informs clinicians about the presence of an active erm gene and presumptive antibiotic choices but is frequently not available from reference laboratories. However, the presence of an active *erm* gene can be ascertained in most mycobacteriology laboratories in a relatively short time frame and is the critical information needed by the clinician to guide antibiotic therapy for isolates initially identified as *M. abscessus*.

M. chelonae is an RGM that causes skin and soft tissue disease similar to that of *M. abscessus*. Unlike *M. abscessus* and *M. fortuitum*, *M chelonae* does not carry an *erm* gene, and therefore effective therapy with a macrolide may be more obtainable in these individuals. Isolates of *M. chelonae* are susceptible to doxycycline (25% of isolates), ciprofloxacin (25% of isolates), tobramycin (100% of isolates), clarithromycin (100% of isolates), imipenem (70% of isolates), clofazimine, and linezolid (65% of isolates). *M. chelonae* is resistant to cefoxitin.

M. fortuitum is also a rapid grower similar to that of *M. abscessus*. It is recognized as a rare cause of lung disease, almost always associated in patients with gastroesophageal issues and/or achalasia [3]. It is also a cause of skin and soft tissue disease. Multidrug therapy with agents shown to be susceptible in vitro, including amikacin, newer quinolones, tetracyclines, and trimethoprim/sulfamethoxazole, should be given for 12 months or until clinical resolution of disease recognizing that without therapy for the underlying gastrointestinal disorder, symptoms rarely improve. *M. fortuitum* isolates are usually susceptible to fluoroquinolones, doxycycline and minocycline (50%), sulfonamides and trimethoprim/sulfamethoxazole, amikacin, imipenem, and tigecycline, and approximately one half of the isolates are susceptible to cefoxitin. Most *M. fortuitum* isolates have a functional *erm* gene so most are macrolide resistant.

Adaptive Immunotherapy for Opportunistic Infections

57

Aspasia Katragkou, Thomas J. Walsh, and Emmanuel Roilides

Introduction

Infectious complications of viral, bacterial, fungal, or parasitic origin are a major cause of morbidity and mortality in patients undergoing solid organ or stem cell transplantation [1–3]. The risk of infection after transplantation is a dynamic interplay between the intensity of immunosuppression and the patient's exposure to infectious organisms. The latter include mainly the patient's endogenous opportunists: the organisms transferred along with the transplant organ and pathogens from the exogenous hospital or community environment [4]. The incidence of opportunistic infections after transplantation varies from center to center, and, according to the classical perception, it is maximal during the first months after transplantation. Moreover, severe infections could occur late after transplantation in patients with particular risk factors such as acute rejection in the early period, chronic graft malfunction, reoperation, previous infections, or lung transplantation [5].

Almost all transplant recipients require lifelong immunosuppression as donor-specific immunotolerance is hard to achieve [6]. Most of the currently used immunosuppressive agents inhibit activation and proliferation of T-cells, weaken antibody response, and cause leucopenia. Conventional anti-infective therapeutic modalities are often compromised by the emergence of bacterial resistance, their side effects, or the emergence of pathogens like *Fusarium* spp. or *Scedosporium* spp., which are intrinsically resistant to most available antifungal agents. Therefore, the current developments in the management and care of transplanted patients have not proven to be a panacea. Knowing the limitations of the current anti-infective armamentarium, approaches that target the host through manipulations to augment the host immune response without increasing the risk of rejection provide a helpful aid to conventional treatment options.

A substantial body of evidence has demonstrated that strategies aiming to stimulate immune response could be feasible approaches that would benefit immunocompromised patients. In the present chapter, we present the immunomodulatory therapeutic and prophylactic approaches that have received interest and have clinical implications in the transplantation field. In particular, we discuss adoptive T-cell immunotherapy and administration of cytokines.

Adoptive T-Cell Therapy After Transplantation

Adoptive immunotherapy typically involves infusion of donor-derived lymphocytes or antibodies to patients suffering from a specific deficiency. T-cells are the most common lymphocytes infused as they play a critical role in controlling viral and fungal infections. The selective restoration of cellular immunity has been a particularly attractive strategy

in the context of hematopoietic stem cell transplantation (HSCT) for the treatment of hematologic malignancies and the prophylaxis or treatment of opportunistic infections. For immunotherapy against infections, peripheral blood lymphocytes of the donor containing pathogen-specific T-cells are stimulated in vitro and then transfused into the patient resulting in control of the specific pathogen replication (Fig. 57.1). An important limitation of this kind of therapy is the potential fatal complication caused by the alloreactive T-cells that are also present in the donor lymphocyte infusion and the low concentration of pathogen-specific T-cells in the donor lymphocyte preparation. However, enrichment of pathogen-specific T-cell by in vitro culture before transfer reduces the risk of graft-versus-host disease (GVHD) [7].

After the pioneering work by Riddell et al. and Walter et al. showing, in the hematopoietic setting, that adoptive transfer of CMV-specific CD8+ T-cell clones into patients at risk protects them from CMV-related complications, Einsele et al. have shown that the adoptively transferred donor-derived CMV-specific T-cell lines have a therapeutic effect, too [8–10]. The most recent single-arm open-label phase I/II trial has shown that the translation of cellular therapy into clinic could be feasible and effective in restoring anti-CMV immunity in patients after HSCT [11]. There are no data available for solid organ transplant recipients for the prophylactic or therapeutic effect of adoptively transferred donor-derived CMV-specific T-cell lines. As recommended by the Transplantation Society International CMV consensus group, this strategy may be an experimental strategy for CMV disease in those who are unresponsive to standard therapies [12].

Polyclonal donor-derived T-cell lines specific for EBV have been used either to treat EBV-associated posttransplant lymphoproliferative disease (PTLD) or to prevent EBV-related immunoblastic lymphoma in HSCT patients [13, 14]. Among the six PTLD-treated patients, five showed complete regression, and the one failure involved a patient with the resolution of immunoblastic lymphoma [14]. The prophylactic administration of T-cell lines in 39 pediatric HSCT patients proved effective as it elicited an immediate decrease in the EBV DNA load, and none of the infused patients developed PTLD [13]. Similar results have been reported by other independent investigators [15–17]. The therapeutic potential of EBV-specific T-cells against EBV-associated PTLD has been investigated in

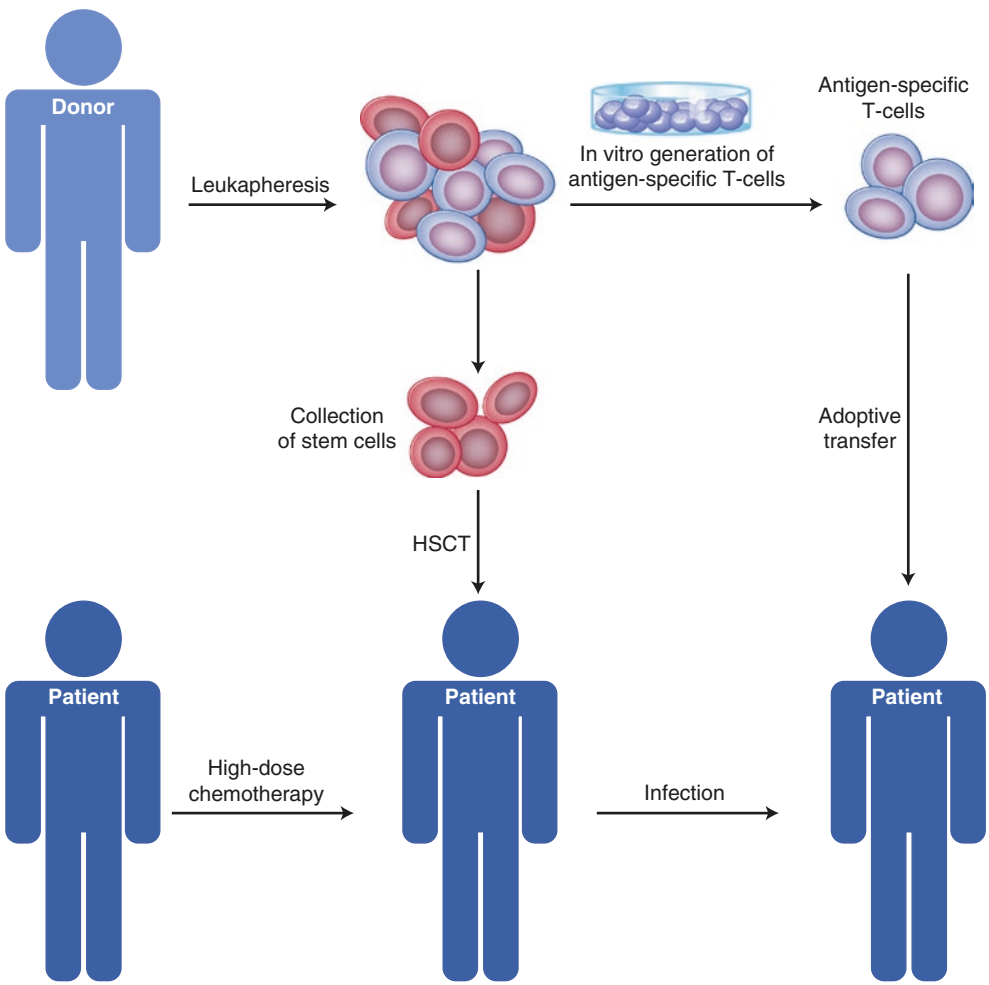

Fig. 57.1 Concept of adoptive T-cell therapy for infections (viral, fungal) after allogeneic hematopoietic stem cell transplantation. HSCT, hematopoietic stem cell transplantation [31]. (Adapted from Tramsen et al. [31])

solid organ transplant recipients. EBV T-cell-specific preparations either derived from the patients themselves or selected on the basis of the best HLA class I antigen match from a bank of such preparations that has been generated and cryopreserved from healthy allogeneic donors [18–22]. The feasibility and effectiveness of adoptive T-cell transfer have been applied for other viral infections such as adenovirus, varicella for HSCT recipients, or BK virus in renal transplant recipients [23–25]. Collectively, all these proof-of-principle studies have shown encouraging results about the safety and efficacy of adoptive T-cell therapy against viral infections which, if could be verified in clinical trials, then would represent an appreciable prophylactic and therapeutic modality for transplanted patients. However, technical requirements and regulatory burdens do not make adoptive T-cell therapy widely popular in the transplant community.

Concerning fungal infections, the first successful adoptive transfer of donor-derived *Aspergillus*-specific T-cells after haplo-identical HSCT without triggering GVHD has been described by Perruccio et al. [26]. The basis of adoptive immunotherapeutic strategies has been studied for *Aspergillus* [27], *Candida* [28], and *Zygomycetes* [29]. Nevertheless, as the therapeutic approach of fungal infections in the posttransplant setting is complicated, future clinical trials assessing the potential of antifungal adoptive immunotherapies should be able to answer questions as which patient subpopulation would benefit from adoptive immunotherapy or whether the prophylactic or therapeutic strategy is related with better outcome [30, 31].

Colony-Stimulating Factors: Preclinical Data

Colony-stimulating factors (CSFs) are a group of pleiotropic glycoproteins that stimulate the growth of specific blood cells and were considered to be a therapeutic "breakthrough" during the early 1990s. Three CSFs with activity on white blood cells have been developed and used clinically: granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and macrophage colony-stimulating factor (M-CSF).

Granulocyte Colony-Stimulating Factor (G-CSF)

Granulocyte colony-stimulating factor (G-CSF) is produced by macrophages, fibroblasts, and endothelial cells in virtually all organs in the body. It exerts its biological actions by binding to its specific cell surface receptors, which are expressed mainly on precursors as well as on mature neutrophils. In particular, G-CSF accelerates the maturation and differentiation of neutrophil precursors and delays the apoptosis of mature neutrophils, hence increasing the number of circulating neutrophils [32]. G-CSF effects not only neutrophil production but also their functions including promotion of chemotaxis, phagocytosis, priming of neutrophil respiratory burst, as well as antibody-dependent cell-mediated cytotoxicity [33]. Moreover, G-CSF has been shown in vitro to promote antibacterial and antifungal activities of mature neutrophils [34–36]. Especially in transplant recipients, ex vivo studies have demonstrated that incubation with G-CSF enhanced the impaired respiratory burst response of neutrophils against *Candida* and *Cryptococcus* [37]. G-CSF, in addition to increasing and activating neutrophils, modulates the inflammatory response exerting anti-inflammatory effects. Ex vivo studies have shown that G-CSF attenuates the capacity of neutrophils to release pro-inflammatory cytokines, such as tumor necrosis factor (TNF)-α, interferon (IFN)-γ, interleukin (IL)-6, IL-1β, and IL-12, whereas it increases the production of the anti-inflammatory soluble TNF receptor p55 and p75, IL-1 receptor antagonist (IL-1ra), and prostaglandin E2 [38–40]. This type of G-CSF-induced immunomodulatory effect has been proven in animal transplantation models to be advantageous for the control of acute graft-versus-host disease and for acute graft rejection reactions. Pretreatment of either the donor before organ retrieval [41, 42] or the recipient [43–45] with G-CSF has been shown to significantly facilitate organ acceptance. Simultaneously, this G-CSF-induced host immune hyporesponsiveness could reduce immunosuppressive agents' requirement and their subsequent adverse events [46].

Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF)

Granulocyte-macrophage colony-stimulating factor (GM-CSF) is produced by T lymphocytes, monocytes, macrophages, fibroblasts, and endothelial cells [34]. Like G-CSF, GM-CSF stimulates numerous activities of mature effector cells, including neutrophils, monocytes, macrophages, and dendritic cells, such as the respiratory burst in vitro and their antibacterial and antifungal activities [47–49]. GM-CSF, however, does not seem to play a significant role in normal neutrophil development and, unlike G-CSF, raises the number of neutrophils by redistributing them and increasing the number of cells from other hematopoietic lineages. The latter finding has raised a theoretical concern of an augmented adaptive immune response and, thus, an increased risk of allograft rejection in transplant recipients or of more severe infections due to intracellular organisms [50]. Nevertheless, in vitro, ex vivo, and in vivo studies have shown that GM-CSF therapy has a differential immune restoration potential. GM-CSF selectively boosts the innate immune response improving host's resistance against infections upon transplantation while simultaneously suppressing

	Innate Immunity	Adaptive Immunity	Response to infection	Graft rejection
Normal Host	~	~	~	NA
Immunosuppressed Host (Dex, CsA)	↓	↓	↓	↓
Immunomodulated Host (GM-CSF)	↑	↓	↑	↓

Fig. 57.2 Panel A: Survival of lethal bacterial (*Salmonella typhimurium*) infection of immunosuppressed mice (CBA/Ca) treated with GM-CSF. Mice were immunosuppressed with dexamethasone (Dex) or cyclosporine (CsA). GM-CSF treatment allowed immunosuppressed mice to survive the lethal bacterial infection without inducing graft rejection. Panel B: GM-CSF differential immune restoration potential. In immunocompromised organ transplant recipients GM-CSF has the capacity of supporting the anti-infectious defense (innate immunity) while continuing the suppression of the adaptive immune response, preventing, thus rejection [51, 52]. (Adapted from Xu et al. [51, 52]). ~, normal; NA, not applicable; ↑, increased; ↓, decreased; Dex, dexamethasone; CsA, cyclosporine A

the adaptive immune response and thus preventing rejection [51, 52] (Fig. 57.2). Moreover, in ex vivo experiments from immunosuppressed or liver transplant blood donors, GM-CSF treatment restored the production of TNF without inducing IL-2 production and T-cell proliferation. Moreover, gene array technology was able to identify the differential reconstitution capacity of GM-CSF after immunosuppression. Namely, gene array experiments demonstrated that in addition to the TNF gene, the reconstitution potential of GM-CSF extends to more genes encoding transcription factors, involved in the innate inflammatory response such as NF-κB (p65 subunit), the stress-activated protein kinase (SAPK)/c-JUN N-terminal kinase (JNK), mitogen-activated protein kinase 38, IL-6, IL-8, and platelet-activating factor receptor. On the contrary, GM-CSF has not been shown to reactivate genes involved to adaptive immunity, such as IL-2, CD27, and T-cell-specific RANTES (regulated upon activation, normally T-cell expressed and presumably secreted) production, T-cell proliferation, and mixed leukocyte reaction [51, 52]. Collectively, these preclinical findings showing the differential pharmacological profile of GM-CSF able to improve host defense resistance to infection without compromising the graft are in favor of GM-CSF clinical use in the transplantation setting.

Macrophage Colony-Stimulating Factor (M-CSF)

Macrophage colony-stimulating factor (M-CSF) is produced by monocytes/macrophages, fibroblasts, and endothelial cells. M-CSF accelerates proliferation and differentiation of the monocyte/macrophage lineage, recruits mononuclear cells to sites of infection, and activates macrophages. Some effects of M-CSF may also be through indirect mechanisms, comprising stimulation of other cytokines (G-CSF, GM-CSF, interleukin-1, tumor necrosis factor-α) which may further stimulate activities against infecting organisms [34, 35]. In vitro, M-CSF augmented antifungal and antibacterial activity of monocytes and tissue macrophages against *C. albicans* [53], *Trichosporon asahii* [54], *Aspergillus fumigatus* [55], *Penicillium marneffei* [56], and *Staphylococcus aureus* [57] partly by enhancing oxidation-dependent mechanisms. Accordingly, in animal models with yeast infections, M-CSF showed a favorable effect in terms of improved survival and reduced fungal burden [58–60]. Administration of high-dose M-CSF has been shown to significantly prolong skin graft survival in mice through inhibition of TNF-α production [61].

Clinical Applications of CSFs in Opportunistic Infections

CSFs have been evaluated by an appreciable amount of randomized controlled studies in oncologic settings [62–65]. These studies have concluded that G-CSF and GM-CSF reduce the duration of neutropenia, length of hospitalization, and duration of parenteral antimicrobial therapy and permit intensification of chemotherapy [65].

Data concerning CSF clinical utility in the prevention or treatment of opportunistic infections in transplant recipients are relatively scarce. On the basis of the above preclinical data, two clinical applications of CSFs as adjunctive anti-infective therapy have been proposed: first to increase the production of neutrophils in neutropenic patients and second to enhance the function of existing neutrophils in non-neutropenic patients.

G-CSF

Prophylaxis During Neutropenia

Neutropenia has long been considered a significant risk factor for infection especially in immunocompromised patients. In transplant recipients, neutropenia could be due to immunosuppressive agents as well as to viral infections (most commonly cytomegalovirus) and antiviral therapy (ganciclovir and related agents) [66]. Given that immunosuppression is intentional and critical for a successful transplantation and antiviral agents should be used, on many occasions, either prophylactically or therapeutically for prolonged periods, the benefit of factors like CSFs able to raise circulating neutrophils appears a viable strategy to prevent opportunistic infections.

In HSCT, G-CSF has been used before transplantation for stem cell priming and after transplantation for better stem cell engraftment to minimize the morbidity and mortality associated with prolonged neutropenia [67]. Administration of G-CSF in the posttransplant period has been associated with an accelerated rate of neutrophil engraftment, shorter duration of hospitalization, and decreased incidence of febrile episodes [68–71]. According to the most recent guidelines of the American Society of Clinical Oncology (ASCO), the use of G-CSF is recommended after autologous but not after allogeneic HSCT [72]. The rationale behind this recommendation is that while among autologous HSCT recipients posttransplant G-CSF use has been associated with shortened duration of hospitalization and savings in the overall medical costs [70], the same has not been noted for allogeneic transplant recipients [73]. Moreover, the use of G-CSF after allogeneic HSCT has been associated with increased incidence of severe GVHD and mortality [74]. However, it should be clarified that G-CSF is safe and effective in patients undergoing allogeneic transplantation when they receive peripheral blood stem cells. In the bone marrow transplantation setting, G-CSF use is not recommended as there are no adequate studies to allow firm conclusions about its safety and efficacy [67]. The optimal time to start G-CSF is a controversial issue in the autologous stem cell setting. The ASCO guidelines recommend G-CSF to be administered between day 1 and 5 after high-dose chemotherapy and continued until neutrophils are 2000–3000/μl [72]. However, several studies have shown that initiation of G-CSF beyond day 5 results in comparable engraftment [75–77]. Additionally, the number of CD34+ cells infused per kg used as a criterion for G-CSF administration is not indicated in autologous recipients [67].

Neutropenia after solid organ transplantation is relatively common and together with other secondary disorders such as operative trauma, blood transfusion, or hypersplenism render transplant recipients vulnerable to infection [78, 79]. However, there are no guidelines for the management of neutropenia in solid organ recipients. The current clinical practice, in many transplantation centers worldwide, is to reduce or discontinue the agents causing neutropenia and in selected patients use G-CSF. Contrary to oncologic patients where G-CSF is widely accepted, similar studies in solid organ transplant recipients are limited. Extrapolating treatment of neutropenia from oncologic patients to solid organ transplant recipients is not feasible due to different degrees and durations of immunosuppression and different patterns of infections [80]. In a national cohort of 41,705 renal transplant recipients from the United States Renal Data System database, neutropenia developed in 14.5% of them and was related with an increased risk of allograft loss and death. In this study G-CSF was used in 12% of the neutropenic patients, and its use was not related with increased risk

of allograft loss [81]. The safety and efficacy of G-CSF in solid organ recipients have been described in few case reports and retrospective studies [79, 80, 82–88]. In a retrospective study of 102 adult kidney and/or pancreas transplant recipients followed for over 1 year, Hartmann, et al. found that treating patients with a short course (mean 3.1 doses) of G-CSF is safe and effective [80]. In a retrospective study of 50 liver and kidney transplant recipients who received G-CSF due to neutropenia, Turgeon et al. noted that the effectiveness of G-CSF was indication-related. G-CSF successfully reversed CMV and ganciclovir-associated neutropenia; however, its effectiveness was particularly poor for the subgroup of patients receiving G-CSF for sepsis-associated neutropenia [83]. Other studies have shown that G-CSF could achieve reversal of leucopenia in all renal allograft recipients and, in most cases, after a single-dose administration [82].

Despite the encouraging results of these studies, their usefulness is limited by their retrospective design, the small number of participating patients with heterogeneous demographics and underlying pathology, different leucopenia definitions, and varying G-CSF dosage and duration regimens. Until further prospective studies are carried out to evaluate the use of G-CSF in solid organ transplant recipients with neutropenia, G-CSF should be used cautiously.

Therapy of Non-neutropenic Patients

The most extensive experience with G-CSF in non-neutropenic solid organ transplants was reported by Foster et al. in a pilot clinical trial with 37 primary liver allograft recipients who received daily G-CSF for the first 7–10 days after transplantation. These were compared with 49 historical controls who did not receive G-CSF. The two groups of patients had no differences regarding the risk factors for sepsis and rejection. G-CSF-treated patients had a decreased number of sepsis episodes per patient (0.92 versus 2.18), a lower percentage of sepsis-related deaths (8% versus 22%), and a decreased incidence of acute rejection episodes (22% versus 51%) [89]. These promising effects of G-CSF to reduce bacterial and fungal sepsis as well as its concurrent antirejection potential in liver transplant recipients have not been subsequently confirmed. Thus, a randomized, placebo-controlled, double-blind, multicenter trial involving 194 liver transplant patients has shown that G-CSF had no beneficial effect on infection, rejection, or survival. Moreover, G-CSF-treated patients had more biopsy-proven rejections and nosocomial pneumonias compared with placebo-treated patients [90]. The reasons proposed for these discrepancies were differences in study design, immunosuppressive agents, antimicrobial prophylaxis, and definitions of infection as well as improvement of care of transplant patients since the Foster trial used historical controls. Consequently, although G-CSF appears to be safe in this patient population, there is no evidence that it prevents or treats infections when used as an adjunct to standard antimicrobial or antifungal therapy.

GM-CSF

Like G-CSF, the predominant clinical use of GM-CSF concerns oncologic patients aiming to accelerate marrow recovery after chemotherapy [34]. Regarding the transplantation setting, GM-CSF efficacy has been mainly evaluated in patients undergoing bone marrow or peripheral hematopoietic stem cell transplantation to accelerate or sustain neutrophil recovery or reduce the incidence of opportunistic infections (Table 57.1) [91–99]. The ASCO guidelines have

Table 57.1 Clinical studies on GM-CSF use according to the type of transplantation [89–96, 99–101]

Transplantation type	Study type	Indication	GM-CSF dose	Ref
Bone marrow transplantation	Phase II/non randomized historical controls	Accelerate neutrophil recovery	60 μg/m^2/day	[89]
	Phase II/non randomized	Accelerate neutrophil recovery	100–400 μg/m^2/day	[90]
	Cohort evaluation	Sustain neutrophil recovery	3–10 μg/kg/day	[91]
	Phase III/randomized, double-blind, multicenter	Accelerate neutrophil recovery	10 μg/kg/day	[92]
	Randomized, double-blind	Accelerate neutrophil recovery	250 μg/m^2/day	[93]
	Cohort evaluation	Enhance peripheral progenitor cell yield	250 μg/m^2/day	[94]
	Phase I, II, III, retrospective, historical controls	Reduce fungal, bacterial infections, pulmonary infections	30–250 μg/m^2/day	[96]
Stem cell transplantation	Phase III/double-blind	Accelerate myeloid recovery, decrease incidence of bacterial infections	10 μg/kg/day	[95]
Solid organ transplantation	Comparison of cases historical controls (renal transplants)	Increase neutrophil count, decrease infections	5 μg/kg/day	[99]
	Safety and efficacy (orthotopic liver transplantation)	Increase neutrophil count, beneficial for severe bacterial infections and sepsis	5 μg/kg/day	[100]
	Randomized, unblinded, placebo-controlled, prospective study (non-neutropenic patients)	Absence of organ failure or mortality	3 μg/kg/day	[101]

provided recommendations for the use of CSFs (either G-CSF or GM-CSF) in patients after bone marrow or stem cell transplantation without commenting on their equivalency [72].

In solid organ transplant recipients, the potential role of GM-CSF has been proposed by few case reports [99, 100] and a limited number of clinical studies with relatively small number of patients [101–103]. GM-CSF combined with appropriate antiviral or antimicrobial treatment proved effective against complicated varicella zoster infection or ecthyma gangrenosum in renal transplant recipients [99, 100]. A single center experience has yielded promising results about the safety and efficacy of GM-CSF in pediatric liver transplant recipients. GM-CSF was used in 13 cases; of these 9 cases were neutropenic and 10 infected and 3 had severe sepsis without neutropenia among the 430 pediatric orthotropic liver transplantation recipients age ranged between 1 and 15 years of age. Not only was the administration of GM-CSF safe and well tolerated, but all patients with sepsis were cured [102]. Patients on tacrolimus did not appear to benefit from GM-CSF contrary to patients with EBV infections [102, 104]. Corroborative were the results of a small study with seven leukopenic renal transplant recipients; three patients with CMV infection being treated with ganciclovir who had a reduced rate of infection and mortality compared with seven historical controls [101]. In a large study of the utility of GM-CSF in adult non-neutropenic patients, including seven solid organ transplant recipients, fulfilling the criteria of systemic inflammatory response syndrome, GM-CSF despite its pro-inflammatory properties, did not cause progression to circulatory shock or other organ failures [103].

Most data on the use of GM-CSF as adjuvant therapy for transplant recipients with opportunistic infections are encouraging, with the caveat that these data are not based on prospective randomized trials and the potential for long-term adverse events cannot be ruled out. Preclinical data show that this cytokine has a good potential, whereas many issues remain to be resolved, like the optimal dose or time to administer as it seems to be a "treatment window." Table 57.1 provides an overview of representative clinical studies on GM-CSF use according to the type of transplantation.

M-CSF

Compared to G-CSF and GM-CSF, clinical experience with M-CSF is limited basically due to its specificity for cells of the monocytic lineage. The efficacy of adding M-CSF to standard antifungal treatment was examined in a retrospective study involving 46 bone marrow transplant patients with documented invasive fungal infection. Survival of patients who received M-CSF was greater (27%) compared to historical controls (5%) [105]. However, the favorable effect of M-CSF treatment on patients' survival was attributed to less severe infection and better functional status in a subgroup of treated patients. Further evolution of critical care techniques may influence the results as M-CSF-treated patients were compared with historical controls [105]. No prospective, randomized, controlled clinical trials of M-CSF for adjunctive therapy of opportunistic infections in transplant recipients have been published.

Toxicity and Adverse Events of CSFs

At present, the licensed CSFs in the USA and Europe are recombinant human G-CSF, GM-CSF, and more recently a pegylated form of G-CSF [106–108]. The commercially available preparations for G-CSF are filgrastim (a non-glycosylated protein expressed in *Escherichia coli*) and lenograstim (a glycosylated protein expressed in Chinese hamster ovarian cells in vitro) and for GM-CSF, molgramostim (a non-glycosylated protein expressed in *Escherichia coli*), sargramostim (a glycosylated protein expressed in *Saccharomyces cerevisiae*), and regramostim (a glycosylated protein expressed in mammalian cells). The pegylated form of G-CSF, available as pegfilgrastim, is a large size molecule that prevents renal clearance. Thus, the drug is eliminated predominantly through a neutrophil self-regulating, "feedback-loop-like" mechanism that allows stimulation of neutrophil production when neutrophil counts are low and rapid clearance as neutrophil counts recover.

Safety data from several clinical settings show an acceptable safety profile of G-CSF with the most commonly reported side effects being mild to moderate bone and musculoskeletal pain observed in approximately 10–20% of recipients depending on the dose administered [109]. However, the incidence of untoward side effects appears to be greater with GM-CSF [110]. This may be attributed to actions on macrophages with GM-CSF priming macrophages for increased formation and release of inflammatory cytokines, whereas G-CSF induces production of anti-inflammatory factors, such as IL-1 receptor antagonist and soluble TNF receptors [108]. GM-CSF's expression system included yeasts, bacteria, or mammalian cells, and its glycosylation status, whether or not it is glycosylated, influenced its clinical toxicity. In general, the reported frequency of adverse events, such as fluid retention, dyspnea, fever, myalgias, bone pains, and rash, was higher in patients treated with *E. coli*-derived GM-CSF [103, 111]. First dose reactions like flushing, tachycardia, hypotension, musculoskeletal pain, dyspnea, nausea, vomiting, and arterial oxygen desaturation have been reported in approximately 5% of the patients receiving intravenous GM-SCF.

On the other hand, the glycosylated form appears to be more antigenic than the non-glycosylated forms, and 1% of patients develop antibodies to the agent [92]. Administration of CSFs involves the theoretical risk of malignant transfor-

mation, but, nevertheless, there is no supporting evidence for this [112]. Another concern is the possibility for aggravating the inflammatory response in patients with pre-existing infections resulting in clinical deterioration. However, this does not constitute a contraindication to CSF administration, since it is rather based on anecdotal reports than on comprehensive studies [113].

There is a theoretical concern that G-CSF use may be harmful for organ graft survival as the G-CSF-induced monocyte, i.e., antigen-presenting cells rise may be the cause of transplant rejection. The use of G-CSF has been associated in some reports with a worsening in graft function [114]; however, in most series, it was not associated with an increased incidence of rejection episodes in solid organ transplant recipients.

Interferon-Gamma (IFN-γ)

IFN-γ is produced endogenously primarily by T-cells and NK cells and is a potent activator of monocytes/macrophages and neutrophils. In vitro, IFN-γ has been shown to enhance the neutrophil and/or macrophage activity against a number of bacteria, fungi, and protozoa [34, 47]. In addition, IFN-γ plays a regulatory role in the cytotoxic function of macrophages and the killing of intracellular pathogens like *Mycobacterium*, *Leishmania*, *Rickettsia*, *Legionella*, and *Chlamydia* species [34, 115, 116]. IFN-γ plays an important role in regulating BK virus infection by exerting a potent inhibitory effect on BK virus expression both at the level of transcription and at the level of translation and viral progeny production in primary cultures of renal tubular epithelial cells proximal [117]. Further studies using a BK infection mouse model provide evidence that IFN-γ directly depresses viral replication and contribute to the antiviral control of BK infection in the host [118]. In animal models, IFN-γ enhances host resistance against invasive *Candida* or *Aspergillus* infection [119, 120].

In clinical trials, IFN-γ has been primarily used in children with chronic granulomatous disease (CGD) [121]. In 1990, IFN-γ was approved for prophylactic use in individuals with CGD for the prevention of bacterial and fungal infections [34].

IFN-γ has never been systematically studied for the treatment or prevention of opportunistic infections in transplant recipients. The safety of IFN-γ was evaluated in a retrospective study of 32 HSCT recipients. Not only was the administration of IFN-γ tolerated without serious adverse events but in high-risk allogeneic transplantation recipients with GVHD the cytokine led to the amelioration of both acute and chronic GVHD [122]. In general, IFN-γ is well tolerated, and adverse events occur only with higher doses [34].

Conclusions

Despite the advantages on our current understanding of the immunopathogenesis of infections in immunocompromised patients, the outcome of opportunistic infections in transplant recipients remains poor. In this regard, the concept of immunomodulatory therapies constitutes a rational approach aiming to selectively restore the innate immunity while keeping the adaptive immune response, which is implicated in graft rejection, suppressed. Among the immunotherapeutic strategies studied in transplant recipients aiming to enhance the adaptive immune response are the adoptive transfer of T lymphocytes and the use of cytokines such as G-CSF, GM-CSF, M-CSF, or IFN-γ. Despite some encouraging results in in vitro and in vivo studies currently available, clinical evidence on the use of these approaches is too limited to allow firm recommendations. Many questions, however, regarding various immunomodulatory approaches, such as safety, efficacy, timing of intervention, dosing, or eligible patients will need appropriately designed and powered clinical trials in order to be answered.

Immunotherapy for Invasive Mold Disease in Transplant Patients: Dendritic Cell Immunotherapy, Interferon Gamma, Recombinant Myeloid Growth Factors, and Healthy Donor Granulocyte Transfusions

William K. Decker, Matthew M. Halpert, Vanaja Konduri, Dan Liang, Christopher N. Hampton, and Amar Safdar

Introduction

In the healthy individual, the incidence of fungal infection is low due to efficient mitigation by appropriate immune responses. Infection is acquired through the inhalation of microconidia or fungal spores, and primary infection takes hold in the lungs where the conidia swell and germinate to produce the hyphal growth pattern typically associated with mold. This is followed by contiguous spread and hematologic dissemination to the brain, kidney, and other organ systems if unchecked [1, 2]. Alveolar macrophages and neutrophils are quick to respond and phagocytose the fungal threat via several different internalization mechanisms, followed by an adaptive response carried out by dendritic cells (DC) and T cells primed for an optimal T_H1 response [3–6]. Despite high efficiency clearance of fungal infections in immunocompetent individuals, there has been a steady rise in opportunistic fungal infections since the 1960s due to the increased incidence of patients with sub-par immune responses mostly due to the advent of solid organ and hematopoietic stem cell transplantation (HSCT), the increased use of chemotherapy and biologic immunosuppressive treatment regimens, and the epidemic of advanced HIV disease [7–13].

As the number of immunocompromised patients in hospitals rises, so do the incidence and mortality associated with invasive fungal diseases. In severely immunocompromised patients, invasive aspergillosis (IA) is caused predominantly by *Aspergillus fumigatus* followed by *A. flavus*, *A. terreus*, *A. nidulans*, and *A. niger.* These species represent important filamentous mold pathogens as they are relatively prevalent and exhibit a high mortality rate approaching 45% to 80% despite antifungal therapy [14–16]. Many of the systemic antifungal therapies that work reasonably well within the general population are far less satisfactory in the immunocompromised setting. The extensive use of empiric antifungal therapies is now a growing concern given the development of drug resistance, including the emergence of the azole-resistant strains of *A. fumigatus* [17]. Additionally, these drugs have numerous limitations, including high toxicity, limited efficacy, and complex drug interactions. Though the immune system is capable of handling a fungal threat when competent, there is currently a dearth of clinically approved vaccines, despite the fact that a 1967 review article cited 32 publications showing preclinical efficacy of various fungal vaccines [18].

Historically, severe and prolonged neutropenia has been the predominant risk factor when assessing who may succumb to IA, though more recent studies have shed light on a broader breadth of relevant antifungal immune responses. For example, IA in allogeneic stem cell graft recipients is more frequently seen late after undergoing transplantation in non-neutropenic patients and often occurs during treatment for chronic graft-versus-host disease [19, 20]. Additionally, IA in patients following solid organ allograft transplantation is an opportunistic disease that is noted in the absence of severe neutropenia [21, 22]. It is important to note that heterozygous nude mice survive intravenous fungal microconidia infection while homozygous nude mice succumb to the disease, indicating an important and non-redundant role for the

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_58

adaptive immune response in fungal clearance [23]. Indeed, both the innate and the adaptive immune response are necessary for proper and efficient fungal clearance and survival of the host [5, 24, 25]. Recently, an increased understanding of the reasons why some patients survive IA and others do not has suggested the use of therapeutic interventions that utilize adaptive immunity as IA survivors typically have a significant proliferation of antigen-specific, IFN-γ-producing T cells, and generally robust T_H1 immune responses [6, 26]. After intranasal challenge of *A. fumigatus*, there occurs a vigorous secretion of pro-inflammatory T_H1 cytokines including IL-12, IFN-γ, TNF-α, and IL-18, and mice deficient for T_H1 cytokines exhibit considerable deficits in effective fungal clearance [3, 4]. Many of these T_H1 cytokines are thought to be produced by type I polarized $CD4^+$ T cells, raising concerns that antifungal immunotherapy may be ineffective in CD4-deficient hosts; however, there also exists encouraging evidence that these patients can be successfully vaccinated and that $CD8^+$ T cells can subsume the roles of $CD4^+$ cells in the development of vaccine-induced adaptive immunity [27–29].

A broad variety of immune-based approaches, some experimental in nature, have been considered for the treatment of invasive fungal disease. Experimental approaches like dendritic cell immunotherapy will be considered first, whereas more clinically relevant approaches such as patient mobilization with recombinant growth factors and granulocyte transfusion are considered later in the chapter.

Dendritic Cell Immunotherapy

Dendritic cells are important mediators of T_H1 responses and orchestrate global antifungal immunity in the lungs [2, 30–33]. Plasmacytoid dendritic cells (pDC), a lymphoid subset of DC that support T_H1 immunity through the production of type I interferons, have been observed to respond to nucleic acids from *A. fumigatus* via TLR-9 activation [34]. However, a majority of antifungal vaccine studies have focused on the use of conventional myeloid DC subsets which have shown a remarkable ability to discern between the conidia and hyphal forms of the emerging fungus [2, 35, 36]. Under physiologic conditions, lung dendritic cells engulf conidia within hours, traffic to the regional lymph nodes and spleen, and prime efficient cytotoxic T-cell (CTL) responses [2]. This concept has been adapted in animal vaccine studies in which vaccination with DC pulsed with *Aspergillus* or transfected with microconidial RNA increased the survival of mice after HSCT, when subsequently challenged with conidial inoculums, from 0% to 95% [31]. This effect could be further enhanced when DC were concurrently pulsed with fungal extracts and transfected with an IL-12-producing adenoviral vector, although there exist more conventional methods that stimulate physiologic secretion of IL-12 [32]. Importantly, the responses appeared to be antigen-specific and most robust when loaded DC were administered directly in contrast to adoptive transfer of pathogen-specific T lymphocytes [31, 32] Fungus-pulsed DC or DC transfected with fungal mRNA have also elicited a reasonable rate of immune efficiency against other types of fungi, including *Candida* [37]. In contrast to the anti-conidia T_H1 immune response, hyphae appear to promote a T_H2-skewed response using both hyphae-pulsed DC and DC-transfected hyphal RNA [2, 33]. Though an ideal antifungal vaccine would exhibit multigenera cross-reactivity, current preclinical vaccines are genus specific, exhibiting little antigenic overlap between genus or species [31].

Interferon Gamma (IFN-γ)

Interferon gamma is the only member of the type II class of interferons. It is a homodimerized soluble cytokine critical for innate and adaptive immune responses against nearly all types of pathogens including viruses, bacteria, protozoa, and fungi [38]. IFN-γ activates macrophages and upregulates MHC class I expression on a broad variety of different cell types. Produced by NK, NKT, CD4, and CD8 cells, IFN-γ both inhibits viral replication and activates macrophages, permitting more effective killing of intracellular organisms.

Preclinical Experience

IFN-γ activation of macrophages via T_H1 cell stimulation induces macrophages to overcome inhibition of phagolysosome maturation caused by mycobacteria [39], and experimental work in vitro suggests that the addition of IFN-γ increases killing of microbes by upregulating T_H1 responses through polymorphonuclear leukocytes, monocytes, and macrophages [40]. IFN-γ appears to prime macrophages for enhanced microbial killing and inflammatory activation through the toll-like receptor pathway [41]. Immune cell activation by IFN-γ is dependent on STAT1 activation which in turn activates interferon-stimulated genes. IFN-γ is also responsible for altering epigenetic governance of macrophages, inducing and priming enhancers to increase transcriptional output in response to TLR signaling [42]. Davis and colleagues demonstrated that IFN-γ prevents fungal inhibition of lysosomal activity, enhancing and maintaining the ability of the macrophage to destroy *Cryptococcus* [39]. Stevens and colleagues demonstrated that pulmonary macrophage and neutrophil function may be upregulated by IFN-γ, including respiratory burst killing of intra- and intercellular fungal infections. Stevens further demonstrated that cyto-

kines themselves are very weakly active, even when administered in combination with antifungal drugs, yet significant synergy occurs when effector cells, cytokines, and antifungal drugs are combined [43]. IFN-γ was approved by the US Food and Drug Administration in February of 2000 to treat chronic granulomatous disease, a genetically diverse disorder characterized by a defect in oxygen metabolite production in phagocytic cells [44]. Marketed as ACTIMMUNE (IFN-γ-1b), this product was authorized by the FDA for treatment of CGD even without evidence of increased superoxide production as a result of treatment. Granulomas include *Aspergillus*, especially *A. fumigatus*, and *Candida* species. Filiz and colleagues subsequently demonstrated that IFN-γ indeed improves the oxidative burst activity of neutrophils in specific subtypes of CGD in vitro, particularly with respect to the $gp91^{phox}$ subgroup [45].

Adjunct Clinical Use

Clinical case reports in HIV-infected and diabetic children with chronic fungal infections have been published, describing the use of IFN-γ in conjunction with various colony-stimulating factors to combat these infections. While this approach was not found to be curative, it did help to stabilize chronic infections over a course of several years [46]. Other clinical reports describe the use of IFN-γ as a curative agent in the treatment of invasive fungal infections following kidney transplant with only a limited, 6-week treatment cycle [47]. Here, it was hypothesized that standard immunosuppressive therapies predispose patients to fungal infection by specifically targeting and downregulating the function of T_H1 cell populations. This results in an inadequate IFN-γ-driven response to fungal insult, allowing the microbes to expand relatively unchallenged. In six of seven reported subjects, otherwise lethal infections were cleared, and long-term follow-ups have remained clear; the remaining patients' blood samples became negative for *C. albicans* 5 days after starting IFN-γ treatment and remained clear for 20 consecutive days until unexpected death from noninfectious causes (*ibid*). Delsing and colleagues report on case studies using recombinant IFN-γ for 2 weeks with partial restoration of immunologic function in the treatment of patients with *Candida* and *Aspergillus* infections. These experimental results showed general leukocyte responses primarily reflected by increased ex vivo IL-1β or TNF-α inflammatory responses as well as increased IL-17 and IL-22 cytokine secretion. This stimulation was however accompanied by concomitant decrease in granulocyte populations [48].

Safety of adjuvant recombinant interferon gamma-1b was assessed in 32 HSCT recipients at a comprehensive cancer center. Among these 32 patients, 81% had undergone allogeneic stem cell graft transplantation. In this retrospective analysis, interferon gamma-1b was mostly administered at a dose of 50 micrograms subcutaneously every other day. Six median doses ranged between 1 and 29 doses among the 32 patients. The median cumulative dose was 487 micrograms and ranged between 35 and 2175 micrograms. Fever was noted in 28% of subjects, and one patient developed reversible, new-onset lymphocytopenia while on cytokine adjunct therapy. None of the patients exhibited interferon gamma-1b-related neutropenia, thrombocytopenia, anemia, or hepatic dysfunction. It was important to note that treatment with recombinant cytokine did not precipitate nor exacerbate existing acute or chronic graft-versus-host disease. Among the 26 patients with aspergillosis, 54% died. It was considered encouraging that 60% of patients with disseminated aspergillosis after HSCT had a favorable response to antifungals and adjuvant interferon gamma-1b therapy. Multicenter clinical trials are needed to evaluate the efficacy of this cytokine therapy in highly susceptible transplant recipients with difficult-to-treat invasive mold disease [49]. Salvage combination cytokine therapy in severely immunocompromised patients with non-*Aspergillus* mold disease such as disseminated *Fusarium* spp. infection has also been reported to result in a favorable response. The authors suggested further clinical development to determine safety and therapeutic feasibility of interferon gamma-1b plus recombinant GM-CSF in highly susceptible allogenic stem cell graft recipients with life-threatening invasive fungal disease [50].

Recombinant Myeloid Growth Factors

Solid tumors, lymphomas, leukemias, and multiple myelomas exhibit similar risks of infectious complications. Myeloablative treatments for oncologic diseases including chemotherapy and/or radiation therapy are often complicated by myelosuppression prominently presenting as severe neutropenia which renders patients susceptible to potentially lethal infections. Gram-negative bacteria including *Pseudomonas aeruginosa* as well as systemic candidiasis and invasive disease due to *Aspergillus fumigatus* are serious and potentially life-threatening complications that are often encountered in patients with prolonged and severe neutropenia [51]. Antimicrobial chemoprophylaxis against bacteria, fungi, and viruses in transplant populations has predictably been largely ineffective even though a marked reduction in the risk for such infections has resulted in their routine implementation in various transplant protocols [52].

Myeloid cells are important in the prevention of fungal infections. In an experimental model of HSCT with post-transplant infection by *A. fumigatus* similar to what is observed in clinical practice, cotransplanation of common myeloid progenitor/granulocyte progenitor (CMP/GMP) cells prevented the establishment of lethal fungal infection in

mice, and survival was significantly increased with addition of granulocyte colony-stimulating factor (G-CSF) [53]. Granulocyte-CSF is a glycoprotein which promotes the proliferation and differentiation of granulocyte precursors and their mobilization into the bloodstream. Currently available recombinant human G-CSF drugs (rhG-CSF) include lenograstim (glycosylated G-CSF), filgrastim (non-glycosylated G-CSF produced in *Escherichia coli*), and pegfilgrastim (pegylated filgrastim). Granulocyte macrophage colony-stimulating factor (GM-CSF) is another glycoprotein which promotes the production of both granulocytes and monocytes and plays an important role in the immune/inflammatory cascade and provides robust defense against systemic infections. The pharmaceutical analogs include glycoprotein produced in Chinese hamster ovary cells (regramostim), *Escherichia coli* (molgramostim), or yeast (sargramostim).

rG-CSF is widely used to mobilize transplanted hematopoietic stem cells [54, 55]. In a multicenter randomized controlled trial in southwestern China, high-risk acute myeloid leukemia (HR-AML) patients receiving HLA-haploidentical HSCT who underwent primary conditioning with rhG-CSF exhibited a lower rate of relapse than those conditioned without rhG-CSF [56]. More importantly, the administration of rG-CSF to healthy individuals induced earlier peak neutrophil counts [57] and has been shown to prevent chemotherapy-induced neutropenia [58]. These observations were mirrored in randomized, multicenter trials in patients with advanced soft tissue sarcoma, small-cell lung cancer (SCLC), non-Hodgkin's lymphoma (NHL), multiple myeloma, acute myeloid leukemia (AML), and others [55, 59–66]. These growth factors also accelerated the recovery of neutrophils following bone marrow (BMT) and $CD34^+$ peripheral blood stem cell (PBSC) transplantation [62, 64, 65, 67–75]. In a trial of patients with de novo AML undergoing HSCT, a regimen of G-CSF and high-dose cytarabine provided optimized disease-free survival (DFS) and low treatment-related mortality (TRM) [70]. Within a group of 221 pediatric patients receiving an allogeneic or autologous bone marrow or peripheral blood progenitor cell (PBPC) transplant, rG-CSF treatment significantly accelerated neutrophil recovery in all groups [76]. The ability of rG-CSF and rGM-CSF to stimulate myelopoiesis was essential to their anti-infectious capabilities [77]. In some trials, time of hospitalization due to infection or antibacterial treatment regimen was significantly shorter with lenograstim than in patients given placebo. In a cohort of German adults with multiple myeloma or lymphoma who received high-dose chemotherapy and PBSC transplantation, G-CSF (lenograstim 263 μg) was given after chemotherapy to all patients, and leukocyte peak was seen 12 hours after the cytokine was administered. The degree to which patient neutrophil counts peaked in response to G-CSF mobilization was negatively correlated with length of neutropenia, infections following PBSC infusion, and the duration of antibiotic therapy. Serious infections such as pneumonia or enterocolitis were less frequent in individuals with a good response, whereas invasive fungal infections were seen only among poor responders [78].

Both G-CSF and GM-CSF have been shown by several investigators to mediate direct, anti-infective activities mediated by granulocytes. Phagocytic and microbicidal functions of granulocytes against *Staphylococcus aureus* (although not against *Candida albicans*) were significantly increased by 50–70% following 1000–4000 units/ml of G-CSF preincubation [79]. On the other hand, GM-CSF protected neutropenic mice from lethal infections caused by *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *C. albicans* and also neutropenic rats from lung injury and mortality caused by *C. albicans* [80, 81]. These effects were not observed among G-CSF-treated animals. GM-CSF also stimulates human monocyte fungicidal activity for *C. albicans* [82–84], and GM-CSF together with IL-3 protected patients receiving high-dose chemotherapy from systemic fungal infections when administered with or without autologous stem cell support [85].

At a comprehensive cancer center, 66 patients in whom GM-CSF was given in conjunction with systemic antifungal therapy were assessed retrospectively. Severe neutropenia (77%) and refractory/relapsed cancer (65%) were common in the group. Prior to GM-CSF therapy, 15% of patients received high-dose corticosteroids for a median duration of 30 days with a median cumulative GM-CSF dose of 1184 mg. Nine patients received systemic steroids during GM-CSF therapy for a median of 16 days. In 9% of patients, modest adverse events were noted. None of the 66 patients exhibited moderate or severe systemic adverse events or cardiopulmonary toxicity. In this cohort, nearly half (48%) of the patients died due to progressive IFD. The probability of death was significantly increased in patients receiving high-dose corticosteroids prior to GM-CSF treatment commenced (odds ratio [OR] = 24.0), and GM-CSF started in the intensive care unit (OR = 10.0). GM-CSF adjunct therapy was well tolerated in these severely immunocompromised patients with opportunistic fungal disease. Antifungal treatment failure remained a challenge in patients treated with high-dose systemic corticosteroids [86].

Normal Donor Granulocyte Transfusion

Advances in leukapheresis technology in the late 1960s and early 1970s established the use of healthy donor granulocyte transfusion (GTx) for the treatment of infections in canine models and severely neutropenic patients [87–92]. However, because the advent of this therapeutic modality was not underpinned by randomized, placebo-controlled trials, the utility of GTx for the treatment of invasive fungal disease has

remained controversial [93] for decades despite widespread adoption of the technique and evidence that neutrophil recovery is associated with local and systemic control of infection [94]. In a 1984 case-controlled study, only granulocytopenia was identified as a significant risk factor associated with the development of invasive pulmonary aspergillosis, whereas sinus disease, history of smoking, recurrent leukemia, chemotherapy, and corticosteroid administration were not significant predictors for this complication. Additionally, others have shown that risk of invasive aspergillosis proportionally rises with the extended duration of granulocytopenia [95].

Early studies of GTx in HSCT populations that were largely inconclusive and relied upon positive anecdotal reports [96, 97] were counterbalanced by larger, retrospective studies indicating little or no benefit [98]. These confounding series of events underscored the need for better-controlled or prospective studies. In 1997, a meta-analysis of eight prophylactic granulocyte transfusion trials performed between 1970 and 1995 identified both granulocyte dose and serum compatibility as important factors for clinical success, demonstrating significantly reduced risk of infection (RR = 0.075), death (RR = 0.224), and death from infection (RR = 0.168) among patients treated with GTx and well-matched control population [99]. This finding was important at the time as the recent contemporaneous advent of recombinant growth factors began to routinely enable increased yields of granulocytes to be harvested from mobilized normal donors. In 2013, Martinez et al. published the results of a well-designed animal study in which neutropenic mice treated concomitantly with antibiotics to prevent bacterial sepsis were inoculated with infectious doses of *Aspergillus* microconidia. In this model system, i.v. administration of 10^7 PMNs derived from syngeneic mobilized donors reduced post-infection mortality from 70% to 10% and completely cleared the infection in up to 50% of survivors as determined by analysis of fungal colony-forming units in the lungs of infected animals. Survival was shown to be correlated directly with the dose of neutrophils administered [100]. In another case control analysis at the MD Anderson Cancer Center, the impact of high-dose GTx (mean 5.5×10^{10} cells) was assessed. Twenty-nine patients with candidemia had received GTx, and 462 patients with candidemia in whom GTx was not given and who were comparable in age, gender, APACHE II score, recent treatment with antineoplastic chemotherapy, broad-spectrum antibiotics, systemic corticosteroids, radiotherapy, presence of intravascular catheter, and concordant antifungal therapy served as concomitant controls [101]. The patients who received granulocyte transfusions had a significantly higher incidence of persistent neutropenia (59% vs. 18%, $P < 0.001$), non-*Candida albicans* species candidemia (including 35% *Candida glabrata* and 31% *Candida krusei*, 90% vs. 67%, $p = 0.01$), and invasive antifungal breakthrough disease (62% vs. 23%, $p < 0.001$). The median duration of neutropenia in GTx group was 28 days compared with 10 days among the control group ($p < 0.001$), and 28% in the GTx group had received HSCT compared with 13% in patients among the control group ($p = 0.03$). Similarly, stays in critical care units were more prominent in the GTx group (62%) vs. patients in the control cohort (40%, $P = 0.02$). The overall attributable mortality rate was 48% in adjunct GTx group vs. 45% among 254 evaluable patients in the control group. On the basis of a reduced multivariate model, a significantly increased risk of candidemia-associated death was found for patients with HSCT (OR 2.51), for patients with persistent neutropenia (OR = 4.57), for patients with leukemia who also had prolonged candidemia (OR = 3.59), for those with disseminated candidiasis (OR = 5.19), and for patients with non-*C. albicans* species candidemia (OR = 5.02). Despite the presence of multiple predictors for significantly higher probability of candidemia-attributable death, recipients of healthy donor-derived, high-dose GTx adjunct therapy were associated with better than expected survival rates in this single center observation.

With increasing acceptance of the basic premise of GTx, subsequent studies were able to focus on the development of best practices including the means by which to increase granulocyte yield, identification of optimal granulocyte storage conditions, and the safe use of unrelated community donors [102–104]. In 2001, Lee et al. attempted to establish an optimal normal donor mobilization regimen for GTx therapy, though the study was successful only in identifying greater utility of GTx for the treatment of fungal or Gram-negative infections. Interestingly, protection was not evident for infections due to Gram-positive bacteria [105]. Additionally, clinicians became increasingly willing to attempt GTx for the treatment of invasive fungal infections such as rhinosinusitis [106], *Candida* septicemia [101, 107], nasal aspergillosis [108], *Candida* meningitis, central nervous system *Aspergillus* infection, and *Absdia* mucormycosis involving the upper airway [109]. Use of GTx for the management of mycoses in neutropenic pediatric populations became commonplace as well [110], and, as with the adults, the data were not without considerable controversy. A review of 66 pediatric trials published by van de Wetering et al. in 2007 reported no evidence of benefit and urged caution absent the future completion of a well-designed, randomized trial in children [111]. Subsequent pediatric studies suggested, as with adults, that cell dose is critical in achieving good clinical outcome [112]. Despite a broad and general contemporary acceptance of GTx efficacy for the treatment of infections in the neutropenic host, there remain advocates of large, randomized, placebo-controlled trials to firmly establish GTx efficacy. The fact that a conclusive study has not been performed in nearly 50 years of clinical experience with GTx indicates that this idealized goal is likely to remain both logistically and morally unfeasible in

practice. Because of these practical and ethical realities, informative data derived from well-designed animal studies may have to suffice for the foreseeable future. Data derived from prophylactic studies of GTx administration are more clear and less equivocal with regard to preventative efficacy [113]; however, prophylactic GTx can often not be justified given the relative paucity of neutropenic patients who ultimately develop serious infections despite traditional antifungal prophylaxis in comparison to the significant costs associated with GTx.

Results of the most contemporary evidence-based approaches indicate that continuous flow centrifugation leukapheresis (CFCL) is the optimal method by which to isolate normal donor granulocyte populations. As opposed to earlier methodologies of isolation and harvest based on adherence, CFCL does not prematurely activate granulocytes thereby contributing to better functional activity and enhanced longevity in vivo following infusion [114]. Because the dose of the transfusion product is so critical to functional efficacy ($>1 \times 10^{10}$ granulocytes/dose in a variety of different studies) [114, 115], it is critical to mobilize donor granulocytes into peripheral circulation prior to leukapheresis and harvest. Optimal donor mobilization in many centers consists of synergistic administration of both corticosteroids such as dexamethasone and recombinant G-CSF, the combination of which produces a 10- to 13.5-fold increase in donor peripheral blood absolute neutrophil count [114, 116–118]. The use of single-agent CXCR4-antagonist plerixafor [119–122] is also under investigational study for use as a neutrophil mobilization agent among GTx donors [114].

Despite limited evidence for efficacy, GTx is also used to prevent and treat opportunistic infections in patients with severe and prolonged neutropenia. In one retrospective study, 373 GTx given to 74 patients were assessed. It was interesting to note that GTx was discontinued because of clinical improvement more often in patients with severe infections than in patients without severe infections (27 vs. 12%, $p \leq 0.002$), whereas deaths resulted in discontinuation of GTx therapy less often in patients with severe infections than in patients without severe infections (8 vs. 39%, $p \leq 0.002$). Patients who died by 12 weeks after GTx initiation were more likely to have not recovered from neutropenia ($p < 0.0001$) and to have started GTx during a critical care unit stay ($p < 0.001$). Concomitant uses of G-CSF ($p \leq 0.02$) and IFN-γ ($p \leq 0.04$) were also more common in patients who survived. It was important to recognize that probability of failure was significantly higher in patients in whom granulocyte transfusion was given if they had pre-existing medical comorbidities (OR 12.6), in whom therapy commenced while the patients were in critical care unit (OR 8.8), or in whom hyperbilirubinemia developed by the end of GTx therapy (OR 2.1). The possibility that a niche neutropenic population, such as those with severe systemic infections administered adjunct recombinant myeloid growth factor plus IFN- γ, might benefit from GTx requires further assessment [123].

The response to antifungal therapy alone often is suboptimal in patients with refractory neutropenia, and even donor-derived GTx has not consistently shown favorable outcomes. At a tertiary cancer center, 20 patients were given high-dose (approximately 5.5×10^{10} neutrophils per transfusion) healthy primed donor-derived GTx and adjunct IFN-gamma1b. Most patients (90%) had recurrent or refractory cancer, and 30% had undergone allogeneic stem cell graft transplantation. The median duration of GTx plus IFN-gamma1b was 26 days and ranged between 12 and 372 days after transplantation. Seventy percent of patients had proven or probable invasive fungal disease. Systemic corticosteroids during GTx plus IFN-gamma1b therapy were given in 40% of the patients in this study. The median doses of GTx were 8 transfusions that ranged between 4 and 28 transfusions, whereas IFN-gamma1b median doses were 9 and ranged between 1 and 28 doses with a cumulative IFN dose of 400 +/− 2621 micrograms. Other concomitant cytokines included G-CSF in 75% of patients, and 70% also received GM-CSF. Fever was the most common adverse event noted in 20% of patients in this group, and 10% developed skin rash. Reversible liver dysfunction in 15% and tachycardia in a single patient were also attributed to IFN-gamma1b therapy, whereas transient dyspnea was considered as a GTx toxicity. Four weeks after therapy started, 45% of patients exhibited complete or partial resolution of infection, and in another 15%, invasive fungal disease had become stable. These results were indicative of tolerability of GTx and adjunct cytokine therapy among this highly vulnerable patient population. IFN-gamma1b immune enhancement in patients being treated with high-dose healthy donor GTx for systemic fungal infections appears an attractive approach and needs further validation trials [124].

In addition, off-the-shelf neutrophil-like cells can be generated and expanded from hematopoietic progenitors [114, 125–129]; however, these largely hypothetical efforts are unlikely to impact clinical medicine in the near future. Given the lack of definitive indications for GTx, only clinically driven suggestions should govern justification for the use of GTx in the treatment of infections among patients with severe and prolonged neutropenia, particularly those with evidence of severe systemic infection such as invasive fungal diseases who fail monotherapeutic antimicrobial therapy [114].

Summary

In summary, while cell therapy and recombinant growth factors appear to play important and relevant roles in the management of posttransplant invasive fungal disease, the use of

such agents remains somewhat controversial. In some cases, definitive evidence of efficacy can only be found in the research literature. In others, adoption of treatment procedures in the absence of randomized, placebo-controlled trials has created an environment in which clinicians are reasonably certain of efficacy and therefore lack the moral authority to withhold such treatments, as would be necessitated by administration of a placebo. As the field grapples with these issues, the development of innovative statistical methods and retrospective studies will likely be necessary to definitively confirm what is already anecdotally known. And in spite of the controversy, there are few who doubt the genuine efficacy of GTx and growth factor administration under appropriate clinical circumstances and fewer still who call for a complete re-evaluation of these treatment regimens in routine management. Nonetheless, future studies are certain to be beneficial in satisfying the needs of evidence-based approaches [130–133].

Antimicrobial Stewardship: Considerations for a Transplant Center

59

Susan K. Seo and Graeme N. Forrest

Introduction

In this era of multidrug-resistant organisms (MDRO), clinicians are facing difficult-to-treat infections with a dearth of novel antimicrobial agents in the pipeline [1, 2]. In order to optimize the use of currently available anti-infective drugs, antimicrobial stewardship encompassing all patient populations has been advocated [3], and the 2015 *National Action Plan for Combating Antibiotic-Resistant Bacteria* has stipulated that all United States (US) acute care hospitals should develop a formal antimicrobial stewardship program (ASP) by 2020 [4]. However, antimicrobial stewardship efforts in immunocompromised patients can be challenging due to the complexity of cases, difficulty with making timely diagnoses, and the high morbidity and mortality associated with invasive bacterial, viral, and fungal infections [5]. While there are limited data for hematopoietic cell transplant (HCT) and none for solid organ transplant (SOT) to date, cost-savings and other benefits of ASPs in the care of transplant recipients are thought to be feasible [6]. The purpose of this chapter is to explore several features of coordinating an ASP at a transplant center. While basic stewardship tenets are applicable [7], there are also unique aspects to consider in the management of transplant patients.

Implementation of ASPs

Effective antimicrobial stewardship is defined as the optimal selection, dose, and duration of an antibiotic, resulting in the cure of an infection with minimal toxicity to the patient and minimal impact on the selection of MDRO [8]. In 2016, the Infectious Diseases Society of America (IDSA) and the Society for Healthcare Epidemiology of America (SHEA) updated an evidence-based guideline for the development of a formal ASP by healthcare institutions [7]. Although many major medical centers in the US have an institutional ASP, not all of these established programs are inclusive of adult and pediatric transplant patients, showing that there is still work to be done [9]. How an ASP is implemented will vary depending on the institution's size and resources, but a comprehensive approach with a full-time dedicated multidisciplinary team can lead to increased infection cures, reduced treatment failures, and cost-savings [10]. From a practical standpoint, the Centers for Disease Control and Prevention (CDC) have summarized the seven core elements for building a successful ASP: administrative support, physician leader responsible for program outcomes, designated personnel with appropriate anti-infective expertise, selection of stewardship strategies, regular audits, prescriber feedback, and education to healthcare providers about resistance and optimal prescribing [11].

The transplant center though represents a distinctive entity, and formation of an ASP should take into account issues that are unique to such a place, such as local susceptibility patterns and the intricacies of managing patients with compromised host defenses. Advances in SOT [12] and HCT [13] have prolonged survival and increased probability of cure in patients with previously untreatable conditions. However, infections continue to be a major threat to the success of transplantation. As a consequence, antimicrobials are commonly prescribed for prolonged periods of time to either prevent or treat infectious complications in transplant recipients. It is not surprising then to find that units caring for SOT and HCT patients have some of the highest rates of antibacterial and antifungal use within hospitals [14, 15].

There is a well-established association between antimicrobial use and emergence of drug resistance and *Clostridium difficile* infection (CDI). At the patient level, the longer the duration of exposure to antimicrobials the greater is the

likelihood of colonization with resistant organisms; at the communal level, areas within hospitals with the highest rates of antimicrobial use are likely to have the highest rates of drug resistance [8]. While quinolone prophylaxis has been beneficial in reducing infection and mortality, breakthrough infections have been connected to quinolone use in HCT recipients [16–18]. An increasing trend of infections caused by methicillin-resistant *Staphylococcus aureus* (MRSA) [19], vancomycin-resistant enterococci (VRE) [20, 21], and multidrug-resistant (MDR) Gram-negative bacteria [21–23] in febrile, neutropenic patients irrespective of quinolone prophylaxis has also been reported.

Colonization and infection by resistant organisms have also been recognized in SOT recipients. The potential for infection by a resistant organism can complicate selection of appropriate initial treatment, and similar to studies in other patient groups, a delay in adequate empiric antibiotic therapy has been correlated with increased mortality among SOT patients [24]. VRE infection has been reported to occur between 4% and 11% among liver and kidney recipients [25, 26] with the majority of infections happening within the first month following transplantation. VRE infections in SOT are often severe and have been associated with persistent and recurrent bacteremia, prolonged hospitalization, and higher risk of death [27]. Data suggest that extended-spectrum beta-lactamase (ESBL)-producing bacteria commonly colonize the gastrointestinal tract of liver and intestinal transplant recipients [28, 29], and sporadic nosocomial outbreaks have occurred in intensive care units managing transplant patients, as well as in liver and renal transplant units [28, 30–32]. At least one group in Spain has found increased morbidity associated with ESBL-producing and Amp C beta-lactamase Gram-negative organisms in a population of kidney recipients [33]. Persistent colonization and infections with MDR *Achromobacter*, *Pseudomonas*, *Stenotrophomonas*, and *Burkholderia* species have been most frequently reported for lung transplant recipients, particularly in those with cystic fibrosis, and their detection seems to have prognostic significance [34]. The presence of *Pseudomonas aeruginosa* might adversely impact survival of lung transplant recipients by favoring the development of bronchiolitis obliterans following transplantation [35], and post-transplant survival among patients colonized with *Burkholderia* hinges on which infecting species is present [36, 37].

Aside from bacterial pathogens, invasive fungal infections (IFIs) occur disproportionately more in patients with compromised host defenses and are associated with considerable morbidity and mortality. The difficulty in diagnosing IFIs often results in the prolonged use of empiric antifungal therapy [38]. The overuse of these agents not only results in increased costs, but also has associated toxicities in this population [39]. Serum and bronchoalveolar lavage galactomannan antigen and the serum (1–3)-β-D-glucan assay, which is non-specific, have improved the ability to diagnose IFIs in SOT and HCT recipients [40, 41], but should these tests be performed off-site, the increased turnaround time lessens the potential to shorten or stop unnecessary antifungal therapy. Even a negative result has to be assessed in the clinical context of the host and radiologic factors to determine whether therapy can be discontinued.

Three potential targets for antimicrobial stewardship in transplant patients are antibacterial prophylaxis, empiric treatment of specific infectious conditions (e.g., fever and neutropenia, pneumonia, sepsis), and prevention and therapy of IFIs. ASP teams can craft practice guidelines with input by their transplant colleagues. However, ASP personnel should be knowledgeable about a wide spectrum of anti-infective agents and also be on the lookout for alternative therapies, including investigational agents, when breakthrough infections occur [42].

Multidisciplinary Collaboration

Antimicrobial stewardship entails a multidisciplinary approach with designated oversight by an ASP team. Core ASP members include an infectious disease (ID) physician and one or more clinical pharmacists with ID specialty training [8]. These members generally have dedicated time expressly for the purpose of antibiotic management and are compensated accordingly. Because antimicrobial stewardship relates to patient safety and is considered to be a medical staff function, the program is usually directed by the ID specialist [8]. In addition, the ASP should have administrative backing; prescriber acceptance; and strong working relationships with information technology (IT), Pharmacy and Therapeutics (P&T) committee, pharmacy, microbiology, and infection control to be successful [11].

A computer-based infrastructure facilitates stewardship efforts. Utilization of healthcare IT in the form of electronic medical records (EMR), computer order entry (COE), and clinical decision support has the potential to improve prescribing and reduce medication errors, as demonstrated by LDS Hospital in Salt Lake City, UT [43–46]. While the computer surveillance and decision-support system of LDS Hospital is ideal, adoption of such technology by individual institutions on a broader scale has been slow. Depending on the IT resources available, the ASP can still find ways to efficiently follow local susceptibilities, monitor antimicrobial use, and target antimicrobial interventions [8]. Several reports confirming the usefulness of COE in reducing the use of a target antibiotic like linezolid [47] or improving compliance with surgical prophylaxis guidelines [48] seem to indicate that hospitals are showing interest in investing in IT support.

Because of the nature of SOT and HCT care, the transplant center is well suited for multidisciplinary collaboration. However, there needs to be a sense by the transplant physicians and surgeons of a shared appreciation for the complexities of caring for immunocompromised patients. Recognizing the heterogeneity of patients is one key way. The net state of immunosuppression can vary greatly among immunocompromised individuals and even in the same person at different times, so being able to assess the degree and type of immunosuppression requires a level of expertise on the part of stewardship personnel working in such a setting [42].

Another way is to share data and demonstrate good outcomes in order to build trust with future interventions [42]. To illustrate, antibacterial prophylaxis was not routine prior to 2006 at a tertiary cancer center in New York City, but the prevention of pre-engraftment viridans streptococcal bacteremia (VSB) in allogeneic HCT became a high priority due to an incidence of 7.4% and an attributable mortality of 21% [49]. Vancomycin-based prophylaxis was instituted in 2006 and was subsequently associated with elimination of VSB and reduced staphylococcal bacteremia in a joint antimicrobial stewardship, ID, and transplant service analysis [50]. Since then, VRE has emerged as the leading cause of pre-engraftment bacteremia, so ongoing surveillance is being conducted at the center [50].

Combining forces to develop local guidelines is a further means to get transplant backing for ASP work. Although evidence-based national guidelines (e.g., management of febrile, neutropenic patients [51]; prevention of opportunistic infections in HCT recipients [52]; surgical transplant prophylaxis [53]) are available, these should be modified within the context of an institution's specific patient characteristics and local epidemiologic factors. The ASP can be an invaluable resource to assist transplant teams in these efforts. Time and energy should then be spent to educate, monitor implementation, assess compliance and outcomes, and update guidelines accordingly [42]. While complete adherence is not likely to occur, improved clinical outcomes have been demonstrated if guidelines are followed [54, 55].

Another important function of the ASP is to assist in the management and update of the hospital's formulary alongside the P&T committee to ensure that appropriate antimicrobial agents are available to support transplant patients [56]. One challenge that has not abated is shortages of drugs that are either first-line agents or the only drugs available to treat specific infections (e.g., foscarnet, the recommended agent for ganciclovir-intolerant patients or ganciclovir-resistant viruses; intravenous (IV) trimethoprim-sulfamethoxazole, the treatment of choice for *Pneumocystis jiroveci* and *Stenotrophomonas maltophilia* infections) [57]. The ASP can be an invaluable asset during contingency planning by working with pharmacy to assess the drug supply and usage, modify service- or hospital-wide guidelines, and communicate with healthcare providers, as described in one ASP's efforts to manage a critical pentamidine shortage [58].

The use of extended interval (EI) dosing of antibiotics for the treatment of serious Gram-negative infections, especially *P.* aeruginosa, has become a major intervention of the clinical pharmacist. The drugs most commonly considered for EI include piperacillin-tazobactam, cefepime, doripenem, and meropenem [59–61]. The use of EI is especially important for nosocomial and MDR Gram-negative infections, a major problem in transplant patients. Monte Carlo simulation models and clinical studies have suggested that EI can achieve or maintain concentrations of the antibiotic greater than the minimal inhibitory concentration of the organism [60]. Clinical outcomes suggest that use of EI can reduce mortality and length-of-stay (LOS), as well as drug use and costs when compared to conventional dosing schedules [59, 62, 63]. Implementation of an EI policy does require effort to establish and maintain adherence and does tie up intravascular access for several hours; this may complicate other IV therapies and even patient transfers for radiology or procedures [64].

A close relationship between the ASP and the microbiology laboratory is essential. The timely identification of pathogens and selective reporting of susceptibilities helps the ASP in making recommendations for appropriate therapy to clinicians [8, 65]. However, the outsourcing of infrequently ordered microbiologic tests to reference laboratories as part of cost-containment and quality-control efforts is a problematic trend [66]. Since these tests may be disproportionately requested for transplant recipients, clinical decision-making may be affected, particularly if there is a lag in receiving results. Although there is limited evidence that they can lead to improved empiric therapy, location-specific antibiograms should be considered since stratification can reveal differences in susceptibilities of pathogenic bacteria in transplant units as opposed to the rest of the hospital [67]. In addition to bacterial infections, opportunistic infections (e.g., viral, fungal) occur frequently in transplant recipients. Testing for antifungal susceptibilities of *Candida* species should be made available since azole prophylaxis is commonly used in immunocompromised patients [68]. Results of antifungal susceptibility testing can improve treatment selection (e.g., patients with fluconazole-resistant isolates) as well as assist in de-escalation (e.g., echinocandin to azole, IV-to-oral switch) [69, 70].

The role of rapid molecular testing for transplant patients has not been clearly established, but one potential advantage is the rapid return of accurate results over standard culture methods. There are many available technologies and not all will be suited to every center. Such assays include non-culture-based methods (e.g., procalcitonin (PCT),T2Candida panel) and pre-Gram stain diagnostics (e.g., direct polymerase

chain reaction (PCR) from whole blood), but the most frequently used are post-Gram stain tests (e.g., real-time (RT)-PCR, broad-based nucleic acid microarrays, matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI-TOF MS), and peptide nucleic acid fluorescence in situ hybridization (PNA FISH)) [71–75].

PCT is a precursor of calcitonin and is a specific and sensitive marker of bacterial sepsis in non-neutropenic hosts. The results are non-specific with regard to which bacterial pathogen is the cause of infection, but an elevation above 0.5 ng/mL is indicative of sepsis and for the purposes of an ASP, no elevation is consistent with a non-bacterial process [72]. Furthermore, results can be reported back to the treating team within an hour if the test is performed at the institution. There are very few studies in neutropenic hosts. One report evaluated PCT in patients with leukemia and found that the sensitivity of PCT to detect bacteremia was 60% and specificity 82% with the cut-off value of 0.8 ng/mL [76]. Koivula et al. did serial monitoring in febrile, neutropenic patients and found that PCT had a sensitivity of 70% and specificity of 77% at 0.5 ng/mL to predict Gram-negative bacteremia after the onset of fever [77]. There are little data in transplant patients and PCT may actually be more useful for streamlining of antibiotics if results are serially negative [78].

The T2Candida Panel (T2 Biosystems), a US Food and Drug Administration (FDA)-cleared test, can detect five species of *Candida* directly from whole blood without the need for culture within 3–5 h. Mylonakis et al. performed a clinical study using the T2Candida panel with 1801 consecutive blood specimens from patients and showed that the median time-to-identification was 4 h and was 99% specific based on spiked blood bottles [79]. This technology is also being developed for rapid bacterial identification from blood.

Direct PCR from the blood for the diagnosis of bacterial and fungal septicemia is commercially available in Europe. The Septifast™ test (Roche, Basel, Switzerland) can identify 25 common bloodstream pathogens using a multiplex PCR format with a turnaround time of 4–8 h [73, 74]. This is a pre-Gram stain test that is drawn at the same time as blood cultures. The current data are mixed on its benefit in immunocompromised hosts. Results suggest that this assay cannot replace blood cultures in the workup of fever and neutropenia although it may be helpful in situations when the blood cultures are negative (e.g., during antimicrobial therapy or in IFI) [80, 81]. However, this is of limited utility for an ASP given the expense of the test and the low barrier to initiation of antimicrobial therapy in this patient population.

The use of RT-PCR in blood cultures with positive Gram stain and for the diagnosis of CDI offers a more targeted benefit for antimicrobial stewardship in both treatment and de-escalation of antibiotics [73, 82, 83]. The currently available commercial PCR tests are only approved for the diagnosis of methicillin-sensitive *S. aureus* (MSSA), MRSA, and coagulase negative staphylococci (CNS) and have a turnaround time of 2 h [73, 82]. This allows for the possibility of reducing vancomycin usage, LOS, hospital costs, and perhaps even the emergence of VRE [82]. The future development of other PCR tests in this area is critically important, especially for Gram-negative organisms and resistance genes.

The use of PCR testing for *C. difficile* has greatly enhanced the diagnosis of this serious infection in the transplant population. Not only is PCR more sensitive than the cytotoxic assay, but it can also identify the NAP1/B1/027 hypervirulent strain. It also is much faster with results attained within 2 h; this provides important information for ASP and infection control [83]. In Europe, a two-step approach is currently recommended with testing for the antigen and then performing PCR if positive or indeterminate [84, 85]. The benefits to an ASP are that it can reduce unnecessary oral vancomycin use and limit costs and emergence of VRE in the stool from its overuse [86, 87].

There are several nucleic acid microarrays that can rapidly identify organisms from blood cultures. In the US, there are two FDA-cleared platforms, the Verigene® Gram-Positive Blood Culture (BC-GP) and Gram-Negative Blood Culture (BC-GN) tests (Nanosphere, Inc., Northbrook, IL) and the FilmArray® BCID panel (bioMerieux, Durham, NC). These technologies can identify within 2 h over 20 Gram-positive and Gram-negative organisms that commonly cause bacterial sepsis, and the FilmArray® BCID panel even detects *Candida* species. The unique feature of these multi-array platforms is the detection of resistance genes such as mecA in *S. aureus* and vanA and vanB in enterococcus, as well as KPC, NDM, CTX-M, VIM, IMP, and OXA genes in Gram-negatives [75]. The impact of early identification of bacteria with their resistance genes has been demonstrated on the Verigene® platform in which a large multicenter prospective study of the BC-GN assay showed improvements in time-to-optimal therapy, antimicrobial cost-savings, and one of the first to show a survival benefit [88]. A prospective randomized controlled trial found that use of the FilmArray® assay was associated with less treatment of contaminant blood cultures, less broad-spectrum antibiotic use, and shorter time-to-appropriate antibiotic escalation and de-escalation [89].

MALDI-TOF MS (Bruker Biotyper, Billerica, MA and bioMerieux MS, bioMerieux, Inc., Durham, NC) can rapidly identify a large number of organisms including bacteria and yeast recovered from cultures of different body sites within 15–20 min [75]. By using MALDI-TOF as recommended in conjunction with an active ASP, Perez et al. demonstrated that they could reduce LOS (average of 2.6 days) and costs (average of $19,547) but were unable to show a reduction in mortality [90]. The inability to identify resistance genes within bacteria is a current limitation of MALDI-TOF MS. There are further studies ongoing to address this need.

PNA FISH (AdvanDx, Woburn, MA) utilizes a DNA mimic to target 16S ribosomal targets in bacteria and yeast. There are multiple probes currently available for staphylococci, enterococci, *Candida* species, *Klebsiella*, *Pseudomonas,* and *Escherichia coli* [71, 91]. The turnaround time after Gram stain is normally 90 min, but recently has been reduced to 30 min [91]. It identifies the selected bacteria to species level but does not detect resistance and requires the use of antibiograms to direct therapy [71]. Several studies have shown that PNA FISH can identify species faster, reduce costs, and vancomycin usage, and with enterococci, reduce mortality [92–94]. All of these studies were performed in conjunction with an active ASP to obtain the best results, as, without their interventions, there are no benefits to performing the testing [95].

Hospital infection control interfaces with the ASP by analyzing the relationship between antibiotic use and trends in bacterial resistance. Monitoring epidemiology of nonbacterial infections is also important since emergent viral and fungal resistance while less prevalent is also being recognized [96–100]. The risks and benefits of prophylaxis also need to be continually weighed, as illustrated by reports of an increased incidence of zygomycosis occurring at transplant centers possibly linked to voriconazole use [101, 102]. Finally, there is a rapidly expanding armamentarium of novel chemotherapeutic and immunomodulatory biologic agents being used in oncology, transplant, and other fields of medicine. It has also been recognized that patients receiving these medications can develop unintended and sometimes fatal infectious consequences, such as hepatitis B reactivation in rituximab recipients [103, 104], cytomegalovirus (CMV), and other opportunistic infections in HCT recipients who received alemtuzumab for lymphoproliferative disorders [105], and invasive aspergillosis in lung transplant patients on daclizumab [106]. Minimizing such infectious complications requires vigilance on the part of the ASP and clinicians caring for these patients [107].

Strategies to Improve Antimicrobial Prescribing

In general, the ASP team should understand their hospital culture in terms of prescribing practice and choose stewardship strategies that fit within the institutional framework. The 2016 IDSA/SHEA guideline for implementing an ASP advocates pre-authorization (also called prior approval) and/or prospective audit and feedback (PAF) over no such intervention [7]. These are not mutually exclusive and can be enhanced with supplemental strategies.

The first core strategy, pre-authorization, is associated with a restricted formulary. The American Society of Health-System Pharmacists (ASHP) has put forth a guideline on how hospital P&T committees can effectively evaluate whether a drug would be suitable for inclusion on the formulary [56]. A well-structured formulary reflects local susceptibilities, minimizes the number of agents available for successful therapy, and avoids duplication [56]. Furthermore, restriction of certain agents with the condition that prescribers call an ID physician or clinical pharmacist for approval has been reported to be effective in reducing inappropriate use and expenditures without detriment to patient care [108–111]. At the Hospital of the University of Pennsylvania (HUP) in Philadelphia, ASP recommendations were more likely to be in accordance with prescribing guidelines (87% vs. 47%, $P < 0.001$) and to result in clinical cure (64% vs. 42%, $P = 0.007$) compared to ID fellows [10]. The HUP findings highlight the need for scheduled time to engage thoughtfully in the approval process as well as staffing by practitioners with expertise in using antibiotics. The downsides of this approach include perceived loss of prescriber autonomy, delay in therapy (while awaiting approval), potential for manipulating the system (e.g., team presents the request to the ASP in a biased way to get approval), and influence on primarily empiric (and not definitive) therapy [7].

In PAF, patients already on empiric therapy are identified by computer-generated screening and targeted for evaluation. When an intervention is deemed necessary, the ASP team communicates with the primary service, either verbally or electronically. Examples of interventions include ensuring appropriate dosing, narrowing coverage (also called streamlining or de-escalation), modifying duration, or stopping antibiotics altogether if there is no evidence for infection. Success of this core strategy is contingent on how feedback is delivered to the prescribers, whether IT support is available, and whether prescribers demonstrate willingness to modify therapy [7].

The report by Schentag et al. was one of the earliest to show that clinical pharmacy specialists in conjunction with ID support could effectively handle streamlining and IV-to-oral conversion [112]. By linking the pharmacy and microbiology computer systems, patients could be screened for inappropriate dosing as well as for mismatches between pathogens and drugs. No adverse outcomes were noted in patients whose regimens were modified or stopped, and antibiotic expenditures declined from 31% of the total pharmacy budget to 21.5% within 1 year. Improvements in antimicrobial use with associated cost-savings have also been reported by other centers [113, 114]. Moreover, Carling et al. noted concomitant decreases in nosocomial infections due to *C. difficile* or resistant Enterobacteriaceae [114]. A significant impact can even be demonstrated at resource-limited hospitals [115].

Much of the literature on antimicrobial stewardship has been on single-center experiences. In 2012, Cosgrove et al. reported on the first multicenter trial in which PAF was

implemented using a standardized approach across five academic medical centers, of which one was a Manhattan tertiary cancer center with a preexisting ASP [116]. Results showed that PAF could reduce broad-spectrum and total antimicrobial use although its efficacy seemed to be more robust at institutions that had invested resources for an ASP. The finding that antimicrobial utilization could decrease at hospitals with the most stringent restriction policies also suggests that combining pre-authorization with PAF may lead to better optimization.

Supplemental strategies include, but are not limited to, education, development of local guidelines, streamlining, and IV-to-oral conversion. Depending on the personnel and available institutional resources, an ASP can combine one or more of these with at least one core stewardship strategy to augment program activities. A full, detailed explanation of these other supplemental strategies is beyond the scope of this chapter, but can be found in other published reviews and guidelines [7, 8, 117, 118].

Briefly, education is the most basic strategy by which to influence clinicians to adopt and maintain good prescribing practices. Initiatives range from one-on-one instruction to formal didactics. Although education is the cornerstone of any ASP, its effectiveness is dependent on the motivation of the clinician to make a behavioral change [119, 120]. Without the incorporation of active intervention, education alone is marginally effective and has not demonstrated a sustained impact on prescribing practices [121–123], and thus the 2016 IDSA/SHEA guideline suggests against relying solely on education for stewardship work [7].

The development of peer-reviewed, evidence-based guidelines simplifies the process of antibiotic selection for prophylaxis or treatment but should be coupled with a plan for dissemination and implementation [7]. Examples of national guidelines that would be of relevance to a transplant center include empiric treatment for fever and neutropenia [51], prevention of opportunistic infections in HSCT recipients [52], treatment of aspergillosis [124], treatment of candidiasis [125], and surgical prophylaxis [53]. Standardized antimicrobial order forms, automatic stop orders, and computerized systems can ease the implementation of guidelines [44, 118].

Streamlining is a process that ensures that antimicrobial therapy is matched to culture and susceptibility data within 48–72 h after initiation of treatment. The objective is thus to avoid prolonged, excessively broad treatment. As seen in the management of ventilator-associated pneumonia (VAP), antimicrobial therapy may be shortened [126] or even stopped based on clinical criteria and negative culture results [127, 128]. Singh et al. also found that the rate of subsequent antibiotic-resistant infections was lower in the group receiving short-course treatment for suspected VAP compared to those receiving standard duration (15% vs. 35%, $P = 0.017$) [127]. An economic benefit has also been derived from this strategy. In one report, recommendations for streamlining occurred in 54% of antibiotic courses over 7 months, resulting in a projected annual savings of $107,637 [129]. In another report, a pharmacist-based intervention to discontinue unnecessary agents was successful in 134 (98%) of 137 episodes [130]. Potential drug cost savings and reduction in redundant antibiotic combination days were $10,800 and 584 days, respectively.

Finally, a systematic plan for IV-to-oral conversion can decrease hospital LOS and healthcare costs. The excellent oral bioavailability of several antimicrobial classes, including the fluoroquinolones, azoles, and oxazolidinones, makes this approach quite reasonable. In contrast to oral formulations, IV medications are generally more expensive and can be associated with adverse events like phlebitis and catheter-related infections. Patients also benefit since oral treatment is convenient and easy [131]. This strategy, however, is reserved for those who are hemodynamically stable, have improved clinically within 48 h of prior IV therapy, and have functioning gastrointestinal tracts. Individuals with severe immunodeficiency states or infections like meningitis and endocarditis are not candidates [131, 132]. Representative studies report a positive experience with IV-to-oral conversion in terms of clinical effectiveness and cost savings [133–137].

What Can Be Accomplished?

Effective ASPs can reduce antibiotic use, improve patient care, and be financially self-supporting in both large academic institutions and small community hospitals [10, 113–115, 138]. While much of the published literature has focused on general patient populations, established stewardship strategies, such as PAF and antimicrobial de-escalation, can be effectively performed in cancer patients [116, 139]. In addition, the disproportionate use of antifungal drugs in immunocompromised patients has led to an emerging literature on antifungal stewardship. Several institutions have successfully used a multi-pronged approach that included PAF, education, and development of local guidelines to improve antifungal prescribing [140–143]. Making available appropriate diagnostic testing for IFI, review of drug–drug interactions, and therapeutic drug monitoring for mold-active azoles are other key components for antifungal stewardship [144].

What is the current state of antimicrobial stewardship for transplant patients? In a recent survey of US medical centers performing SOT and/or HCT, the majority of respondents had an institutional ASP [9]. Yet, of the 62 ASPs, the proportion performing stewardship activities was 46 (74%) for adult SOT, 44 (71%) for adult HCT, 29 (47%) for pediatric SOT, and 31 (50%) for pediatric HCT [9]. This finding shows that there is a sizeable number of ASPs that need to think

about how to incorporate transplant patients. This same study found that ASPs that did oversee anti-infective utilization in the transplant setting employed a variety of strategies, including formulary restriction, guideline development, education, antimicrobial de-escalation, and IV-to-oral conversion in combination with at least one core strategy, of which PAF had a slight edge over pre-authorization [9]. Perceived challenges to antimicrobial stewardship in transplant include undefined duration for certain infections, diagnostic uncertainty, the tendency for prescribers to want to escalate therapy, prescriber opposition, and expensive drugs [9, 145]. Another challenge is the lack of published data on stewardship effectiveness in transplant, which may be due to the lack of robust monitoring in this patient group with the exception of *C. difficile* rates and antimicrobial costs [9]. Tracking antimicrobial utilization, as well as both process and outcome metrics, has been emphasized in the 2016 IDSA/SHEA guideline [7]. Efforts examining whether antimicrobial stewardship interventions are effective in the transplant setting should thus be encouraged.

Conclusion

The emergence and spread of MDR pathogens coupled with a meager antimicrobial pipeline have led to the realization that optimization of currently available agents is an important priority. Advocacy by the ID professional societies has led to a national call that all healthcare institutions create an ASP that encompasses all patients, including transplant. Transplant recipients are very important targets for antimicrobial stewardship since they are exposed to prolonged courses of prophylactic and therapeutic anti-infectives, and because they receive multi-faceted care, multidisciplinary collaboration between an ASP and the transplant team is feasible. While it is anticipated that transplant patients can benefit, studies pertaining to stewardship efforts in the transplant setting and their measured outcomes are needed.

The Use of Palliative Care in Organ Transplant Patients and End-of-Life Issues

60

Jenny S. Ayala and Joseph Lowy

Introduction

Patients suffering from organ failure experience a reduction in quality of life with a burden of symptoms which are physical, psychosocial, and spiritual. Since the first solid organ transplant in the 1950s, great advances have been made in the field. Organ transplantation can be life-saving but the surgery and postoperative medications have their own complications. More patients are being considered for transplantation but the demand far outstrips the supply and many organ transplant candidates may become too sick to transplant or die waiting.

The transplant team consists of transplant coordinators, physicians, nurses, social workers, psychologists, and financial coordinators. It is rare for a palliative care provider to be involved until the patient is near terminal. Palliative care has been shown to improve quality of life and even prolong life in patients with certain types of malignancy. The provision of palliative care has consistently shown a reduction in cost of care and improved patient satisfaction. Several studies have now demonstrated a beneficial impact of palliative care on the transplant patient.

Dame Cicely Saunders first introduced the concept of caring for the terminally ill in London back in the mid-1950s. This became known as hospice care, and by the 1970s, the state of Connecticut founded its first hospice facility in Branford. While hospice provides care for patients whose survival is expected to be less than 6 months, palliative care is specialized care for the patient with serious illness and can be provided at any stage of the disease. All transplant candidates, by definition, qualify. Like transplant medicine, palliative care is also interdisciplinary. It is person/family centered and provides support along with aggressive symptom management. Patients are screened for pain and other physical symptoms as well as for psychosocial and spiritual distress. Palliative care also fosters communication between the patient/family and health-care providers. The patient's values and principles are elicited so that concordant medical care is provided. Implementing palliative care (sometimes referred to as supportive care) early in the disease trajectory has helped transition patients into hospice care once curative options have been exhausted.

This chapter will elucidate why patients with organ failure who are candidates for transplantation or patients suffering from complications of transplantation are excellent candidates for palliative care and why a palliative care provider should be part of the transplant interdisciplinary team.

Organ Transplantation: The Facts

The field of solid organ transplantation has soared to great heights since the first kidney was transplanted back in 1954. The successful transplantation of kidney, heart, lung, liver, pancreas, and small intestine is now routine. However, the success of organ transplantation has caused a demand and supply mismatch. The number of patients waiting for an organ far exceeds the number of deceased and living donors available. As of November 2017, there were over 116,000 people in need of a life-saving organ transplant [1]. Candidates include all ethnicities and ages, as young as <1 year old to older than 65 years old [1]. Survival rates vary depending on the organ transplanted and whether the organ was from a deceased or a living donor as seen with kidney and liver transplants. Lung transplants have the lowest rate of patient survival [1] (Fig. 60.1) due to primary graft failure and infections [2].

Transplant candidacy depends on organ, extent of the disease, risk of mortality, response to treatment, and individual factors. Patients who are referred for organ transplant have to undergo an extensive evaluation by the transplant team composed of clinical transplant coordinators, transplant physicians, financial coordi-

[8], © 2009, with permission from John Wiley and Sons

nators, and social workers. Waiting time for organs can be days to months to years and is based on the level of urgency and organ availability. Different organ allocation systems have been established that take into account the level of acuity of disease and mortality rate if not transplanted [1, 2]. Kidney and pancreas transplants are exceptions as their allocation system is solely based on genetic compatibility and waiting time.

Organ Transplantation and the Role of Palliative Care

Patients diagnosed with end-stage organ failure may feel similarly to patients with terminal cancer. The symptom burden that patients live with greatly affects their quality of life as well as their families and the people around them. Studies have shown that implementation of early palliative care alongside cancer treatment improves quality of life and mood [3, 4]. These improvements are the result of having a team that specializes in delineating realistic goals of care, symptom control, quality of life, and emotional well-being, while acting as a bridge of communication between patients, family, and medical doctors without altering appropriate treatment plans [5]. Prognosis of patients with cancer is related to their performance status based on the Karnofsky Performance Status (KPS) [6] and Palliative Performance Scale (PPS) [7], which measure the physical function and ability to self-care. See Appendix for full description.

Patients with end-stage organ failure have a more unpredictable disease trajectory marked by periods of symptom exacerbation and disease progression [8] (Fig. 60.2).

Several studies suggest benefit from the integration of palliative care in end-stage heart, lung, liver, and kidney failure [9–12]. Palliative care integration has become part of the guidelines for treatment of end-stage heart and lung failure, as it has shown to improve patients' quality of life and clarify end-of-life wishes and goals [9, 10].

Physicians should understand that the goal of palliative care is to minimize suffering from physical and emotional symptom burden for all patients going through a life-threatening illness, regardless of their diagnosis and should not be considered exclusively as an alternative to curative plans, limited to end-of-life care, or only for non-transplant candidates. Patients living with life-threatening illnesses have identified five domains that they consider important when discussing quality of life [13]:

- *Adequate pain and symptom management*
- *Avoidance of inappropriate prolongation of dying*
- *Achievement of a sense of control*
- *Relief of the burden of their disease on others*
- *Strengthening of relationships with loved ones*

Therefore, it is essential to provide patients living with end-stage organ failure a sense that they are not alone, that we will continue to care for them whether or not they are transplant candidates ("non-abandonment"), and that we will strive to understand their concerns and help them achieve realistic goals.

> The good physician treats the disease; the great physician treats the patient who has the disease. (William Osler)

Understanding the Difference Between Palliative Care and Hospice Care

It is important to differentiate between palliative care and hospice care in order to provide the patient with the right service at the right time. Patients, families, and health-care providers may have the misconception that palliative care

equals hospice care, signifying the care of the terminally ill. As stated previously, palliative care may be introduced early in the disease trajectory and alongside curative treatments. However, this is not the same for hospice care. Both specialties embrace the principles of lessening symptom burden and improving quality of life, but hospice focuses specifically on end-of-life care goals and needs of the patient and family. The family of a dying patient may feel significant stress and anxiety. Hospice social workers and pastoral care provide support and counseling to the patient and to the family before and after the death of a loved one. Hospice nurses and physicians provide symptom control and assist with decision-making when patients are home or in an institutionalized setting [14]. If palliative care is implemented early in the disease process and all curative alternatives have been exhausted (e.g., transplantation), but the disease has continued to progress, patients may easily be transitioned into hospice care. While all patients with advanced disease can receive palliative care, not all patients can receive hospice care. There are specific criteria set forth by Medicare and private insurers that must be met in order to qualify for coverage. These include the following: (1) disease is far advanced and alternatives for curative treatment have been exhausted; (2) based on the disease progression, patient has a prognosis of less than 6 months if the disease is allowed to take its natural course; and (3) patient agrees to forgo any further curative therapies and focus on comfort measures only [15]. Hospice care may be provided in multiple settings, such as home, nursing home, hospice inpatient unit, or hospital. Studies have shown that patients, as well as families, prefer home hospice to dying in institutionalized settings; they feel that the needs of the patient are better met at home with hospice care services and family support [14, 16]. It is very important that physicians are aware of the distinction between palliative care and hospice so that patients and their families may receive the appropriate level of treatment and care to which they are entitled.

> Hospice care provides palliative care, but all palliative care is not hospice care. (Ministry Health Care)

Review of End-Stage Organ Failure Diseases and the Role of Palliative Care

End-Stage Heart Failure

Cardiovascular disease remains the number one killer in patients older than 65 years, accounting for 27% of total deaths in the USA [17]. Among cardiovascular diseases, heart failure has a high mortality and morbidity risk, and the number of people affected by the disease continues to increase. Latest data shows over 6.5 million Americans are living with heart failure [18]. The New York Heart Association and American College of Cardiology/American Heart Association have classified heart failure into four stages based on symptom severity. The most advanced stage, IV/D, includes patients who are symptomatic at rest living with ~50% 1-year survival rate. Patients at this stage are considered to have end-stage organ failure and require more specialized and, often, invasive treatments in order to prolong survival and improve quality of life. Treatments available for this stage include intravenous inotrope infusion, mechanical circulatory support devices, such as the left ventricular assist device (LVAD), and, ultimately, cardiac transplantation, if feasible [19]. Patients living with stage IV HF have a very poor quality of life due to overwhelming symptoms of fatigue, shortness of breath, depression, and pain [20–22]. A model used to predict survival in heart failure patients using clinical and laboratory data is the Seattle Heart Failure model. It predicts the 1-, 2-, and 3-year survival and can be individualized to each patient by adding the use of devices or certain heart failure medications [23]. It has also proven to be helpful in combination with the Heart Failure Survival Score when referring patients for transplantation [24].

When the disease reaches a point when it is refractory to any type of treatment other than LVAD or cardiac transplantation and the patient is not a candidate for these measures or refuses, the disease will take its course, inevitably ending in death. Currently, there are over 3000 patients on the waiting list for a heart with the average waiting time being 1–2 years [1]. Ten percent of the patients die while waiting and 12% are removed from the list because the patient becomes too sick to transplant [1]. Because of the symptom burden, quality of life issues, and high mortality rate of advanced heart failure, the ACC/AHA have modified their guidelines to include palliative and hospice care as a Class I Recommendation. The goal is to educate the patient and family regarding the services that can be offered by palliative and hospice care to assist in alleviating symptom burden, discussing prognosis, decision-making including setting realistic goals, and, when necessary, end-of-life care [25]. Schwarz et al. studied patients referred for cardiac transplantation who were evaluated by a palliative care team. This intervention resulted in better symptom management with less use of pain medications. Goals of care, advance care planning, and end-of-life goals were discussed actively, and patients' spiritual and psychosocial needs were met either by referral to chaplaincy, psychiatry or through the use of pharmacology [26].

End-Stage Pulmonary Disease

Respiratory insufficiency may be defined as the inability to maintain adequate gas exchange and is classified according

to the Global Initiative for Chronic Obstructive Lung Disease. Severity of disease is based on spirometry assessment post bronchodilator, and patients with a FEV1 (Forced Expiratory Volume in 1 s) <30% are considered to have very severe disease causing significant impairment in the daily life [27].

Chronic lower respiratory disease is the third leading cause of death in the USA [17]. End-stage lung failure, seen in patients with class 4, can be seen in multiple pulmonary conditions, but the most common is chronic obstructive pulmonary disease (COPD). About 15 million Americans suffer from COPD and over 11,000 people die annually [17]. Patients suffering from COPD are classified based on the decline of the FEV1 using the GOLD criteria. Those with GOLD IV have an FEV1/FVC < 0.70 and FEV1 < 30% predicted [28] and tend to suffer greater number of exacerbations as compared to lower stages [29]. It has also been shown that patients who suffer repeated COPD exacerbations, especially those who require hospitalization, have a more rapid decline in lung function and higher mortality risk [30–33]. In addition, their post exacerbation quality of life changes for the worse as they become more dependent on others and require more medical interventions [32]. Patients living with severe COPD suffer from a number of symptoms, such as dyspnea, fatigue, pain, cough, weight loss, depression, and decreased functional status. When compared to lung cancer patients, patients with COPD receive significantly less treatment for these symptoms [34]. This difference in intervention is especially evident for dyspnea and pain, symptoms that respond to the use of opioids. Unfortunately, there are many barriers to the utilization of these medications, including the misconception of hastening death [35].

Palliative care has been shown to have significant impact on quality of life in patients with end-stage COPD, shown in a study of home-base palliative care, where the main goal was symptom management and pain relief. Through these interventions, patients had improved quality of life and fewer emergency room visits and hospitalizations [36]. The American Thoracic Society now promotes and recommends the integration of this service as part of the management of any chronic pulmonary disease, especially COPD [37]. Patients whose disease has become refractory to treatment may be candidates for lung transplant. In the last year, about 2,000 lung transplants were performed in the USA, and the number of patients waiting for a transplant continues to exceed the number of donor lungs available [1]. Currently, there are about 1400 patients on the waiting list, and as the number of patients continues to increase so does the number of patients being removed due to death of the patient (10%) or because the patient becomes too sick to transplant (12%) [1]. Although lung transplantation provides resolution of symptoms with improved quality of life, survival rates remain a limitation, averaging only a 54% 5-year survival rate which is significantly lower than the rates for heart, liver, and kidney transplantation [1] (Fig. 60.1). Physicians caring for end-stage COPD patients should make an effort to educate patients about their disease process, symptoms, treatment option, prognosis, and end-of-life goals. This will lead to proper symptom management and appropriate referral to palliative care and hospice for medical, emotional, and psychosocial needs.

End-Stage Liver Disease

Cirrhosis is the common final pathway in chronic liver disease (CLD). The liver is known to be one of the only organs with the ability to regenerate itself after acute injury. However, when cirrhosis has taken place, regeneration is no longer possible and the damage becomes permanent leading to End-Stage Liver Disease (ESLD). CLD and cirrhosis rank as the 12th leading cause of death in the USA and kills over 30,000 patients annually [17]. There are multiple causes for ESLD including hepatitis, drug toxicity, and genetic errors, but chronic alcohol use is responsible for approximately 50% of cases [17]. Patients diagnosed with ESLD have no available curative options other than liver transplant. Treatment is focused on managing the complications rather than reversing the disease process. While there are patients with "compensated cirrhosis" who live for many years and are asymptomatic, many patients with "decompensated cirrhosis" are consumed by the many complications that arise from this condition such as ascites, hepatic encephalopathy, spontaneous bacterial peritonitis, esophageal variceal bleeding, and hepato-renal syndrome. Patients presenting with decompensated cirrhosis require hospitalization. Despite treatment, a patient's 1-year mortality risk increases to about 20% [38]. Hepatorenal syndrome (HRS) is the most severe complication of ESLD and is associated with a 2-week mortality risk of 80% in patients presenting with Type I [39], defined as the rapid deterioration of renal function in less than 2 weeks, with the serum creatinine doubling by >2.5 mg/dL or a 50% reduction in the 24-h creatinine clearance to <20 mL/min [40]. Common causes include systemic bacterial infections, paracentesis with significant volume loss, or bleeding. Type II also occurs in ESLD but its progression is much slower [40]. ESLD like other end organ failure conditions, have a very unpredictable disease trajectory, marked by periods of decompensation and return to baseline. For this reason, integrating palliative care early in the disease process is beneficial even if the patient is referred for transplantation. Patients referred for liver transplant have to deal with the stress and uncertainty of whether and when they would receive an organ. Currently, over 13,500 patients are on the waiting list, and 10,000 patients are removed from the list

annually, most commonly for death and for being "too sick" to transplant [1]. Because the number of candidates far exceeds the available donor organs, an allocation system was developed to prioritize those patients who are acutely ill and have a high mortality risk based on the MELD score. This model uses laboratory values of serum bilirubin and creatinine and international normalized ratio (INR) to predict a 3-month mortality in patients with ESLD; the higher the MELD score, the higher the mortality risk present [41].

In a study, Lamba et al. incorporated a palliative care approach into the care of liver transplant patients in the ICU and showed an increase in discussion of goals of care, resuscitation preferences, improved symptom management, and better communication with the family and among the physicians involved in the patient's care [42]. Patients with ESLD suffer from multiple physical, emotional, and psychological issues that have a profound negative impact on quality of life [43–45]. Among these are fatigue, insomnia, lethargy, and depression. The latter is associated with higher mortality rates among patients with cirrhosis awaiting a transplant [45]. For this reason, and the ones mentioned before, we must continue to work hard to integrate services that will help patients living with ESLD improve their quality of life by focusing on every aspect of the disease and its impact on the patient.

End-Stage Kidney Failure

There are 3.9 million patients living with kidney disease today, and annually more than 48,000 patients die from this condition making it the ninth leading cause of death in the USA [17]. Chronic kidney disease (CKD) is classified into five different stages. Stage 5 ESRD is defined as having a GFR <15 mL/min/1.73 m^2 [46]. There are multiple causes of CKD, but the most common are diabetes, hypertension, polycystic kidney disease, and irreversible drug-induced kidney injury. Like many other end organ failure conditions, the treatment options are limited. When a patient reaches end stage of the disease, the only treatments available are maintenance dialysis or kidney transplantation. For this reason, the Kidney Disease Outcomes Quality Initiative (KDOQI) [46] recommends that patients with a GFR <30 mL/min/1.73 m^2 should be educated about disease progression so that they and their families understand the options and avoid having to make decisions when the patient becomes cognitively impaired by uremic encephalopathy. Depending on quality of life and goals of care, the choices would include permanent access for dialysis, "preemptive kidney transplantation" (kidney transplantation prior to starting dialysis) or hospice.

Patients who are started on maintenance dialysis have been found to have a greater decline in their physical, mental, emotional, and social functioning as well as an annual 25% mortality risk compared to those who are not started on dialysis [47, 48]. Dialysis patients also experience a profound symptom burden, the most common being fatigue, pruritus, insomnia, depression, and pain [49–52]. Depression impacts quality of life and is associated with increased mortality risk among maintenance dialysis patients [53]. Other complications of renal failure, such as anemia, low albumin, poor nutritional status, and worsening co-morbidities, also negatively impact quality of life in dialysis patients [54–56]. Over 16,000 transplants are done annually. As is the case for other organs, the number of candidates exceeds the number of available kidneys suitable for transplant [1]. The median waiting time is between 2 and 4 years depending on the blood type and HLA typing [1]. Over 25,000 patients are removed from the waiting list annually for death of the patient (16%) or for the patient being too sick to transplant (8%) [1]. Preemptive kidney transplantation leads to a 25% reduction in graft failure and a 26% reduction in patient mortality as compared to patients who have been on maintenance dialysis before referral [57]. Patients undergoing kidney transplantation before the initiation of dialysis, a term referred as pre-emptive transplantation, has shown improvement in functional status and improved quality of life compared to those who are started on dialysis and undergo transplantation after [58]. Given the high symptom burden and quality of life issues in ESRD, nephrologists and palliative care specialists must work together to address patient and family needs and concerns so that medical decisions and treatments can be implemented appropriately.

Bone Marrow Transplantation

Hematopoietic stem cell transplantation was pioneered by E. Donall Thomas in 1957. Since then, its use has evolved beyond treatment for acute leukemia and aplastic anemia to include many other hematopoietic diseases and the number of transplants performed annually has continued to increase in number (Figs. 60.3 and 60.4) [59].

Transplantation may be autologous or allogenic (related and unrelated donors) and donor stem cells may be derived from bone marrow, umbilical cord, or peripheral blood. Nonmalignant and malignant blood disorders can qualify patients for transplantation (Figs. 60.3 and 60.4) [59]. Indications for transplantation in malignant blood disorders include failure of chemoradiation therapy and multiple relapses. Referral guidelines can be obtained at http://www.asbmt.org [60]. Patients who undergo bone marrow transplant (BMT) are prone to multiple complications. Before undergoing BMT, patients are given chemotherapy along with total body irradiation in order to destroy the residual marrow cells and allow for the transplant to "engraft". Post-transplant patients remain in the hospital for weeks to months to recover

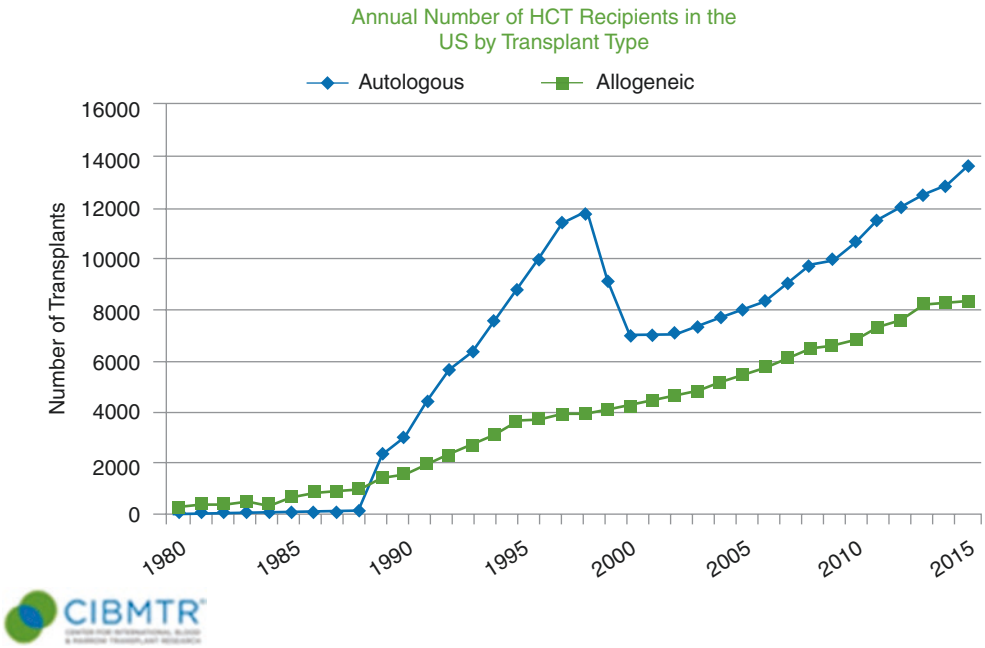

Fig. 60.3 Annual number of HCT recipients in the US by transplant type [59]. Reprinted from D'Souza and Zhu [59]

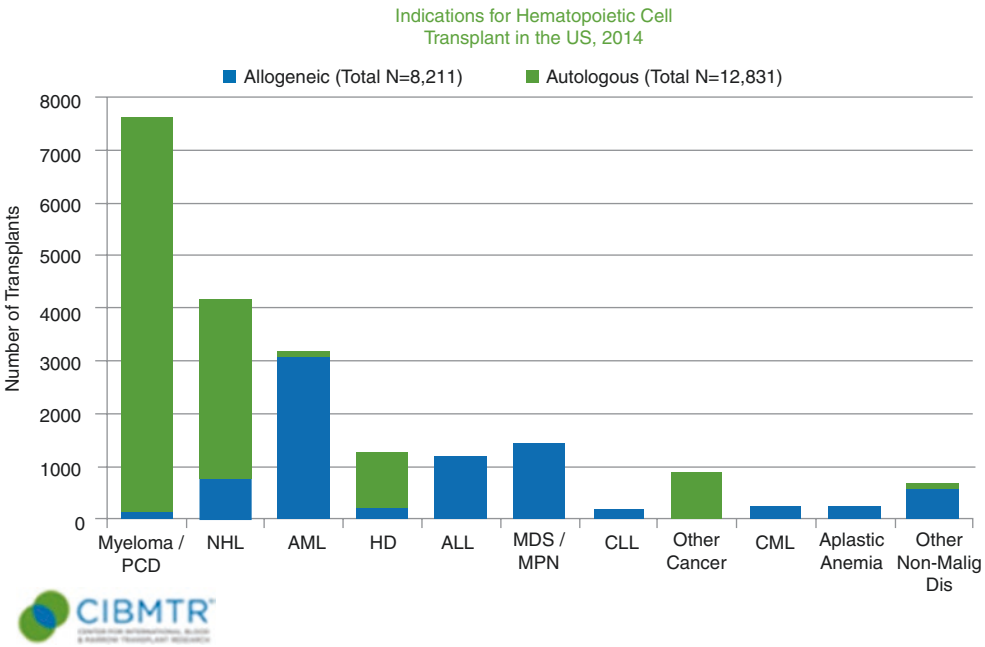

Fig. 60.4 Indications for hematopoietic cell transplant in the US, 2014 [59]. Reprinted from D'Souza and Zhu [59]

as they are susceptible to opportunistic infections. Common side effects due to chemotherapy and irradiation include mucositis, diarrhea, nausea, vomiting, loss of hair, infertility and organ toxicity. Patients are placed under strict isolation, which, in turn, can cause emotional distress. Osama et al. followed post-BMT patients for 1 year after transplant and found they suffered from severe psychological distress as a result of fear of cancer recurrence (68%) and development of new cancer (58%) as opposed to those who did not undergo transplant [61]. Patients also expressed high levels of depression, pain, and decreased coping skills post-transplant [61]. Patients suffer the most stress and fear of uncertainty during the period of initial hospitalization when enduring intensive therapy composed of chemotherapy, total body irradiation, patient isolation, and decreased physical activity [62, 63]. The level of anxiety, depression, anger, and uncertainty are greater at this time compared to any other [64]. Studies have shown that there is a significant emotional cost as a result of loss of per-

sonal control in the period prior to transplant and 1 year thereafter. Subsequently, sense of personal control improved, as did emotional symptoms [64, 65] El-Jawahri et al. (2016) demonstrated that inpatient integration of palliative care in this patient population leads to improvement in depression and PTSD symptoms at 6 months post-transplant [66].

Importance of Prognostication

Clinical prognostication involves "foreseeing", that is, formulating the prediction of a medical outcome, and "foretelling", that is, communicating the prediction to the patient [67]. Medical education focuses on the identification and treatment of disease and the return to health. While some patients may respond to treatment, there are many who do not, and the disease may progress even in those who are able to recover from an acute exacerbation. Studies show that patients want to know their prognosis in order to make informed decisions regarding the type of treatment they choose [68, 69]. All patients should complete a health-care proxy so that a health-care agent is identified if and when the patient loses the capacity to make decisions. The health-care agent is morally and legally bound to follow the patient's directives. For the minority of patients who do not want to know their prognosis, the health-care agent should be informed of the status, prognosis, and range of available treatment options so that they can make decisions that are based on the patient's known wishes, best interest, values, and principles. Physicians vary in their ability to "communicate bad news". This is a skill that is an essential part of medical school training but can be learned or improved at any point in a physician's career. Communication of prognosis is essential for patients who suffer from end-stage organ failure. While many patients are able to undergo transplantation, there are still a greater number of patients who succumb to their disease because they are not transplant candidates or do not survive to get a transplant. Patients often undergo a prolonged and painful death, involving uncomfortable, invasive and expensive care because of lack of communication between providers and the patient/family about realistic prognosis and goals when they could understand and make informed decisions about treatment options [70].

Many different prognostic tools have been developed to aid physicians in the task of formulating a prognosis. Tools commonly include the Karnofsky Performance Status (KPS), Palliative Performance Scale (PPS), the Palliative Prognostic Index (PPI), and the Palliative Prognostic Score (PaP). Palliative care consultation is often requested to help with communication of prognosis, goals of care, and advance directives, as the primary care physician often fails to initiate such discussions beforehand [71]. Prognosis for survival is not communicated as a specific amount of time, but rather as a timeframe that is meaningful to the patient and family, such as hours to days, days to weeks or weeks to months [72]. Physician surveys have indicated that among generalists and specialists, "professional norms of prognostication" are often followed which consist of providing limited information to patients and families because of uncertainty of the prediction, being optimistic, and not sharing prognosis/prediction unless asked. There is also a fear of being judged by the patient, family, or other clinicians if their prognostication is incorrect [73]. For this reason, communication of prognosis has become a core clinical skill for palliative care physicians.

Palliative Performance Scale (PPS)

The PPS is one of the most used tools available for clinicians to evaluate a patient's clinical status. It is based on ambulation, activity, self-care, intake, and level of consciousness. The scale ranges from 10% (totally bedbound, unable to do any activity, extensive disease, drowsy to comatose) to 100% (fully ambulatory, normal level of activity, no evidence of disease, fully conscious). A PPS of <50% generally represents loss of ability to perform activities of daily living independently [7]. This tool was modified from the KPS to include intake and level of consciousness, which the KPS does not take into account. This scale is not limited to cancer patients nor to end of life. It can be used in patients living with chronic illness who are experiencing progression of disease to assist in prognosticating survival. PPS cores have been used in cancer and non-cancer patients and across settings including hospital and nursing homes and correlate well with survival and symptom distress [74–77]. In a study involving Japanese patients admitted to a palliative care unit and stratified according to PPS, overall median survival was as follows: PPS 10–20%, median survival 6 days; PPS 30–50%, median survival 41 days; and PPS 60–70%, median survival of 108 days [78]. A similar correlation between PPS and survival was seen in a large community-based hospice center [77].

Prognosticating Survival in Non-cancer Patients

While there have been multiple tools developed to accurately prognosticate survival in cancer patients, these patients tend to undergo a more predictable decline compared to non-

cancer patients. Patients with chronic illnesses, such as those with end-stage organ failure, often suffer multiple periods of exacerbations followed by stabilization until finally culminating in death [8] (Fig. 60.2).

For this reason, formulating an accurate prognosis becomes a real challenge to the treating physician. In an emergency room study, physicians identified 17% of patients admitted with CHF exacerbation to have a 10% chance of surviving 90 days when, in fact, 67% did not survive [79]. Palliative care specialists are trained to assess the status and prognosis of patients with serious and chronic illness and to communicate this information in a compassionate way to patient and family so that they may make an informed decision with regard to options for care. One of these options is hospice, a Medicare and insurance benefit for patients who are not expected to survive more than 6 months given the natural history of the disease. Patients with end-stage organ failure who are on the list for organ transplantation are often denied the opportunity to have palliative care services because of the misconception that palliative care is equivalent to hospice care and end-of-life care. As noted previously, palliative care may be introduced into the care of patients with serious illness concurrent with curative attempts such as transplantation. This would provide improved symptom control as well as increased support for their emotional and spiritual needs.

The National Hospice and Palliative Care Organization (NHPCO) developed guidelines that can aid a physician in formulating a prognosis, when the disease has become far advanced, so that they may communicate with patients and families regarding realistic treatment goals at the end-of-life. According to the NHPCO: "A life-limiting condition with evidence of either disease progression and/or impaired nutritional status indicated by an involuntary weight loss greater than 10% of body weight in past 6 months. The goal of treatment should be relief of symptoms, not cure." [80] (Table 60.1).

Table 60.1 Guidelines for prognosis in selected non-cancer diseases [81]

Heart disease	Recurrent symptoms of heart failure or angina at rest, discomfort with any activity (NYHA IV) Patient already optimally treated with diuretics and vasodilators
Pulmonary disease	Disabling dyspnea at rest Progressive pulmonary disease (e.g. increasing emergency department visits of hospitalizations for pulmonary infections and/or respiratory failure) Hypoxemia at rest on supplemental oxygen O_2 $pO_2 \leq 55$ mmHg on supplemental O_2 O_2 sat $-\leq 88\%$ on supplemental O_2 or Hypercapnia: $pCO_2 \geq 50$ mmHg
Liver disease	End-stage cirrhosis; not a candidate for liver transplant PT > 5 s over control or INR > 1.5 and serum albumin < 2.5 g/dL At least one of the following: Ascites despite treatment Spontaneous peritonitis Hepatorenal syndrome Hepatic encephalopathy despite treatment Recurrent variceal bleeding
Renal disease	Chronic renal failure; coming off or not a candidate for dialysis Creatinine clearance <10 cc/min (for diabetics <15 cc/min) Serum creatinine >8.0 mg/dL (for diabetics >6.0 mg/dL) Signs and symptoms associated with renal failure Uremia: nausea, pruritus, confusion, or restlessness Oliguria: output <400 cc/24 h Intractable hyperkalemia serum >7.0 Uremic pericarditis Hepatorenal syndrome Intractable fluid overload

Symptom Management in Chronic Illness and the Role of Palliative Care

While the field of palliative medicine enhances the treatment of emotional, spiritual, and psychosocial suffering of patients with serious illness, it also focuses on pain and non-pain symptom management. By integrating palliative care along with curative care early in the disease trajectory, chronically ill patients nearing the end of life reported improved satisfaction with care and demonstrated fewer acute interventions [82]. Patients suffering from chronic illness have a longer life trajectory that is complicated by an intensifying symptom burden, which is similar to the symptoms experienced by cancer patients [83] (Table 60.2). The patient's illness progression and symptom burden can guide the clinician as to the best time to introduce palliative care, though one can argue that it is never too early, even if it is only to address goals of care, help establish advance directives, and most of all, serve as a bridge of communication between patient, families, and treating physicians.

Table 60.2 Symptoms common to malignant and non-malignant conditions [83]

Physical	Social	Psychosocial	Existential
Pain Breathlessness Anorexia Immobility Constipation	Loss of employment Role change Fear for dependants	Depression Fear and anxiety Uncertainty Guilt	Religious Nonreligious Meaning of life Why?

In a systematic review of symptom burden in end-stage organ failure, it was reported that daily symptom burden is likely to be high, irrespective of the underlying disease [84]. The most common symptoms experienced by patients with end-stage organ failure are fatigue, dyspnea, insomnia, and pain [84, 85]. Management of these symptoms must be specific to the underlying disease and patient, as response to and tolerance of medications varies.

End-of-Life Care for Transplant Patients

While palliative care addresses much more than end-of-life issues, primary care physicians and staff often consult the palliative care service to assist with the care of patients who are actively dying. As the disease progresses, symptoms increase and curative options (such as transplantation or re-transplantation) are exhausted, patients and families should receive the additional support they need. While it is recommended that goals of care (including end-of-life care) be discussed early in the disease trajectory or when patients are listed for organ transplantation, it is not often done because of both physician and patient barriers to these discussions. A study by Schickedanz et al. showed that discussions of end-of-life advance care planning were primarily impeded by the perception of irrelevance by the patient/family, lack of relationship between patient and family, patient's personal problems, and physician time constraints [86]. When end-of-life issues are addressed early, while the patient is still able to discuss his/her wishes and preferences, the patient's quality of life can improve [87, 88]. A study of bereaved family members demonstrated that they were satisfied with life-sustaining interventions but not with the lack of communication and pain control. Of the 461 patients studied, 46% of the discussions involved patients directly, 14% involved discussion with family members of a patient who lacked decision-making capacity, 6% involved discussion with the family of patient who had capacity, and 23% had no discussion at all [89]. Wright et al. suggest a number of strategies for initiating the topic of advance care planning at the end of life to help overcome many physicians' reticence due to lack of experience or fear (Table 60.3) [87].

Palliative care physicians must continue to work collaboratively with the primary care physicians and specialists involved in a patient's care in order to provide the patient with end-of-life plans that are acceptable and in keeping with their principles and values. When organ transplantation is no longer an option or if a patient is clearly dying despite prior transplantation, it is the palliative care physician's duty to communicate with patients and families about the option of death in hospice (in home or inpatient) surrounded by family and friends rather than in isolation on artificial life support.

Table 60.3 Strategies for Initiating conversation with patients about advance care planning for end of life [87]

Acknowledge emotions "Is talking about these issues difficult for you?"
Legitimize the feelings "Of course, talking about this makes you sad- it wouldn't be normal if it didn't"
Offer support "No matter what the road holds ahead. I'm going to be there with you"
Explore "You just mentioned feeling scared. Can you tell me more about what scares you the most?"
Hope for the best but prepare for the worst "Have you thought about what might happen if things don't go as you wish? Sometimes having a plan that prepares you for the worst makes it easier to focus on what you hope for the most" "I wish too that this transplant had lasted longer. If we cannot do another transplantation, what other short-term goals might we work toward?" "What sorts of things are left undone for you? Let's talk about how we might be able to make these happen"

Appendix

Karnofsky Performance Status

100	Normal, no complaints, no evidence of disease
90	Able to carry on normal activity, some minor symptoms of disease
80	Normal activity with effort: some symptoms of disease
70	Able to care for self but unable to carry on normal activity or active work
60	Requires occasional assistance but is able to care for most of personal needs
50	Requires considerable assistance and frequent medical care
40	Disabled: requires special care and assistance
30	Severely disabled: hospitalization is indicated, death not imminent
20	Very sick, hospitalization necessary: active treatment necessary
10	Moribund, fatal processes progressing rapidly
0	Death

Palliative Performance Scale (PPSv2) [87] Reprinted with permission from Victoria Hospice Society, BC, Canada (2001) www.victoriahospice.org

	Ambulation	Activity and evidence of disease	Self-Care	Intake	Conscious level
100%	Full	Normal activity and work. No evidence of disease	Full	Normal	Full
90%	Full	Normal activity and work. Some evidence of disease	Full	Normal	Full
80%	Full	Normal activity *with* effort. Some evidence of disease	Full	Normal or reduced	Full
70%	Reduced	Unable normal job/work. Significant disease	Full	Normal or reduced	Full
60%	Reduced	Unable hobby/house work. Significant disease	Occasional assistance necessary	Normal or reduced	Full or confusion
50%	Mainly sit/lie	Unable to do any work. Extensive disease	Considerable assistance required	Normal or reduced	Full or confusion
40%	Mainly in bed	Unable to do most activity. Extensive disease	Mainly assistance	Normal or reduced	Full or drowsy +/− confusion
30%	Totally bed bound	Unable to do any activity. Extensive disease	Total care	Normal or reduced	Full or drowsy +/− confusion
20%	Totally bed bound	Unable to do any activity. Extensive disease	Total care	Minimal to sips	Full or drowsy +/− confusion
10%	Totally bed bound	Unable to do any activity. Extensive disease	Total care	Mouth care only	Drowsy or coma +/− confusion
0%	Death	–	–	–	–

Instructions for Use of PPS (See also Definition of Terms)

1. PPS scores are determined by reading horizontally at each level to find a "best fit" for the patient which is then assigned as the PPS% score.
2. Begin at the left column and read downwards until the appropriate ambulation level is reached, then read across to the next column and downwards again until the activity/evidence of disease is located. These steps are repeated until all five columns are covered before assigning the actual PPS for that patient. In this way, "leftward" columns (columns to the left of any specific column) are "stronger" determinants and generally take precedence over others.

   Example 1: A patient who spends the majority of the day sitting or lying down due to fatigue from advanced disease and requires considerable assistance to walk even for short distances but who is otherwise fully conscious level with good intake would be scored at PPS 50%.

   Example 2: A patient who has become paralyzed and quadriplegic requiring total care would be PPS 30%. Although this patient may be placed in a wheelchair (and perhaps seem initially to be at 50%), the score is 30% because he or she would be otherwise totally bed bound due to the disease or complication if it were not for caregivers providing total care including lift/transfer. The patient may have normal intake and full conscious level. Example 3: However, if the patient in example 2 was paraplegic and bed bound but still able to do some self-care such as feed themselves, then the PPS would be higher at 40 or 50% since he or she is not "total care".
3. PPS scores are in 10% increments only. Sometimes, there are several columns easily placed at one level but one or two which seem better at a higher or lower level. One then needs to make a "best fit" decision. Choosing a

"half-fit" value of PPS 45%, for example, is not correct. The combination of clinical judgment and "leftward precedence" is used to determine whether 40 or 50% is the more accurate score for that patient.

4. PPS may be used for several purposes. First, it is an excellent communication tool for quickly describing a patient's current functional level. Second, it may have value in criteria for workload assessment or other measurements and comparisons. Finally, it appears to have prognostic value.

Definition of Terms for PPS

As noted below, some of the terms have similar meanings with the differences being more readily apparent as one reads horizontally across each row to find an overall "best fit" using all five columns.

1. *Ambulation*
   The items *mainly sit/lie*, *mainly in bed*, and *totally bed bound* are clearly similar. The subtle differences are related to items in the self-care column. For example, "totally bed 'bound' at PPS 30% is due to either profound weakness or paralysis such that the patient not only can't get out of bed but is also unable to do any self-care. The difference between 'sit/lie' and 'bed' is proportionate to the amount of time the patient is able to sit up vs need to lie down."

   Reduced ambulation is located at the PPS 70% and PPS 60% level. By using the adjacent column, the reduction of ambulation is tied to inability to carry out their normal job, work occupation or some hobbies or housework activities. The person is still able to walk and transfer on their own but at PPS 60% needs occasional assistance.
2. *Activity and Extent of disease*
   Some, *significant*, and *extensive* disease refer to physical and investigative evidence which shows degrees of progression. For example in breast cancer, a local recurrence would imply "some" disease; one or two metastases in the lung or bone would imply "significant" disease, whereas multiple metastases in the lung, bone, liver, brain, hypercalcemia, or other major complications would be "extensive" disease. The extent may also refer to progression of disease despite active treatments. Using PPS in AIDS, "some" may mean the shift from HIV to AIDS, and "significant" implies progression in physical decline, new or difficult symptoms, and laboratory findings with low counts. "Extensive" refers to one or more serious complications with or without continuation of active antiretrovirals, antibiotics, etc.

   The above extent of disease is also judged in context with the ability to maintain one's work and hobbies or activities. Decline in activity may mean the person still plays golf but reduces from playing 18 holes to 9 holes, or just a par 3, or to backyard putting. People who enjoy walking will gradually reduce the distance covered, although they may continue trying, sometimes even close to death (e.g., trying to walk the halls).
3. *Self-Care*
   Occasional assistance means that most of the time patients are able to transfer out of bed, walk, wash, go to toilet, and eat by their own means but that on occasion (perhaps once daily or a few times weekly) they require minor assistance.

   Considerable assistance means that regularly every day, the patient needs help, usually by one person, to do some of the activities noted above. For example, the person needs help to get to the bathroom but is then able to brush his or her teeth or wash at least hands and face. Food will often need to be cut into edible sizes but the patient is then able to eat of his or her own accord.

   Mainly assistance is a further extension of "considerable." Using the above example, the patient now needs help getting up but also needs assistance washing his face and shaving, but can usually eat with minimal or no help. This may fluctuate according to fatigue during the day.

   Total care means that the patient is completely unable to eat without help, go to toilet, or do any self-care. Depending on the clinical situation, the patient may or may not be able to chew and swallow food once prepared and fed to him or her.
4. *Intake*
   Changes in intake are quite obvious with *normal intake* referring to the person's usual eating habits while healthy. *Reduced* means any reduction from that and is highly variable according to the unique individual circumstances. *Minimal* refers to very small amounts, usually pureed or liquid, which are well below nutritional sustenance.
5. *Conscious Level*
   Full consciousness implies full alertness and orientation with good cognitive abilities in various domains of thinking, memory, etc. *Confusion* is used to denote presence of either delirium or dementia and is a reduced level of consciousness. It may be mild, moderate or severe with multiple possible etiologies. *Drowsiness* implies either fatigue, drug side effects, delirium, or closeness to death and is sometimes included in the term stupor. *Coma* in this context is the absence of response to verbal or physical stimuli; some reflexes may or may not remain. The depth of coma may fluctuate throughout a 24-h period.

replaces the first PPS published in 1996 [J Pall Care 9(4): 26-32]. It cannot be altered or used in any way other than as intended and described here. Programs may use PPSv2 with appropriate recognition. Available in electronic Word format by email request to edu.hospice@viha.ca

Part VI

Infection Prevention

Infection Control Strategies in Transplant Populations

61

S. Cutro, M. Phillips, and H. W. Horowitz

Introduction

The immunocompromised host presents both routine and unique challenges from an infection control and prevention perspective. Cell-mediated and humoral immune deficiencies in the pre-transplant and post-transplant periods lead to increased susceptibility to a wide variety of viral, bacterial, parasitic, and fungal pathogens: some endogenous and others originating from the host's environment. Innate immune defects including severe neutropenia during the pre-engraftment period and secondary graft loss due to cancer recurrence, drug toxicity, or myelosuppressive viral opportunistic infections are also of significant concern in transplant patients. The "net state of immunosuppression" is helpful in stratifying patients' risk for developing infections and is determined in large part by the nature of the immune suppression employed. However, environmental factors, preexisting immune deficits, metabolic derangements, and antimicrobial exposure all play a role in determining the risk for infection [1]. The use of prophylactic antimicrobials, including antibacterial, antiviral, antiparasitic, and antifungal agents, has led to a reduction in all-cause mortality, infection-related mortality, and risk of clinically and microbiologically documented infections [2–4]. However, despite prophylaxis, infections remain a significant threat in this patient population.

Autologous and allogeneic stem cell transplant (SCT) recipients carry the greatest risk for post-transplant infection, with anywhere from 35% to 100% of adult SCT recipients developing infections after transplant [5, 6]. Infection-related mortality among SCT recipients ranges from 5% to 33% and is the leading cause of death in 8% of autologous and 17–20% of allogeneic SCT recipients. This difference is due in large part to greater immune suppression employed in allogeneic transplantation versus autologous transplantation [6, 7]. Among solid organ transplant (SOT) recipients, infectious complications are also of significant concern, with bacterial infections occurring in 33–68% of liver, 21–30% of heart, 35% of pancreas, 47% of kidney, and 54% of lung transplant recipients [8]. Cytomegalovirus (CMV) infection occurs in 44–85% of kidney, heart, and liver transplant recipients, while varicella-zoster virus (VZV) reactivation occurs in 5–13% of SOT recipients [8]. Systemic fungal infection occurs in 5–17% of heart, 14–22% of heart-lung, 2–42% of liver, and 2–14% of kidney transplant recipients [8]. In the SOT population, infection is the leading cause of death among patients receiving lung, intestine, and liver transplants [9, 10].

A temporal relationship exists between the development of particular infections and the time of transplantation and engraftment as outlined in Table 61.1. This chapter considers potentially preventable infections using infection control practice in the context of time from transplantation/engraftment and focuses specifically on the most common infections that transplant patients are at risk to develop during the various stages of transplantation: pre-transplant period, early post-solid organ transplant/pre-engraftment period, intermediate post-solid organ transplant/early post-engraftment period, and late post-solid organ transplant/late post-engraftment period. Antimicrobial prophylaxis and pre−/post-transplant vaccinations are discussed elsewhere in this book and are beyond the scope of this chapter.

Table 61.1 Common pathogens in transplant patients based on time relative to transplant/engraftment and type of transplant [7, 88, 89]

SOT	*Timeframe*	Pre-transplant	Early post-transplant (<1 month)	Intermediate post-transplant (1–6 months)	Late post-transplant (>6 months)
	Pathogens	Typical community organisms if no recent healthcare exposures Nosocomial pathogens if recent healthcare exposures Endemic infections	Gram-positive organisms (including MRSA and VRE) *C. difficile* *Aspergillus*, *Candida*	*Listeria*, *Nocardia* HSV, CMV, HBV, HCV, EBV, BK virus *Toxoplasma*, *Strongyloides*, *PCP*, *TB*, *Leishmania*	Typical community organisms CMV *Aspergillus*, dermatophytes
SCT	*Timeframe*	Pre-transplant	Pre-engraftment (15–45 days post-transplant)	Early post-engraftment (30–100 days post-transplant)	Late post-engraftment (>100 days post-transplant)
	Pathogens	Typical community organisms if no recent healthcare exposures Nosocomial pathogens if recent healthcare exposures Endemic infections	Gram-negative rods, gram-positive organisms, gastrointestinal *Streptococcus* spp. HSV, respiratory and enteric viruses *Aspergillus*, *Candida*	Gram-positive organisms, gram-negative rods (lower frequency), gastrointestinal *Streptococcus* spp. HSV, CMV, HHV, EBV, respiratory/enteric viruses *Aspergillus*, *Candida*, PCP	Encapsulated bacteria HSV, VZV, HHV, EBV, respiratory and enteric viruses *Aspergillus*, PCP

SOT solid organ transplantation, *SCT* stem cell transplantation

While there are many unique infection control and prevention considerations in this patient population, standard hand hygiene, disinfection of medical equipment and surfaces in patient rooms, and isolation precautions should be applied to transplant patients per established guidelines [11–13]. Some hospitals may choose to place all transplant recipients on isolation precautions even in the absence of active infection or colonization with organisms of interest. However, evidence-based guidelines to support this approach do not exist, and studies to determine the most effective isolation precaution strategies in immune compromised patients are needed. Infection control and prevention practices should be implemented to prevent device-related infections such as central line-associated bloodstream infection (CLABSI), catheter-associated urinary tract infection (CAUTI), and ventilator-associated pneumonia (VAP). Routine hand hygiene and use of antiseptic handwash/rub should be stressed as in non-transplant populations [14]. Standard perioperative antimicrobial prophylaxis should be used and other recommended procedures and processes should be followed to minimize surgical site infections [15].

Pre-transplant Period

The home and work environments are the primary sources of infection that clinicians and transplant candidates must consider during the pre-transplant period. Community-acquired organisms, colonization with nosocomial pathogens due to recent healthcare exposure, and exposures to environmentally endemic pathogens are all of great concern during this period. Clinicians should identify and treat active infections, review available microbiological data for previous infection/colonization with methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE), and multidrug resistant (MDR) gram-negative rods, and screen candidates for the presence of latent infections that may reactivate with subsequent immune suppression. Understanding previous infection/colonization history is important in order to risk-stratify patients for post-transplant prophylaxis and to help guide future empiric antimicrobial therapy decisions. Clinicians should counsel transplant candidates to avoid certain environmental situations that may predispose them to infections [16]. Some daily activities such as gardening, pigeon rearing, farming, drinking well water, spelunking, potholing, and traveling may expose patients to endemic bacterial, fungal, and parasitic organisms that manifest in severe infection after transplantation. Serologic testing for Chagas disease, *Coccidioides*, *Histoplasma*, *Cryptococcus* spp., *Strongyloides stercoralis*, *Schistosoma* spp., and human T-lymphotropic virus (HTLV) 1/2 should be considered based upon initial risk factor assessment for potential exposure and therefore at-risk individuals [17, 18].

A complete medical history, including country of origin, travel history (both within and outside of the United States), pet exposure, risk factors for tuberculosis (TB), family history, work history, and social history should be obtained. History of recent/prior hospitalizations also should be obtained, with a particular focus on any infections and the name/type of antimicrobials received. For both SCT and SOT candidates, serologic screening for herpes simplex virus (HSV), VZV, CMV, human immunodeficiency virus (HIV), hepatitis B virus (HBV), hepatitis C virus (HCV), Epstein-Barr virus (EBV), and *Toxoplasma gondii* are recommended [7, 19, 20]. Potential SCT donors are also screened for potentially communicable diseases in accordance with published guidelines, and this topic is covered elsewhere in this book [21].

Table 61.2 High-risk foods that should be avoided in transplant recipients, with pathogens of concern and acceptable alternatives [7, 90–92]

Food group	Unacceptable foods	Pathogens of concern	Acceptable alternatives
Dairy	Nonpasteurized or raw milk Cheeses containing uncooked vegetables Cheeses with molds (Bleu, Stilton, Roquefort, gorgonzola)	*Listeria monocytogenes* *Salmonella enteritidis* *E. coli*	Pasteurized milk and milk products Commercially packaged hard and semisoft cheeses (cheddar, mozzarella, etc.)
Meat	Raw or undercooked meat, poultry, fish, game, tofu Raw or undercooked eggs, nonpasteurized egg substitutes (including certain preparations of hollandaise sauce and Caesar dressing) Raw or undercooked seafood Deli-style ready-to-eat meats and poultry Uncooked hot dogs or sausage Uncooked smoked seafood (salmon/lox) Tempeh products	*E. coli* O157:H7 *Salmonella enteritidis* *Campylobacter jejuni* *Clostridium perfringens* *Toxoplasma gondii* *Vibrio* spp. *Listeria monocytogenes*	Well-done meats, cooked to safe minimum cooking temperatures Eggs cooked until both white and yolk are firm Canned meats Pasteurized eggs and egg substitutes Cooked hot dogs or sausage Refrigerated smoked seafood if cooked to 160°F
Fruits and nuts	Unwashed raw fruits Nonpasteurized fruit and vegetable juices Fresh fruit salsas Unroasted raw nuts or nuts in shells	*E. coli* O157:H7 *Salmonella enteritidis* Norovirus Hepatitis A virus *Shigella* *Cryptosporidium* *Giardia*	Well-washed raw and frozen fruit Cooked, canned, and frozen fruit Pasteurized juices and frozen juice concentrates Dried fruits Canned or bottled roasted nuts Commercially packaged nut butters
Vegetables and soups	Unwashed raw vegetables or herbs Fresh nonpasteurized vegetable salsa Raw vegetable sprouts (alfalfa, clover, etc.) Salads Miso products (soups, paste)	*E. coli* O157:H7 *Salmonella enteritidis* Norovirus Hepatitis A virus *Shigella* *Cryptosporidium* *Giardia*	Well-washed raw and frozen vegetables Cooked fresh/frozen/canned vegetables Shelf-stable bottled salsa Cooked vegetable sprouts Fresh, well-washed herbs and dry herbs used in cooked foods
Others	Raw honey	*Clostridium botulinum*	Commercial “Grade A” honey

Originally published in Cutro et al. [92]

Clinicians should also screen transplant candidates for latent tuberculosis infection (LTBI) using an interferon gamma release assay (IGRA) or tuberculin skin test (TST). TB incidence among SOT recipients in non-endemic countries ranges from 1.2% to 6.4% and most commonly occurs within the first year after transplantation, while the incidence of TB in SCT recipients in the United States ranges from 0.0014% to 3% [22–24]. In SOT candidates, pre-transplant treatment of LTBI has been shown to decrease the risk of reactivation to 0% and therefore should be strongly considered [23]. TST is often unreliable in immunosuppressed patients and may underestimate the prevalence of LTBI in these high-risk patients. IGRAs tend to have increased sensitivity in immunosuppressed patients but can generate frequent “indeterminate” results in this population, especially among patients with end-stage liver disease, high Model for End-Stage Liver Disease (MELD) scores, and end-stage renal disease [23, 25, 26]. In patients from TB-endemic regions, combination testing using TST and IGRA can be considered.

Primary infection with and reactivation of CMV are of great concern in transplant populations, especially in SCT recipients. In addition to serologic screening for CMV, SCT candidates should avoid sharing cups, glasses, and eating utensils with others and should use latex condoms with new sexual partners or known partners that are CMV-serodiscordant to decrease the risk of CMV transmission [7, 27]. Similarly, candidates should avoid contact with oral and genital HSV lesions during the pre-transplant period, especially among candidates with no serologic evidence of HSV 1 or 2. Transplant candidates should also avoid contact with persons who developed a post-vaccination rash after receiving varicella/zoster vaccines until resolution of the rash/skin lesions [27]. Avoidance of areas of high dust exposure such as construction sites, chicken coops, caves, and activities that disturb soil is recommended in the pre-transplant period [27, 28]. Certain high-risk foods, including raw fruits and vegetables, shellfish, and undercooked meats, should be avoided. Some of these high-risk foods, with pathogens of concern, and acceptable alternatives are outlined in Table 61.2.

Early Post-Solid Organ Transplant (<1 Month)/Pre-engraftment (Days 15–45 Post-SCT) Period

Early infections in transplant recipients arise almost exclusively in the hospital setting and are most often attributed to surgical complications, compromise of normal mucosal barriers, the presence of invasive devices such as central venous

catheters (CVCs), environmental exposures within the hospital, and/or ill healthcare workers (HCWs) or visitors. During this period, bacterial pathogens (including MRSA, VRE, gram-negative rods, and *Clostridium difficile*), viruses, and fungal species (*Aspergillus* and *Candida*) are of greatest concern for SOT and SCT patients (Table 61.1).

Hospital Exposures and Healthcare Workers

This period typically represents the first extensive exposure to HCWs and the hospital environment for transplant recipients, so targeting potentially preventable infections is critical. Hospitals should enact a comprehensive vaccination policy that adheres to Centers for Disease Control and Prevention (CDC)/Advisory Committee on Immunization Practices (ACIP)/Healthcare Infection Control Practices Advisory Committee (HICPAC) recommendations to decrease the transmission of infectious diseases from HCWs to patients [29]. Ideally, HCWs should receive inactivated vaccines instead of live vaccines to minimize the risk of transmission of vaccine virus to transplant recipients. Although transmission of live attenuated influenza virus from intranasal influenza vaccine has not been reported in healthcare settings, this vaccine is contraindicated for HCWs caring for transplant recipients. HCWs who receive this vaccine inadvertently should avoid contact with transplant recipients, although the duration of avoidance has not been determined [29]. Vaccine-strain poliovirus in oral polio vaccine (OPV) can be transmitted from person-to-person. Therefore, OPV administration is contraindicated for HCWs caring for transplant recipients as well as household contacts of transplant recipients. If OPV is inadvertently administered, the vaccine recipient should avoid contact with transplant recipients for 4–6 weeks [30]. HCWs, family members, close contacts, and visitors who do not have a documented history of varicella infection or who are seronegative should receive varicella vaccine before being allowed to visit or have direct contact with a transplant recipient, and vaccination should be completed at least 4 weeks prior to commencement of the transplant process [30].

In accordance with published guidelines, every effort should be made to restrict/minimize direct patient contact between HCWs with potentially transmissible infections and transplant candidates/recipients [31]. Hospitals should also develop screening policies for visitors to transplant units, especially during respiratory virus season, to reduce exposure to pathogens such as influenza and respiratory syncytial virus (RSV). While these respiratory viruses are primarily transmitted via respiratory droplets, dispersion by airborne droplets is possible under certain circumstances [32, 33]. Visitors and HCWs with infectious symptoms or with recent exposure to communicable infections should avoid direct contact with transplant candidates/recipients [34]. While guidelines exist for organisms and syndromes that require droplet isolation precautions, some transplant centers choose to place all transplant recipients on droplet isolation precautions during respiratory virus season [11].

Screening for Carriage of Bacterial Pathogens

There is insufficient evidence to recommend routine MRSA screening of all transplant recipients and insufficient evidence to support decolonization of these patients [7]. However, routine surveillance cultures can be considered in certain settings such as intensive care units to help reduce the incidence of MRSA infections [35]. A study of liver transplant recipients and candidates found that patients colonized with MRSA were more likely to develop subsequent MRSA infection, while those colonized with VRE had an increased risk of subsequent VRE infection and death [36]. At another liver transplant center, implementation of a multi-faceted infection control protocol, which included active surveillance for MRSA, contact precautions for those colonized with MRSA, cohorting patients with culture-positive MRSA, and nasal decolonization of those colonized with MRSA, led to decreased rates of new MRSA nasal carriage and decreased rates of *Staphylococcus aureus* infection and bacteremia [37]. Extended-spectrum β-lactamase (ESBL)-producing organisms and carbapenem-resistant *Enterobacteriaceae* (CRE) and *Acinetobacter* spp. present significant challenges for transplant patients, and asymptomatic carriage of these organisms has been associated with subsequent infection [38, 39]. Importantly, it has been reported that transplant recipients colonized with ESBL/CRE organisms may introduce these organisms into hospital settings, presenting an ongoing challenge for hospital-wide infection control departments [38, 39]. While active surveillance of MRSA, VRE, and other MDR organisms may be considered, no current guidelines support this approach in transplant populations.

Isolation Precautions

Likewise, no transplant-specific evidence-based guidelines exist regarding initiation and discontinuation of isolation precautions. Until additional studies are performed in this patient population, adherence to HICPAC guidelines for isolation precautions is recommended [11, 13]. At some transplant centers, patients with a history of VRE infection/colonization are presumptively placed on contact isolation precautions during subsequent hospital admissions. Although there are insufficient data to guide discontinuation of contact precautions in these patients, individual transplant centers may

implement local criteria for discontinuation of these precautions [7, 11, 13, 40]. Interestingly, the results of a 2008 survey of European SCT centers showed significant variability in the nature and level of isolation precautions implemented at individual centers. This variability reiterates the need for additional studies on which to base the development of guidelines for severely immunocompromised populations [41]. Readmitted patients with a history of MRSA, VRE, or MDR/CRE infection/colonization represent a challenge to clinicians and infection control practitioners alike, given the potential long-term carriage of resistant organisms among these patients. Unfortunately, the exact duration of carriage of these organisms has not been adequately studied in transplant patients. Data do exist, however, regarding carriage following hospital discharge in the general population. One study found MRSA carriage can persist on average 566 days in patients readmitted at least once and longer persistence is associated with a greater number of colonized anatomical sites [42]. Among discharged patients found to have VRE colonization, median duration of VRE culture positivity from time of discharge was found to be 5.57 weeks [43]. The risk of prolonged carriage was increased if patients received inpatient antibiotics, surgery, or dialysis, and if patients were discharged to a nursing home [43]. For CRE, prior fluoroquinolone use, history of inter-facility transfer, and time interval ≤3months from last positive CRE screen were associated with a greater probability of positive CRE screen on readmission. Persistence of CRE carriage was on average 387 days following hospital discharge, with 78, 65, and 39% of patients retaining CRE carriage at 3, 6, and 12 months, respectively [44, 45]. Because transplant recipients may have longer carriage periods for these organisms, hospitals may consider placing all patients with a history of infection/colonization with MRSA, VRE, or MDR/CRE on contact isolation precautions should they be readmitted to the hospital [40].

Protective Environment Rooms and Hospital Facilities Management

Despite an absence of robust data, use of a protective environment (PE) room is recommended for allogeneic SCT recipients, and can also be considered in patients with profound immunosuppression including autologous SCT recipients, those with prolonged neutropenia, and during episodes of graft-versus-host disease (GVHD) [7, 34, 46]. Allogeneic SCT recipients should ideally be placed in a PE room that includes: ≥12 air exchanges per hour, central or point-of-use high-efficiency particulate air (HEPA) filters (with 99.97% efficiency for removing particles ≥0.3 μm in diameter), directed air flow so that air intake occurs at one side of the room and exhaust occurs at the opposite end, consistent positive air pressure differential between the patient's room and hallway >0.19 mmHg, well-sealed rooms, continuous pressure monitoring, and self-closing doors to maintain constant pressure differentials [34]. Laminar air flow rooms have been used in the past, but aside from some benefit in reducing cases of *Aspergillus* linked to construction, they are not routinely recommended for SCT recipients [28, 47]. Scrupulous maintenance of air supply systems is critical. The hospital facilities department should ensure that filter banks are inspected and routinely changed, water incursion into heating, ventilation, and air conditioning (HVAC) ducts is prevented, and air intakes into the system are kept free of conditions which may result in patient exposure to environmental pathogens (e.g., birds' nests containing *Cryptococcus* spp.). Backup electrical and ventilation systems should be in place for transplant units during emergencies and scheduled downtimes. Anterooms are optional except in the case of SCT recipients requiring airborne precautions for infections such as TB, measles, varicella, or disseminated zoster [34]. Fresh, cut, or potted flowers/plants should not be permitted in PE rooms due to the risk of acquiring infection due to *Aspergillus* spp. and water-borne bacteria that colonize plants [28, 48, 49]. The necessity of PE rooms for allogeneic SCT recipients and other severely immunocompromised hosts is becoming increasingly controversial, and several studies have suggested that morbidity and mortality are not significantly different between patients who were placed in PE rooms and those who were either discharged to their home environments or who did not utilize PE rooms in the hospital setting [50–53]. Further studies should help to elucidate the optimal timing of and nature of isolation precautions for SCT recipients and the role of PE rooms [46].

During hospital construction/renovation, an infection control risk assessment (ICRA) should be performed for each construction site. The ICRA should specify the appropriate environmental controls enacted to minimize dust generation and reduce the risk of fungal dispersion [54]. In addition to routine inspections to ensure the measures outlined in the ICRA are followed, infection control personnel should ensure patients in the vicinity of the construction site are placed in rooms which minimize risk; the use of negative pressure/airborne isolation rooms is avoided unless indicated by the patient's condition [55]. Transplant recipients should avoid construction areas in the hospital if possible and should wear an N95 respirator or a powered air-purifying respirator (PAPR) when being transported outside of the PE room if they are unable to avoid these areas [28]. However, it should be noted that neither of these methods has been specifically tested and proven to decrease the risk of *Aspergillus* infection in this patient population [27, 34]. Surgical masks do not protect patients from airborne particles and their efficacy in preventing exposure to environmental mold spores is unknown. Floor surfaces in SCT units should be smooth and non-porous to facilitate cleaning/disinfection. Furthermore, carpeting and

other materials that may harbor mold must be avoided in transplant units. Daily wet dusting of horizontal surfaces using cloths moistened with hospital disinfectant/detergents should be performed in transplant units and cleaning methods that disperse dust should be avoided.

Avoidance of Central Line-Associated Bloodstream Infections

Because of the high utilization of CVCs in transplant patients due to the frequent need for total parenteral nutrition, maintenance of reliable intravenous access, and infusion-related complications when using peripheral catheters, adherence to evidence-based guidelines for preventing CLABSI is crucial [56, 57]. The CLABSI rate (infections per 1000 central line days) for SCT recipients ranges from 2.5 for permanent catheters to 3.0 for temporary catheters, while the infection rate ranges from 0.3 for permanent catheters to 1.2 for temporary catheters in SOT recipients [57]. In comparison, CLABSI rates in general medical or medical/surgical floors range from 0.9 to 1.4 [57]. If implementation of standard practices such as "bundles" during CVC insertion is not effective in reducing the infection rate or if the CLABSI rate is >1, the use of CVCs impregnated with either chlorhexidine/silver sulfadiazine or minocycline/rifampin can be considered [56]. In one study of cancer patients, the use of minocycline/rifampin-impregnated catheters led to a CLABSI rate of 0.25 compared to patients with non-impregnated catheters who had a rate of 1.28 [58]. Another study among patients receiving chemotherapy followed by SCT demonstrated that chlorhexidine/silver sulfadiazine-impregnated CVCs had decreased catheter colonization and a nonstatistically significant trend toward decreased bloodstream infections as compared to non-impregnated CVCs [59]. Utilization of chlorhexidine/silver sulfadiazine-impregnated CVCs has also led to decreased bacterial colonization of catheters and concomitant infections in SOT recipients [60]. While antibiotic lock therapy may be an encouraging approach for line salvage, it is not currently recommended for routine prophylaxis in transplant populations [7]. Although not specifically studied in the transplant population, chlorhexidine-impregnated dressings/sponges at the CVC insertion site should be considered in transplant patients, as they have proven effective in reducing the incidence of CLABSIs and exit-site/tunnel infections among non-transplant recipients with CVCs [61, 62]. Practices to minimize the risk of contamination of CVCs during use, such as disinfection of IV valve devices whenever IV tubing is connected, routine replacement of IV valves, use of alcohol-impregnated caps and scheduled changes of IV tubing must be standardized and rigorously followed. Most importantly, as in all patients, the CVC should be removed as soon as clinically feasible.

Respiratory Viruses

Nosocomial transmission of respiratory viruses has been well-reported [63]. SOT and SCT recipients are at higher risk for developing significant complications related to exposure to respiratory viruses including influenza, RSV, adenovirus, parainfluenza, and human metapneumovirus [64, 65]. Exposure prevention is a key component in reducing the risk for respiratory virus illness in transplant patients because many of these viruses have no treatment options other than supportive care. HCWs and visitors with upper respiratory tract infection (URI) symptoms must avoid contact with SOT and SCT recipients. Active surveillance for URI signs/symptoms should be performed daily in all transplant recipients and their visitors during respiratory virus season [27]. If URI signs/symptoms are present, the patient should be placed on droplet and contact precautions until the precise infectious etiology of signs/symptoms is determined using rapid molecular-based technologies if available [11, 27]. Future studies in transplant patients are needed to define optimal isolation precautions for respiratory viruses owing to the potential for airborne transmission of these viruses [32, 33]. Immunocompromised patients may shed respiratory viruses for weeks to months after initial infection. Therefore, continuing isolation precautions for the duration of the hospitalization should be considered during respiratory virus season [66]. Because pre-engraftment SCT recipients carry the greatest risk of developing severe RSV pneumonia, early diagnosis and treatment are critical when URI symptoms are present in this population. Among SOT recipients, especially lung and renal transplant recipients, influenza infection has been associated with a greater risk of acute transplant rejection [66]. The risk of influenza is highest among lung transplant recipients (41.8 cases/1000 person-years), followed by liver transplant recipients (4.3 cases/1000 person-years), and renal transplant recipients (2.8 cases/1000 person-years) [66]. HCWs, family members, and other close contacts with transplant recipients, should receive seasonal influenza vaccination. If the vaccine is received during an outbreak, antiviral chemoprophylaxis for 2 weeks can be considered for these close contacts of transplant recipients until an appropriate vaccine response is achieved. In the setting of an institutional influenza outbreak, antiviral chemoprophylaxis is recommended for transplant patients in accordance with CDC/ACIP guidelines [67].

Gastrointestinal Infections

Transplant recipients experiencing symptoms consistent with gastrointestinal infection, including nausea, vomiting, and diarrhea, must be considered infectious until an alternative explanation for these symptoms is identified. Prolonged

viral shedding of norovirus and other viruses has been reported in transplant recipients even when gastrointestinal symptoms have resolved, therefore, we advocate symptom-based instead of laboratory-based initiation of isolation precautions in these patients [68–71]. While norovirus, rotavirus, and astrovirus have been associated with outbreaks in transplant populations, making a laboratory-based diagnosis is often challenging. The advent of newer molecular techniques for GI pathogen detection offers the promise of improved differentiation between infectious and non-infectious causes of diarrhea; however, their use in transplant recipients has been limited. Due to prolonged and varied viral shedding in transplant recipients, hospitals may consider initiating contact isolation precautions among patients who have a history of gastrointestinal infection if they are readmitted to the hospital even in the absence of gastrointestinal symptoms at the time of readmission.

Varicella Zoster Virus

While VZV is more commonly seen in the late post-transplant period, clinicians must remain vigilant during the early post-transplant period because VZV infection during this period frequently presents as disseminated disease, capable of airborne spread and transmission to susceptible patients and hospital staff [11]. Contact and airborne precautions for VZV should be continued until all lesions are dried and crusted over. Transplant recipients with potential VZV exposure while in the hospital, including being in an enclosed air space with a contagious source patient or having close contact with a contagious source patient in an open area, should be placed on airborne precautions from days 8 to 21 after exposure unless the patient has been given varicella zoster immunoglobulin (VZIG) or acyclovir postexposure chemoprophylaxis, in which case airborne precautions should continue from days 8 to 28 after exposure [11, 72].

Institutional Food and Beverages

Food and beverages consumed in the hospital setting are also potential sources for infection in transplant recipients. Efforts to serve "sterile" food have been unsuccessful, due in large part to lack of palatability of the food [73]. "Low-bacteria" or "neutropenic diets," with highly variable definitions in the literature and in practice, have been used at many institutions. However, data are not convincing that these diets lead to fewer infectious complications and improved clinical outcomes. In fact, one study found a higher rate of infections in transplant recipients who received a "neutropenic diet" as compared to those receiving a general diet [74]. Institutional food handling should adhere to federal, state, and local regulations. Several published guidelines describe safe and unsafe foods for SCT and SOT recipients, and these recommendations are outlined in Table 61.2 [7, 10, 27, 75]. Given the risk of cryptosporidiosis, SCT and SOT recipients should avoid tap water during the early post-transplant period and should only drink bottled water that has been processed to remove *Cryptosporidium* by reverse osmosis, distillation, or 1 μm particulate absolute filtration [7]. Transplant recipients should also avoid fountain beverages and ice made from tap water, as rare instances of nosocomial legionellosis have been reported. An aggressive water-testing program in hospital areas housing susceptible patients should be implemented. Hyperchlorination, silver/copper ionization, and/or superheating should be employed to reduce *Legionella* spp. in the water supply in accordance with published recommendations [7, 48, 76].

Intermediate Post-Solid Organ Transplant (1–6 Months)/Early Post-Engraftment Period (30–100 Days)

Patients often spend the intermediate post-SOT period and the early post-engraftment periods within the hospital environment. Pathogens of concern vary with ongoing immune reconstitution. SOT recipients are at higher risk of developing listeriosis and *Nocardia* infections during this period, while SCT recipients carry higher risks of developing gram-positive infections and respiratory/enteric viral illness (Table 61.1). Both SOT and SCT recipients have a greater likelihood of acquiring or reactivating herpesvirus infections such as HSV, CMV, and EBV during this period. During ongoing and/or recurrent hospitalizations, previously described infection control practices should be followed to minimize exposure to healthcare-associated pathogens.

Blood Products and Cytomegalovirus

Patients in this period frequently require transfusion of blood and blood products due to anemia and thrombocytopenia. CMV-seronegative allogeneic SCT recipients with CMV-seronegative donors (R-D-) should only receive leukocyte-reduced/CMV-seronegative red blood cells or leukocyte-reduced platelets to prevent transfusion-associated CMV infection [27]. However, insufficient evidence exists to support this strategy in CMV-seronegative recipients with CMV-seropositive donors (R-D+) [27]. In CMV-seronegative autologous SCT recipients, CMV-seronegative red blood cells and leukocyte-reduced platelets can be used but are not routinely recommended [7]. In addition to blood products, a comprehensive CMV prevention strategy should continue for SCT patients through first 100 days after transplantation. This

strategy should include antiviral prophylaxis, aggressive and regular CMV screening, and use of gloves by HCW when handling blood products or other potentially contaminated biologic materials to prevent transmission of CMV to susceptible SCT recipients. Among SOT recipients, CMV-seronegative donor/recipient pairs (D-R-) should receive only leukocyte reduced/CMV-seronegative blood products [77].

Late Post-Solid Organ Transplant (>6 Months)/Late Post-Engraftment Period (>100 Days)

Patients spend most of the late post-SOT period and late post-engraftment period outside the hospital environment, with the majority of healthcare contacts occurring during outpatient clinic visits. CDC has recently published an infection control and prevention framework for outpatient oncology settings, and these recommendations should also serve as a basis for outpatient transplant clinics [78]. Although still immune suppressed, the spectrum of infectious complications during this period changes dramatically. For SOT recipients, bacterial pathogens from the community predominate. There is also a second peak of invasive *Aspergillus* infections [16]. For SCT and SOT recipients, CMV remains a concern and transmission in the home environment can occur from many sources. Transplant recipients and their household contacts must be educated to practice good hand hygiene, especially if handling soiled diapers and when in contact with nasal secretions so that they prevent exposure to CMV and respiratory viruses. Several guidelines and expert opinions to reduce household exposure to infectious pathogens following transplantation have been published for SCT and SOT recipients [7, 79–81]. Despite the absence of strong evidence, most published reports agree that SCT and SOT recipients have the greatest risk of infection in the first 6 months after transplantation and when immune suppression is augmented to prevent rejection [27, 81]. Allogeneic SCT recipients with chronic GVHD, those with cancer recurrence, and those with secondary graft loss or graft compromise remain at highest risk for infections during this period. Among SOT recipients, recurrence of the primary malignancy, namely liver and kidney, and patients receiving antineoplastic therapy for late-onset neoplasms remain at highest risk for development of infections during this period.

Avoidance of Infections After Transplantation

While avoidance of potentially infectious organisms is paramount, appropriate vaccination of transplant recipients is also important during this period as discussed elsewhere in this book. A thorough discussion with the patient and their close contacts regarding the risks of infections developing outside the hospital environment is crucial and must take into account the desire for the transplant recipient to regain a sense of normalcy post-transplant. Most infectious organisms in this period are acquired through direct contact, ingestion, or inhalation. Hand hygiene is a key component of reducing infectious risk: hands should be washed before preparing food, eating, and touching mucous membranes. Good hand hygiene needs to be followed after transplant recipients handle or clean up after pets, garden or touch plants/soil, change diapers, and touch secretions/excretions and after touching items that have had contact with human or animal feces [27, 81]. Gloves should be worn during outdoor activities when handling soil, moss, or manure, walking barefoot should be avoided, and long-sleeved shirts/long pants should be worn while performing yard work to minimize abrasions and cuts from bushes and shrubs. These efforts will decrease exposure to potentially invasive fungal diseases such as sporotrichosis [28, 79]. To minimize the risk of respiratory illness, transplant recipients should avoid close contact with persons with respiratory illnesses and crowded areas during respiratory virus season. Frequent use of alcohol-based handwash/rub may decrease the risk of infection [14]. Tobacco smoking and marijuana should be avoided to decrease the risk for respiratory virus infection and exposure to *Aspergillus* spp., respectively [28, 82, 83].

Transplant recipients may also need to consider changes in their occupation and consider delaying return to work until after the critical 6-month period post-transplant has elapsed. If delayed return to employment is not possible, patients should be counseled extensively regarding protective measures if their occupation places them at risk for particular infections. Some such workplace risks include airborne mold (construction), TB (healthcare), or respiratory virus infection (education, retail, healthcare, or office settings). In addition, transplant recipients who work with animals should avoid this work environment if possible for the first 6 months after transplantation. SCT recipients living in or visiting areas with endemic levels of coccidiomycosis should avoid or minimize exposure to disturbed soil, while recipients living in or visiting areas with endemic levels of histoplasmosis should avoid chicken coops or other bird-roosting sites and caves during the first 6 months after transplantation [27]. While exercise and outdoor activities are recommended and may be beneficial for transplant recipients, some activities including hunting, camping, fishing, spelunking, and canoeing can be associated with the development of invasive fungal disease in immunocompromised hosts. Therefore, these activities should be limited at least for the first 6 months after transplantation or during times of increased immunosuppression [79].

Counseling about sexual behaviors is also important in the late post-transplant period for SCT and SOT recipients. Latex condoms should be used to reduce the chance of exposure to HIV, HBV, HCV, HSV, and CMV. Sexual partners of transplant recipients could also consider receiving serologic testing for CMV to better characterize risks of transmission [7].

During periods of maximal immune suppression, especially during the first 6 months after transplantation, transplant recipients should avoid contact with domesticated animals that have diarrheal illness and should wash hands regularly after handling pets. Transplant recipients should avoid cleaning bird cages and litter boxes, handling animal feces including bird droppings, and should wear gloves when cleaning aquariums or designate another household member to perform this task [16]. If avoidance of the above activities is not possible, transplant recipients should wear disposable gloves and wash hands with soap and water for 15 s after removing gloves. Transplant recipients should avoid stray animals, animal bites, and contact with nonhuman primates. Transplant recipients and clinicians should be mindful of infectious risks posed by certain animals: rodents (lymphocytic choriomeningitis virus), young cats (*Bartonella henselae*), all cats (*Toxoplasma gondii*), and reptiles/chickens/ducklings (*Salmonella* spp.) [81]. Finally, recipients should defer obtaining a new pet until 1 year after transplantation and when on a stable immunosuppressive regimen.

Consumption of contaminated water or inadvertent ingestion of water during recreational activities may increase the chance of developing infections after transplantation. *Cryptosporidium* has been identified as a cause of severe diarrhea in both SCT and SOT populations [81]. Unlike other organisms, *Cryptosporidium* is not killed by chlorine. Therefore, even treated water supplies cannot be assuredly free of this organism. In order to eliminate the risk of *Cryptosporidium*, transplant recipients can boil water for at least 1 min or use filtered/bottled water as described earlier in this chapter. Well, lake, and river water should not be ingested. In addition, transplant recipients should avoid swimming in water likely to be contaminated with human or animal waste. Hot tubs should be avoided to reduce the risk of *Pseudomonas* folliculitis, legionellosis, and nontuberculous mycobacterial infections (NTM). "Hot tub lung" caused by *Mycobacterium avium* complex and *Mycobacterium kansasii* can present with significant cough, fever, and hypoxia, while exposure to other NTM such as *Mycobacterium chelonae* (cutaneous infections), *Mycobacterium abscessus* (pulmonary and cutaneous infections), and *Mycobacterium marinum* (cutaneous infections) can lead to a diverse presentation of illnesses. Water leaks within the home or basement should be promptly repaired and water-damaged materials should be removed within 48 hours if still damp to avoid mold growth [81]. Guidelines regarding foods to be avoided have been published and are described in Table 61.2 [7, 10, 27]. The FDA has published a practical patient handout for transplant recipients describing food safety practices in the home environment [84].

Transplant recipients and clinicians need to be aware of geographic risk factors associated with travel to or residence in various parts of the world where the risk for endemic infections may differ from their location of origin. This issue is paramount during times of significant immune suppression. In general, allogeneic SCT recipients should not travel to developing countries for 6–12 months after transplantation, while autologous SCT recipients should defer travel for 3–6 months after transplantation [16, 27]. SOT recipients should defer travel to developing countries until 3–6 months after transplantation [80]. All transplant recipients should avoid regions with visceral leishmaniasis (Kala-Azar) and trypanosomiasis and rural parts of Africa, Mexico, South and Central America, and Asia to avoid potential exposure to various diseases including rabies. A hallmark of disease prevention when traveling to the developing world is appropriate vaccination, which is outlined elsewhere in this book as well as in CDC's Yellow Book published online [85]. The Yellow Book also provides detailed information about geographic risks for endemic pathogens. A recent review summarizes risks of fungal infections in immunocompromised travelers [86]. Transplant recipients should consider evaluation at a travelers' health clinic prior to such travel, as each destination presents unique geographic risk factors. Diarrheal illness is common among travelers and may lead to dehydration and acute kidney injury, which can subsequently lead to increased levels and toxicity of immunosuppressive agents. Transplant recipients should be cautioned to consume only boiled or bottled water/beverages and to avoid raw food and food sold by street vendors while abroad. Transplant recipients should bring antibiotics, typically fluoroquinolones or azithromycin, to treat empirically for infectious diarrhea while traveling. Clinicians should inform patients that azithromycin might increase the levels of cyclosporine and tacrolimus [80]. The risk of influenza varies based on travel location: in tropical climates, influenza is seen year-round; in the northern hemisphere, influenza peaks between October and April; and in the southern hemisphere, influenza peaks between May and October. Malarial prophylaxis should be considered when traveling to an endemic area, but clinicians should note the potential drug-drug interactions between antimalarial medications and immunosuppressive medications. Additional discussion of travel-related zoonoses and malaria can be found in other sections of this book.

Conclusion

Infection control and prevention in transplant populations presents challenges to clinicians and infection control practitioners in both the pre-transplant and post-transplant periods.

Guidelines and recommendations in this population are frequently based on small studies and historical experiences, and often more questions than answers are generated by clinicians owing to lack of conclusive evidence in this field [87]. However, despite the absence of definitive studies in this population, standard precautions, appropriate antimicrobial prophylaxis, and avoidance of potential sources of infection should be emphasized throughout the entire transplantation process to reduce the likelihood of infections in this vulnerable population.

Travel and Transplantation

62

Camille Nelson Kotton and José G. Montoya

Introduction

Transplant recipients are growing in number, and as their overall health improves, they are more likely to engage in foreign travel and experience exposures to endemic pathogens. Transplant recipients are at higher risk of complications from travel-related infections and are less likely to respond to vaccines; furthermore, vaccines containing live attenuated strains are contraindicated in the subset of severely immunocompromised recipients. This review will summarize the medical literature regarding travel medicine and travel-related vaccines in the adult transplant recipient population. In addition, the infectious disease risks of "transplant tourism" that includes travel by either the donor or recipient for the express purpose of undergoing organ transplantation will be discussed.

A travel medicine specialist who is familiar with patients' immunocompromised state and medications should see transplant recipients who wish to travel. Optimizing their care should include excellent and comprehensive advice and education on travel medicine and vaccinations. Travel medicine specialists for complex patients should confer with the travelers' other physicians as needed to develop an appropriate plan. Three recent surveys of transplant centers found significant rates of illness in transplant recipients during foreign travel and insufficient rates of pre-travel counseling and interventions. In one survey of 267 solid organ transplant recipients at the University of Toronto, 36% indicated that they had recently traveled outside Canada and the United States; 66% of travelers sought pre-travel advice, primarily from their transplant physician. In general, many of the recommended preventative measures were overlooked: 63% traveled to areas where hepatitis A was endemic, but only 5% had received hepatitis A immunization; 50% traveled to dengue- and malaria-endemic areas, but only 25% adhered to mosquito prevention measures; and 10% reported behaviors that exposed them to blood or body fluids [1]. A review at the Mayo Clinic, Rochester, Minnesota, found that of 1130 solid organ transplant recipients, 27% had reported travel outside of the United States or Canada after undergoing transplantation; 16% had traveled to destinations at higher risk for infectious diseases, and travelers to these destinations were more likely to be men (73% vs 54% of low-infection risk travelers; $P = 0.018$) or born outside the United States or Canada (29% vs 6%; $P < 0.0001$) [2]. Liver recipients were more likely to travel than other organ recipients. Ninety-six percent of travelers reported that they did not seek specific pre-travel healthcare consul before foreign trip; 8% of travelers required medical attention because of illness, and illness was significantly more likely among travelers to high-infection risk (18%) than low-risk (6%) destinations ($P = 0.004$). Another cross-sectional, descriptive study of 290 Dutch kidney transplant recipients evaluated their travel health knowledge, attitudes, and practices while staying abroad. Thirty-four percent had traveled outside Western Europe and Northern America; 22% of these travelers did not seek pre-travel health advice, and 29% were ill during their most recent journey [3]. Transplant physicians were most frequently (53%) consulted for the pre-travel advice. Four of 17 ill recipients (24%) needed hospitalization, reflecting the high morbidity of travel-related diseases in the susceptible transplant population.

Planning Travel

Numerous factors can alter the risks of travel, as outlined in Table 62.1. Timing of travel can be an important decision. Significantly immunocompromised hosts include those who underwent hematopoietic stem cell transplantation (HSCT) within the past 2 years or recipients of solid organ transplant (SOT) within a year after transplantation [4, 5] (Table 62.1) Additional factors associated with higher levels of immune suppression include patients with recent treatment for rejection after SOT or significant doses of immunosuppressive medications for treatment of graft-versus-host disease (GVHD), AIDS with low CD4 counts, active leukemia or lymphoma, metastatic solid organ malignancy, aplastic anemia, congenital immunodeficiency, or persons who have received recent radiation therapy [4]. Patients with chronic hepatic disease due to cirrhosis and alcoholism, chronic renal disease, poorly controlled diabetes, asplenia, and nutritional deficiencies could be considered moderately to severely immunosuppressed, depending on the details of their disease [4]. Transplant recipients more than 2 years after HSCT and who are not on immunosuppressive drugs and without GVHD or solid organ transplant recipients more than 1 year after transplant on standard low-dose antirejection medications without recent allograft rejection episode are less immunocompromised and could be better able to face the risks associated with foreign travel.

Table 62.1 Travel planning and educational topics for travel medicine in immunocompromised hosts

Travel planning: Defining and moderating risk
Timing after transplant (> 1 year for destinations with infection risk) [4]
Net state of immunosuppression
Delay travel after treatment of rejection or periods of higher immunosuppression
Location of travel
Risk of specific infection(s); esp. yellow fever zones
Availability of good healthcare/medications
Rich country vs tropical poor country
Type and length of travel
Visiting friends and relatives (VFR) conveys risk of infection
Luxury versus backpacking
Short stay versus relocation
Educational topics
Food and water precautions
Mosquito precautions
Blood-/sex-borne infection precautions
Sun and altitude precautions
Traveler's diarrhea
Every patient travels with antibiotics
Respiratory, skin, other infections
Plan if sick in foreign country
Medical evacuation insurance

Location of travel is another important decision. Certain regions may convey a higher risk of specific infections, i.e., as with meningococcal disease and yellow fever virus. Immunocompromised hosts should be encouraged to defer travel during outbreaks of dengue fever, chikungunya, Eastern equine encephalitis, Zika virus endemic regions, and viral hemorrhagic illness such as Ebola virus disease. Regional outbreaks of novel respiratory tract infection such as Middle East respiratory syndrome (MERS) may cause serious illness in the immunosuppressed transplant recipients and should be avoided. The availability of good healthcare, medications, and other resources may improve outcomes. Also, the overall level of risk of infection in developed compared with developing or underdeveloped tropical countries may be lower.

Type and length of travel can also impact risk for acquiring an infection. Visiting friends and relatives (VFR) conveys a higher risk of numerous infections. Similarly, luxury travel is less likely to result in infection, compared with travel, e.g., involving backpacking. Short-stay travel for less than 2 weeks of tourism also conveys a lower risk compared with a month or longer stays.

Non-vaccine Preventable Illness

Diarrhea is the most common illness of travelers, affecting 10–60% of travelers with suppressed immune function. Dehydration may compromise renal function and markedly increase nephrotoxicity of calcineurin inhibitors such as tacrolimus; further worsening in renal function promotes systemic toxicity of these drugs due to unintended rise in serum drug concentration. Complications of diarrhea may include altered intestinal absorption and metabolism of oral immunosuppressive medications, as well as intestinal translocation of bacteria and less commonly yeasts resulting in hematogenous dissemination and seeding of distant body sites. Prior to international travel, organ recipients should be instructed in appropriate food and water precautions [6]. In general, SOT recipients should be cautioned to drink boiled or bottled water and other beverages, to avoid food sold by street vendors and raw foods with the exception of fruit and vegetables that can be peeled after thoroughly washing them in previously boiled water, and to be cautious about the cleanliness of the source of their food. If transplant recipients develop diarrhea for more than 2 days while traveling, especially with fever, vomiting, and/or bloody stools, patients should consider seeking medical attention; they should carry appropriate self-treatment oral medications such as ciprofloxacin or azithromycin. Due to microbial resistance, trimethoprim-sulfamethoxazole is generally ineffective against travelers' diarrhea. There are no data regarding the use of antimotility agents in transplant recipients with

diarrhea; however, such agents may delay clearance of toxins from the gut. Transplant recipients with an acute decline in renal function may be at a higher risk for salicylate toxicity; in the gastrointestinal tract, bismuth subsalicylate commercially available as Pepto-Bismol is converted to salicylic acid and insoluble bismuth salts. Prophylaxis against bacterial traveler's diarrhea with daily antibiotics is very rarely indicated and should only be considered for short-term use, after considering the risks of antibiotic resistance, *Clostridium difficile* colitis, microbiome alterations, potential for drug interactions, and side effects.

Respiratory infections are the second most common infection affecting travelers [7]. Endemic fungal pulmonary infections, such as histoplasmosis, coccidioidomycosis, and blastomycosis in North America, paracoccidioidomycosis in Central and South America, and talaromycosis (formerly known as penicilliosis) due to *Talaromyces* (*formerly known as Penicillium*) *marneffei* infection in Southeast Asia, could be acquired during travel [8, 9]. SOT recipients are at higher risk for invasive fungal infection and should avoid activities such as spelunking and excavating, activities that have been associated with exposure to *Cryptococcus neoformans* or *Histoplasma capsulatum*. The appropriate use of masks may be helpful.

Malaria and dengue fever are the most common arthropod-borne illnesses of travelers. Most cases of dengue fever are self-limited in the normal host; the risk for complications in transplant recipients is not well understood. In a series of eight renal transplant recipients with dengue fever living in India, three developed dengue hemorrhagic shock syndrome and died [10]. In a 20-year retrospective study of 1917 renal transplant recipients, 13 (0.7%) recipients were diagnosed with laboratory-confirmed dengue with a median age of 39 years (interquartile ranges [IQR], 22–46); 54% were males [83]. All patients resolved without complications, except one had hemophagocytic lymphohistiocytosis. Ten (76.9%) patients experienced eGFR reduction with a median of 13.7 mL/min/1.73 m^2 (IQR, 8.3–20.5); eight (80%) had a full allograft function recovery. Authors concluded that although a transient decline in allograft function can occur, the overall clinical and allograft outcomes seem to be favorable [83]. Malaria is a significant risk for all travelers to endemic areas. Prophylaxis against malaria should be based on the travel itinerary; the CDC Yellow Book provides country-specific guidelines (wwwnc.cdc.gov/travel/destinations/list.htm wwwnc.cdc.gov/travel/destinations/list.htm) [6]. Transplant recipients should be instructed on ways to minimize insect bites, including the use of repellents containing DEET (N,N-diethyl-3-methylbenzamide), bed nets, protective clothing, and permethrin-impregnated clothing [6].

Travelers to endemic regions may contract parasitic infections such as *Strongyloides stercoralis* infections, when larvae from contaminated soil penetrate skin or mucous membranes. Unlike other intestinal parasites, *Strongyloides* can replicate inside the human host, which allows the perpetuation of autoinfection. *Strongyloides* infection may persist for decades and can flourish in the setting of immunosuppression, resulting in life-threatening hyperinfection and disseminated infection. Travelers should wear socks and shoes to avoid contact with this and other pathogens. Swimmer's itch due to *Schistosoma* spp., cryptosporidiosis, and other parasitic infections can be prevented by avoiding swims in non-chlorinated freshwater ponds, lakes, and rivers.

The large African snail invasion in South America has heightened the concerns for accidental infection due to rat lungworm or *Angiostrongylus cantonensis*. Travelers to South America (or to other areas of world known to host *A. cantonensis* such Asia, Pacific Islands, and Africa) should be counseled regarding *A. cantonensis* infection and the risk for potentially life-threatening eosinophilic meningitis. These infections are acquired by intentional and inadvertent consumption of raw or undercooked intermediate hosts of the parasite such as snails or slugs. Infection can also be transmitted via consumption of poorly prepared or raw freshwater shrimp, crabs, and frogs that are not essential for the parasites' life cycle but may serve as paratenic host. Consumption of snails and uncooked shellfish is not recommended for transplant recipients and must always be avoided.

Echinococcosis is caused by the ingestion of eggs of either the *Echinococcus granulosus* or *Echinococcus multilocularis*. *E. granulosus* is a parasite of domestic dogs that causes hydatid or unilocular cystic disease, whereas *E. multilocularis* is a parasite of wild canines that causes alveolar cyst disease. Patients with hydatid cysts are usually asymptomatic for years. Echinococcosis is not uncommon in rural India, rural Mexico, Alaska, and other regions of the developing world. Transplant patients with severe B-cell dysfunction, especially those receiving aggressive anti-B-cell therapy for allograft rejection, may present echinococcosis with highly unusual accelerated growth and rapidly enlarging tumor-like mass lesion [11]. Transplant patients should avoid travel to the rural endemic regions and keep their essential travel to a brief stay. Furthermore, contact with all non-domesticated canines should be avoided.

Acute toxoplasmosis acquired in certain areas of Latin America may have unusual and more severe manifestations than when acquired in Europe or the United States and Canada. Transplant physicians should entertain the possibility of acute toxoplasmosis in travelers returning from Latin America who present with fever of unknown origin, severe headaches, acute community-acquired pneumonia, hepatitis, chorioretinitis, brain abscesses, myositis, and myocarditis. In order to decrease the possibility of acquiring *T. gondii*, patients should be advised to avoid ingestion of raw or undercooked meat or shellfish; consumption of untreated water or unwashed veg-

etables of fruits; exposure to soil or feces of domestic, wild, or stray cats; and eating food that has been prepared in surfaces where raw meat was manipulated.

Transplant recipients have a markedly increased risk of skin cancer that correlates with the intensity of sun exposure, and it is important to recommend the use of hats, sunglasses, protective clothing which are also useful for prevention of arthropod-borne infections, and sun protection lotions with ultraviolet A and B protection.

Travelers who rapidly ascend to altitude are at risk for altitude sickness. Acetazolamide accelerates acclimatization and decreases the risk of altitude sickness [12]; its use in organ transplant recipients is unstudied. Travelers to high attitude should be advised to avoid vigorous activities for the first few days at high altitudes. Acetazolamide should be offered to those travelers ascending rapidly to greater than 2500 meters since there is at least a 15–25% risk of altitude sickness. Small series suggests that selected and well-prepared transplant recipients can perform strenuous physical activities and tolerate exposure to high altitude similar to normal healthy people [13, 14].

Drug interactions are of particular concern in transplant recipients, and they should be cautioned about using new medications that may be given by unknowledgeable practitioners or purchased "over the counter." Online drug interaction calculators may be helpful to savvy travelers. Chloroquine can increase serum levels of cyclosporine and perhaps sirolimus and tacrolimus. Data are limited regarding other possible interactions between travel-associated drugs and immunosuppressive medications (Table 62.2). Short courses of ciprofloxacin or azithromycin for travelers' diarrhea seem unlikely to have a major impact on cyclosporine levels (Table 62.2).

Acquisition of new viruses should be avoided, via safer sex practices, use of clean needles and syringes, or avoidance, if possible, of blood transfusions in foreign countries. Sterile needles and syringes may be given to a traveling transplant recipient with a physician's letter stating they are for medical use. Patients with end-stage renal disease, either prior to or after organ transplant, and who undergo hemodialysis in resource-limited countries, where suboptimal infection control policies pose a risk of exposure to blood-borne viruses, are at significant risk of acquiring new viral infections. A number of cases of hepatitis C have been reported in Western travelers to the Indian subcontinent, Tenerife, Egypt, Saudi Arabia, Singapore, and Slovakia [15, 16]. Such exposures may have an impact on policies in transplant centers regarding evaluation of those on the waiting list for solid organ transplants [17].

Vaccination and Response

In general, many of the indications for vaccination are the same in immunocompromised and non-immunocompromised hosts, with a few exceptions. When possible, vaccination for travel should be started several months before the trip, to allow time for further serologic evaluation and possible additional booster doses, as needed. Emergency travel may present a potentially high-risk situation in which passive immunization could be used, such as administration of intramuscular immunoglobulin to protect against hepatitis A virus infection. To optimize the immunologic response, immunocompromised hosts should be vaccinated during periods of no or low exogenous immunosuppression when possible, such as before undergoing solid organ or hematopoietic stem cell transplantation. When possible, vaccination should be avoided in the initial 3–6 months after solid organ or hematopoietic stem cell transplant, since during this period, vaccine response will be significantly stunted due to the severity of immune suppression [18] and also to avoid confusion with early graft dysfunction or rejection. Whether

Table 62.2 Interactions between transplant and travel-related medications

	Calcineurin trimethoprim/ inhibitors (CNI)	Sirolimus	Sulfamethoxazole
Azithromycin	May ↑ CNI levels		
Mefloquine	May ↑ CNI levels	May ↑ sirolimus levels	May increase risk of cardiac toxicity, QT prolongation, torsades de pointes or cardiac arrest
Atovaquone			May increase risk of proguanil of bone marrow toxicity
Doxycycline	May ↑ CNI levels	May ↑ sirolimus levels	
Chloroquine	May ↑ CNI levels		May increase risk of cardiac toxicity, QT prolongation, torsades de pointes or cardiac arrest
Primaquine	May ↑ CNI levels		
Sulfadoxine/ pyrimethamine	May ↓ CNI levels		May increase risk of bone marrow toxicity
Acetazolamide	May ↑ CNI levels		

Adapted from MicroMedex® DrugReax® interactive drug interactions and Lexi-Comp OnlineTM interaction analysis
Significant interactions of travel medicines and azathioprine, mycophenolate mofetil, and corticosteroids have not been reported; significant interactions of transplant medicines and levofloxacin, diphenoxylate hydrochloride, and atropine sulfate tablets or loperamide have not been reported; minimal data available

vaccinations could contribute to acute rejection or GVHD has been an area of debate, although this does not seem likely based on the available data. In a study of 20 autologous stem cell transplant recipients who were serially vaccinated with the diphtheria-tetanus-poliomyelitis, pneumococcal, and conjugated *Haemophilus influenzae*, type B (Hib) vaccines showed that a minimum threshold level of CD19(+) cells was needed to generate adequate vaccine response [19].

The measure of antibody titers following immunization may prove useful in certain settings. In general, a fourfold increase in titer is often considered evidence of seroconversion, and titers above certain levels are considered evidence of seroprotection; both of these concepts were derived from data in normal hosts. Transplant recipients are less likely to have a significant immunologic response, although this does not mean that they are not at least partially protected. In addition, immune responses to vaccination may wane more rapidly. Booster doses of vaccine are occasionally administered to those with lower or undetectable antibody titers, but such practices have not been subjected to rigorous trials nor evaluated for protective efficacy. The efficacy of vaccine adjuvants, such as aluminum hydroxide and incomplete Freund's adjuvant, as well as experimental agents, has been variable in limited studies in transplant recipients [20–22]; until more is known, it may be prudent to avoid adjuvants, especially in allogeneic transplant recipients where they could abrogate the delicate immunologic tolerance and potentially increasing the risk for allograft rejection [23].

Routine Vaccines

Adults often miss standard recommended vaccines [24], and transplant recipients are no exception [25]. Some physicians, perhaps concerned about causing harm, may elect to skip vaccination of this vulnerable population. Annual recommendations for routine adult vaccinations, including immunizations for immunocompromised individuals, are available through the Centers for Disease Control and Prevention [26]; additional publications also have helpful travel-related guidelines for immunocompromised hosts [5, 27–33]. Table 62.3 includes recommendations on both routine and travel-related vaccinations in immunocompromised hosts (Table 62.3).

Hematopoietic stem cell transplant recipients lose immunologic memory of exposure to infectious agents and vaccines and therefore need to be revaccinated. Standard guidelines for revaccination after HSCT were developed through collaboration between numerous international groups [34]. Standard recommendations for revaccination after hematopoietic stem cell transplant include diphtheria and tetanus toxoids, pertussis vaccine, *Haemophilus influenza* type B conjugate, 23-valent pneumococcal polysaccharide, inactivated influenza and polio vaccine, and live attenuated measles-mumps-rubella vaccine, as well as other vaccines [35]. Re-immunization protocols may vary among transplant centers but should be considered in all recipients. Vaccination either primary or booster in allogeneic stem cell graft donor can be effective [36] and should occur well before stem cells are harvested. In a study, antibody levels among recipients of allogeneic HSCT correlated most with recipient pre-transplant antibody levels, whereas donor antibody levels prior to obtaining the stem cell graft had less of a correlation; other factors such as patient or donor age, total body irradiation, and presence of GVHD or its treatment did not appear to have an effect, suggesting that immunization of the recipient and the donor before transplant may be more effective in improving antibody-mediated immunity after transplantation compared with managing GVHD, altering preparatory conditioning regimens, or increasing the number of lymphocytes in the HSCT graft [37].

Tetanus is rare in the industrialized world, where vaccination rates are quite good; it has a much higher prevalence in

Table 62.3 Vaccination in transplant recipients

Vaccine	Recommendation
Routine vaccines	
Influenza-parenteral	Yearly
Influenza-intranasal[a]	Contraindicated in patients/ family members
Pneumococcal polysaccharide	Recommended, with booster after 5 years
Tetanus/diphtheria/pertussis	Recommended
Human papilloma virus	Recommended
MMR[a]	Contraindicated
Varicella[a]	Contraindicated
	Contraindicated
Vaccines for selected transplant recipient travelers when indicated by destination and/or circumstances	
Bacille Calmette-Guerin[a]	Contraindicated
Cholera	Recommended when indicated/available
Hepatitis A	Recommended when indicated
Hepatitis B	Recommended when indicated
Japanese encephalitis	Recommended when indicated
Meningococcal polysaccharide	Recommended when indicated
Meningococcal conjugate	Recommended when indicated
Polio (OPV)[a] (oral)	Contraindicated in patients/ family members
Polio (IPV) (injectable)	Recommended when indicated
Rabies	Recommended when indicated
Salmonella typhi Ty21a[a] (oral)	Contraindicated
Typhim vi (injectable)	Recommended when indicated
Yellow fever[a]	Contraindicated

Adapted from the Centers for Disease Control "Recommended Adult Immunization Schedule—United States"[26], "Advising Travelers with Specific Needs: The Immunocompromised Traveler" in Centers for Disease Control's "Health Information for International Travel" [4], and "Guidelines for vaccination of solid organ transplant candidates and recipients" [27]

[a]Live, attenuated

resource-poor regions, although is still rare among travelers. Tetanus boosters are routinely recommended for SOT and HSCT recipients and should be up to date before traveling. Diphtheria is common in resource-poor regions with 5–10% mortality among normal hosts, despite therapy. A diphtheria antibody level of >0.1 IU/mL suggests adequate protection. Patients with a lower titer and those vaccinated more than 10 years prior to travel should be revaccinated before entering an area in which diphtheria is endemic or resurgent. For immunocompromised travelers entering high-risk areas, diphtheria antibody levels may be measured a month or more after vaccination. There has been an increased amount of disease activity in the United States due to pertussis in recent times, and recommendations are for more adults to be vaccinated [38]. Prior pertussis vaccines caused significant side effects in adults, which largely precluded their use. A new acellular pertussis vaccine is now available for adults and is included in the vaccine for tetanus and diphtheria, called Tdap. This has not been studied in immunocompromised hosts thus far but could be considered for use in the appropriate setting.

Vaccination against influenza should occur annually in most immunocompromised hosts. In a recent study, 616 transplant patients from 20 centers in the United States, Canada, and Spain with microbiologically confirmed influenza (477 SOT; 139 HSCT) were prospectively studied [84]. The receipt of influenza vaccine in the same season was associated with a decrease in disease severity as determined by the presence of pneumonia (odds ratio [OR], 0.34 [95% confidence interval {CI}, 0.21–0.55], $P < 0.001$) and ICU admission (OR, 0.49 [95% CI, 0.26–0.90], $P = 0.023$). In patients with influenza A, pneumonia, ICU admission, and not being immunized were also associated with higher viral loads at presentation ($P = 0.018$, $P = 0.008$, and $P = 0.024$, respectively). Early antiviral treatment (within 48 h) was also associated with improved outcomes. Annual influenza vaccination and early antiviral therapy are clearly associated with a significant reduction in influenza-associated morbidity and should be emphasized as strategies to improve outcomes of transplant recipients [84]. Those who underwent transplantation, treatment of rejection, or other profound immune suppression in the past few months may be an exception, in whom vaccination should be delayed, balancing the risks of infection with the likelihood of developing an immune response, for example, in North America, deferring such a vaccine from early October to December after a kidney transplant performed in August may allow for a better immune response (immunogenicity) and better protection against influenza (vaccine efficacy) [23]. Given the year-round influenza activity in the tropics, it may be prudent to vaccinate all immunocompromised travelers to those areas if they were not vaccinated within the past year. Influenza immunity wanes, and it is not known whether such travelers should be given booster vaccines prior to travel. An alternative strategy to the conventional one-dose influenza vaccine is the booster strategy proposed from the results of a recent study [85]. A total of 499 SOTR were enrolled. Although seroconversion at 10 weeks did not meet significance in the modified intention-to-treat population, seroconversion rates were significantly higher in the booster arm for the per-protocol population (53.8% vs 37.6% for influenza A(H1N1); 48.1% vs 32.3% for influenza A(H3N2); and 90.7% vs 75% for influenza B; $P < 0.05$). Moreover, seroprotection at 10 weeks was higher in the booster group: 54% vs 43.2% for A(H1N1), 56.9% vs 45.5% for A(H3N2), and 83.4% vs 71.8% for influenza B ($P < 0.05$). Clinical efficacy (99.2% vs 98.8%) and serious adverse events (6.4% vs 7.5%) were similar for both groups. Authors concluded that in solid organ transplant recipients, a booster strategy 5 weeks after standard influenza vaccination can be safe and effective in inducing increased antibody responses compared with standard (single dose) influenza vaccination [85]. Pneumococcal vaccine should be given to immunocompromised hosts, optimally at times of less immune suppression, and it may be sensible to vaccinate before travel. Data suggests that immunity to pneumococcal vaccine wanes more rapidly in renal transplant recipients, and conjugate vaccines do not improve the durability of response when compared with the pure polysaccharide vaccine [39].

Measles is a global illness, with approximately 30 million cases annually, resulting in approximately 750,000 deaths. Measles vaccination in the United States is usually performed with a trivalent live viral vaccine including measles, mumps, and rubella (MMR). Live vaccines are generally contraindicated in immunocompromised individuals [6, 30, 40–42]. In a small study of 18 pediatric patients vaccinated with MMR after liver transplantation, immunity developed in 7 children by serologic criteria, and there were no complications attributed directly to immunization [43]. Prior to travel to endemic areas, serologic evidence of immunity against measles, mumps, rubella, and varicella should be evaluated in transplant recipients. Immune globulin should be considered for measles-susceptible, severely immunosuppressed travelers who travel to measles-endemic countries and are at risk for exposure. In general, MMR could be given 24 months after HSCT in patients with no evidence of chronic GVHD or those not receiving systemic immunosuppressive therapy [34].

Immunization against hepatitis B before travel may be indicated for certain immunocompromised hosts, including those with new sexual partners while traveling and those living in endemic areas for extended periods or who are likely to need transfusions or medical procedures while traveling. Compared to the immune response following immunization pre-transplantation [30, 40], the efficacy of standard hepatitis B vaccination is reduced when the vaccine is administered

post-transplantation with severely diminished response rates of 5–15% [44]. In comparison, 20 liver transplant patients given extra doses of hepatitis B vaccine with 1 of 2 new adjuvants demonstrated a serologic response rate of 80% [45]. A group of 24 renal transplant patients who did not respond to intramuscular vaccine had an overall response rate of 63% to a series of 8 intradermal vaccinations followed by an intramuscular vaccination [46]. For immunocompromised adults, some authorities recommend immunization with a vaccine containing 40 mcg of hepatitis B surface antigen such as two 1 ml Engerix-B® vaccines, each containing 20 mcg, or a special formulation of Recombivax-HB® given at one site, in a three- or four-dose schedule [38], although this regimen has been predominantly evaluated in dialysis patients. HSCT recipients are at higher risk for hepatitis B acquisition given their exposure to blood products, and it would be prudent to vaccinate them. In a cohort of 292 recipients of unrelated or related allogeneic stem cell allografts given recombinant hepatitis B vaccine, 64% of patients seroconverted; in multivariate analyses, response was adversely affected by age older than 18 years and history of prior chronic GVHD but not by donor type or by use of T-cell depletion, adoptive immunotherapy, or treatment with rituximab [47]. It was interesting to note that 89% of the nonresponders mounted a threefold or greater rise in polio titers following three doses of inactivated poliovirus vaccine, demonstrating that response to vaccination can be highly variable.

Varicella is less common in childhood in the tropics, especially in rural areas, and thus it is more common for an adult to have chickenpox than in the higher latitudes. Varicella (Varivax®) and varicella zoster (Zostavax®) vaccines have lower and higher doses, respectively, of the attenuated live Oka strain of varicella, and, in general, their use should be deferred in transplant recipients until there is more data regarding their safety. When possible, patients who are seronegative for varicella should be vaccinated with two separate doses of varicella vaccine at least 1–3 months before undergoing exogenous immunosuppression, as in pre-SOT assessment. There are several small studies in carefully selected pediatric SOT recipients given varicella vaccine, but similar data has not yet been shown in adult SOT recipients. One pilot study of nine autologous HSCT recipients who were seropositive for varicella and who were vaccinated 3–4 months after HSCT with the Oka strain demonstrated a boost in varicella-specific cellular immunity as measured by lymphocyte proliferation, without significant systemic side effects [48]. A recombinant zoster vaccine (Shingrix®) has been recently approved by the US FDA for healthy adults 50 years and older, two doses separated by 2–6 months [86]. This recombinant zoster vaccine provides strong protection against shingles and postherpetic neuralgia (PHN) in healthy adults and should be considered the zoster vaccine of choice over the live attenuated vaccine (Zostavax®) since it is not contraindicated in transplant recipients unless recipients are undergoing immunosuppression thought to interfere with an effective and durable immune response. Studies of the recombinant zoster vaccine in transplant recipient have not been published yet in peer review literature.

Immunization for Travel-Associated Infections

Hepatitis A

The risk of hepatitis A in nonimmune travelers in resource-poor regions has been estimated to be 1 in 1000 per week for those on a usual tourist route and 1 in 200 for those on more adventuresome travel [7]. A recent Swiss study showed much lower rates, with an actual incidence of hepatitis A in travelers to countries of high or intermediate risk of transmission of 3–11 per 100,000 person-months abroad for all travelers [49]. Hepatitis A could be a devastating illness in immunocompromised hosts. Pooled immunoglobulins, given as intramuscular gamma globulin, are 85–90% effective at protecting against hepatitis A infection, although this effect only lasts for 3–6 months and dependent on the dose given; new recommendations suggest a larger dose be routinely used [87]. Prior to development of hepatitis A vaccine, gamma globulin was the standard for hepatitis A protection. Some transplant recipients with hypogammaglobulinemia are given routine immunoglobulin repletion with intravenous immunoglobulin (IVIG); this dose is much higher (0.66 mL/kg, delivering at least ~100 mg/kg immunoglobulin) than the dose used for gamma globulin (0.02 mL/kg, the dose recommended for 3-month protection against hepatitis A, which delivers ~3 mg/kg immunoglobulin), and such patients would not need additional antibody protection. The preparations are similar, although IVIG has had immune aggregates removed such that it can safely be given intravascularly.

Hepatitis A vaccine is less effective in solid organ transplant recipients. In a study of 37 hepatitis A seronegative liver transplant recipients who were given hepatitis A vaccine 6 months apart, only 8% had seroconverted at 1 month following vaccination and only 26% at 7 months, 1 month after the second vaccination [50]. In another study, zero of eight liver transplant recipients responded to the two doses of vaccine given 2 months apart [51]. In a third trial, liver and renal transplant recipients, 39 in each group, received 2 doses of hepatitis A vaccine 6 months apart [52]; response after the primary dose occurred in 41% of the liver transplant patients and 24% of the renal transplant patients, while after the second dose, the respective conversion rates were 97% and 72%. Discrepancies between studies may be explained by differences in patient selection, severity of liver disease, immunosuppressive medications, and type of vaccine used.

Organ transplant recipients have a more rapid antibody decline than controls: 2 years after vaccination, only 59% of liver transplant and 26% of renal transplant recipients who seroconverted retained protective titers [53], while mathematical models of vaccination in normal hosts have predicted antibodies to persist for at least 20–25 years [54]. Hepatitis A vaccine has not been well studied in the HSCT population.

Overall, immunologic response to hepatitis A vaccine among transplant recipients shows attenuated rates and shortened durability. Use of higher or more doses of hepatitis A vaccine has not been studied in the immunocompromised population. If there is enough time before travel, it may be useful to vaccinate SOT recipient travelers with two doses of hepatitis A vaccine 6–12 months apart when the transplant recipients are at least a year after the transplantation procedure and are on a modest dose immunosuppressive regimen; titers should be checked to assess seroconversion. SOT recipients who do not have adequate time before travel or do not respond to immunization should be given intramuscular immunoglobulin prior to travel [6].

Salmonella enterica serovar Typhi

An estimated 16–33 million cases of typhoid fever and 500,000–600,000 related deaths occur worldwide each year [55]. Approximately 300–400 cases of typhoid fever are reported in the United States each year, and most cases are related to international travel. Severe complications can occur in immunocompromised individuals during infection with *Salmonella enterica* serovar Typhi, and they should be immunized against typhoid prior to travel to endemic areas. There are currently two vaccines commonly available: the injectable polysaccharide vaccine (TyphimVi®, Aventis Pasteur SA) and the oral live, attenuated vaccine Ty21a (Vivotif®, Berna). The live oral typhoid vaccine has not been shown to cause disseminated disease; however, for theoretical reasons, the inactive parenteral vaccine should preferentially be administered to immunocompromised individuals. Immune response in immunocompromised hosts to either typhoid vaccine is usually poor, and data are minimal in immunocompromised hosts. As a relatively well-tolerated vaccine in general [56], and given the significant morbidity and mortality with typhoid fever, it may be prudent to vaccinate transplant recipients with the injectable vaccine when they travel to endemic areas.

Polio

Poliomyelitis caused by wild-type poliovirus has been eradicated from the Western hemisphere; wild-type virus exists in sub-Saharan Africa and South Asia. Outbreaks of vaccine-associated poliomyelitis occasionally occur, due to neuro-virulent reversion of live attenuated poliovirus from the oral polio vaccine. Vaccine-associated outbreaks of poliomyelitis have recently occurred in Hispaniola (Haiti and the Dominican Republic), the Philippines, Madagascar, and Cape Verde. Worldwide, two forms of the polio vaccine are available: the orally administered, live, attenuated virus (OPV or Sabin) and the injected inactivated poliovirus vaccine (IPV or Salk). Since attenuated vaccine strain polioviruses may spread through fecal-oral contact, transplant recipients and household contacts of immunocompromised individuals should not receive OPV. OPV is no longer distributed in the United States and Canada. Travelers should have received a primary series of polio vaccine during childhood and at least one booster as an adult. Some authorities recommend booster immunization if more than 10 years have elapsed since administration of the last polio vaccine, especially for individuals traveling to areas of the world with a polio outbreak or with circulating wild-type polio viruses; waning immunity in transplant recipients may require more frequent immunization.

The longevity of the response to revaccination with poliovirus after allogeneic stem cell transplant was studied in 134 patients who were given three doses of trivalent inactivated polio vaccine starting 12 months after HSCT and who survived at least 5 years after vaccination with a mean follow-up of 8 years (range, 1–19 years) [57]. Twenty-one patients (15.6%) became seronegative to at least one of the poliovirus serotypes during follow-up; in multivariate analysis, the only risk factor for loss of immunity was younger patient age, and there was a strong trend for patients with chronic GVHD to lose immunity more rapidly. All 14 patients given a booster dose of an inactivated poliovirus vaccine responded. Poliovirus immunity was thus shown to be retained long term after revaccination in most patients after allogeneic SCT. Response to vaccination after SOT has not been well studied but should be considered in anyone traveling to an endemic region.

Meningococcus

Meningococcal disease has high case-fatality rates of 5–15%. In the United States, a quadrivalent polysaccharide vaccine against *Neisseria meningitidis* A, C, Y, W-135 strains has traditionally been used; a similar protein conjugate vaccine is also available. Two new vaccines (MenB) have been approved for the prevention of disease caused by serogroup B. Meningococcal vaccines (ACYW-135 vaccine and B vaccine) are indicated for individuals traveling to areas of the world with known outbreaks of invasive meningococcal disease, those traveling to the meningitis belt of sub-Saharan

Africa, especially during the dry winter months from December through June, and for those traveling to Saudi Arabia for the Muslim pilgrimages of *Hajj* or *Umrah*, where proof of vaccination is required. There are no published data regarding the response of solid organ transplant recipients to immunization with the polysaccharide or protein conjugate meningococcal vaccine.

A recent study of the tetravalent protein-conjugated meningococcal vaccine (MCV4) in 46 recipients of related and unrelated allogeneic HSCT found a poor response to a single MCV4 vaccination is poor and recommended that administration of a 2-dose series, as currently recommended for patients with asplenia, complement deficiency, and HIV infection, should be evaluated in this patient population [58]. The majority of 44 patients who were given the polysaccharide vaccine 8 or 20 months after HSCT had significant immune responses to serogroups A and C; these responses were higher in individuals 20 months after transplantation than 8 months after transplantation and declined sharply over the first 6–12 months after vaccination suggesting revaccination should be considered for those at risks of exposure to meningococcal infection [59]. As transplant recipients are more likely to have significant morbidity and mortality from meningococcal disease, vaccination would seem prudent for those with potential exposure; safety and efficacy remain to be ascertained. The CDC website has information on areas with frequent epidemics of meningococcal meningitis at http://wwwnc.cdc.gov/travel/images/map3-13-frequent-epidemics-meningococcal-meningitis.jpg [60].

Yellow Fever

Yellow fever, a mosquito-borne viral hemorrhagic fever with a high case-fatality rate, occurs in tropical regions of South America and sub-Saharan Africa and kills an estimated 30,000 people every year. The CDC says transplant patients should not travel to yellow fever zones; if they must, they should travel with waivers, which must be completed and signed by a physician in the Medical Contraindications to Vaccination section of the International Certificate of Vaccination or Prophylaxis, which can only be given by approved yellow fever immunization centers [61]. Case fatality may surpass 20%; no specific treatment exists. Yellow fever may be a risk for travelers to endemic countries. The yellow fever vaccine contains a live attenuated viral strain and is distributed only through the Department of Public Health-certified vaccination centers, including travel clinics and some county health departments. A listing of approved yellow fever vaccination centers is available from local Departments of Public Health and the US CDC (available at http://wwwnc.cdc.gov/travel/yellow-fever-vaccination-clinics/search.htm) [62].

As a general rule, the yellow fever vaccine should not be given to immunosuppressed individuals [30, 42, 63–66]. While a few mildly immunosuppressed travelers have tolerated the vaccine including individuals with early HIV infection or a distant history of hematological malignancy not currently being treated with antineoplastic therapy [67–70], vaccine complications including death have been reported in immunosuppressed individuals [42, 71]. Optimally, the immunocompromised traveler should avoid regions where yellow fever is endemic or decrease risk by avoiding travel to those regions during peak season like January through March in Brazil and July through October in rural West Africa [42].

A travel physician who has decided to issue a waiver must complete and sign the Medical Contraindications to Vaccination section of the International Certificate of Vaccination or Prophylaxis, which can only be given by approved yellow fever immunization centers. The clinician should also give the traveler a signed and dated exemption letter on the physician's letterhead stationery, clearly stating the contraindications to vaccination and bearing the stamp used by the yellow fever vaccination center. Transplant recipients must understand the increased risk for yellow fever infection associated with non-vaccination and how to minimize this risk by avoiding mosquito bites. Some countries may still deny entry without immunization. To improve the likelihood that the waiver will be accepted at the destination country, clinicians may suggest that the traveler before beginning travel should obtain specific and authoritative advice from the embassy or consulate of the destination country or countries and request documentation of their requirements for waivers and retain this information along with their waiver. Further information is available from the Centers for Disease Control website (wwwnc.cdc.gov/travel/destinations/list.htm) [42]. Family members of immunosuppressed persons may receive yellow fever vaccine.

Rabies

Many travelers are at an increased risk of exposure to rabid animals while traveling. Long-term travelers, individuals expecting intense exposure to animal, and individuals who plan to be far from medical care should be considered candidates for pre-travel immunization against rabies. Since transplant recipients may not mount adequate antibody responses to the rabies vaccine, titers >0.5 IU/ml are considered adequate, some authorities recommend administration of human rabies immunoglobulin (HRIG) after all at-risk exposures; normally, HRIG is only given to previously nonimmunized individuals [72]. Intradermal administration of rabies vaccines may result in variable immune responses even in immunocompetent individuals and is not recommended by most authorities. Data are minimal in

SOT and HSCT recipients. One study of seven HIV + patients with low CD4 T lymphocyte counts (<200 cells/uL) found poor neutralizing antibody responses to pre- and post-exposure rabies vaccination even with doubling of the intradermal doses of cell culture rabies vaccine. Three HIV-infected patients with higher CD4 T lymphocyte counts ranging between 295 and 472 cell/uL tended to have better antibody responses to post-exposure rabies vaccination [73]. Since transplant recipients may be less likely than others to participate in adventure travel or to spend long duration of time away from civilization, vaccination should be considered in those with significant risks factors such as significant animal, exposure, and prolonged stays in endemic regions, and careful post-exposure prophylaxis is strongly advised.

Japanese Encephalitis

Japanese encephalitis (JE) may cause up to 10,000 deaths annually in Asia. Immunization against Japanese encephalitis should be considered for individuals with intense rural travel in areas of Asia endemic for JE, especially during periods of increased transmission [6, 74]. The JE vaccine is a killed viral vaccine and estimated to be 80– 90% effective. Hypersensitivity reactions in immunocompetent individuals occur in 0.6% of recipients and include generalized urticaria and angioedema or both. Neurologic adverse reactions including acute disseminated encephalomyelitis may rarely occur. The efficacy of the JE vaccine is not studied in SOT and HSCT recipients. In a study of HIV-infected Thai children who were given 2 doses of JE vaccine at 12 months of age, 5 of 14 (36%) HIV-infected children and 18 of 27 (67%) uninfected children had positive JE antibody titers after immunization [75]. In another study of HIV+ Thai children with immune recovery on HAART and who were seronegative for JE, 88% developed protective antibody after JE revaccination [76]. Since this vaccine is more likely to elicit systemic toxicity, careful observation after administration with an eye to transplant graft function would be prudent.

Bacille Calmette-Guerin

Bacille Calmette-Guerin (BCG) is one of the most commonly administered vaccines in the world; a live, attenuated strain of *M. bovis*, it is used to prevent tuberculosis, especially in infants and children. BCG is rarely given in the travel medicine setting and is contraindicated in immunocompromised hosts, as they can develop a disseminated infection. No specific prophylaxis other than infection control measures have been shown to be helpful in the immunocompromised population. Patients with compromised immune system may wish to wear masks when in healthcare settings in areas endemic for tuberculosis. Pre- and post-travel tuberculosis skin tests with the purified protein derivative (PPD) or gamma-interferon-based testing may be helpful, although PPD is more likely to be falsely negative in the immunocompromised population.

Cholera Vaccine

The oral cholera vaccine, available outside of the United States, has not been studied in immunocompromised hosts but has been safe in populations of healthy people and may provide protection. Two oral vaccines are available outside the United States: Dukoral (Crucell, the Netherlands) and Shanchol (Shantha Biotechnics, India)/mORCVAX (Vabiotech, Vietnam). Compared with the previously licensed injectable vaccine, these vaccines appear to be safe, provide better immunity, and have fewer adverse effects. However, CDC does not recommend these vaccines for most travelers because of the low risk of cholera to US travelers and the incomplete immunity that the vaccines confer [6]. No country or territory requires vaccination against cholera as a condition for entry.

Vaccination of Close Contacts of Immunocompromised Hosts

Close contacts of transplant recipients could transmit some live, attenuated vaccine strains to the immunocompromised host. In general, certain live viral vaccines such as oral polio, nasal influenza, and smallpox should be deferred from use in close contacts of immunocompromised hosts. Administration of other live vaccines such as measles, mumps, rubella, yellow fever, oral Salmonella, varicella (Varivax®) [77], and zoster (Zostavax®) vaccines are much less likely to be transmitted and may be given to close contacts of immunocompromised hosts. If a rash develops with varicella vaccine, the immunocompromised host should avoid direct contact with the rash.

Post-travel Evaluation

For routine, short-stay travel, most patients do not need to be evaluated afterward, unless they are ill. Clinicians seeing transplant recipients who are ill after travel should consider both routine and atypical, geographic-, and travel-related infections. Travel destinations are associated with the probability of the diagnosis of certain diseases, which can guide clinicians diagnostically; destination-specific information can be obtained from the Centers for Disease Control

Travelers Health website (available at wwwnc.cdc.gov/travel/destinations/list.htm [78]. A report from 30 GeoSentinel sites that specialized travel or tropical medicine clinics on 6 continents found that dengue and malaria were among the most frequent causes of systemic febrile illness among travelers [79]. Travelers from all regions except Southeast Asia presented with parasite-induced diarrhea more often than with bacterial diarrhea. Among travelers returning from sub-Saharan Africa, rickettsial infection, primarily tick-borne spotted fever, occurred more frequently than typhoid or dengue.

Recent case reports of travel-related infections in transplant recipients include visceral *Leishmania* in a pancreas and kidney transplant recipient who traveled to Greece [80], disseminated histoplasmosis in a renal transplant recipient after traveled to Bangladesh [81], disseminated *Penicillium marneffei* infection in an Australian renal transplant patient who presented shortly after a 10-day holiday to Vietnam [9], and *Vibrio parahaemolyticus* septicemia in a liver transplant recipient who traveled to the Gulf of Mexico [82]. Transplant recipients may manifest unusual infections or unusual manifestations of routine infections, and clinicians caring for them should be prepared for broad array of diagnostics and treatment.

Conclusions

Every year there are more transplant recipients with an increasing variety of immunosuppression. As their health improves, they may wish to travel more frequently. Research on vaccines and transplant recipients in recent years has been quite helpful in eliciting the potential immunogenicity and safety of various vaccines in this population. Hopefully within the next 5 years, we will begin to understand more of the immunology in these hosts, which should allow for better vaccination. Improved vaccines, the ability to safely give adjuvants to boost immunogenicity, and more selective immunosuppression may allow for better protection of travelers in this vulnerable population.

In summary:

- Transplant recipients are increasing in number, as is the extent of global travel; thus this issue will continue to expand. Further studies are needed and will help guide clinical management. Prior to foreign travel, it is prudent to have transplant recipients seen by travel medicine specialists familiar with this complex and vulnerable population. Travel vaccines should be guided by the details of the travel in combination with details of the immunosuppressive regimen.
- Transplant recipients are more vulnerable to infection and are less likely to have a strong immunologic response to immunization. Vaccination either before undergoing immunosuppression or optimizing the time of vaccination after immunosuppression may help optimize the immunologic response.
- Routine immunization is important to consider and may have been overlooked or avoided in this population. Routine immunization should be considered before patients undergo solid organ or stem cell transplant. In addition, booster doses should be considered, especially after HSCT.
- Although not generally evidence based, additional or higher doses of certain vaccines may result in better protection, as has been demonstrated with hepatitis B vaccine in immunocompromised hosts.
- Immunoglobulin may provide protection against hepatitis A, measles, and other illnesses when the recipient is less likely to have an immunologic response, vaccination is contraindicated, or does not have enough time to develop protection.
- Evaluation of serologic response after vaccination may provide an index of seroprotection and may help guide the use of additional vaccinations. Serologic response is primarily a measure of humoral immunity and does not generally include information on cellular immunity. Even in situations where the antibody titers are low or undetectable, these subjects may be more protected than those that were never vaccinated (i.e., even minimal immunity may be better than none).

Vaccination in Organ Transplant Patients

63

Lara Danziger-Isakov and Camille Nelson Kotton

Introduction

Vaccination has saved more lives than any other therapeutic modality in medicine, yet this remains an overlooked and underutilized tool for protection in immunocompromised hosts, especially adults. According to the 2015 National Health Interview Survey (NHIS), pneumococcal vaccination coverage in high-risk adults aged 19–64 years was only 23% and 74% in adults ≥65 years; zoster was only 31% of those ≥60 years, and 62% of adults have had tetanus boosters [1]. Pediatric patients tend to be much better vaccinated than adults, although some of those with chronic illness may have missed vaccines, and pediatric transplant patients have been documented to miss numerous vaccines [2]. With the rise in vaccine avoidance and alternative vaccination strategies for children due to unfounded concerns regarding potential side effects, the need for vaccines in immunocompromised children is even more acute as herd immunity to common vaccine-preventable diseases is waning as evidenced by recent outbreaks of measles and mumps. Studies from Iran, Brazil, and Switzerland have shown that pediatric solid organ transplant candidates have incomplete vaccination status prior to transplantation [2–4]. A single center survey of adult solid organ transplant (SOT) recipients found that more than half had received no information on vaccination [5]. Routine adult and pediatric vaccine schedules appear on the CDC website [6]. A summary of vaccines that can be used in transplant recipients appears in Table 63.1.

This lack of vaccination in immunocompromised hosts stems, in part, from concerns about potentially doing harm in the setting of a suppressed immune system. While live vaccines should be avoided in immunosuppressed hosts, most other vaccines are well tolerated and do not have significant adverse effects. Live vaccines that should generally be avoided (or used very cautiously, as discussed below and in the chapter on "Travel Medicine") include those against varicella, zoster, measles, mumps, rubella, rotavirus, polio or *Salmonella typhi* (for the last two, avoid oral vaccine; injectable is not live), tuberculosis (as attenuated *Mycobacterium bovis* or *Bacillus* Calmette-Guérin (BCG)), yellow fever, and smallpox; some are highlighted as contraindicated in immunocompromised hosts in Table 63.1. While there is some emerging data that influenza vaccine may be associated with de novo alloantibody formation and/or augmented cellular alloimmunity [7, 8], the long-term impact remains unknown, and vaccination has never been clearly associated with a risk of acute or chronic organ transplant rejection.

In general, vaccination in immunocompromised hosts is at least partly protective and may attenuate disease severity, if not prevent it all together [9]. Studies show a broad array of response to vaccination; overall responses to influenza vaccination have ranged from 15% to 93% with lower responses seen in lung transplant and greater responses several years after kidney transplant [10]. Factors that contribute to a reduced immunologic response to vaccination include exogenous immunosuppression, including both induction agents (i.e., thymoglobulin, alemtuzumab, belatacept, rituximab) and those used for chronic immunosuppression (i.e., mycophenolate mofetil, cyclosporine, tacrolimus, prednisone, sirolimus, azathioprine, and others); underlying disease states (lupus, rheumatoid arthritis, vasculitides); comorbidities (diabetes, human immunodeficiency virus (HIV), renal or hepatic insufficiency, obesity); hypogammaglobulinemia; age; and numerous other factors. Hepatitis A	Inactivated	Yes	Yes[b]	Yes	Yes[b]
Human papillomavirus (HPV)	Inactivated	Yes	Yes	Yes	Yes
Measles, mumps, rubella (MMR)	Live, attenuated	Yes	Yes[a]	No	No

[a]Nonimmune or nonvaccinated individuals
[b]With specific risk factors

specific immunosuppressive agents have an impact on response to vaccination remains poorly understood, as studies have been variable and sometimes contradictory. Response rates to specific vaccines are discussed in further detail below.

To improve response to vaccination, transplant clinicians may wish to vaccinate during periods of lower immunosuppression. Pretransplant vaccination is likely to result in higher levels of protection, especially for those recipients not yet on immunosuppression, and this is an excellent window of opportunity for vaccination, especially since live vaccines could be given then (assuming at least a 1-month washout period before immunosuppression is begun) [11]. Routine vaccines, as outlined on the Centers for Disease Control and Prevention (CDC) website [6], should be updated during the pretransplant period. Experts would generally avoid vaccination during the first few months after transplant, when immunosuppression is generally most potent [12]. A group of transplant infectious disease experts recently recommended that influenza vaccines should be given no earlier than 3 months after transplantation or intensified immunosuppression for rejection, although during periods of pandemic or high influenza activity, vaccine can be given as early as 1 month posttransplant with the caveat that incomplete protection may be achieved and that if influenza activity is still significant, it may be a reasonable approach to reimmunize children and adults who received early vaccination (i.e., at <3 months posttransplant) [10]. The Infectious Disease Society of America's recommendations in immunocompromised hosts suggest waiting at least 2 months after SOT for influenza vaccination [13].

Household contacts of severely immunocompromised patients may be given live-virus vaccines such as yellow fever, measles-mumps-rubella (MMR), or varicella/zoster vaccines [14], but should not be given transmissible vaccine such as oral polio or smallpox vaccines [13, 15]. Live-attenuated influenza vaccine (LAIV) should be avoided if possible but has been used for household contacts in circumstances where inactivated injectable influenza vaccine is not available. Whether rotavirus can safely be given to infants in homes with immunocompromised hosts is unknown; the virus has been shown to cause diarrhea in infants with severe combined immunodeficiency [16], and the vaccine strain has been shown to shed for up to 9 days after vaccination [17]. However, transmission vaccine-strain rotavirus from a recently vaccinated infant to immunocompromised caretaker has not been reported, and standard precautions when handling potentially infectious materials are recommended. Clinicians must weigh the risks of vaccination of household contacts with the benefits of protection and avoiding active disease with potentially higher rates of transmission of wild-type disease to the immunocompromised host. Pet owners should be aware of the risk of transmission to them of live vaccines such as *Bordetella bronchiseptica*, which has been transmitted to immunocompromised hosts resulting in clinical infection [18, 19].

Patients may be considered for an accelerated vaccination series prior to transplant, given the improved efficacy of vaccination prior to transplant, although such vaccination has not been systematically evaluated in adult pediatric transplant candidates. Accelerated vaccination schedules for traveling infants have been published and include MMR vaccine from 6 months of age and meningococcal vaccine from 9 months of age [20]. Catch-up vaccination schedules for children who have missed or delayed vaccines are reviewed biannually and updated by the ACIP and available on the CDC website.

Adverse reactions to vaccines should be reported so that other providers can be aware of the potential risk. Reporting can be done in the United States either by filling out the Vaccine Adverse Event Reporting System (VAERS) form on the VAERS website (http://www.vaers.hhs.gov) or by calling 1-800-822-7967; reporting in other countries varies.

Specific Vaccines

Influenza

Influenza is an orthomyxovirus with three types, A, B, or C. Influenza A viruses are further divided into subtypes on the basis of their surface hemagglutinins (17 types) and neuraminidases (10 types). Combinations of the hemagglutinin and neuraminidase determine the circulating strains (e.g., H1N1 or H3N2). Influenza B does not have subtypes but can be subdivided into strains (Yamagata and Victoria lineages), and neither influenza B nor influenza C are reported to cause epidemics. Historically, around 40–50% of respiratory tract infections have been attributed to influenza in solid organ transplant recipients during the winter months with the current literature suggesting that 1–4% of recipients are infected annually [16, 21–24].

Influenza can cause significant morbidity and mortality in solid organ transplant (SOT) recipients. The recent 2009 H1N1 influenza pandemic provided an opportunity to delineate risk factors for severe illness. Kumar and colleagues reported recent augmentation of immune suppression, lymphopenia, infancy, diabetes, and delay in the initiation of antiviral therapy as risks for more severe diseases [16]. While 4% of adult patients died, mortality in pediatric patients did not occur in this cohort which is significantly decreased from a prior pediatric cohort from the early 1990s with a 23% mortality [16, 25, 26]. Early institution of antiviral therapy appears to substantially affect outcome [16].

Influenza vaccines were first available in 1945 but have evolved with improved immunogenicity, efficacy, and safety profiles. Current formulations include standard-dose intramuscular, high-dose intramuscular, adjuvanted vaccine, and live-attenuated influenza vaccine (LAIV) [10]. Specific content of these formulations is adjusted annually based on the predictions for circulating viral strains and usually contains antigens for influenza A (two strains) and influenza B (one strain in trivalent vaccine, two in quadrivalent vaccine). Live-attenuated vaccines are cold adapted and should not replicate at 37°C; however, due to the small theoretical risk of replication, LAIV is not recommended after transplant [10]. The pediatric age group is unique in that two doses of vaccine are recommended for first-time vaccine recipients under the age of 9 regardless of immunologic status.

Adult

Vaccination of adult transplant recipients is recommended by national and transplant groups [11, 13, 27]. Various nuances of influenza vaccination are covered in Table 63.2. Trials regarding immunogenicity of influenza vaccine all vary with

Table 63.2 Recommendations for influenza vaccine graded according to strength of recommendation and quality of evidence [10]

Seasonal inactivated influenza vaccine should be recommended for annual administration in pre- and posttransplant recipients (recommendation supported by WHO, ACIP, AST) (strong, moderate)
The benefit of vaccination outweighs any theoretical safety concerns related to rejection[a]
LAIV is not recommended for posttransplant recipients (strong, moderate)
Influenza vaccine should be given no earlier than 3 months after transplantation or intensified immunosuppression for rejection (weak, moderate)
During periods of pandemic or high influenza activity, vaccine can be given as early as 1 month posttransplant, although incomplete protection may be achieved (strong, low)
If influenza activity is still significant, a reasonable approach is to reimmunize children and adults who received early vaccination (i.e., at <3 months posttransplant) (weak, low)
There are insufficient data to recommend
High-dose influenza vaccine
Adjuvanted vaccine
Intradermal vaccine
Booster doses of vaccine within the same season
Close contacts of transplant patients should be immunized (strong, moderate)
Inactivated vaccine is preferred if available (strong, low)
HCW including those working with transplant patients should be immunized (strong, moderate)
Inactivated vaccine is preferred if available (strong, low)
Organs from donors who recently received LAIV (in the past 7 days) (including lung transplant donors) can be transplanted (strong, low)
Influenza vaccination for children should follow the standard age and dose recommendation
At this time, vaccine dosing and the number of doses should follow age-appropriate recommendations as for nontransplant patients.
Vaccine is not approved for administration to children younger than 6 months of age.
Two doses 4 weeks apart are recommended for children younger than 9 years of age who have not been previously vaccinated against influenza (strong, high).
Persons with known severe allergic reactions to chicken or egg protein should not receive influenza vaccine; it can be considered to give vaccine under the supervision of an allergy expert (strong, high).

[a]Excluding vaccine-related history of Guillain-Barre syndrome

respect to host, vaccine dose and type, adjuvant use, and evaluation of immunologic outcome [28]. Nonetheless, they are notable for a trend toward diminished immune response in organ transplant recipients, with some minor augmentation of immune response in those given multiple vaccine doses. Use of adjuvant or multiple doses did not necessarily impact immunogenicity across various studies. Given the enhanced complexity of double vaccination (patients returning for a second visit, cost, etc.) conclusive recommendations cannot yet be made regarding the optimal number of vaccine doses. Durability of protection against influenza is also diminished; whether a second, appropriately timed dose might provide longer coverage remains to be determined and could be considered for certain higher risk transplant recipients. The role of adjuvants to augment response to vaccination of transplant patients is somewhat controversial; there are safety concerns that adjuvants may increase the risk of organ rejection by immune stimulation, although this has never been proven, and some vaccines are not commercially available without adjuvants.

Optimal timing of vaccination after solid organ transplant is likely to be very important in optimizing the immunologic response. Unfortunately, there are few trials that analyze optimal timing with respect to vaccination response. Most vaccine trials exclude patients who underwent organ transplant within the past 2 to 6 months. The potent immunosuppression given at the time of organ transplant is likely to result in muted immunologic response to vaccination for at least several months. Many programs defer vaccination of their transplant patients in the first few months after transplantation. One early study of mixed organ transplant recipients saw no difference in the time after transplant in vaccine nonresponders versus responders [29]. In a series of 51 liver transplant recipients who underwent influenza vaccination, vaccine response corresponded to the length of time after transplant: within 4 months of transplantation, 1/7 (14%) responded; within 4–12 months, 6/9 (67%); and after 12 months, 30/35 (86%) subjects responded to the H1 strain; overall, more than 55% of the subjects vaccinated 4–12 months posttransplantation had adequate antibody seroconversion to the three strains of the influenza vaccine [30]. Another study showed lower antibody titers in kidney transplant recipients vaccinated within 6 months of transplantation [31]. One third of the 53 transplant recipients were 6 months or less from the time of kidney transplantation. The muted response to vaccination was more marked with response to seroresponse (fourfold increase in antibody titer) than with seroprotection (antibody titer $\geq$1:32).

There have been reports of human leukocyte antigen (HLA) and donor-specific antibody (DSA) production after influenza vaccination. Thus far, there is no rejection or graft dysfunction following immunization reported in studies that have specifically looked at this outcome (summarized in Kumar et al. [10]). In a retrospective case-control series of 60 heart transplant patients, of whom 15 had been vaccinated with H1N1 virus antigen with ASO3 adjuvant vaccine within 21 days, the overall rate of all grades of cellular rejection was not statistically different between groups; however, acute cellular rejection, >/=grade 2 (1990 ISHLT criteria), was more frequent among those who were recently vaccinated (control: 1/45 vs. 6/15, $p = 0.001$) [7].

In the absence of strong data to drive the clinical decision regarding timing, many programs develop local protocols. A survey of 239 transplant programs showed that the majority of the respondents began posttransplant vaccination within the first 6 months, with 42% of programs giving influenza vaccine within the first 3 months, 43% at 3–6 months, 13% at 6–12 months, and 3% more than 12 months after transplant [32]. Guidelines from the American Society of Transplantation Infectious Diseases Community of Practice suggest restarting vaccination 3–6 months after transplant, while Infectious Diseases Society of America (IDSA) guidelines suggest starting as early as 2 months posttransplant [11, 13]. Expert guidelines based on the 2009 H1N1 pandemic experience suggested that transplant recipients begin to receive influenza vaccine during a pandemic as soon as 1 month after transplant [33].

Pediatrics

As in adults, vaccination for pediatric solid organ transplant recipients is recommended beginning 3–6 months after transplantation [11]; however, earlier administration in pediatrics has been considered in pediatric lung recipients and reported after pediatric heart transplantation [34, 35]. Compared to studies in adult transplant recipients, studies of influenza vaccine safety, immunogenicity, and efficacy in pediatric transplant recipients are limited. Many of these studies were performed in the 1990s when immunosuppressive regimens differed significantly from current use although data from the 2009 H1N1 pandemic regarding vaccination has been emerging.

Seasonal influenza vaccination prior to 2009 in both pediatric liver and renal transplant recipients demonstrated seroprotective responses ranging from 15% to 85% depending on the influenza antigen used with lower responses to influenza B antigens as has been reported in healthy controls [36–38]. In liver transplant recipients, younger age and time closer to transplant have been associated with decreased influenza vaccine responses, and repeat vaccination did not significantly improve responses in some studies [37, 39]. While most studies focus on humoral responses, Madan and colleagues showed similar seroprotection and seroconversion in a cohort of long-term pediatric liver transplant, but interferon gamma production was decreased compared to healthy sibling controls [36].

Data on 2009 pandemic H1N1 influenza vaccine responses in pediatric transplant patients have also emerged. In Germany,

Goldschmidt et al. retrospectively evaluated the efficacy of an adjuvanted 2009 H1N1 vaccination in pediatric liver transplant recipients without measuring seroresponses; they reported higher rates of H1N1 infection in unvaccinated (25%) compared to vaccinated (4%) individuals [40]. In pediatric renal transplant recipients, Esposito et al. detailed 81–100% seroprotection with 2009 A/H1N1 MF59-adjuvanted influenza vaccine [41]. Five pediatric heart transplant recipients received adjuvanted vaccine between 5 and 23 weeks after transplant with 60% developing seroprotection despite recent induction with antithymocyte globulin [35]. Conversely, fewer than 50% of pediatric transplant recipients, predominantly renal, developed seroprotection after administration of nonadjuvanted vaccination [42]. Haller and colleagues reported increased seroprotection from 66.6% to 89.5% after a second dose of nonadjuvanted 2009 H1N1 influenza vaccine unlike previous reports for seasonal vaccination [37, 39, 43]; the authors concluded that a two-dose regimen should be considered in pediatric liver transplant recipients in the pandemic setting. Further, a recent study suggested that high-dose vaccination (60 μg) may have improved immunogenicity compared to routine dosing (15 μg) for pediatric transplant recipients [44]. Importantly, significant side effects from vaccination including acute rejection were not found in studies of seasonal or pandemic influenza vaccines in the pediatric population.

Pneumococcal (Polysaccharide/Protein Conjugate Vaccines)

Pneumococcal disease is among the most common infections, and a broad range of hosts should be vaccinated according to guidelines, including transplant recipients [27]. Transplant recipients who remain on trimethoprim/sulfamethoxazole may be protected against *Streptococcus pneumoniae* infections, as well as other infections; pneumococcal vaccination would still be recommended. The vaccine comes in the traditional polysaccharide 23-valent form (PPV23, commercially known as Pneumovax) and protein-conjugate forms. The 7-valent (PCV7, marketed under the trade name Prevnar) has recently been replaced by the 13-valent (PCV13, marketed under the trade name Prevnar 13, which in addition to the 7 serotypes included in the original PCV7 contains the 6 pneumococcal serotypes responsible for 63% of invasive pneumococcal disease cases now occurring in children younger than 5 years; PCV13 is replacing PCV7). While PCV7 is no longer available in the United States, PCV13 has not yet been studied in transplant recipients, and subsequent studies of conjugate vaccines discussed were performed with PCV7. Clinicians should be aware that PCV7 and PCV13 provide a narrower spectrum of coverage (7 and 13 serotypes, respectively), while PPV23 covers 23 serotypes. Use of both together is recommended.

Response to vaccination in SOT recipients is generally adequate, although lower than controls [45]. A trial of 43 adult kidney transplant recipients immunized with PPV23 demonstrated a significant increase in total antibody concentration against the 14 serotypes tested, from a median of 12.1 mg/L (range: 2.6–124.0) before vaccination to 51.9 mg/L (4.0–160.7) 4 weeks after vaccination, as well as a significant increase in the number of serotypes recognized, from a median of 9 (0–13) to 13 (3–14) [46]. Antibody responses after vaccination were only slightly lower than in a published cohort of vaccinated healthy controls. The estimated glomerular filtration rate correlated with response to vaccination. In another trial of PPV23 in renal transplant recipients, almost all antipneumococcal IgG titers were greater than the protective titer recommended by the World Health Organization (WHO) [47]. A trial of adult kidney transplant recipients comparing a single dose of PPV23 or PCV7 found a response rate was not significantly different between groups; there was a trend toward enhanced immunogenicity for PCV7 by ELISA; however, functional antibody responses were not different [48].

Multiples studies have investigated the utility of serial dosing of different pneumococcal vaccine formulations, i.e., PCV7 prior to PPV23, and the optimal dosing strategy for pneumococcal vaccine in transplant recipients remains uncertain due to conflicting reports in the literature. A trial of 113 adult liver transplant recipients given either PCV7 followed by a PPV23 booster 8 weeks later or placebo followed by a standard single dose of PPV23 found similar results with respect to response to at least 1 serotype, mean number of serotypes to have a response, and functional antibody titers (measured by opsonophagocytic assay); the authors concluded that administration of a single dose of PPV23 should continue to be the standard of care for adult liver transplant recipients [49]. A pediatric study in which 81 pneumococcal vaccine-naive transplant recipients (31 heart, 18 liver, 5 lung, and 27 kidney) were given 3 doses of PCV7 at 8-week intervals, followed 8 weeks later by a dose of PPV23, demonstrated that PCV7 was safe and immunogenic and that PPV23 when administered more than a year after transplant was useful in boosting antibody responses in recipients demonstrating lower rates of responsiveness [50]. Two doses of PCV7 induced ≥ twofold increases in geometric mean concentrations in all organ groups; cardiac and lung recipients demonstrated additional benefit from a third dose of PCV7. Gattringer et al. evaluated serial vaccination with PCV7 followed by PPV23 in 26 adult heart or lung transplant recipients; while PCV7 was immunogenic in these patients, PPV23 did not further augment the immune response to those 7 serotypes but did provide protection against other serotypes [51].

The timing of vaccination after SOT has not been well studied. In one study of 158 recipients of allogeneic bone

marrow transplant, PCV7 vaccination at 3 months after stem cell transplantation was found to be not inferior to PCV7 vaccination at 9 months after transplantation, at 79% versus 82%; the authors suggested that the durability of protection might be shorted in this population [52]. Whether such data is transferrable to SOT recipients is not known; perhaps earlier vaccination of naïve patients, with a plan to repeat, may provide better protection than a delay (and possible omission).

Repeat vaccination may be indicated to provide optimal protection; however, unlike other vaccines, a booster effect is not generally seen with pneumococcal vaccination. One-time revaccination 5 years after the first dose is recommended for persons 19 through 64 years of age with immunocompromising conditions, and those who received PPV23 before age 65 years for any indication should receive another dose of the vaccine at age 65 years or later if at least 5 years have passed since their previous dose; no further doses are needed for persons vaccinated with PPV23 at or after age 65 years [27]. In normal hosts, both primary vaccination and revaccination with PPV23 induce antibody responses that persist during 5 years of observation [53]. Concerns about hyporesponsiveness with multiple doses of pneumococcal vaccine have not borne out in all trials and has not been studied in transplant recipients. A trial in adults of single-dose PPV23 given to 14 dialysis and 37 kidney transplant recipients demonstrated a response of 96% at 4 weeks, 94% at 6 months, and 85% 1 year after transplant; authors postulate that such a decline may warrant more frequent vaccination [54]. In general, testing for pneumococcal antibody response is not clinically useful, and clinicians should be the revaccination timing on the net state of immunosuppression and predicted response and durability of vaccination, as well as ease of administration.

Meningococcal (Polysaccharide/Protein Conjugate)

Neisseria meningitidis can cause a life-threatening meningitis or disseminated disease (meningococcemia), both in normal and immunocompromised hosts, and less commonly carditis, septic arthritis, or pneumonia. Patients who have undergone splenectomy are at higher risk for infection from these encapsulated bacteria, and vaccination is recommended before and periodically after splenectomy. The previously used polysaccharide vaccine (Menomune) has mostly been replaced by the meningococcal conjugate vaccines (Menactra and Menveo) containing groups A, C, Y, and W-135 along with diphtheria toxoid due to better immunogenicity in normal hosts. Experts expect that this will provide better protection in immunocompromised hosts as well [55]. Meningococcal B vaccination was also recently approved (Bexsero and Trumemba) to cover the additional Group B; however, no studies in transplant recipients have been reported to date.

Meningococcal vaccine is poorly studied in SOT recipients, although it is generally recommended. One study in 10 pediatric SOT recipients showed that a single dose of conjugate meningococcus C vaccine resulted in all patients demonstrating an increase of serum bactericidal antibody titers after vaccination; a significant decrease in titers was seen after 6 months; however, all patients maintained protective titers ($\geq$ 1:8) [56]. Until we have better data, this vaccine should be used as per standard guidelines (available at https://www.cdc.gov/vaccines/schedules/ [6]), especially in vulnerable teenagers and those after splenectomy, perhaps with more frequent booster doses in SOT recipients [11, 55].

Varicella/Zoster

Varicella-zoster virus (VZV) is an α-herpesvirus that establishes latency in sensory ganglia [57–59]. Primary VZV infection, often called chickenpox, presents with a disseminated vesiculopapular rash, fever, and transaminitis. Herpes zoster (HZ), the reactivation of VZV, is usually characterized by a painful or prutitic rash which follows the dermatome of the affected nerve [60, 61]; it sometimes causes disseminated disease. The largest series of pediatric transplant recipients with VZV infection, reported from the prevaccination era, revealed infection in approximately one of every seven solid organ transplant recipients; primary chickenpox and herpes zoster were equally represented [62]. VZV infection has been reported despite the postexposure prophylactic use of acyclovir and varicella-immunoglobulin in naïve recipients.

Varicella vaccines are live-attenuated varicella virus derived from the Oka strain. Several formulations are available including Varivax (Merck, NJ, USA) and Okavax (Biken, Osaka, Japan) for over 12 months of age and Varilrix (GlaxoSmithKline, Rixensart, Belgium) for over 9 months of age. A combination vaccine with MMR (Proquad, Merck, NJ, USA) is also available. Additionally, Zostavax (Merck, NJ, USA) targeted to reduce HZ infections is approved for immunocompetent patients over 50 years of age. In immunocompetent individuals, varicella vaccine has excellent seroconversion in naïve individuals, with 94–99% of children and 94% of adults responding after two doses [63–65]. Quadrivalent vaccination (VZV-MMR, Proquad) showed seroprotection of >90% after one dose and 99% after two doses equivalent to concomitant dosing of individual varicella vaccine [66]. Approximately 64–85% of adults maintained seroprotective titers for 1–6 years postvaccination [65]. Even one dose of varicella vaccine prevented typical chickenpox and drastically reduced the incidence of breakthrough infections to <5% within 3 years of vaccination [67].

Pediatrics (Varicella Vaccine)

In pediatric transplant recipients, varicella vaccine given prior to transplant has been shown to be effective in preventing posttransplant infection. Vaccination is recommended in pediatric solid organ transplant candidates if no other contraindications to vaccination exist; however, as a live-virus vaccine, it is not routinely recommended after transplant [11]. Pediatric renal transplant recipients who had received vaccination prior to transplant developed significantly fewer varicella infections after transplant (12%) compared to those without a history of varicella vaccine or infection (45%) [68]. In pediatric heart transplant recipients vaccinated a median of 16 months pretransplant, the majority (> 80% of those evaluated) had sustained vaccine responses up to 1 year after transplant [50].

Although live-viral vaccines are not recommended after transplantation, several groups have evaluated their administration in pediatric liver and kidney recipients as seropositivity against varicella has been shown to decline after transplant [69]. Eleven living donor liver transplant recipients received varicella vaccination with 87% seroconversion rate, although three had also received vaccination prior to transplant [70]. Khan and colleague retrospectively identified 35 pediatric liver transplant recipients who had received varicella vaccination after transplant; seroconversion occurred in 65% without any significant safety events [71]; this mirrors the response rate of 6 pediatric kidney transplant recipients and 7 additional liver transplant recipients who were also vaccinated in other studies [72, 73]. Another 16 VZV-naïve pediatric liver and/or intestine transplant recipients showed 87% seroconversion, but four developed fever and rash remote from the injection site and three were treated with oral acyclovir for this postvaccine reaction [74]. Further, prospective evaluation of 79 pediatric liver transplant recipients received varicella vaccination in a controlled study that showed safety and immunogenicity, including humoral and cellular responses, to vaccination in this population [75]. Overall, in selected populations of stable liver and kidney pediatric transplant recipients, varicella vaccination after transplantation could be considered but should not be routinely recommended. Routine evaluation for declining antibody titers should be performed, however, to assess potential risk of VZV exposure in immunocompromised pediatric solid organ transplant recipients. Similarly, nonimmune adults should be vaccinated prior to transplant whenever possible.

Adults (Zoster Vaccine)

Zoster occurs in one third of adults and at much high rates in SOT recipients, with an estimated incidence in SOT recipients that is 10- to 100-fold higher than the general population [76]. The vast majority (≥95%) of adults have had prior VZV infection and are at risk for reactivation as clinical zoster, either dermatomal or disseminated [76]. Zostavax®, a higher dose of the attenuated Oka varicella vaccine strain, is Food and Drug Administration (FDA) approved for healthy adults ≥50 years old; there are no published data on its safety and efficacy among immunocompromised patients. The goal of the zoster vaccine is to boost prior immunity, which wanes with time, age, and immunosuppression, increasing the risk of developing clinical zoster. SOT recipients could be vaccinated before transplant, in hopes of decreasing the risk of zoster before and after transplant; there are no data as to whether this is efficacious in this setting and whether it might be helpful in younger transplant patients (i.e., below the FDA-approved age of 50), although a clinical trial is underway to evaluate this. The vaccine is contraindicated after transplant when they are on active immunosuppression [14]. A new nonlive zoster vaccine is being developed and may be in useful in immunocompromised patients [77].

Tetanus, Diphtheria, and Pertussis

Protection against three disparate bacterial diseases—tetanus, diphtheria, and pertussis—is often grouped together in combination vaccines. Tetanus ("lockjaw") and diphtheria (involving thick membranes in the throat) remain relatively rare diseases in the developed world. Pertussis ("whooping cough") is an upper respiratory infection caused by the *Bordetella pertussis* or *Bordetella parapertussis* bacteria, which may lead to coughing with emesis; periodic epidemics occur every 3 to 5 years, with frequent outbreaks. Whether transplant recipients are more susceptible to these infections is not known. A clinical case of severe tetanus in a renal transplant recipient in Brazil has been reported, with autonomic dysfunction, requiring intensive care unit (ICU) care and mechanical ventilation, tetanus-induced acute kidney injury, and sepsis; he was discharged after 37 days of hospitalization with recovered renal function, and authors highlight the importance of vaccination [78].

The vaccine components often include diphtheria and tetanus toxoids (Td), sometimes with acellular pertussis (in DTaP and Tdap). Prior versions contained killed whole cells of the organism that causes pertussis, which was much more reactogenic and less well tolerated. Pertussis outbreaks have occurred in recent years in the United States and elsewhere, and although the vaccine has not yet been studied in this population, it would seem prudent to protect transplant recipients. Currently, the American guidelines recommends a single dose of Tdap as a booster for adults whose last Td was >10 years ago, for health-care workers and for persons who are in close contact with infants <12 months of age. Tdap can be given as soon as 2 years (or shorter intervals) after Td vaccine in high-risk persons [27]. Vaccination is generally felt to be safe and is recommended before and after SOT [11, 55]. A single-center survey of vaccination practices

in 464 transplant recipients found that seroprotection rates against tetanus were fairly high in liver (85.3%) and renal (86.8%) transplant recipients and lower for diphtheria (73% and 60%, respectively) (pertussis was not measured), with considerably lower rates for hepatitis A and influenza [5]. Huzly et al. compared 164 renal transplant recipients with healthy controls before and after tetanus vaccination and found that all patients developed protective tetanus antibody levels that remained protective for at least 1 year after immunization [79]. Diphtheria antitoxin titers before and after booster vaccination were lower in transplant recipients than in controls: 88.5% of patients versus 96.2% of controls developed protective diphtheria antibody titers, and 12 months after vaccination, diphtheria antitoxin values were below the protective level (0.1 IU/ml) in 38% of patients. Neither rejection episodes nor change in renal function was noted after immunization, suggesting that vaccination was safe in this population.

There is little information on the incidence or severity of pertussis or diphtheria in transplant recipients. Another species, *Bordetella bronchiseptica*, the etiologic agent of "kennel cough" in dogs, has caused serious respiratory illness in patients who undergo pediatric lung transplantation [80], heart transplantation [81], and hematopoietic stem cell transplantation (HSCT) [82, 83]. Several of these case patients had pet dogs. The "kennel cough" live vaccine, which contains a mixture of parainfluenza virus and *B. bronchiseptica*, has the potential to cause human *B. bronchiseptica* infection [84]; transplant recipients should be aware of the risk of transmission to them from their pets.

Hepatitis B

Transplant recipients tend to be poorly protected against hepatitis B; in one series of liver, heart, and kidney transplant recipients, 76% were seronegative [85]. This is likely due to multiple factors, including oversight (most commonly), lack of immune response, and insufficient time prior to transplant to give the multiple doses required for sustained seroconversion. In pediatrics, recommendations for hepatitis B vaccination range from universal vaccination of all infants in the United States, Australia, and Switzerland to targeted vaccination of high-risk infants in other European countries including Denmark and the United Kingdom [86–88]. Canada utilizes targeted vaccination in infancy based on the provincial prevalence of hepatitis B and universal vaccination during adolescence in low-prevalence provinces [89]. Regardless, all children undergoing transplant evaluation should be vaccinated [11]. American guidelines recommend vaccination in adults for those with end-stage renal disease, chronic liver disease, and diabetics younger than 60 years as soon as feasible after diagnosis (those over 60 should be vaccinated at the discretion of their clinician), as well as other at-risk populations [27]. High-titer antibody to hepatitis B surface antigen before liver transplantation has been shown to prevent de novo hepatitis B infection, which is especially important in endemic regions; in a pediatric study in Taiwan, 8 of 9 de novo hepatitis B virus (HBV)-infected recipients had anti-HB titers <200 mIU/mL [90].

High-dose vaccine has been more successful in various populations with organ insufficiency. The American guidelines recommend that adult patients receiving hemodialysis or with other immunocompromising conditions receive 1 dose of 40 μg/mL (Recombivax HB) administered on a 3-dose schedule or 2 doses of 20 μg/mL (Engerix-B) administered simultaneously on a 4-dose schedule at 0, 1, 2, and 6 months [27]. Nonetheless, response is still not soaring; a study of 138 immunosuppressed patients (86 with cirrhosis, 42 dialysis patients, 10 allogeneic hematopoietic cell transplants) and 26 healthy subjects as controls who were vaccinated utilizing a high-dose vaccine (40 mcg) and a shortened immunization schedule showed that while 98% of controls responded, only 48% of the immunosuppressed patients seroconverted ($p < 0.001$) [91].

Hepatitis B vaccination is less likely to be effective after SOT. In a series of liver, heart, and kidney transplant recipients who underwent vaccination against hepatitis B (40 ucg dose), 73/98 (74.5%) responded to vaccination; response correlated with more doses (> 4) of vaccine and age less than 52 years old [85]. In another trial, only 3 of 17 liver transplant recipients responded who had undergone transplant for HBV-related disease and were subsequently vaccinated using intramuscular doses (40 ucg) of recombinant vaccine at month 0, 1, and 2, followed, in nonresponders, by a second cycle of 6 intradermal 10 ucg doses every 15 days [92]. Hepatitis B vaccination is less likely to be effective in those with prior hepatitis B exposure. A study of recipients of HBV cAb+ donors showed that none of the 15 chronic HBV carriers succeeded in maintaining HBsAb titers, yet 5 of 6 non-HBV patients with HBcAb-positive donors achieved HBsAb >100 IU/l [93]. This may relate to various genetic issues that decrease their immunologic response to HBV and their ability to clear virus, increasing their risk of developing chronic HBV disease.

As more children and adults are vaccinated against HBV prior to immunosuppression, the population will be more protected at baseline and in less need of complex vaccination schedules before or after SOT. When needed for poor seroconverters, clinicians can consider using multiple and higher vaccine doses, intradermal administration, and sometimes the use of adjuvants to boost immune response. Adjuvants are generally discouraged after SOT, given concerns about immunostimulation and potentially abrogating tolerance, thus elevating the risk of rejection [92].

Hepatitis A

Hepatitis A is relatively rare in the United States, although recently outbreaks have occurred. About half of cases are associated with foreign travel; a recent survey of cases from 2005 to 2007 demonstrated that risk factors were international travel (45.8%), contact with a case (14.8%), employee or child in a daycare center (7.6%), exposure during a food- or waterborne common-source outbreak (7.2%), illicit drug use (4.3%), and men who had sex with men (3.9%) [94]. Universal vaccination of children was recently added to the US national guidelines, but other countries employ prevalence-based (Australia) and individual risk-based administration (Canada) for hepatitis A [87, 89, 95]. Vaccination of adults focuses on those with risk, including men who have sex with men, and persons who use injection drugs, persons working with HAV-infected primates or with HAV in a research laboratory setting, persons with chronic liver disease, persons who receive clotting factor concentrates, persons traveling to or working in countries that have high or intermediate endemicity of hepatitis A, and unvaccinated persons who anticipate close personal contact (e.g., household or regular babysitting) with a recent international adoptee from a country with high or intermediate endemicity [27].

Whether organ transplant recipients (especially liver transplant) are at higher risk for complications from hepatitis A is not known. There have been case reports of recurrent hepatitis A after initial liver transplant for fulminant hepatitis A [96]. With recommendations to protect patients with chronic hepatitis B [97] and hepatitis C [98] against hepatitis A given the potentially augmented risk of fulminant hepatic failure in this population, it would seem prudent to vaccinate liver transplant recipients prior to transplant, as well as any other patients with risk factors for acquiring hepatitis A; whether all transplant recipients should be vaccinated has not been determined but may be reasonable and is currently recommended by most experts [11, 13].

Hepatitis A vaccine is less effective in solid organ transplant recipients. In a study of 37 hepatitis A seronegative liver transplant recipients who were given hepatitis A vaccine 6 months apart, only 8% had seroconverted at 1 month following vaccination and only 26% at 7 months (1 month after the second vaccination) [99]. In another study, none of the eight liver transplant recipients vaccinated responded to the two doses of vaccine given 2 months apart [100]. In a third trial, liver and renal transplant recipients (39 in each group) received 2 doses of hepatitis A vaccine 2 months apart [101]; response after the primary dose occurred in 41% of the liver transplant patients and 24% of the renal transplant patients, while after the second dose, the respective conversion rates were 97% and 72%. In a series of liver, heart, and kidney transplant recipients who underwent vaccination against hepatitis A, 13/17 (76%) responded to vaccination [85]. In a small pediatric study, among 18 patients who had been immunized with one dose before transplant, only seven of 18 (39%) had anti-HAV antibodies 1 year after transplant [2]. A study of 34 children with chronic liver disease found the seroconversion rate 4 weeks after primary hepatitis A immunization to be 76% (94% in controls); 1 month after second dose (6 months later), the seroconversion rates were 97% and 100%, respectively [102]. Discrepancies between studies may be explained by differences in patient selection, severity of liver disease, immunosuppressive medications, and type of vaccine used. In addition, organ transplant recipients have a more rapid antibody decline than controls: 2 years after vaccination, only 59% of liver transplant and 26% of renal transplant recipients who seroconverted retained protective titers [103], while mathematical models of vaccination in normal hosts have predicted antibodies to persist for at least 20–25 years [104]. Use of higher, more than two, or booster doses of hepatitis A vaccine has not been studied in the immunocompromised population but could be considered in the individual patient. SOT recipients who do not have adequate time before higher risk exposure such as travel or do not respond to immunization should be given intramuscular immunoglobulin prior to travel [15]; for more information, see Chap. 62 on "Travel and Transplantation."

Haemophilus Influenzae Type B

Haemophilus influenzae type b (Hib) is an encapsulated pleomorphic gram-negative coccobacillus that causes pneumonia, meningitis, bacteremia, epiglottitis, cellulitis, osteomyelitis, and otitis media among others in healthy children and adults. In the prevaccination era, pneumonia and bacteremia from Hib were reported in solid organ transplant recipients [105, 106].

Hib vaccinations are Hib capsular polysaccharides conjugated to carrier proteins. Hib vaccine has been available in the United States since 1987 with universal infant vaccination recommended since 1990. Since the institution of vaccination in the United States and elsewhere, meningitis, bacteremia, and other invasive infections due to Hib have significantly decreased with up to 95% decreases reported in children under 5 years of age [107, 108]; however, in areas where vaccination is not routine, like much of Africa, Hib continued to cause over 30% of meningitis in the past decade [109].

Stable adult kidney transplant recipients tolerated vaccination with Hib and showed excellent responses regardless of immunosuppressive strategy [110]. In pediatrics, Hib vaccine is routinely recommended as part of routine childhood vaccinations and in the pretransplant setting [11, 13, 111]. In one

study, all 42 children under 5 years with chronic renal failure who received Hib vaccination developed protective responses [112]. Compared to the HSCT population, few studies have assessed the seroprotection against Hib after solid organ transplant. Nearly 100% of pediatric cardiac recipients regardless of the age at which they were transplanted responded to conjugated Hib vaccine after transplant [113]. Further, Urschel and colleagues recently studied 46 pediatric cardiothoracic transplant recipients and reported that only 17.4% had titers below protective levels without booster dosing [114].

Polio

Polio, an enterovirus, has been the focus of a worldwide eradication program. Polio which is spread by the fecal-oral and respiratory routes occurs only in humans. While nearly 95% of infection are asymptomatic, other presentations include aseptic meningitis, sore throat, and fever or, in less than 1% of cases, rapid onset of flaccid paralysis and areflexia. Polio vaccines have eradicated disease in most of the world, with the last reported case of wild-type polio infection acquired in the United States in 1979. Since that time, imported infection or vaccine-associated infections have occurred rarely. Polio vaccines are available in two formulations, an inactivated poliovirus vaccine (IPV) and a live-virus vaccine (OPV). IPV is available alone or in combined formulations with DTaP, Hib, or HBV. OPV can cause vaccine-associated paralytic polio in infants and immunocompromised individuals; therefore, only IPV is recommended in transplant candidates and recipients [11, 13].

Polio vaccination responses have been evaluated in both adult and pediatric transplant recipients. In adult kidney transplant recipients, prevaccination responses to serotype 2 were decreased compared to healthy controls, but seroprotection rates for all three serotypes were equivalent after the booster vaccination [79]. Diana and colleagues reported on a Swiss cohort for which only 43% of pediatric liver transplant candidates had received recommended number of polio vaccine doses [2]. An evaluation of pediatric liver and kidney transplant recipients compared to healthy controls and those with underlying liver or kidney disease assessed geometric mean titer responses to polio serotypes 1, 2, and 3 [115]. Responses were decreased in pediatric kidney transplant recipients compared to pediatric liver recipients and controls.

Measles, Mumps, and Rubella

Measles, mumps, and rubella are all RNA viruses that cause infections that were common in childhood prior to vaccine development. Measles is characterized by the development of cough, coryza, conjunctivitis, and erythematous maculopapular rash that causes acute encephalitis in approximately 1 in every 1000 cases. Mumps is characterized by fever and swelling of salivary glands including parotids, aseptic meningitis, and orchitis. Rubella is generally a subclinical infection but can cause fever, lymphadenopathy, and erythematous maculopapular rash. Encephalitis with rubella is rare (fewer than 1:5000 cases). All three have become less common since vaccination was introduced.

While the first measles vaccine was developed in 1958, a commercially available vaccine was not approved until 1963. The combination vaccine with mumps and rubella was introduced in 1971, and the strains have been refined over time. MMR vaccine led to significant declines in infection rates; however, outbreaks still occur despite vaccination in some cases [116–120]. Single-antigen components are not currently produced in the United States. Quadrivalent vaccine that includes MMR and VZV (Proquad, Merck, NJ, USA) was licensed in the United States in 2005 and showed >90% seroprotection equivalent to concomitant dosing of individual vaccine components [66].

MMR vaccination prior to transplant in children with chronic renal or liver disease has been evaluated. Eight infants with chronic renal disease vaccinated at a mean of 11.6 months old showed 88–100% response to each of the vaccine components comparable to healthy children [121], while ten toddlers (15–33 months of age) on dialysis showed 80%, 50%, and 80% responses to measles, mumps, and rubella, respectively [122]. Forty-two older children awaiting renal transplant had a 98% seroconversion rate with measles vaccination [123]. When single-antigen components were administered to liver transplant candidates, response rates were 82%, 90%, and 100% to measles, mumps, and rubella, respectively [73].

Adults born before 1957 are generally considered immune to measles. Those born after 1957 until about 1980 were less well protected by the measles vaccines and are considered at risk for infection. Transplant clinicians may wish to check antibody titers before transplant in this vulnerable population and use this preimmunosuppression phase to vaccinate nonimmune hosts [11]. After transplant, the vaccine is contraindicated, as it could cause life-threatening disseminated disease including encephalitis, for which there are no specific antiviral agents. Nonimmune (or those at high risk for being nonimmune) SOT recipients at risk for being exposed or who have been exposed to measles should be given immune globulin for protection [15].

Again, live-viral vaccines are not routinely recommended after transplantation; however, their administration after pediatric liver and kidney transplantation has been studied as seropositivity against measles has been shown to decline or be absent after liver and thoracic transplant [69, 114]. The earliest report of posttransplant MMR vaccination occurred when 7 of 18 liver transplant recipients had at least transient

seroconversion in 1993 [124]. Additional studies in liver transplant recipients including over 50 patients revealed seroconversion rates ranging from 73 to 100% for MMR components without significant safety events [70, 71, 73]. Reports of MMR vaccination after other pediatric solid organ transplantation are lacking.

Human Papillomavirus (HPV)

Human papillomaviruses are generally clinically unremarkable; however, some cause clinically apparent epithelial proliferation (warts), and others are associated with anogenital dysplasia and cancers (HPV 16 and 18). Estimates in the United States report over 6.2 million new acquisitions of genital HPV and 11,100 new cases of cervical cancer yearly [125]. The prevalence of an anogenital malignancy in a large cohort of renal transplant recipients was 1.6%, and the majority were associated with a high-risk HPV types [126]. Furthermore, using Medicare billing, Kasiske and colleagues report a five-fold increase in cervical and vulvovaginal cancers in female kidney transplant recipients compared to the general population in the United States [127]. Similar increases in cervical cancer and cervical intraepithelial neoplasia have been reported in heart and lung transplant cohorts, respectively [128, 129].

Human papillomavirus vaccines currently available include the bivalent (Cervarix; GlaxoSmithKline Biologicals, Rixensart, Belgium with HPV 16 and 18) and nonavalent (Gardasil; Merck & Co Inc., West Point, PA, USA with HPV 6, 11, 16, 18, 31, 33, 45, 52, and 58) which cover up to 90% of the oncogenic strains leading to cervical and anogenital cancers. Both vaccines are given in series and are approved in the United States in both young women since 2006 and men since 2009. Vaccines were shown to be efficacious against the acquisition and persistence of HPV infection as well as progression to cervical or anogenital disease in multiple randomized double-blind placebo-controlled trials [125, 130–133].

Limited data in transplant recipients exist; however, Kumar and colleagues reported data on 47 transplant recipients vaccinated with the quadivalent vaccine showing both vaccine safety and vaccination response between 50 and 70% depending on the HPV serotype. Further, decreased responses were seen early after transplant, in lung transplant recipients, and with increased tacrolimus levels. In addition, vaccine responses waned by 12 months postvaccination [134].

Conclusions

Vaccination of transplant recipients is a power tool for protection of this vulnerable population and yet remains an underutilized resource. The majority of vaccines are safe and well tolerated. Live viral vaccines should not generally be used in immunocompromised hosts, and there should be at least a one-month lag time after vaccination and before transplant. Additional research regarding optimal doses, number of vaccines, use of adjuvants, impact of immunosuppressive regimens, and timing of vaccination is much needed in solid organ transplant recipients.

Prevention of Fungal Disease

64

Shirish Huprikar and John R. Wingard

Introduction

Invasive fungal infections (IFIs) are serious complications associated with significant morbidity and mortality in solid organ transplant (SOT) and hematopoietic cell transplant (HCT) recipients. The recent epidemiology of IFIs in SOT and HCT recipients in the United States was described by the Transplant-Associated Infection Surveillance Network (TRANSNET), a consortium of 23 transplant centers in the United States that prospectively identified IFIs in SOT recipients [1] and HCT recipients [2]. The 1-year incidence of first IFIs in SOT patients was as follows: small bowel transplant (11.6%), lung (8.6%), liver (4.7%), heart (4%), pancreas (3.4%), and kidney (1.3%). The 1-year incidence of first IFIs in HCT patients was as follows: mismatched related donor (8.1%), matched unrelated donor (7.7%), matched related donor (5.8%), and autologous (1.2%). The most common IFIs in SOT recipients were invasive candidiasis (IC) (53%), invasive aspergillosis (IA) (19%), cryptococcosis (8%), endemic IFIs (5%), and mucormycosis (2%). The median onset of IC and IA was 103 and 184 days, respectively. In contrast, the median onset of cryptococcosis was 575 days after transplantation. The most common IFIs in HCT recipients were IA (43%), IC (28%), and mucormycosis (8%). The median times of onset of IC and IA were 61 and 99 days, respectively.

Strategies to prevent early IFIs in SOT and HCT recipients are generally advocated in patients with established risk factors. In this chapter, we review the literature regarding antifungal prevention in the various transplant types and consensus antifungal prophylaxis guidelines that may exist (Table 64.1).

Liver Transplantation

Current guidelines recommend antifungal prophylaxis with fluconazole to target *Candida* in high-risk liver transplant recipients with ≥2 of the following risk factors: prolonged or reoperation, re-transplantation, renal failure, ≥ 40 blood product units, choledochojejunostomy, and perioperative *Candida* colonization [3]. Although no definitive recommendation for duration exists, it is reasonable to continue prophylaxis until risk factors have resolved. Some experts will also consider antifungal prophylaxis with a lipid formulation of amphotericin B or an echinocandin to target *Aspergillus* in patients with ≥1 of the following risk factors: re-transplantation, renal replacement therapy, reoperation, and fulminant hepatic failure [4].

Antifungal prophylaxis is a very common practice in liver transplant centers in North America. A survey study conducted in 2006 and 2007 indicated that 91% of responding centers used either universal (28%) or targeted (72%) antifungal prophylaxis [5]. Although the antifungal choice and duration were quite variable, universal or targeted fluconazole prophylaxis was the preferred approach in the majority of centers. The most common indications for targeted prophylaxis were re-transplantation (78%), dialysis (72%), re-exploration (61%), and colonization with *Candida* (57%). Other indications included prolonged intensive care unit (ICU) stay or mechanical assisted ventilation, high transfusion requirements, and receipt of T cell-depleting agents. Recent studies also demonstrate MELD score as a risk factor for IFI after liver transplantation [6].

Universal Antifungal Prophylaxis Strategies

Universal prophylaxis strategies with both amphotericin B formulations and azoles have been extensively explored in liver transplant recipients. In an observational study, 58 liver transplant recipients received 1 mg/kg of AmBisome for 7 days [7, 8]. There was one *Candida* infection and three fatal *Aspergillus* infections.

Table 64.1 Summary of antifungal prophylaxis in stem cell and solid organ transplantation

Transplant type	Preferred antifungal regimens	Alternative antifungal regimens	Relative cost (least expensive to most expensive)	Comments
Allogeneic HCT, standard risk	FLU MICA	ITRA VORI L-AmB	FLU ITRA VORI, POSA MICA/L-AmB	FLU lacks mold activity - monitoring important ITRA, VORI, and POSA should not be used concomitantly with cyclophosphamide and vincristine; doses of concomitant calcineurin inhibitors should be adjusted; blood concentrations may vary so monitoring may be necessary Most experts deem the ECH as therapeutically equivalent
Allogeneic HCT, high risk	VORI POSA	MIC ITRA FLU L-AmB	FLU ITRA VORI, POSA MICA, L-AmB	Definitions of high risk vary but generally include mismatched or unrelated donor transplants, cell-depleting maneuvers, cord blood grafts, older age, acute myelogenous leukemia, and GVHD Randomized trials show strong (usually nonsignificant) trends for reduced rates of IA with anti-mold agents in this subset although an alternative approach would be anti-yeast prophylaxis with close monitoring, including galactomannan screening and aggressive evaluation of syndromes suspected to be fungal in origin with preemptive antifungal therapy
Allogeneic or autologous HCT with prior IFI	VORI If prior IFI was *Aspergillus*, ECH or FLU if prior IFI was *Candida*, L-AmB if prior IFI was mucormycosis	Any agent that is active against the prior IFI	FLU ITRA VORI, POSA MICA, L-AmB	There are no randomized trials, but retrospective case series suggest strong protective effect with secondary prophylaxis; most experience is with VORI
Autologous HCT	FLU	MICA	FLU ITRA VORI, POSA MICA, L-AmB	The most common IFI risk is Candida, in conditioning regimens that cause mucosal damage The risk for aspergillus and other molds is low
Liver, High risk	FLU	ECH, L-AmB	FLU ECH, L-AmB	No indication for prophylaxis in low-risk patients
Lung	Ae-AmB	VORI	Ae-AmB, ITRA VORI	No randomized placebo-controlled trials for ae-AmB
Heart, High risk	ITRA Ae-AmB		ITRA, ae-AmB	
Pancreas, High risk	FLU			
Small bowel	FLU	ECH	FLU ECH	

HCT hematopoietic stem cell transplant, *FLU* fluconazole, *MICA* micafungin, *ITRA* itraconazole, *VORI* voriconazole, *L-AmB* lipid formulation of amphotericin B, *POSA* posaconazole, *ECH* echinocandin, IFI invasive fungal infection, *Ae-AmB* aerosolized amphotericin B.

The first randomized controlled study of universal antifungal prophylaxis in liver transplant recipients was conducted in 86 consecutive liver transplant recipients in a single center [9]. Patients were randomized to either 1 mg/kg of liposomal amphotericin B (L-AmB) or placebo for 5 days. The overall incidence of IFIs was 0% vs. 16%, respectively ($p < 0.01$), but there was no difference in mortality. There were five *Candida albicans* infections and one *Aspergillus niger* pneumonia in the placebo arm.

There is another single-center randomized, double-blind, placebo-controlled study in 212 liver transplant recipients who received fluconazole prophylaxis (400 mg daily) or placebo for 10 weeks [10]. Overall IFIs were observed in 45 (43%) of the placebo arm compared to 10 (9%) of the fluconazole group ($p < 0.001$). Significantly fewer IFIs were observed in the fluconazole group (6% vs. 23%; $p < 0.001$). The majority were *Candida* infections. Risk factors for IFI were assignment to placebo, United Network Organ Sharing classification 1, baseline fungal colonization, and re-transplantation. In low-risk patients without a risk factor; there was no difference in IFIs between the groups. Furthermore, there was no difference in overall mortality although there were fewer deaths attributed to IFIs in the fluconazole group (2% vs. 13%; $p = 0.003$).

In a multicenter randomized controlled study, 143 liver transplant recipients were randomized to daily oral fluconazole (100 mg) or nystatin for 28 days [11]. Lower rates of *Candida* colonization (25% vs. 53%, $p = 0.04$) and *Candida* infections (13% vs. 34%, $p = 0.022$) were observed in the fluconazole group. However, most of the *Candida* infections

were superficial infections; there was no difference in invasive *Candida* infections or mortality.

Another single-center randomized, double-blind, placebo-controlled study [12] was performed in 71 liver transplant recipients who were randomized to either itraconazole 5 mg/kg orally preoperatively and 2.5 mg/kg orally twice daily postoperatively or placebo for a maximum of 56 days or until discharge from the hospital or treatment with systemic antifungal therapy for a proven, suspected, or superficial IFI. Fewer "fungal infection endpoints" were observed in the itraconazole group (4% vs. 24%; $p = 0.04$); however, none of these patients had a proven IFI. Furthermore, there was no difference in mortality.

In another single-center randomized controlled study, 188 evaluable liver transplant recipients were randomized to oral itraconazole solution 200 mg every 12 hr. or fluconazole given 400 mg every 24 hr for 10 weeks [13]. Proven IFIs were observed in 9% of the itraconazole group and 4% of the fluconazole group ($p = 0.25$) with no difference in mortality. Fungal pathogens included *Candida glabrata* (4), *Candida albicans* (3), and *Aspergillus* species (2) in the itraconazole group and *Candida glabrata* (2), *Candida krusei* (1), and *Aspergillus* species (1) in the fluconazole group. There were more gastrointestinal side effects in the itraconazole group.

In another single-center randomized placebo-controlled study of universal antifungal prophylaxis, 131 patients were randomized to one of three arms: 1 mg/kg of AmBisome for 7 days followed by 200 mg of itraconazole for 3 weeks; 400 mg of fluconazole for 7 days followed by 200 mg of itraconazole for 3 weeks; and placebo [14]. There were no significant differences in infection or mortality between the groups, and the authors concluded that routine use of antifungal prophylaxis is not justified.

Targeted Antifungal Prophylaxis Strategies

Observational studies demonstrate lower rates of IFIs with targeted antifungal prophylaxis with amphotericin B or fluconazole in high-risk liver transplant recipients when compared to historical data [15–18]. Furthermore, in the previously mentioned study that compared universal prophylaxis with itraconazole versus fluconazole, a trend favoring fluconazole was observed in high-risk liver transplant recipients with at least one risk factor such as UNOS classification 1, fungal colonization at the time of transplantation, or repeat transplantation [13].

Dosing of prophylactic amphotericin B was explored in a single-center observational study targeting high-risk liver transplant recipients [19]. All patients received nystatin for 3 months, and patients with risk factors including fulminant hepatic failure, re-transplantation, or ICU treatment also received fluconazole prophylaxis (100 mg daily). Consecutive patients requiring mechanical ventilation or continuous venovenous hemofiltration for ≥5 days after transplantation received additional prophylaxis with Abelcet until discharge from ICU or death (5 mg/kg daily for the first 10 patients, 2.5 mg/kg daily for the next 10 patients, and 1 mg/kg daily for the last 10 patients). Median duration of Abelcet prophylaxis in these 30 patients was 7 days and ranged from 1 to 37 days. There were no proven IFIs observed within 12 months of follow-up in all survivors. Of the six deaths, there was no histologic evidence of IFI in three who underwent postmortem examination.

In another single-center retrospective study of 186 consecutive liver transplant recipients, the incidence of IFIs was significantly higher in patients who required renal replacement therapy [20]. Among the patients requiring renal replacement therapy, the incidence of IFI was significantly lower (0%) in those who received prophylaxis with a lipid formulation of amphotericin B compared with those who received no prophylaxis (36%). Antifungal prophylaxis was independently associated with prevention of IFIs but not reduction in mortality.

Another single-center retrospective study examined targeted prophylaxis in 280 consecutive liver transplant recipients [21]. Starting in 1998, prophylaxis with a lipid formulation of amphotericin B was administered to patients with ≥4 of the following risk factors: > 30 units of packed red blood cells, renal failure, dialysis requirement, re-transplantation, surgical re-intervention, positive cytomegalovirus antigenemia or disease, acute rejection, mold colonization, > 5 days of antibiotic therapy, and ICU stay before transplantation. There was a trend toward fewer IFIs with preemptive amphotericin B prophylaxis compared to no prophylaxis in patients with >4 risk factors (14% vs. 36%; $p = 0.07$).

A single-center randomized controlled study [22] compared prophylaxis with conventional amphotericin B 15 mg daily or AmBisome 50 mg daily in 92 high-risk patient episodes based on ICU stay >4 days following transplant, fulminant hepatic failure, or readmission to ICU within 3 months of transplantation. IFIs were uncommon including 5 *Candida* infections and didn't differ between the groups. However, there was a significant difference in survival to ICU discharge favoring the AmBisome arm, 60% vs. 80% ($p = 0.038$).

In a single-center prospective observational study of 100 consecutive liver transplant recipients [23], 21 were identified as high risk and received 1 mg/kg of AmBisome for 7–10 days based on the presence of >1 of the following risk factors: acute liver failure, > 7 days of mechanical ventilation, re-transplantation, re-laparotomy, > 14 days of antibiotic therapy, > 20 packed red blood cell units, and biliary leak. No difference in the rate of IFIs was observed between the low-risk (5/79) and high-risk groups (2/21). Both infections in the high-risk group were due to *Aspergillus* species.

A randomized, double-blind controlled study [24] compared liposomal amphotericin B and fluconazole prophylaxis in high-risk liver transplant recipients with ≥2 of the following risk factors: choledochojejunostomy anastomosis; re-transplantation; ≥ 40 units of intraoperative blood product; reoperation for bleeding, anastomotic leak, or vascular insufficiency; renal insufficiency; and *Candida* colonization. Patients were randomized to either 2 mg/kg of liposomal amphotericin B or 400 mg of fluconazole daily for 14 days. Ten of 71 patients developed proven or probable invasive IFIs due to intra-abdominal *Candida* infection (n = 6), *Candida* bloodstream infection (n = 3), and *Cryptococcus* (n = 1); however, there were no differences between the two groups in rates of IFI or death.

The use of echinocandins for prophylaxis in liver transplant recipients has also been explored [25, 26]. In a multicenter prospective observational study [25], high-risk patients with ≥1 major criteria such as re-transplantation, renal replacement therapy, or fulminant hepatic failure or ≥ 2 minor criteria including renal failure, ≥ 40 intraoperative blood product units, choledochojejunosotomy, ≥ 2 surveillance cultures with *Candida*, or reoperation within 5 days of liver transplant received caspofungin for 21 days. Only two (2.8%) of the 71 patients developed IFIs at the surgical site due to *Candida albicans* and *Mucor* spp. infection.

In a multicenter prospective double-blind trial [26], 200 high-risk liver transplant recipients were randomized to either anidulafungin or fluconazole prophylaxis. The overall incidence of IFI was similar: 5.1% in anidulafungin and 8% in fluconazole treated patients. Anidulafungin prophylaxis was associated with favorable trends in preventing *Aspergillus* colonization and infection, lower breakthrough IFIs in patients with pretransplant fluconazole exposure, and fewer cases of antifungal resistance. There were no differences in graft rejection, fungal-free survival, or mortality.

The safety of withholding prophylaxis in low-risk liver transplant recipients has been described in two studies [27, 28]. In a prospective multicenter observational study [27], low-risk recipients were identified with ≤1 of the following risk factors: choledochojejunostomy anastomosis; re-transplantation; ≥ 40 units of intraoperative blood product; reoperation for bleeding, anastomotic leak, or vascular insufficiency; renal insufficiency; and *Candida* colonization. Of the 192 eligible patients, only 7 (4%) developed invasive IFIs. Only 3 (2%) were early *Candida* infections that were potentially preventable with fluconazole prophylaxis. In a cohort study of 12 Spanish hospitals [28], 799 low-risk liver transplant recipients were identified without risk factors such as renal failure in the first 15 days after transplant, urgent transplant, re-transplant, or choledochojejunostomy. Three hospitals performed universal prophylaxis with fluconazole for a minimum of 7 days. There were 11 episodes of IFI in 10 patients but no differences in the incidence of IFI between the patients receiving versus not receiving prophylaxis (4/206 or 1.9% vs. 6/593 or 1%; p-0.36).

Two meta-analyses have evaluated antifungal prophylaxis in liver transplant recipients [29, 30]. Cruciani, et al. [29] evaluated 698 patients from six randomized studies that compared fluconazole, itraconazole, or liposomal amphotericin B with placebo or oral nystatin and demonstrated that prophylaxis was associated with reduced fungal colonization, proven superficial and invasive infections, and mortality attributable to IFI but was not associated with overall mortality. Playford, et al. [30] evaluated 1106 patients from ten randomized studies comparing any antifungal prophylactic regimen with either no prophylaxis or another regimen and also demonstrated that antifungal prophylaxis reduced the rate of IFIs but not mortality.

Lung Transplantation

According to current guidelines [4], antifungal prophylaxis for up to 1 year is considered reasonable in lung transplant recipients with pre- or posttransplant *Aspergillus* colonization and also may be considered if ≥1 of the following risk factors is present: early airway ischemia, induction with alemtuzumab or thymoglobulin, single lung transplant, CMV infection, rejection and augmented immunosuppression, or acquired hypogammaglobulinemia. A meta-analysis and systematic review of controlled studies demonstrated no significant reduction in invasive aspergillosis or *Aspergillus* colonization with universal prophylaxis [31].

Antifungal prophylaxis strategies in lung transplantation have evolved over time with significant variation in practices. In a survey of 37 lung transplant centers in the United States that was conducted in 2001 [32], 76% of the centers provided posttransplant antifungal prophylaxis with targeted prophylaxis in 24% of these centers. Aerosolized amphotericin B was the most preferred agent (61%) followed by itraconazole (46%), parenteral amphotericin B formulations (25%), and fluconazole (21%). The median duration of prophylaxis was 3 months and ranged between <1 month and lifetime. In an international survey of 43 lung transplant centers between September 2002 and February 2003 [33], 69% provided universal antifungal prophylaxis. Aerosolized AmBd alone or in combination with itraconazole was the preferred strategy in 56% of the centers. The median duration of aerosolized AmBd and itraconazole was 1 month and 3 months, respectively. In a recent international survey of 58 lung transplant centers in 2009–2010 [34], universal prophylaxis was used in the majority of centers (58.6%) with nearly all of these centers (97.1%) targeting *Aspergillus*. The preferred first-line agents were voriconazole alone or in combination with inhaled amphotericin B. Preemptive or targeted approaches were used in 36.2% of centers. Of these, 90.5%

targeted *Aspergillus* and favored voriconazole prophylaxis. The survey also noted the use of posaconazole and echinocandins as first-line prophylactic agents in some centers.

The safety of aerosolized amphotericin B formulations has been demonstrated in a number of studies [35–40]. The most frequent adverse effects include cough, bronchospasm, nausea, and change of taste; however, discontinuation due to adverse effects is uncommon. A few studies have explored the pharmacokinetics of aerosolized amphotericin B formulations. A study of 12 lung transplant recipients demonstrated that delivery of aerosolized amphotericin B lipid complex (ABLC) is well distributed in the lungs although delivery to the native lung was suboptimal in some cases [41]. Another prospective study in 35 lung transplant recipients demonstrated that aerosolized ABLC administered daily for 4 days achieved concentrations in epithelial lining fluid above the minimum inhibitory concentration of *Aspergillus* up to 168 hours after that last dose [40].

There are no randomized placebo-controlled studies regarding the efficacy of aerosolized formulations of amphotericin B in lung transplant recipients; however, a number of observational studies [35, 36, 38, 39, 42] and one randomized controlled comparative study [43] have been published. In an early single-center study of lung, heart-lung, and predominantly heart transplant recipients [35], aerosolized amphotericin B deoxycholate (AmBd) was administered three times daily during the hospital stay. The incidence of *Aspergillus* infection was significantly decreased compared to a historic control group ($p < 0.005$). In another single-center study of 55 lung transplant recipients, 44 received nebulized AmBd three times daily for 120 days and then once daily for life [36]. Eighteen (33%) developed *Aspergillus* infection after a mean of 8.8 months including 14/18 (78%) within 2 months of transplantation. In multivariate analysis, nebulized AmBd was independently associated with a decreased risk of *Aspergillus* infection.

The efficacy of aerosolized ABLC was assessed in a prospective single-center study of 51 lung or heart-lung transplant recipients who were treated daily for 4 days and then weekly thereafter for up to 2 months [42]. The overall rate of pulmonary IFI included two (4%) anastomotic infections, no fungal pneumonia, and 8% with extrapulmonary IFI. One year survival was 78%. The treatment was subjectively well tolerated in 98%, and fewer than 5% developed worsening of pulmonary mechanics.

The efficacy of aerosolized L-AmB was assessed in an observational study of 104 consecutive lung transplant recipients in two centers [38]. Aerosolized L-AmB was administered three times per week up to day 60 followed by once weekly until day 180 and then every other week for life. IFIs were observed in only two patients with invasive pulmonary aspergillosis and tracheobronchitis. Outcomes were similar in 49 historic controls who received AmBd three times daily for 120 days and then daily for life thereafter.

A single-center prospective, randomized double-blind study comparing aerosolized ABLC and AmBd was conducted in 100 lung transplant recipients [43]. Patients received prophylaxis daily for 4 days and then weekly for 7 weeks. There were no fungal pneumonias observed. Other IFIs within 2 months included anastomotic and pleural space infections as well as candidemia, but there was no difference between the groups. More adverse events were observed in the AmBd group vs. ABLC including shortness of breath (19.9% vs. 2.1%), cough (10.6% vs. 2.1%), and change in taste (10.6% vs. 7.7%), respectively. Treatment discontinuation was also more frequent in the AmBd group (12.2% vs. 5.9% in ABLC group). Another retrospective single-center study compared aerosolized liposomal amphotericin B (L-AmB) and AmBd in 38 patients and found no difference in risk for IFIs or adverse effects [44].

The efficacy of aerosolized amphotericin B in combination with azoles has also been explored in observational studies. In a retrospective single-center study of 52 lung transplant recipients who received fluconazole 400 mg daily and aerosolized AmBd for at least 1 month [45], no IFIs were observed during the follow-up period. This was compared to a rate of 23% in a historical cohort from the same center. In another retrospective single-center study, there were 16 cases of invasive aspergillosis among 88 lung transplant recipients without prophylaxis compared to 4 cases among 81 recipients who received prophylaxis with aerosolized amphotericin B followed by itraconazole (18.2% vs. 4.9%; $p < 0.05$) [46]. In a retrospective study of 60 lung transplant recipients in 2 centers who received aerosolized ABLC once every 2 days for 2 weeks and then weekly for ≥13 weeks in addition to fluconazole (200 mg) for 21 days, there was only one patient with possible IFI, likely *Aspergillus fumigatus* colonization in the 6-month follow-up period, and only four patients experienced nausea and vomiting but without treatment discontinuation [39].

Observational studies have also explored the prophylactic use of azoles without aerosolized amphotericin B. In a single-center retrospective study of lung transplant recipients, invasive aspergillosis occurred in only 2/82 (2%) after implementing a prophylaxis strategy with voriconazole in patients with pretransplant *Aspergillus* colonization compared to 6/75 (8%) who had received itraconazole prophylaxis [47]. In a single-center retrospective study of 40 lung transplant recipients who received oral itraconazole 200 mg twice daily for 6 months, there were no *Candida* infections and only two *Aspergillus* infections, both occurring after itraconazole prophylaxis had been discontinued [48].

Low rates of invasive aspergillosis have been observed in patients receiving voriconazole prophylaxis. In a single-center nonrandomized study [49], 65 lung transplant recipients received universal voriconazole prophylaxis, while 30

received either fluconazole (200 mg) prophylaxis for 3 months or targeted prophylaxis with itraconazole +/– inhaled amphotericin B for 4–6 months in patients with pre- or posttransplant *Aspergillus* colonization except *A. niger*. The rates of IA at 1 year were 1.5% and 23% ($p = 0.001$), respectively. Rates of non-IA IFI were also lower in the voriconazole group (3% vs. 23%; $p = 0.004$). Voriconazole prophylaxis was more frequently associated with elevations in liver enzymes. In another retrospective single-center study, 32 lung transplant recipients received itraconazole prophylaxis (200 mg twice daily) for 3 months and 35 received voriconazole prophylaxis (200 mg twice daily) for 3 months plus inhaled amphotericin B for 2 weeks [50]. There were four IFIs in the itraconazole group compared to one IFI in the voriconazole arm. However, there was more hepatotoxicity with voriconazole (12/35 vs. 0/32); $p < 0.001$). Another single-center retrospective study compared itraconazole and voriconazole prophylaxis [51]. Forty lung transplant recipients received itraconazole, and 20 received voriconazole for 3 months. There were no differences in invasive IFIs, but tacrolimus dosing required greater dose reduction with itraconazole than voriconazole.

Heart Transplantation

Antifungal prophylaxis targeting *Candida* is not routinely recommended in heart transplant recipients [3]. Risk factors for *Aspergillus* infection include isolation of *Aspergillus fumigatus* from bronchoalveolar lavage, reoperation, CMV disease, hemodialysis, and an episode of IA in the program 2 months before or after heart transplant [52–54]. Current guidelines recommend targeted prophylaxis with itraconazole or voriconazole in heart transplant recipients with ≥1 of these risk factors [4]. In a single-center study, oral itraconazole prophylaxis was associated with fewer cases of IA and better 1-year survival [53]. In another study, prophylaxis with either oral itraconazole or inhaled amphotericin B for 3 months was associated with fewer episodes of IA [55]. Targeted antifungal prophylaxis in high-risk patients following heart transplantation is associated with reduction in invasive aspergillosis [56].

Pancreas and Kidney Transplantation

Risk factors for invasive candidiasis in pancreas transplant recipients include enteric drainage, vascular thrombosis, and post-perfusion pancreatitis [57], and current guidelines suggest that prophylactic fluconazole should be considered if risk factors are present [3]. In one study, intra-abdominal IFIs occurred in 6% of pancreas transplant recipients who received fluconazole prophylaxis for 7 days compared to 10% in those without prophylaxis [57]. Graft and patient survival were significantly worse in patients with IFI. In another study, fluconazole prophylaxis was associated with fewer IFIs [58]. Since rates of invasive IFIs in isolated kidney transplantation are low, antifungal prophylaxis is not recommended [3].

Small Bowel Transplantation

Although clinical trials are lacking, current guidelines recommend antifungal prophylaxis in small bowel transplantation due to high rates of *Candida* infections in these patients [3]. Local epidemiology should guide the choice between fluconazole and echinocandins. The appropriate duration of prophylaxis is not established, but some experts recommend a minimum of 4 weeks or until complete healing of the anastomosis [3]. In the setting of rejection and intensified immunosuppression, continued prophylaxis should be considered.

Allogeneic HCT

Invasive candidiasis historically was the chief pathogen accounting for IFI after allogeneic HCT; IC rates of 16–18% were observed [59, 60]. Oral nystatin or amphotericin B was routinely used as prophylaxis in many HCT centers but without demonstrable efficacy. With the introduction of fluconazole, clinical trials demonstrated a marked reduction in IC.

In a randomized double-blind trial of fluconazole 400 mg once daily versus placebo in 356 patients undergoing HCT comprising of half allogeneic and half autologous where prophylaxis was begun at the start of the conditioning regimen and continued until engraftment, fewer systemic IFIs were noted in the fluconazole group (3% versus 16% in placebo arm) [59]. Also noted were fewer superficial IFIs and lower rates of *Candida* colonization. Deaths due to IFIs were less, but overall survival was similar. Of note, there were few IA cases in both arms, in keeping with the observations of multiple studies that most episodes of IA occur later in the course of HCT after engraftment; the interval of the trial was pre-engraftment. Fluconazole was well tolerated. Unfortunately, the analysis did not break down if there were differences between allogeneic and autologous HCT as to efficacy and toxicity.

A second randomized trial of fluconazole versus placebo in 300 patients undergoing allogeneic HCT was conducted with prophylaxis extending to 75 days after transplant, encompassing both the neutropenic pre-engraftment and GVHD risk periods [60]. Fewer IFIs were noted in the fluconazole group (7% vs. 18%) due principally to fewer invasive *Candida* infections in the fluconazole arm. There were also fewer superficial IFIs, less use of empiric antifungal therapy

for suspected IFIs, and no increase in non-albicans *Candida* infections. Overall survival was significantly higher in the fluconazole arm. Fluconazole was well tolerated without increased toxicity. A follow-up study demonstrated enduring benefit with fewer late *Candida* deaths and an enduring overall survival benefit [61]. Interestingly, there was less gastrointestinal involvement by GVHD in patients receiving fluconazole.

On the basis of such trials demonstrating both safety and efficacy, consensus guidelines recommend the routine use of fluconazole prophylaxis [62]. One trial examined the optimal dose of fluconazole and found 200 mg once daily was as effective as 400 mg daily [63]. One concern has been the risk for emergence of fluconazole-resistant *Candida* species and an increase in mold infections. Despite some single-center reports raising these concerns, fluconazole has remained effective for two decades without substantive resistance in this population. Today, IFIs due to *Candida* are infrequently encountered after HCT. Attention has shifted to IA and other mold pathogens. During the 1990s, greater numbers of IA were noted [64].

The echinocandins have an advantage over fluconazole with a broader spectrum of activity against several non-*albicans* species less susceptible to fluconazole, such as *C. krusei* and *C. glabrata*, as well as activity against *Aspergillus*. Micafungin at a once daily dose of 50 mg was compared to fluconazole as prophylaxis in 882 allogeneic or autologous HCT recipients administered from the start of the conditioning until time of engraftment in a randomized, blinded trial [65]. Both study drugs were well tolerated. Success, defined as no suspected or documented IFI, was greater in micafungin than fluconazole (80% vs. 74%). The greater success rate with micafungin was driven largely by fewer courses of empiric antifungal therapy for suspected IFI. Rates of candidemia were similar. There was a trend to fewer IAs (0.2% vs. 1.5%), but the rate of IA was low in both arms as would be expected in the pre-engraftment phase after HCT. This trial established the echinocandins as suitable alternatives to fluconazole for prophylaxis after HCT.

Since the echinocandins require intravenous administration, they are not well suited for prolonged administration in the outpatient setting to cover the later phases of HCT after engraftment in which IA is most likely to occur. The extended spectrum azoles available in oral formulations are particularly well suited for prolonged administration. They also have the attractive attribute of having both *Candida* and *Aspergillus* activity. Itraconazole, posaconazole, and voriconazole have been evaluated for antifungal prophylaxis.

In a randomized open-label trial, itraconazole at a dose of 200 mg twice daily was compared with fluconazole as antifungal prophylaxis in 140 patients undergoing allogeneic HCT [66]. Both were initially given intravenously and then changed to oral as tolerated. The study drug was started after completion of the conditioning on day 1 of transplant and continued to day 100. There were fewer proven IFIs in the itraconazole arm (9% versus 25%). The rates of superficial IFIs were similar in the two groups. There was an imbalance in factors associated with the risk for IFI in the two study arms, suggesting that the fluconazole group was overall at greater risk, and this may in part explain the very high rate of IFI in the fluconazole arm, much higher than would be expected in this patient population, even without any antifungal prophylaxis. Adjusting for risk factors known to be associated with IFI, itraconazole remained associated with fewer IFIs, but the small sample size of the trial makes such adjustments difficult to truly compensate for imbalances. There were more adverse events in the itraconazole arm and a greater proportion of patients who had discontinuation of study drug due to adverse events or death in the itraconazole arm. There was a trend to more deaths in the itraconazole arm, and overall there was no improvement in patients alive and free of IFI at 6 months in the itraconazole group.

A larger randomized, open-label comparison between itraconazole and fluconazole was conducted in 304 allogeneic HCT patients in a single center [67]. This trial had several important design differences from the Winston trial. Study drugs were initiated prior to the conditioning regimen; duration of prophylaxis was 180 days; dosing was 2.5 mg/kg three times daily; itraconazole drug levels were assessed because of the known variability in absorption after oral administration; and doses were adjusted to reach a predetermined level thought to be associated with antifungal efficacy (0.5 ug/ml). In this trial, more patients receiving itraconazole developed hepatotoxicity and nephrotoxicity, and more were discontinued due to gastrointestinal intolerance or toxicity (36% vs. 16%). Overall, there was no reduction in the rate of IFI (13% vs. 16%) with itraconazole. However, for patients who were able to tolerate study drug, there were fewer IFIs (7% versus 15%). This protective effect was due to fewer mold infections, with a similar protection against yeast pathogens. There was a trend toward a lower rate of fungal-free survival in the itraconazole arm (61% vs. 69%). Patients who received cyclophosphamide were noted to have greater toxicity with itraconazole, leading to a protocol amendment to initiate study drug after completion of the conditioning regimen. A subsequent analysis indicated an increase in toxic metabolites of cyclophosphamide potentiated by concomitant itraconazole [68]. The lingering concerns regarding tolerance and drug interaction-related toxicity with itraconazole have dampened widespread adoption of itraconazole, but the suggestions of reduction in invasive mold infections encouraged further testing with other extended spectrum azoles.

Recognizing the association of GVHD with a higher risk for IFI, posaconazole was tested in a randomized double-blinded comparison with fluconazole in 600 allogeneic HCT

recipients with GVHD [69]. Study drugs were given for 16 weeks. Posaconazole was dosed 200 mg three times daily. There was a trend to fewer IFIs of all types (5% vs. 9%) and a significant reduction in IA (2% vs. 7%) with posaconazole. There were fewer deaths due to IFI in the posaconazole group (1% vs. 4%), but overall survival was similar in both study groups. Both all and severe treatment-related adverse events occurred at similar rates. An important observation in this study was that serum galactomannan assays were performed at study entry and 51 patients were positive. The galactomannan results were not used in the trial but analyzed afterward. The group with negative baseline galactomannan tests did not benefit from posaconazole (IFI rates, 5% vs. 8%); a reduction in IFI was observed in the patients given posaconazole who had positive galactomannan test results (10% vs. 23%). This suggests that the benefit of posaconazole was evident in patients who had incipient IA. Thus, an alternative interpretation of the results of this trial is that these findings are supportive of a preemptive treatment of early IA.

Two trials tested voriconazole as prophylaxis in allogeneic HCT recipients. The dose of voriconazole used in the two trials was 200 mg twice daily. There were several important design differences in the two trials. In one trial, the comparator was fluconazole, the study drugs were blinded, the endpoint was free from IFI or death at 6 months, and the sample size was 600 subjects [70]. In the second trial, the comparator was itraconazole; the study drugs were administered in an open-label fashion; the endpoint was free from IFI, death, and interruption of study drug for more than 2 weeks; and the sample size was 489 subjects [71]. In the first trial, there was no difference in fungal-free survival or overall survival at 6 months [70]. There were trends to fewer IFIs (7% vs. 11%), fewer cases of IA, and fewer empiric trials of antifungal therapy (24% vs. 30%) with voriconazole. There were no differences in adverse events. In a post hoc analysis, there were fewer IFIs and a higher rate of fungal-free survival in the subgroup of patients who were transplanted for AML. In the second trial, there was a higher rate of success with voriconazole compared to itraconazole (49% vs. 33%) [71]. The rates of IFI (1% vs. 2%) and survival (82% vs. 81%) were similar at 6 months. There were fewer empiric trials of empiric antifungal therapy (30% vs. 42%) with voriconazole. The tolerance of study drug was much better with voriconazole than itraconazole (54% vs. 39%) and accounted for the higher success rates of voriconazole.

Several single-center reports suggested an increase in IFIs due to the agents of mucormycosis with voriconazole prophylaxis [72–74]. It is important to note that voriconazole was not uniformly used in a standardized approach and presumably clinicians chose to use voriconazole in patients who were at high risk for all types of mold IFIs; thus, elimination of IA might open the door for mucormycosis. The prospective voriconazole prophylaxis multicenter trials did not show any increase in the risk for mucormycosis in patients given voriconazole [70, 71].

These two voriconazole prophylaxis trials suggest that the rates of IFI after standard-risk allogeneic HCT may not be sufficiently high to either demonstrate a benefit for anti-mold prophylaxis and to warrant the routine use of anti-mold therapy. However, there still remains the issue as to whether or not anti-mold prophylaxis has a role in higher-risk HCT patients. The trends in patients transplanted for AML (at higher risk for IFI and in whom lower IFI rates were seen with voriconazole)[70] and the trends for fewer IFI in the GVHD trial [69] suggest there may be a protective role in such individuals. An important group of high-risk HCT patients are those with prior IFI before HCT. Earlier studies have shown a high rate of reactivation of IFI even when they had been brought under control prior to HCT [75]. Indeed, the high risk of fungal deaths after HCT in patients with prior IFI subsequently led to many transplant centers excluding patients from consideration for transplant. However, several observational studies indicate that secondary prophylaxis prevents secondary recurrence [76, 77] and now many such patients can proceed to transplant.

Autologous HCT

The risk for IFI is lower in autologous transplants. Since the duration of neutropenia after autologous transplant was similar to that of allogeneic HCT, especially if bone marrow is used as the source of stem cells and the conditioning regimens were similar, a number of the earlier prophylaxis trials testing anti-yeast prophylaxis included both allogeneic and autologous HCT patients [59]. Although often not analyzed separately, it was assumed the risk for IFI was similar in the two types of transplant. Some trials included autologous HCT patients with patients undergoing induction therapy for AML [78]. In general, a benefit accrued to fluconazole. Other antifungal agents, including amphotericin B formulations, were also studied as prophylaxis, but toxicity of amphotericin B deoxycholate, the high cost of the lipid formulations of amphotericin B, the lack of clear superiority over the azoles, the lack of rigor of many of the studies, and the much lower risk for invasive mold infections have led most clinicians to not see a need for routine use of these other agents. Today, the conditioning regimens for autologous HCT are more heterogeneous. Since one of the major risk factors for IFIs due to *Candida* is mucosal injury, which allows gut *Candida* easier entry into the bloodstream, the risk for *Candida* IFI varies according to conditioning regimen. Additionally, there is a shorter time to engraftment today with optimization of stem cell grafts using G-CSF and apheresis collections of peripheral blood progenitor cells.

Thus, the routine use of antifungal prophylaxis to prevent *Candida* IFIs in autologous HCT remains uncertain.

Immune reconstitution after engraftment is more rapid than after allogeneic HCT since immunosuppressive medications are not necessary and there is no risk for GVHD. Thus, the risk for IA or other molds is low compared to allogeneic HCT. Thus, there is no substantial risk for IA after engraftment.

Coccidioides and Other Endemic Mycoses in SOT and HCT Recipients

Current guidelines recommend targeted lifelong fluconazole prophylaxis in SOT recipients with a history of coccidioidomycosis or with positive serologies, which are known risk factors for reactivation after transplantation [79, 80]. Prophylaxis is also recommended if the donor has infection or positive serologies. Although randomized, controlled trials are lacking, prophylaxis has decreased the risk of reactivation [81–84]. Some experts have recently recommended universal antifungal prophylaxis in liver and lung transplant recipients who reside in endemic areas [85, 86].

Antifungal prophylaxis for blastomycosis is not recommended as there are no sensitive or specific assays to detect latent or active blastomycosis and clinical trials are lacking [79]. Since the risk of reactivated histoplasmosis is low after transplantation [87], pretransplant screening is not routinely recommended [79].

The role of antifungal prophylaxis for endemic fungal pathogens has not been studied in HCT recipients. Currently, there are no consensus guidelines regarding these pathogens in HCT recipients. However, for allogeneic HCT recipients who are on active immunosuppressive therapy, similar approaches to those taken for SOT are sensible.

Summary

Routine or targeted antifungal prevention strategies are considered standard of care in both solid organ and stem cell transplant recipients. Future studies should continue to explore the safest and most cost-effective strategies.

Antimicrobial Drug Prophylaxis: Challenges and Controversies

65

Gaurav Trikha, Marcio Nucci, John R. Wingard, and Amar Safdar

Introduction

Prevention is the best way to manage an infection, especially in the susceptible transplant population. In these patients, the diagnosis is usually difficult, and response to treatment is often suboptimal. Antimicrobial drugs are the cornerstone for the prevention of opportunistic and other routine infections during the high-risk periods following solid organ and hematopoietic stem cell transplantation (SOT, and HSCT, respectively). However, there are many controversies associated with antimicrobial prophylaxis. These include (a) an appropriate selection of the subgroup of transplant recipients at a greater risk for infection, (b) selection of effective antimicrobial drugs, and, importantly, (c) how long such preventive interventions should be given. In general, antimicrobial prophylaxis is beneficial during periods when risk of a particular infection is higher due to a well-recognized complication following transplantation procedure. In a number of other situations, a clear benefit from such innervation is not certain. In this chapter, a comprehensive discussion regarding antimicrobial prophylaxis in recipients of HSCT and SOT is presented with a focus on controversies associated with such practices in the prevention of bacterial, fungal, and viral infections.

Antibacterial Prophylaxis

Hematopoietic Cell Transplantation

Bacterial infections are common after HSCT and may significantly influence morbidity and patients' survival. There are other potential effects of bacterial infection on transplant biology. During a systemic bacterial infection, in some patients release of proinflammatory cytokines in excess may accentuate tissue damge; this phenotypic differential in cytokine response to a systemic bacterial infection has been speculated as a possible trigger for the onset of graft-versus-host disease (GVHD) or exacerbation of existing GVHD. Stem cell allograft recipients may experience systemic bacterial infections during the following periods at a significantly higher rate: a) pre- and post-engraftment severe neutropenia (ANC < 500 cells/mm); b) acute and chronic GVHD.

Neutropenia during the pre-engraftment and less commonly post-engraftment period is approached in a similar manner as patients with severe neutropenia while undergoing antineoplastic therapy for acute myeloid leukemia (AML) [1, 2]. There is limited data regarding efficacy and feasibility of antibiotic prophylaxis in HSCT population during the pre-engraftment neutropenia. Furthermore, no prospective trials have been conducted to assess this intervention in patients who may develop severe neutropenia after stem cell engraftment that is frequently seen in patients with relapsed cancer; drug-induced or viral myelosuppression potentially resulting in the loss of hematopoietic stem cell graft [3]. Several stud-

ies suggest that there may be unique issues that are clinically relevant in the transplant population compared with non-transplant patients receiving induction chemotherapy for acute leukemia. Antibiotics and antineoplastic therapy are now increasingly recognized to have a direct impact on the hosts' gut microbiota [4]. For example, in pediatric patients with AML, treatment with daunorubicin and etoposide may reduce the growth of anaerobic and aerobic microbes, whereas cytarabine therapy resulted in no such effect. There is also a differential effect of various drugs on the growth of different bacterial species. The antineoplastic and immune modulator agents commonly used for preparatory conditioning and the prevention of GVHD in allogeneic HSCT protocols appears to have a variable impact on the hosts' gut micorflora compared to the anticancer agents. Routine use of oral, absorbable, and nonabsorbable antibiotics given for prophylaxis to patients following transplantation may further complicate the aberration in physiologic composition of the gut microbiome in ways that are still not well understood.

Fluoroquinolones are generally chosen for prophylaxis during neutropnia. A report in allogeneic HSCT patients compared an earlier experience with ceftazidime prophylaxis subsequently switched to prophylaxis with levofloxacin [5]. Patients who received levofloxacin experienced more episodes of fever and need for a change in antibiotic regimen; however in this group, less bacteremia episodes, unchanged spectrum of bacterial pathogens, and low costs were encouraging findings. Such data may suggest that different prophylactic antibiotics may have variable effect on gut microflora and consequently subsequent risk for invasive disease, i.e., ciprofloxacin has greater anti-*Pseudomonas* activity but poor activity against *Streptococcus* and *Enterococcus* spp., whereas levofloxacin has protective activity against important Gram-positive pathogens including *Streptococcus* spp. including *Streptococcus pneumoniae*; beta-hemolytic streptococci like *Streptococcus pyogenes* and *Streptococcus agalactiae* among others. A major limitation of levofloxacin coverage includes limited activity against *Enterococcus* spp. and *Streptococcus* viridans group. Moxifloxacin has activity against common clinical anaerobes. How use of these antibiotics for extended periods given for prevention of infection may have a variable impact on hosts' commensal microbiota and overtime the risk of breakthrough systemic bacterial infections; yeast overgrowth and risk for subsequent invasive candidiasis as a consequence of antibacterial prophylaxis remains uncertain. These influences may playout differently as purturbation in homeostatsis of patients' microflora is widely diverse; probably representing a culmunation and permutation among a number of intrinsic i.e., genetic haecciety and external influences that may include household environment and diet, travel-related exposure, treatment with antineoplastic and immunosuppressive drugs, and prolonged exposure to hospital microenvironment, among others.

The role of antibiotic prophylaxis in the autologous HSCT setting is less clear. Some studies have demonstrated benefit [6]. There are many different conditioning regimens used in autologous HSCT, and the degree of mucosal injury, an important risk factor for neutropenic fever and bacteremia, varies considerably depending on the preparatory regimen used. Therefore, it stands to reason that the risk for neutropenic bacterial infections may also be different. Unfortunately, none of these issues have been studied in depth. Additionally, drugs given to patients to treat cancer prior to undergoing transplantation such as rituximab, an anti-B-cell antibody commonly used in treatment of B-cell lymphoma, or purine analogues that affect T-cell immunity, and corticosteroids that additionally affect neutrophil, monocyte, macrophage functions and T-cell immune response. Furthermore iron and other heavy metal overload conditions may exist in patients prior to transplantation, which may also influence a protean risk for infection in patients undergoing transplantation procedure.

The emergence and spread of antibiotic resistance accompanied by a shift in inherent less drug susceptible bacterial species such as *Stenotrophomonas maltophilia, Achromobacter xylosoxidans,* and *Burkholderia cepacia*, to name a few is a well-recognized concern with routine antibacterial prophylaxis. In some transplant centers, high frequency of drug resistant bacterial infections has led to a serious reevaluation of routine practices in antibiotic prophylaxis. A vigilant approach and continued surveillance for monitoring trends in drug resistance and emergence of infections due to difficult-to-treat bacterial species are recommended for hospital units caring for patients undergoing transplantation.

Clostridium difficile-associated diarrhea (CDAD) has become a serious and potentially life-threatening complication in transplant recipients [7, 8]. Various novel approaches and perspectives in CDAD risk mitigation CDAD [**delet "CDAD"]** include prophylaxis with fidaxomycin and antitoxin antibodies [9, 10]. Such interventions, if effective and routinely introduced in this population, are bound to alter hosts' intestinal microflora. It remains to be seen what degree of alteration in microbiota may occur and for how long it may persist plus the influence of such changes may have on the risk of subsequent bacterial and, possibly fungal infections. It is important to note that this risk may be accentuated in recipients of HSCT and solid organ allograft transplantation who are routinely given immunosuppressive drugs like systemic corticosteroids to prevent and treat GVHD and allograft rejection, respectively.

Animals transplanted in a germ-free environment had superior outcomes in experiments assessing relationship between infection and GVHD [11, 12]. It is believed that bacterial by-products, such as lipopolysaccharides, entering the bloodstream across a damaged gut mucosa stimulate the production of proinflammatory cytokines such as TNF

and IL6 that in turn upregulate cellular mediators of GVHD [13]. A general hypothesis, now several decades old, was developed that suppression of bacterial flora and infection by antibiotics coupled with a protective environment may reduce the risk for GVHD and may improve survival following HSCT. A number of studies conducted at one institution have indicated a potential benefit from such an approach [14], whereas others were not able to reproduce this benefit from adherence to rigorous protective environment. The ongoing pyrosequencing studies of bacterial 16S rRNA genes to examine the composition of gut microbiota and the changes that may happen over time after HSCT and its impact on hosts' inflammatory response, risk for infection, and risk for GVHD are of great interest [15, 16]. These studies we hope will provide further insight into what appears to be a complex relationship between the host and its resident microbiota; new strategies may then be devised to harness and exploit such interactions for the benefit of patients who are undergoing evaluation for future transplantation procedures.

Presence of chronic GVHD, hypogammaglobulinemia, or IgG subclass deficiencies are particularly problematic; and so are impaired reticuloendothelial function including functional asplenia or hyposplenism. Susceptibility to infection by encapsulated bacteria is higher than general population, and so is the risk for devastating uncontrolled disseminated bacterial infection that often carries a greater risk of death. Although no randomized trials have been conducted, antibiotic prophylaxis has been shown to improve survival when compared with the results from older studies [17]. The consensus guidelines recommend institution of appropriate antibacterial prophylaxis in such patients [18]. The optimum choice of antibiotic, duration, or dose schedule is not validated; furthermore, increasing prevalence of community *S. pneumoniae* isolates that have become resistant to penicillin, erythromycin, azolides, and other antibiotics complicates the selection of appropriate agent in this setting. Moreover, the duration of risk is not well understood. In allogeneic HSCT patients with chronic GVHD, antibiotic prophylaxis is frequently discontinued as chronic GVHD subsides and patients are taken off anti-GVHD therapy. However, the immune deficits may persist for a long duration; studies to assess the duration of such immune defects after resolution of chronic GVHD are needed. It will be of interest to validate and incorporate immune reconstitution assays as a surrogate guidance for the decision as to the optimal timing to stop antibacterial prophylaxis in patients, in whom chronic GVHD has improved or resolved. Formal parameters for immune restitution-based guidance in stopping antibiotic prophylaxis will require prospective validation studies.

Alternatively, antibiotic prophylaxis may be supplanted by the emerging, and much desired interventions to boost hosts' immune response. The periodic administration of intravenous immunoglobulins in patients with hypogammaglobulinemia is regarded as standard-of-care for decades [19]. However, due to infusion-related toxicity, high cost, and no durable benefit, this intervention is selected for patients with severe and prolonged hypogammaglobulinemia with recurrent disabling sinopulmonary and less commonly, skin and skin structure infections [20, 21]. Targeted use of IVIG may also benefit patients with chronic GVHD, in whom chronic airway damage resulting from bronchiolitis obliterans and bronchiectasis leads to irreversible loss of pulmonary function; there is a growing consensus that such an intervention may lead to preservation of pulmonary function [22].

Immunization against *S. pneumoniae*, *H. influenzae*, and *N. meningitidis* is recommended for all patients undergoing HSCT [18]. Waiting to vaccinate until 12 months after transplantation is being revisited. Earlier immunization, especially with newer conjugated vaccines (Prevnar13) with higher immunogenicity, albeit limited serotype protection compared with older pneumococcal capsular polysaccharide vaccine (Pneumovax) that is marginally immunogenic; immunization with conjugate vaccines can be given as early as 3 months after HSCT [23]. However, responses to early immunizations may not be durable, and a booster dose is recommended for individuals with low antibody titers between 6 to 12 months after the first immunization. It was also encouraging that concomitant use of systemic corticosteroids or presence of GVHD did not severely impede in developing response to new-generation vaccines using conjugate protein construct. Further studies are needed. Pneumovax, a 23-valent capsular polysaccharide vaccine, has a broad spectrum of pneumococcal serotype coverage; however, due to pure polysaccharide construct, it has low immune stimulatory potential, especially in patients undergoing stem cell allograft transplantation. Some experts recommend an initial series of 2 to 3 Prevnar doses given at 3-month intervals followed by a single dose of Pneumovax 12 months after HSCT [24]. The newer Prevnar 13 does somewhat mitigate the concern regarding limited coverage compared with the earlier iteration of conjugate Prevnar 7 vaccine [25].

Solid Organ Transplantation

Bacterial infections in this population involves surgical site wounds, deep surgical bed infections, infections of the transplanted organ allografts site, deep tissue infected seroma or hematoma, infections involving the urinary tract, respiratory tract, and vascular-access devices, among others. In the pretransplant period, patients with end-stage heart, lung, liver and kidney disease and those with severe intestinal failure, are exposed to extensive antibiotics due to greater susceptibility for local and systemic infections and recurrent episodes of sepsis. However, the overall risk of bacterial infection from the donor allograft remains low [26], with the exception of patients undergoing lung transplantation [27]. Except for an organ procured from a donor with bacterial meningitis,

simple bacteremia, or complicated bloodstream infection with or without endovascular source of infection; there is no convincing evidence that the recipient should be given antibacterial prophylaxis that is commonly started intraoperatively and continued during early posttransplant period.

Standard surgical antibiotic prophylaxis is recommended for all organ transplant procedures. Choice of drug(s) may vary with the type of organ transplantation being performed. Colonization with Gram-positive bacteria or *Candida* spp. needs appropriate coverage, but no consensus or evidence exists for the management of Gram-negative bacterial colonization, with the exception of patient with ESLD with high MELD score and presence of sepsis or complicated peritonitis. Patients with LVAD infections undergoing heart transplant and those with cyctic fibrosis during and after early lung transplant period, the choice of primary and secondary antibacterial prophylaxis is varied and center-specific protocols are generally implemented.

During the first 6 months after transplant, there is no consensus or evidence for using antibacterial prophylaxis. Trimethoprim-sulfamethoxazole (TMP-SMX) is routinely given for the prevention of *Pneumocystis jirovecii* pneumonia. The ancillary benefit of TMP-SMX prophylaxis similar to that seen in patients with HIV/AIDS, provide added protection against *Streptococcus pneumoniae*, *Listeria monocytogenes*, and *Nocardia* spp. infections. A recent systematic review and meta-analysis of renal transplant patients receiving antibacterial prophylaxis showed no significant reduction in all-cause mortality or adverse events; results were conflicting regarding the development of bacterial drug resistance following prolonged exposure to antibiotics [28]. These findings underscore the need for randomized controlled trials to assess ideal prophylactic antibacterial regimen and its optimum duration in this population.

Antifungal Prophylaxis

Hematopoietic Cell Transplantation

The use of antifungal agents to prevent the occurrence of invasive fungal disease (IFD) in HSCT recipients is appealing for the following reasons: the incidence of IFD is high, timely diagnosis is fraught with uncertainty, and high risk for death. Despite a number of randomized clinical trials, antifungal prophylaxis continues to generate controversies. Allogeneic HSCT recipients are at high risk for IFD in the early neutropenic pre-engraftment period with treatment-induced mucosal damage; the other two high-risk periods coincide with the development of acute and chronic GVHD. The risk for IFD during the latter two risk periods involves T-cell immune defects, whereas unlike pre-engraftment neutropenia, most patients have adequate number and functional peripheral blood neutrophils. Invasive candidiasis and aspergillosis account for the majority of IFD in this population. In the autologous HSCT, the risk for IFD is almost completely limited to the early posttransplant period, which coincides with the duration of profound neutropenia and severity of mucositis; invasive systemic candidiasis being the main concern. In addition, severe T-cell immunodeficiency may exist in heavily pretreated patients with refractory, relapsed lymphoma, or multiple myeloma, in whom autologous stem cell transplantation may also heighten the risk for invasive mold disease such as invasive aspergillosis (IA). Most patients who respond to an initial episode of IFD, especially those with a mold infection, require secondary suppressive antifungal therapy.

Two randomized clinical trials showed that fluconazole reduced the rate of superficial and systemic candidiasis, as well as infection-related mortality in patients undergoing allogeneic HSCT [29, 30]. Fluconazole was given until day 75 after HSCT in one trial; a post hoc analysis revealed prolonged protection against invasive candidiasis resulting from an extended fluconazole prophylaxis [31]. Prophylaxis with fluconazole has become the standard of care for the prevention of invasive *Candida* spp. infection in patients undergoing allogeneic HSCT. In autologous stem cell transplant recipients, routine use of fluconazole, especially beyond periods of severe neutropenia, remains controversial. It is recommended to give fluconazole prophylaxis to autologous HSCT recipients, in whom severe and prolonged mucositis is expected [32]. The problem is accurately predicting severity mucositis prior to transplant procedure. There is also a debate regarding the optimum dose of fluconazole (200 mg vs. 400 mg/day) in patients undergoing allogeneic HSCT; in one trial, no clear advantage was noted with higher 400 mg daily dose [33]. Most experts recommend giving 400 mg daily fluconazole dose as this was the dose chosen for the major prospective validation trials [32]. Still, the optimal duration of prophylaxis with fluconazole in allogeneic HSCT recipients with various posttransplant complications is not clearly defined.

In addition to fluconazole, other antifungal agents have been studied following allogeneic HSCT for the prevention of invasive candidiasis and include micafungin [34], oral itraconazole solution [35, 36], and voriconazole [37]. Posaconazole is another potential option; it was only assessed for post-engraftment high-risk periods [38]. These agents, especially mold-active azole-based drugs and echinocandins, are particularly useful in the following two situations: (a) high incidence of invasive candidiasis due to fluconazole-resistant or nonsusceptible *Candida* spp. such as *C. glabrata* and *Candida krusei, respectively* and (b) if anti-*Aspergillus* coverage is needed.

Use of anti-mold prophylaxis in HSCT recipients still generates controversy.

Due to IA-associated devastating illness in HSCT recipients, effective prevention is highly sought after [39]. However, the results of randomized clinical trials are not as clear as they were with fluconazole prophylaxis for the prevention of invasive candidiasis. Oral itraconazole solution was compared with fluconazole in two randomized clinical trials [35, 36]. In both these studies, prophylaxis was given during pre- and post-engraftment periods. In one trial, the overall incidence of IFD was lower in the itraconazole arm [35], whereas in the other, itraconazole was associated with less invasive mold infections; however, this benefit did not extend in prevention of invasive candidiasis [36]. In both studies, gastrointestinal intolerance noted in one fourth of itraconazole-treated patients was the main limitation. Prophylactic posaconazole was compared with fluconazole in allogeneic HSCT patients with GVHD [38]). The primary endpoint including incidence of IFD on day 112 of prophylaxis showed no significant advantage for posaconazole use ($p = 0.07$); however, there was a significant reduction in the incidence of IA among patients given posaconazole (2.3%) vs. fluconazole (7%;$p = 0.006$). The fourth study compared voriconazole with fluconazole, given during pre- and post-engraftment periods [37]. The primary endpoint was fungal infection-free survival 180 days after HSCT; there was no difference in either group (75% in fluconazole vs. 78% in voriconazole; $p = 0.49$). Therefore, despite the fact that voriconazole is considered the drug of choice for the treatment of IA and that itraconazole and posaconazole showed benefit in reducing the incidence of IA, voriconazole failed to show superiority over fluconazole.

A careful analysis of the study design of these different trials, including procedures during protocol, population of patients, and endpoints, may in part explain these unexpected puzzling results. For example, when analyzing the incidence of IA, there was a trend for a benefit for voriconazole use over fluconazole (9 vs. 17 IA cases; $p = 0.09$). The study population in the posaconazole vs. fluconazole trial was allogeneic HSCT recipients with moderate to severe (stage II to IV) acute GVHD or extensive chronic GVHD, or substantial number of patients receiving intensive immunosuppressive therapies, or a select population at the highest risk for IA. In the voriconazole vs. fluconazole trial, most allogeneic HSCT enrollees did not end up developing GVHD. Furthermore, studies had different endpoints, and therefore it is difficult to compare results obtained from these trials despite all of the trials having a similar objective: to determine what is the most effective agent for IFD prophylaxis.

The important differences in the procedures that patients were submitted during the study period are outlined as follows. In the voriconazole vs. fluconazole trial [37], all patients were monitored biweekly until day 60 and then weekly from day 60 to day 100 after HSCT, including serial serum galactomannan monitoring. Empiric antifungal therapy was initiated in the event that patients developed a positive galactomannan assay and found to have radiographic and/or clinical features consistent with IFD. Therefore, another way of looking at the results of this trial would be that fluconazole prophylaxis plus a structured galactomannan monitoring for appropriate initiation of antifungal therapy was as good as prophylaxis with voriconazole in susceptible HSCT population. Important to note is that the trial enrolled "standard risk" HSCT patients, excluding those at high risk for transplant complications. Patients at higher risk for transplant complications such as GVHD are also at higher risk for IFD; therefore, it is possible that anti-mold prophylaxis may have a protective role in such patients. Important to note is that there were 3 risk factors for IFD in multivariate analysis [37]: older age, GVHD, and transplant for AML as the underlying disease. In the group transplanted for AML, a post hoc analysis showed there were fewer IFDs in those receiving voriconazole (8.5% vs. 21% in fluconazole); there was no protective effect in older patients or those with GVHD [37].

Due to all these variables in validation, randomized trial recommendations for anti-*Aspergillus* prophylaxis in allogeneic HSCT recipients remain controversial, for example, selection of at-risk subpopulation among all allogeneic HSCT recipients who would benefit the most from effective anti-*Aspergillus* prophylaxis. A group identified using the well-established risk factors for such susceptibility as illustrated in Table 65.1 may lend to a more focused and targeted approach towards anti-*Aspergillus* prophylaxis. As a general rule, the higher the risk is, the more likely prophylaxis will be of benefit. Another topic that should be considered is the potential for the emergence of drug resistance. For *Candida* spp. infection, there is little doubt that fluconazole use has resulted in a shift from highly susceptible *Candida* spp. such as *C. albicans*, *C. parapsilosis*, and *C. tropicalis* to less susceptible or inherently drug-non-susceptible species such as *C. glabrata* and *C. krusei*, respectively [40]. Recent studies have reported an alarming trend of the emergence of azole-resistant *Aspergillus* isolates in England and the Netherlands [41, 42]. Azole-resistant *Aspergillus* strains presently do not pose a clinical problem; however, a future potential for the development of resistance among disease-causing mold isolates following prolonged exposure to azole-based drugs given for prophylaxis does exist. The authors recommend a close monitoring of pathogen susceptibility trends and potential benefit of prophylaxis vs. the alarming risk of potential drug resistance among clinical fungal isolates be constantly assessed.

Another topic of controversy regarding anti-*Aspergillus* prophylaxis in allogeneic HSCT recipients is the optimal duration of prophylaxis. While in the pre-engraftment period the risk of IA is related to neutropenia and the period for such risk can be estimated, the same is not true for assessing

Table 65.1 Factors to take into consideration for deciding for anti-*Aspergillus* prophylaxis in allogeneic hematopoietic cell transplantation

Factor	Prophylaxis	No prophylaxis
Pre-engraftment period		
Type of transplant	Myeloablative	Non-myeloablative
Type of room	No HEPA filter and positive pressure	HEPA filter and positive pressure
Building construction or renovation	Yes	No
Local incidence	High	Low
Stem cell source	Bone marrow or cord blood	Peripheral blood
Post-engraftment period		
GVHD	Acute and/or chronic	No GVHD
Donor relatedness and HLA compatibility	Unrelated and/or HLA mismatch	HLA-matched related
All phases		
Serial serum galactomannan testing	Nonavailable	Available
Immunogenetics: MBL deficiency, TLR polymorphisms	Present	Absent
Comorbidities: iron overload, smoking, chronic sinusitis, or lung disease	Present	Absent

HEPA high efficiency particulate air, *GVHD* graft-versus-host disease, *HLA* human leukocyte antigen, *MBL* mannose-binding lectin, *TLR* toll-like receptor

risk during the post-engraftment period. It is reasonable to assume that once prophylaxis is initiated for patients receiving intensive immunosuppressive regimens for the treatment of severe GVHD, it should be maintained as long as severe immunodeficiency persists. The problem is that objective parameters to evaluate the severity of immune defect(s) are mostly available for research purposes and not widely used in patient care. Once sophisticated immune testing becomes clinically feasible, this will, as expected, substantially improve optimization of the duration of anti-*Aspergillus* prophylaxis during the post-engraftment period.

Finally, patients undergoing autologous HSCT may develop IA in the setting of extensive prior exposure to antineoplastic therapy for refractory multiple myeloma [43]; for such patients, currently there is no recommendation to initiate anti-*Aspergillus* prophylaxis.

Solid Organ Transplantation

The incidence and specific etiology of IFD vary in frequency according to the type of organ transplant procedure and the transplant center [44, 45]. A multicenter, prospective surveillance data showed 1-year cumulative incidences of the initial posttransplant IFD were 11.6% in recipients of small bowel transplantation, followed by 8.6% in lung, 4.7% in liver, 4.0% in heart, and 3.4% in pancreas and 1.3% after kidney transplantation [46]. The 1-year incidence was highest for invasive candidiasis (1.95%) followed by aspergillosis (0.65%). *Candida* spp. infections were a significant complication in liver and pancreas transplant recipients, whereas the impact of IA was high after heart and lung transplantations. An estimated 9.3% of deaths in lung transplant recipients and 16.9% in liver recipients are due to IA [47].

In liver transplant recipients, aspergillosis when present is notable during early post-transplant period; patients are uniquely predisposed to disseminated *Aspergillus* infection beyond the lungs and involvement of the central nervous system is not uncommon.[**the pargraph below belongs here]**

The overall, disseminated extrapulmonary disease has been described in 50–60% of liver transplant recipients with IA [47]. Liver transplant recipients are also recognized to have high risk for invasive candidiasis. Longer operation time, blood loss, repeated operations, re-transplantation, broad-spectrum antibiotic use, and renal failure are prominent risk factors for invasive candidiasis in this population [44].[**the following paragraph belong here**]

In a Cochrane database review, it was found that fluconazole prophylaxis significantly reduces the incidence of IFDs with no definite mortality benefit. Given a 10% incidence of IFD, 14 liver transplant recipients would require fluconazole prophylaxis to prevent one infection. In transplant centers where the incidence of IFD is high, or in situations where the individual patient's risk is greater, antifungal prophylaxis should be considered [48].

Antifungal prophylaxis is routinely used in most lung transplant programs during the early postoperative period. The duration for antifungal prophylaxis varies from center to center [49]. To prevent the occurrence of pulmonary aspergillosis, multiple strategies have been used including oral itraconazole, voriconazole, or aerosolized amphotericin B (AMB), used alone or in combination. Aerosolized drug delivery bypasses systemic circulation, mitigating concerns for drug-drug interaction and systemic toxicity [50]. Several centers have reported safety of aerosolized AMB deoxycholate in a variety of dosing regimens for patients undergoing heart, heart-lung or lung transplantation [51–53]. Aerosolized AMB lipid formulations have also been used successfully in this setting [53–55]. Monforte et al. have demonstrated that aerosolized deoxycholate AMB and lipid preparations of AMB are safe and achieve high concentrations in the bronchoalveolar lavage fluid within the first 24 h and 14 days, respectively. These lipid formulations allow a delayed administration every 7–14 days. With respect to oral prophylaxis, a recent study examined efficacy and toxicity of universal antifungal prophylaxis with voriconazole [56]. In this study, the overall rate of IA at 1-year interval was reduced to

1.5% in patients treated with prophylactic voriconazole compared with 23.5% rate in patients given a targeted prophylaxis approach. Interestingly, the rate of *Candida* colonization particularly that of non-*albicans* spp. in the voriconazole group was significantly higher [56]. In the cohort given voriconazole prophylaxis, 27% of the lung transplant recipients had normal liver enzymes during the course of the study. The main limitation of using voriconazole in lung transplant recipients was a potentially serious interaction with antirejection medication; therefore, in such patients, a preemptive dose reduction of calcineurin inhibitors is recommended along with a close monitoring of serum drug levels. Of interest, universal voriconazole prophylaxis was not associated with an increased rate of non-*Aspergillus* IFD including mucormycosis. Most transplant centers now use universal prophylaxis during the first 3 months after transplantation. After 3 months, a variety of permutations exist among transplant centers in the choice of agent used and how long such measures are continued. In patients who exhibit a higher risk of IA after undergoing lung transplantation such as (a) patients with chronic rejection and (b) those with *Aspergillus* spp. colonization of the respiratory tract, effective antifungal prophylaxis is recommended, and often given for a duration of 6 months [57]. In certain high-risk subgroups, anti-IA prophylaxis may have to be continued indefinitely.

Given the uncertain clinical benefits of prophylaxis, expense of drug cost, potential drug-drug interactions, and drug toxicity plus a concern for the emergence of resistant organisms, antifungal prophylaxis may not be routinely administered to all solid organ transplant recipients. Transplant centers use a targeted approach, i.e., prophylaxis is introduced only for patients at an increased risk of IFD and continued for a duration that coincides with the presence of precipitating risk factor(s) [58, 59]. The 2009 Infectious Diseases Society of America guidelines for the management of candidiasis recommend fluconazole (200–400 mg [3–6 mg/kg] daily) or liposomal AMB (1–2 mg/kg intravenously daily) prophylaxis for at least 7–14 days in patients undergoing liver, pancreas, and small bowel transplantation that are considered high risk of invasive fungal infection [60].

Antiviral Prophylaxis

Hematopoietic Cell Transplantation

Several viral infections that are commonly inconsequential in most immunocompetent patients pose serious threat to patients undergoing HSCT. In this regard, viruses belonging to *Herpesviridae* family of DNA viruses are common. Effective and safe prophylaxis with acyclovir or valaciclovir has dramatically reduced recrudescence of often severe herpes simplex virus (HSV) and varicella-zoster virus (VZV) infections. Furthermore, emergence of drug resistant breakthrough viral infection after prolonged exposure to antiviral drugs is not a significant problem, in most cases.

Cytomegalovirus (CMV) reactivation and/or rarely adult-onset acute CMV infection is a well-recognized serious life-threatening complication in patients undergoing allogeneic HSCT. Three decades ago, nearly one in four CMV-seropositive HSCT recipients died as a result of CMV disease; this changed after routine CMV control strategies were realized. Despite extensive research and debate, CMV infection continues to pose a serious challenge in providing optimized management for highly susceptible individuals after stem cell allograft transplantation.

With the development of effective antiviral therapy and the use of anti-CMV prophylaxis or preemptive therapy, infection rates have fallen and early posttransplant CMV disease rates have declined to nearly 3% [61, 62]. Ganciclovir or valganciclovir prophylaxis is effective in prevention of CMV end-organ disease and considered superior to monitoring and exercise in preemptive treatment approach. Routine use of these drugs with potential for myelotoxicity is fraught with increase morbidity due to myelosuppression, and overall survival benefits from their routine use are difficult to demonstrate. Presumably, antiviral benefits are offset by a higher frequency of secondary bacterial and fungal infections that may result from drug-induced myelosuppression. There remains an urgent need for effective, oral, and, importantly, less toxic antiviral drug(s). Maribavir appeared to be safe and effective in a randomized phase 2 trial; however, in phase 3 trial, it did not meet the criteria for efficacy [62]. Study design issues may have been the culprit in undoing of this promising anti- CMV drug include suboptimal dose schedule, delayed initiation of the study drug until after engraftment, exclusion of high risk patients with severe GVHD, and the regulatory agency's requirement at that time to demonstrate a reduction in CMV disease, which is an infrequent event, rather than a reduction in a more clinically relevant endpoint like CMV viremia [63, 64]. The requirement of regulatory oversight at that time was predicated on the assumption that a prophylaxis trial must demonstrate a reduction in CMV end-organ disease, an endpoint that now is seldom (<3%) seen in allogeneic HSCT recipients. This posesan impediment in demonstrating efficacy for new prophylaxis drugs and novel vaccine trials. This could dampen the enthusiasm for R&D in new technology that could eventually be licensed for clinical use. In recent years, there is a more receptive posture to accept surrogate markers with an aim to improve feasibility of clinical trials in the high-risk transplant population. Another promising antiviral agent under investigation is CMX001 (brincidofovir), a lipid conjugate of cidofovir with oral bioavailability[65]. The phase 3 study did not find a benefit, noting problems with diarrhea as

a limiting toxicity [66], which may have overlapped with intestinal GVHD and may have confounded drug efficacy evaluation. Brincidofovir has a broad spectrum of antiviral coverage against a number of clinically relevant viral pathogens, including adenovirus and BK and JC polyomaviruses. Letermovir (AIC246) another agent in clinical trials has promising activity against laboratory and clinical strains of CMV [67]; in phase 3 trial it has demonstrated a significant reduction in CMV viremia [68].

Preemptive therapy with ganciclovir was associated with survival benefits, which could not be demonstrated in the case of routine anti-CMV prophylaxis [69]. The reasons for this puzzling observation remain unclear; limited exposure to this potentially myelotoxic drugs may well be the contributing factor. Most HSCT centers, therefore, have adopted preemptive therapy approach over routine long-term prophylaxis with ganciclovir. Patients undergoing cord blood stem cell transplantation are a notable exception due to a high risk for CMV infection and end-organ disease compared with other allograft HSCTprocedures; in such patients, intensified program of anti-CMV prophylaxis with ganciclovir before transplantation and high-dose acyclovir after transplant has been effective rather than a preemptive anti-CMV treatment approach [70].

An increase in late onset CMV disease is a clear limitation for preemptive therapy [71]. Risk factors for late CMV disease include early viremia, GVHD, and lymphopenia; patients at risk should be monitored and considered for preemptive therapy [72], although the benefit of preemptive therapy for late CMV disease in transplant population is also not certain. The limited ability to monitor CMV reactivation in patients dispersed to communities far from the transplant center may impede correct estimation of the true frequency and hands-on management of this serious complication. This continues to be a major challenge for which, the authors currently do not have good solutions, although boosting immunity to reduce the risk of late CMV disease; perhaps once effective vaccine becomes available may address this unmet need.

Resistance to antivirals is not a common problem in patients following HSCT; however, it is recognized as an evolving issuein the recipients of SOT [73]. New antiviral drugs are urgently needed. Maribavir is a benzimidazole that has activity against drug-resistant CMV strains, due to a novel mechanism by binding to the UL97 viral protein kinase, thereby inhibiting encapsidation and nuclear egress [74]. Maribavir was shown to successfully treat infections due to drug-resistant CMV infections in transplant recipients [75]. Leflunomide, a protein kinase and pyrimidine inhibitor, has long been considered as a promising therapy for ganciclovir-resistant CMV [64, 76]; however, there is limited clinical efficacy data to support its routine use. Letermovir, AIC246, has a novel mechanism that blocks UL56-mediated DNA processing or packaging; it is active against both drug-sensitive and drug-resistant strains [68]. New drug development remains an area of high and urgent priority.

Cellular immunotherapy has long been noted as a promising modality for prevention and treatment of opportunistic infections in the severely immunosuppressed patients. The ultimate control of CMV infection requires restoration of CMV-specific cytotoxic natural killer cells and T lymphocytes [77, 78]. Adoptive immunotherapy generated ex vivo from donor-derived, target-specific cytotoxic T lymphocytes is an area of interest and active research in prevention and treatment of CMV reactivation among at risk stem cell transplant population [79]. Recently, other targets include NK cells [78] and T cells armed with anti-CD3- and anti-CMV-specific antibodies [80]. These cell preparations have potential advantages over conventional T cells as they do not require analogous HLA and low risk for GVHD. The main advantage of immunotherapy approach is the efficacy against all viral strains independent of drug susceptibility. However, the daunting obstacle in development of cellular immunotherapy and availability for clinical use is technical complexity and high cost [81].

New vaccines are also promising. Glycoprotein B vaccines was found to boost both antibody and cellular responses in women with chronic viral infection [82]. Boosted antibody response and shortened viremic episodes in renal and liver transplant recipients are also encouraging [83]. A DNA vaccine was found to induce immune responses and to reduce viremia after HSCT in a randomized phase 2 trial [84]; phase 3 trial is underway. Effective immunization holds an enormous promise in preventing CMV infection and end-organ disease. As mentioned earlier, with drug prophylaxis trials, endpoint selection will be a crucial element in study design to assess clinical feasibility for such vaccines. Clear benefit in garnering protective immune response, a favorable impact on frequency and duration of CMV viremia, and avoidance, or short duration preemptive antiviral therapy were noted in randomized phase 2 trials; there may not be a reduction on the elusive, now a rare endpoint of CMV end-organ disease; if this remains as a requisite to measure success of phase 3 trials. Of interest, in the event CMV vaccines are effective, the need for drug prophylaxis will certainly lessen. However, since it is unlikely that a vaccine will be fully protective in all HSCT recipients, monitoring and preemptive therapy will still be needed, albeit less frequently.

Relationship between polymorphisms in innate immune response genes and the inherent risk for CMV infection (viremia) and potential for organ disease is an exciting new field. The ability to identify subgroup of patients with a higher propensity for viral disease, when available, will allow a more personalized approach for infection prevention, viral monitoring, and selective allocation of preemptive therapy. A study identified certain polymorphisms in genes

encoding chemokine receptor 5, interleukin 10, and monocyte chemoattractant protein 1 that corroborated with CMV reactivation and CMV organ disease, even when controlled for well-established risk factors such as T-cell depletion or CD34 selection and/or presence of GVHD [85]. Importantly, these gene-products serve as virtual targets of the virus in its quest to suppress host antiviral immune response [86]. Additional, larger studies are needed to confirm these early observations, however there is considerable excitement that we are on the threshold of a new era of constructing individualized risk profiles and customizing prophylaxis based on such attributes.

Although CMV reactivation may occur frequently in recipients of autologous HSCT, it is seldom that these patients will present with end-organ CM disease. Accordingly, prophylaxis has not been considered in this patient population. Removal of T cells or CD34+ cell selection from the stem cell graft may increase the risk for CMV disease [87]. Several recent reports suggest that patients with multiple myeloma who underwent tandem autologous transplants and those who have received bortezomib are at higher risk for CMV disease just as they are at an increased risk for VZV reactivation. This may mean that in the future some patients undergoing autologous HSCT will be candidates for anti-CMV prophylaxis. With the growing use of purine analogues and an increasing array of monoclonal antibodies in use for lymphoma therapy may accentuate the net state of immune suppression among certain autologous transplant recipients; the likelihood of these emerging antineoplastic treatment advances on the risk for CMV disease in this traditionally low risk transplant group need to be seen.

EBV is a major pathogen after HSCT and can cause febrile syndrome; however, posttransplant lymphoproliferative disease (PTLD), infrequent albeit, a serious complication associated with this virus. Primary EBV infection in seronegative patients carries a high risk. Patients most vulnerable for the development of PTLD are those with profound T-cell deficiency; risk factors include mismatched or cord blood stem cell transplants, T cell depleted graft, use of ATG, or prolonged high-dose corticosteroid therapy. Monitoring EBV DNA by a blood EBV quantitative PCR can identify those at risk, and rise in viral titers typically occur several weeks prior to the clinical manifestation of lymphoproliferative disease. Drug prophylaxis is not effective, and immune modulation remains the mainstay of prevention and therapy. Preemptive reduction in iatrogenic immune suppression when possible, or treatment with anti-CD20 rituximab may prevent PTLD in high risk patients [18]. Alternatively, unselected donor lymphocyte infusions or infusions of donor-expanded, EBV-specific T cells or third-party EBV-specific cytotoxic T-cell lines (CTLs) can be given prophylactically or as therapy [88]. Unselected donor cells are appealing due to their simplicity of not requiring ex vivo manipulation, although they do carry a greater risk for GVHD [89]. The optimal strategy and refined parameters to identify at risk subgroupsare the goals for ongoing study.

HHV6 is associated with viral pneumonitis, encephalitis, myelosuppression, and infectious cause of graft compromise along with a variety of other syndromes like viral hepatitis, enterocolitis during post allogeneic transplant period. The relationship between HHV6 reactivation and its potential to cause end-organ disease remains a topic of controversy [90]. Ultimately, it will take a prophylaxis trial to determine if prevention of HHV6 reactivation leads to reduction in such clinical syndromes. Currently there is no generally accepted effective HHV6 prophylaxis strategy.

Solid Organ Transplantation

CMV infection remains one of the most common opportunistic viral infections in solid organ transplant patients despite availability of effective antiviral drugs [91]. Acute infection may occur via allograft from CMV + donor given to a seronegative recipient, or by reactivation of recipients' latent CMV infection. Seronegative patients who acquire organs from seropositive donors are at the greatest risk for developing infection; these primary infections tend to be most severe [92]. In addition to the direct impact of viral end-organ infection and organ damage, CMV infection appears to enhance the overall level of host immunosuppression, promoting risk for other opportunistic infections and malignancies. More insidiously, CMV infection is linked to chronic allograft dysfunction and risk for allograft loss [93]. The risk for CMV disease persists for life, although most cases occur shortly after antiviral prophylaxis is discontinued, and seen within the first year after transplantation [94].

In an attempt to minimize the adverse impact of CMV infection during the posttransplantation course, emphasis has shifted from premeptive therapy to preventive strategies. Numerous prospective randomized trials, summarized in several reviews and in one met analysis, have documented the efficacy of antiviral prophylaxis in reducing the risk of CMV infection and end-organ disease [93–96]. Valganciclovir is an effective anti-CMV agent for prophylaxis and treatment of CMV disease that is widely used in providing care for patients undergoing solid organ allograft transplantation [97–100]. Universal prophylaxis of all seronegative recipients with grafts from seropositive donor is recommended due to the amplified risk and prospect of CMV disease [101, 102]. A meta-analysis of 17 universal prophylaxis trials and 9 preemptive therapy trials demonstrated that both universal antiviral prophylaxis and preemptive strategies were equally effective in reducing the incidence of CMV end-organ disease [103]. However, only

universal prophylaxis favorably influenced patient survival, reduced graft rejection, incidence of posttransplant opportunistic infections and PTLD; therefore, this strategy is preferred for at-risk SOT populations [103, 104].

The risk of CMV disease is significantly lower in seropositive organ allograft recipients, independent of donor CMV status; it has been argued that universal prophylaxis in this group leads to overtreatment, increasing the cost of care, and unduly exposing patients to the risk of drug toxicity and drug-drug interaction. In this population, preemptive strategies using targeted antivirals exclusively for patients demonstrating a rising CMV viral load are being developed [102, 105].

Emergence of ganciclovir-resistant strains of CMV threatens to unravel the therapeutic gains made in the past few decades. Across all populations, CMV donor-positive and recipient-negative status confers greatest risk for developing viral drug resistance, which probably is a reflection on high-grade viremia associated with primary CMV infection during a period of recently introduced, boosted drug-induced immune suppression seen in the early post-transplant period [106, 107]. Other risk factors include the use of potent immunosuppressive agents such as antilymphocyte antibodies, use of daclizumab, and prolonged exposure to ganciclovir [106, 107]. Unpredictable bioavailability of oral ganciclovir vs. valganciclovir, and therefore, prolonged potential underexposure to ganciclovir is of particular significance in promoting viral drug resistance mutants [108]. Foscarnet is the agent of choice for the treatment of ganciclovir-resistant end organ disease; however, potentially serious drug-induced nephrotoxicity may limit its use. In patients undergoing lung transplantation, CMV disease due to ganciclovir-resistant virus is an important predictor for poor survival [107].

Conclusions

Antimicrobial prophylaxis is a common and an important practice in the management of infectious complications among transplant recipients. However, despite many clinical trials in different scenarios, controversies regarding the appropriate use of such intervention continue to exist. Use of antimicrobial prophylaxis has been of great benefit in the prevention of serious and life-threatening infections after transplantation. However, it is imperative to periodically assess the potential benefit versus limitations of existing practices in antimicrobial prophylaxis including (a) drug safety, tolerabilty and toxicity profile; (b) potential for drug-drug interaction, (c) novel transplant procedures and protocols, (d) changes in hosts' susceptibility for infection, and (e) shifts in the causative pathogens including emergence and reemergence of less drug susceptible pathogens; change in prevalence of drug-resistant microorganisms, and exposure to novel pathogens among patients undergoing transplantation.
