This Springer imprint is published by the registered company Springer Science+Business Media, LLC part of Springer Nature.
The registered company address is: 233 Spring Street, New York, NY 10013, U.S.A.

This book is dedicated to my parents, Taj & Safdar, for enduring inspiration and tenacity of purpose.

Preface

In pursuit of recognizing the risk of infection in patients undergoing transplantation, prescient cognizance requires sagacious understanding of hosts' home and healthcare environment, factors pertaining to the level of immune suppression that may have accumulated overtime, and, importantly, recent alterations in immune function resulting from additional immunosuppressive treatments such as donor lymphocyte transfusion, antineoplastic therapy, and immune modulatory biologic drugs and medical disorders like graft-versus-host disease, donor allograft rejection, posttransplant opportunistic malignancies, recrudescent or newly acquired cytomegalovirus infection, and relapsed hematologic neoplasms.

It is prudent to establish a targeted approach toward diagnosis, an approach which portends recognition of the true etiology with the help of assiduous investigation based on patient-specific vulnerability for infection. Special consideration needs to be placed upon the possibility of noninfectious processes that clinically are often difficult to distinguish from infection or sepsis-like syndrome. Toxicity due to commonly used drugs in the posttransplant period, thromboembolic events, acute engraftment syndrome, postsurgical deep tissue and body cavity hematoma, tissue ischemia and necrosis, opportunistic malignancies, and the potential for less common paraneoplastic disorders including tumor fever may initially present as a nonspecific acute febrile illness, with or without features suggestive of systemic inflammatory response syndrome. Similarly, a host of noninfectious maladies involving the skin and skin structures, brain, orointestinal tract, liver, kidneys, and lungs may clinically resemble infection. It is important to take into account that such processes may occur concurrently or sequentially in patients with a known infection diagnosis. Furthermore, in immunosuppressed patients after hematopoietic or solid organ allograft transplantation, plurality of simultaneously occurring infections makes selection of targeted, pathogen-specific empiric therapy a daunting task.

Individuals' genetic haecceity and its influence on susceptibility or inherent resistance to certain infections is evolving. Once validated and available for clinical use, this has the potential to reliably identify select subgroups of transplant recipients that are additionally vulnerable to specific infection(s). Infection prevention and empiric or preemptive treatment strategies in such patients may advance from the putative and arbitrary risk profiles presently in use.

This volume aims to provide a comprehensive and in-depth review of the issues pertaining to infectious diseases in patients undergoing transplantation.

Part I

Principles of Transplantation and Overview of Infectious Diseases

Infections in Transplantation: Introduction and Overview

1

Amar Safdar

Transplantation remains a pioneering scientific innovation that has a significant impact on restoring well-being for patients and benefit society as a whole. Blood and marrow hematopoietic stem cells have become accepted and, in some instances, established approach to treat incurable neoplastic diseases and congenital disorders of immune system [1]. Similarly, use of allografts in patients with end-stage organ disease involving the liver, kidneys, intestines, heart, and lungs has provided a possibility for continuation of life and a potential for patients to integrate and resume participation in their communities [2]. Recent advances in limb, integument, and face transplantation underscore the substantial leap forward in restoring normalcy for individuals with devastating and often catastrophic physical encumbrance [3, 4].

In patients undergoing solid organ transplantation, advancement in understanding the complex interplay within various facets of immune response against the transplanted allogeneic tissue that recipients' immune system fails to recognize as "self" has resulted in encouraging long-term outcomes [5]. These achievements in decoding higher mammalian immunity underscore the recent progress made in development and implementation of refined strategies to harness potentially devastating immune rejection of the implanted solid organ allograft [6]. The antirejection strategies, as expected, involve a delicate balance that favors preservation of a functioning allograft and aims at limit severity of drug-induced suppression of recipients' immune function, which is crucial for the surveillance against various neoplastic processes; conventional and opportunistic infections.

A similar, albeit an opposing role of undesired immune response comes into play in patients undergoing hematopoietic blood and marrow stem cell transplantation from a foreign donor. The conflict arises from aforementioned disconnect between immune recognition of self versus nonself [7, 8]. These transplanted stem cells install foreign effector immune cells in the recipient, and if remain unabated, the resulting graft-versus-host disease is capable of unleashing potentially ruinous systemic inflammation resulting in irreversible tissue damage and death [7]. The stem cell graft restores immunity and functional marrow in patients in need for myeloablative antineoplastic therapy. Furthermore, it is the foreign, graft-mediated, adaptive cancer immune surveillance that has now been widely recognized as the pivotal feature that sustains cancer in remission following successful allogeneic hematopoietic stem cell transplantation. This feature of stem cell graft-assisted antitumor response is recognized as "graft-versus-leukemia or graft-versus-tumor effect." Donor-derived adaptive antitumor immunity is an important objective of allogeneic stem cell transplantation, especially in patients with hematologic malignancies, and forms the bases for donor lymphocyte infusions to treat cancer recurrences during posttransplant period [9]. As in patients following solid organ transplants, in recipients of allogeneic HSCT, anti-GVHD therapy is assessed and continuously refined to achieve the lowest possible cumulative iatrogenic immune suppression required to prevent or treat GVHD, whereas an earnest attempt is made for preservation of recipients' immune function such that the risk of conventional and opportunistic infections and malignancies do not overwhelm the projected efficacy and feasibility of these lifesaving procedures.

A number of agents have been successfully used for prevention and treatment of graft-versus-host disease and solid organ allograft rejection [8, 10]. Severity of immune dysfunction is in most instance a direct consequence of treatment with these agents that are commonly prescribed

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_1

as combination drug regimens. Cyclosporine was the first major breakthrough in this regard; subsequent generation calcineurin inhibitors (CNI) have improved therapeutic index although resultant severe immune suppression and the risk for opportunistic infection like CMV, BK virus, and certain posttransplant cancers question the therapeutic feasibility for agents such as tacrolimus, especially in patients with low risk for allograft-related complications. Serious infections due to cytomegalovirus including viremia and end-organ disease, BK virus viremia, viruria, and BK virus allograft nephropathy with risk for potential graft compromise, rare progressive multifocal leukoencephalopathy due to polyomavirus, higher potential for opportunist cancers such as Kaposi's sarcoma, EBV lymphoproliferative disorders among others, are well-recognized limitations in individuals given tacrolimus for extended duration with doses leading to prolong high serum drug concentration [11]. Experience with sirolimus, a macrolide xenobiotic that induces potent immune suppression via inhibition of mechanistic target of rapamycin (mTOR; a conserved threonine and serine protein kinase) was associated with lower incidence of CMV infection in solid organ transplant recipients. This protective antiviral effect of mTOR inhibitors against BK virus nephropathy after renal transplantation has not been noted consistently. Additionally, antitumor properties of mTOR inhibitors may favorably influence the lower incidence and risk for posttransplant malignancies in recipients of solid organ allografts, especially those with a profile that indicates low risk for graft rejection [12].

Monoclonal antibodies against T- and B-cell pathways have also gained prominence, as potential treatment options. Alemtuzumab (Campath) is a monoclonal antibody that targets C52 antigen expressed on all lymphocytes. Treatment with Campath results in profound lymphocyte depletion. The drug-induced immune suppression may last for up to 9 months, although maximum degree of lymphopenia is noted between 8 and 9 weeks after therapy. As part of HSCT preparatory condition regimen, treatment with alemtuzumab was associated with reduced risk for GVHD following allogeneic hematopoietic stem cell transplantation [13].

In kidney transplant recipients, the risk for organ rejection was low in patients given alemtuzumab; however, this benefit was mainly observed in patients that were at a low risk for allograft rejection [14]. Other trials are underway with the aim to explore regimen(s) that may spare CNI (tacrolimus) for the prevention of allograft rejection.

Humanized monoclonal antibody rituximab that targets CD20 antigen expressed prominently and selectively on B lymphocytes forms the cornerstone for treatment of solid organ antibody-mediated renal allograft rejection. It is also considered the standard of care for the treatment of posttransplant B-cell lymphoproliferative disorders [15].

Systemic glucocorticoids have maintained relevance in drug cocktails given to prevent and treat solid organ graft rejection and GVHD. Since the early observation enabled addition of corticosteroids to successfully reduce cyclosporine dose that was traditionally needed to prevent rejection of transplanted allograft, this observation was regarded as a major breakthrough and forged the path for preservation of transplanted organs without serious, life-threatening CNI toxicity. Detailed discussion regarding immunosuppressive agents for prevention and treatment of allograft rejection is provided in chapters throughout this book.

A keen understanding of patients' underlying immune defect(s) is the knowledge cornerstone, essential for optimizing infection risk stratification, assessing need for preventive, preemptive or empiric antimicrobial therapy. This information serves as an imperative in establishing meaningful patient-centered management and infection prevention paradigm [16, 17]. Table 1.1 provides an outline for such a relationship between underlying immune defects and susceptibility for particular group of pathogens. It is also important to note that a combination of unrelated immune defects may overlap. Furthermore, such patients may present with multiple infections concurrently, sequentially, or in close proximity to a primary infection episode, with a variety of conventional and opportunistic microorganisms.

An extensive exposure to hospital environment poses risk for transplant recipients to acquire infections that may not respond to conventional antimicrobial drugs. The recent interest in exploring the potential influence of perturbation and reorganization of hosts' microbial flora or microbiota resulting from extensive exposure to healthcare environment, broad-spectrum antimicrobial drugs among other factors, has yielded greater insight into a field that was largely underappreciated for decades. Altered orointestinal microbiota has been proposed in limited observational studies to influence the risk for acquiring infection, recurrence of previously resolved infection, suboptimum response to antimicrobial therapy, and importantly, long-term viability of the transplanted allograft [18–20]. The possibility of noninfectious complications and their potential relationship with altered hosts' microbiota are currently under investigation.

An important approach in the assessment of transplant patients lends from the understanding and knowledge of temporal relationship for the risk of infection that may occur during various clinical phases after transplantation procedure (Table 1.2, with Figs. 1.1, 1.2, 1.3, 1.4, 1.5, and 1.6). For example, patients with long-standing chronic GVHD are

Table 1.1 Infections in transplant patients in relationship with the underlying immune defects

Immune defect	Bacteria	Yeasts and dimorphic fungi	Filamentous molds	Viruses	Parasites
Granulocytopenia	*Staphylococcus aureus*	*Candida* spp.	Hyalohyphomycetes (hyaline or clear wall)	Herpes simplex virus type I and II	
[ANC < 500 cell/ml]	*Streptococcus pneumoniae*	*Candida albicans*[a]	*Aspergillus fumigatus*	Varicella zoster virus	
	Streptococcus gp A, and gp B	Non-*albicans Candida* spp.	*Aspergillus flavus*		
	Enterococci including VRE[b]	*Candida glabrata*[c]	*Aspergillus niger*		
	Coagulase-negative *Staphylococcus*[d]	*Candida krusei*[e]	*Aspergillus terreus*[f]		
	Enterobacteriaceae	*Candida parapsilosis*[g]	*Aspergillus nidulans*		
	Escherichia coli	*Candida guilliermondii*[g]	Non-*Aspergillus* hyalohyphomycetes

Table 1.1 (continued)

Immune defect	Bacteria	Yeasts and dimorphic fungi	Filamentous molds	Viruses	Parasites
Humoral immune defects	Encapsulated bacteria			Varicella zoster virus[s]	*Giardia lamblia*
	Streptococcus pneumoniae			Echovirus and other enteroviruses	*Babesia microti*
	Haemophilus influenzae				
	Neisseria meningitidis				
	Campylobacter jejuni				
Splenectomy and functional hyposplenism	Encapsulated bacteria				*Giardia lamblia*
	Streptococcus pneumoniae				*Babesia microti*
	Haemophilus influenzae				
	Neisseria meningitidis				
	Capnocytophaga canimorsus				
Mixed immune defects	*Streptococcus pneumoniae*		*Pneumocystis jirovecii*	Respiratory viruses	*Toxoplasma gondii*
	Staphylococcus aureus		*Aspergillus* spp.	Adenovirus	*Strongyloides stercoralis*
	Haemophilus influenzae		*Candida* spp.	Varicella zoster virus	
	Klebsiella pneumonia		*Cryptococcus neoformans*		
	Pseudomonas aeruginosa		Mucormycoses		
	Acinetobacter spp.		Endemic mycoses		
	Enterobacter spp.		Dematiaceous (black) molds		
	Stenotrophomonas maltophilia				
	Nocardia asteroides complex				
	Listeria monocytogenes				
	Legionella spp.				
	Campylobacter jejuni				

Patients with mixed immune defects include recipients of allogeneic hematopoietic stem cell transplant; patients receiving treatment for acute or chronic graft-versus-host disease; acute or chronic solid organ allograft rejection

Abbreviations: VRE vancomycin-resistant enterococci, *SARS* severe acute respiratory syndrome, *MERS* Middle East respiratory syndrome

[a]In the past two decades, the prevalence of non-albicans invasive candidiasis is seen in excess of *Candida albicans* infections; the emergence of invasive disease due to *Candida auris* with limited susceptibility to currently used antifungal drugs is a challenge

[b]Certain transplant units across the USA have seen a high level of VRE colonization and subsequent risk for invasive disease; these infections are often a surrogate and reflect hosts' high-risk status

[c]Increasing reports of echinocandin resistance among clinical isolates of *C. glabrata* is an alarming trend, where this to become more prominent in the future

[d]Among CoNS group of bacteria, an emerging and recently described highly virulent *Staphylococcus lugdunensis* causes tissue-destructive infections similar to *S. aureus* with an emphasis on necrotizing and difficult-to-treat endocarditis

[e]*Candida krusei* is intrinsically nonsusceptible to fluconazole and to some extent itraconazole; these yeasts are uniformly susceptible to the broad-spectrum triazoles such as voriconazole, posaconazole, and isavuconazonium sulfate

[f]*Aspergillus terreus* is the only clinically relevant *Aspergillus* species that exhibit variable degree of resistance to amphotericin B, thereby increasing the probability of failure to amphotericin-based therapy

[g]*Candida parapsilosis* and *C. guilliermondii* have demonstrated less inherent in vitro susceptibility to the echinocandins; alternative antifungal agents are suggested to treat such infections

[h]Non-*Candida* and non-Cryptococcal yeasts are rare cause of fungemia seen mainly in patients with severe immune dysfunction and those with chronic lung disease

[i]*Fusarium* spp. infections are now increasingly attributed to food-related intestinal tract colonization and invasive disease during periods of severe immune suppression, such as profound and prolonged neutropenia, especially in patients with extensive orointestinal mucosal disruption; other filamentous fungal pathogens from food are *Aspergillus* and *Mucor* spp. Rare organisms linked to food and food products include *Lichtheimia*, *Curvularia*, *Phoma*, *Trichoderma*, *Alternaria*, *Acremonium*, *Paecilomyces*, *Penicillium*, *Achaetomium*, *Amesia*, *Botryotrichum*, *Chaetomium*, *Dichotomopilus*; *Microascus*, *Scopulariopsis*, and *Wallemia*. *Mucor circinelloides* was isolated from yogurt samples and presumed to cause illness in >200 consumers

Table 1.1 (continued)

[j]*Geotrichum capitatum* is now named *Saprochaete capitata*
[k]Mucormycoses in transplant recipients remain an uncommon cause of invasive fungal disease, although patients with voriconazole breakthrough mold disease have significantly higher probability of mucormycosis
[l]*Strongyloides stercoralis* may lead to serious, life-threatening hyperinfection syndrome in patients with marked cellular immune defects following allogeneic allograft transplantation, albeit, this remains a rare complication in patients undergoing transplantation even in the endemic regions
[m]These strains of human coronavirus may cause potentially serious lower respiratory tract disease in the immunocompromised host
[n]*L. donovani* and *L. infantum* may lead to serious visceral leishmaniasis in patients with profound cellular immune defects; *L. donovani* is seen in Africa and Asia
[o]These novel outbreak stains of coronavirus have been observed to cause serious illness in immunosuppressed patients and those with diabetes mellitus, ischemic heart disease, or end-stage kidney disease
[p]*L. infantum* is seen in Africa, Europe, Mediterranean, Central and South America
[q]Systemic extrapulmonary infection including viral encephalitis along with viral pneumonitis in allogeneic stem cell transplant recipients has been noted to cause devastating and life-threatening illness
[r]The incidence of campylobacter disease in AIDS patients is 40-fold higher than in the general population; patients with humoral and cellular immune defects are considered susceptible; it is important to recognize the serious sequelae such as Guillain-Barre syndrome, and reactive arthritis may follow acute infection episode in a small group of patients
[s]VZV is rarely associated with systemic dissemination in patients with humoral immune defects or even those with mixed immune dysfunctions

Table 1.2 Infections in recipients of allogeneic hematopoietic stem cell transplantation

Pathogens	Pretransplant disease or high-risk exposure-related infections	Pre-engraftment during neutropenia (0–30 days)	Post-engraftment including acute GVHD (30–100 days)	Posttransplant including chronic GVHD (>100 days)	Posttransplant seasonal community-onset infections
Bacteria	*Streptococcus pneumoniae*[a]	*Staphylococcus aureus*[b]	GPB and GNB bacteremia[c]	Encapsulated bacteria[d]	Community acquired pneumonia
	Staphylococcus aureus[b]	Coagulase-negative staphylococcus[e]	*Listeria monocytogenes*[f]	GPB and GNB bacteremia[c]	Community onset sinusitis
	Coagulase-negative staphylococcus[e]	*Enterobacteriaceae*[g]	Nocardiosis[h]	*Listeria monocytogenes*	Community onset or travel-related enterocolits
	Enterobacteriaceae[g]	*Escherichia coli*		Nocardiosis	Community onset urinary tract infection including pyelonephritis
	Escherichia coli	*Klebsiella pneumoniae and Klebsiella oxytoca*			Community onset *Clostridium difficile*-associated diarrhea
	Klebsiella pneumoniae and Klebsiella oxytoca	Nonfermentative gram-negatives[i]			
	Nonfermentative gram-negatives[i]	*Pseudomonas aeruginosa*			
	Pseudomonas aeruginosa	*Stenotrophomonas maltophilia*			
	Stenotrophomonas maltophilia	*Clostridium difficile*-associated diarrhea[j]			
	Clostridium difficile-associated diarrhea[j]				
Mycobacteria	*M. tuberculosis*[k]			Reactivation of latent tuberculosis	
	M. kansasii[l]			Relapse of previously treated *M. kansasii* infection	
	Nontuberculous mycobacteria			New or relapse MAC infection[m]	
	Rapid-growing mycobacteria				
	Slow-growing mycobacteria				

(continued)

Table 1.2 (continued)

Pathogens	Pretransplant disease or high-risk exposure-related infections	Pre-engraftment during neutropenia (0–30 days)	Post-engraftment including acute GVHD (30–100 days)	Posttransplant including chronic GVHD (>100 days)	Posttransplant seasonal community-onset infections
Viruses	Herpes simplex type 1 and II	Herpes simplex type I and II	Cytomegalovirus[n]	Cytomegalovirus[o]	Influenza A and B[p]
	Human cytomegalovirus[q]	Varicella zoster virus[r]	Human herpesvirus[s]	Human herpesvirus 6[s]	Parainfluenza
	Varicella zoster virus	Cytomegalovirus[t]	Adenovirus[u]	Adenovirus[u]	RSV[v]
		Human herpesvirus 6[s]	BK virus cystitis[w]	Epstein-Barr virus PTLD[x]	hMPV[y]
		Adenovirus[u]	Epstein-Barr virus PTLD[x]	Parvovirus B 19[z]	hCoV[aa]
				BK virus cystitis[w]	
				JC virus PML[ab]	
Molds and yeasts	Invasive aspergillosis	*Candida fungemia*[ac]	Invasive aspergillosis[ad]	Invasive aspergillosis[ae]	
	Endemic mycosis	Invasive aspergillosis and rare molds[af]	Invasive candidiasis[ag]	Invasive candidiasis[ah]	
	Cryptococcal disease		*Pneumocystis jirovecii*[ai]	*Pneumocystis jirovecii*	
	Invasive candidiasis		Zygomycosis[aj]	Zygomycosis[aj]	
			Fusariosis[ak]	Fusariosis[ak]	
			Dematiaceous (melanin pigmented) molds[al]	Dematiaceous (melanin pigmented) molds[al]	
			Cryptococcal disease[am]	Cryptococcal disease[am]	
Parasites	*Toxoplasma gondii*		*Toxoplasma gondii*[an]	*Toxoplasma gondii*[an]	
	Strongyloidiasis[ao]		Strongyloidiasis[ap]	Strongyloidiasis[ap]	
	Chagas disease[aq]		Chagas disease	Chagas disease	
	Leishmaniasis[ar]		Leishmaniasis	Leishmaniasis	

[a]Pneumococcus is the leading cause of community-onset bacterial pneumonia, and patients with hematologic malignancies, especially those with cancer or antineoplastic therapy-related humoral immune dysfunction and various other medical comorbid conditions such as diabetes mellitus, chronic structural lung diseases like emphysema, end-stage kidney disease, and cirrhosis of liver to name a few, are at risk for potentially severe systemic disease

[b]The emergence and global spread of community-acquired methicillin-resistant *S. aureus* has made empiric use of anti-staphylococcal penicillin's obsolete

[c]Catheter-related bloodstream infection, extensive healthcare environment exposure and hospital-acquired pathogens, persistent mucositis, orointestinal or cutaneous hyper-acute and acute GVHD, and accelerated iatrogenic immune suppression including need for high-dose corticosteroids are salient factors that promote invasive bacterial infections during this period. Pretransplant colonization due to VRE, MRSA, or MDR GNB including MRD Pseudomonas, ESBL-producing *Enterobacteriaceae*, and some food-borne fungi such as Fusarium spp., especially in transplant unit located in certain geographic areas, are thought to promote infections due to these pathogens

[d]Hyposplenism after HSCT is a late complication and commonly attributed to late-onset acute GVHD, most frequently noted in patients with chronic GVHD. It is however important to recognize that a number of allogeneic HSCT recipients without clinical diagnosis of GVHD may have functional hyposplenism and are at risk for severe, systemic infection due to encapsulated bacteria

[e]Indwelling prosthetic devices including intravascular access catheters; surgical drains; implanted prosthesis such as heart valves, joints, biliary, bronchial, urinary tract stents; and other various implantable surgical devices promote infections due to CoNS and *Candida* spp. that commonly colonizes the skin and genitourinary and orointestinal tracts

[f]Listeria bacteremia and meningitis are rare complications in patients receiving TMP-SMX prophylaxis for PCP. The incidence of bacterial meningitis is 30-fold higher in HSCT recipients compared with persons without HSCT. As expected, patients undergoing allograft stem cell transplant are at a significant higher risk compared with those undergoing autologous HSCT (70 vs. 16 per 100 000 patients per year). In HSCT recipients *Streptococcus pneumoniae* is the most common pathogen associated with bacterial meningitis, *Neisseria meningitidis*, *Streptococcus mitis*; listeriosis may be rarely seen

[g]Increasing frequency of multidrug-resistant strains to fluorinated quinolones and regional high prevalence of extended-spectrum beta-lactamases producing GNB including carbapenem-resistant *Enterobacteriaceae* has seriously curtailed treatment options for such infections. *Enterobacteriaceae* include *Salmonella* spp., *Escherichia coli*, *Yersinia pestis*, *Klebsiella* spp., *Shigella*, *Proteu*s, *Enterobacter*, *Serratia*, and *Citrobacter*

[h]CNS nocardiosis is difficult to distinguish from brain toxoplasmosis, tuberculosis, aspergillosis and other neurotropic clear (hyaline) and black mold infections, and CNS lymphoma

[i]Nonfermentative gram-negatives include *Pseudomonas aeruginosa*, *Burkholderia cepacia*, *Stenotrophomonas maltophilia*, *Acinetobacter baumannii*, other *Acinetobacter* spp., *Alcaligenes* and *Achromobacter* spp., and emerging cases of *Sphingomonas paucimobilis*. Inherent or acquired drug resistance is a major concern in selection of effective empiric therapy for pathogens in this group, which may either lack the drug target site or produce extended-spectrum hydrolyzing enzymes aginst a variety of commonly used antimicrobials; these bacteria may also exhibit phenotypes with reduced expression of outer membrane porins and/or heightened expression of efflux pumps among other mechanisms for antimicrobial drug resistance

[j]Orointestinal mucositis increases the risk of CDAD and so does exposure to broad-spectrum antimicrobials and possibly antineoplastic chemotherapy-induced alteration in hosts' intestinal protective anaerobic microbiota

Table 1.2 (continued)

[k]It now considered standard of care to perform interferon-gamma release assays for diagnosis of latent tuberculosis infection; treatment with isoniazid is considered gold standard and should be administered for a minimum of 6 months prior to the transplantation procedure, with the aim to prevent active tuberculosis infection during the post-transplant period. Such infections tend to be more serious and, due to potential drug toxicity and drug-drug interaction, often difficult to treat after allograft transplantation

[l]*M. kansasii* leads to clinical disease indistinguishable from *M. tuberculosis* infection; risk for infection relapse, drug resistance, and infection recalcitrance are reason for longer duration of therapy

[m]In a recent study from South Korea, in 7342 SOT and 1266 HSCT recipients, 22 patients developed NTM after a median 2 years following transplantation. *Mycobacterium avium-intracellulare* complex was the most common pathogen isolated; nodular bronchiectasis (~80%) was common presentation. A near 70% response to antimicrobial therapy in this group was encouraging. However, disseminated NTM including MAC disease in severely immunosuppressed patients following high-risk allogeneic HSCT may occasionally present as salvage therapy-refractroy recalcitrant bacteremia with high fatality

[n]Risk of CMV infection is highest in CMV-seronegative recipients in whom allograft is given from a CMV-seropositive donor. Ganciclovir prophylaxis effectively prevents CMV disease in high-risk patients during the first 100 days after allogeneic HSCT

[o]Late CMV disease is associated with high mortality rate nearing 45% and seen 170 median days after HSCT. It is important to recognize that close to 40% of patients that respond to the initial episode of late posttransplant CMV infection will develop a second CMV episode within a median of 11–12 weeks. Three months after HSCT, patients with positive CMV-pp65 antigenemia; post-engraftment severe lymphopenia of less than 100 lymphocytes/mm^3, especially those with helper T-cell lymphocytopenia of less than 50 cells/mm^3; presence of GVHD; and those with undetectable CMV-specific T-cell responses are at higher risk for late CMV end-organ disease. Furthermore, after 100 days following transplantation, presence of CMV viremia or pp65 antigenemia and severe lymphopenia endorsed by less than 300 lymphocytes/mm^3 is considered strong predictors for late CMV disease and death

[p]Most frequently detected viruses in symptomatic HSCT or SOT recipients with URTI are picornaviruses (~40%), such as rhinovirus and enterovirus, whereas coronavirus and influenza are isolated in nearly 20% of such patients, each. Influenza URTIs similar to RSV and unlike parainfluenza virus infections have the potential for progression to the lower respiratory tract. Viral pneumonitis is a serious complication in patients following allogeneic stem cell transplantation. It is important to recognize that hosts' immune response to influenza infection garners a high IFN-gamma state resulting in a transient increased susceptibility for secondary bacterial infections like pneumococcus, *S. aureus*, and *Pseudomonas* spp. The resulting superimposed bacterial pneumonia may precipitate life-threatening sepsis and respiratory failure. Furthermore, RTVIs are recognized as fostering enhanced susceptibility for invasive fungal lung disease during early and late transplant periods

[q]Serologic evaluation of the donor and recipient for latent CMV infection is the cornerstone during pretransplant assessment. Dissonance between D+ and R- CMV serology is the most important complicating factors during early and late posttransplant period. Antiviral prophylaxis, preemptive and empiric therapy approaches are based on CMV serologic disparities

[r]It is standard to provide prophylaxis for HSV and VZV during preparatory conditioning regimen and continue during the early post-HSCT period. Prophylaxis may have to be extended in patients with acute GVHD, cancer recurrence, patients undergoing high-risk transplantation procedure, and those with primary or secondary allograft compromise

[s]HHV-6 high-grade viremia by DNA analysis has been associated with central nervous system (CNS) dysfunction, although viral interstitial/alveolar pneumonitis is not an uncommon disease attributed to HHV6 infection following allogeneic HSCT. HHV6 may also present as limbic encephalitis with subcortical temporal lobe seizure activity presenting as memory loss and insomnia. Febrile partial or complete myelosuppression and/or skin rash should alert the physicians regarding HHV6 as a potential treatable cause of secondary stem cell allograft loss. Viral gastroduodenitis, colitis, and pericarditis are other clinical manifestations attributed to HHV6 infection in this vulnerable population. An association with post-HSCT HHV6 viremia with delayed monocyte and platelet engraftment, increased platelet transfusion requirements, risk for high-grade GVHD, and all-cause mortality needs further evaluation

[t]Early CMV low-grade viremia was observed by the use of ultrasensitive nucleic assays, within 3–4 weeks after high-risk allogeneic stem cell graft transplantation

[u]The incidence of adenovirus disease ranges from 3% to as high as 47% in high-risk pediatric allogeneic HSCT recipients. Patients undergoing T-cell-depleted stem cell grafts and those with acute graft-versus-host disease are also at increased risk for severe life-threatening adenovirus disseminated disease, which is a well-recognized complication in patients with persistent peripheral blood lymphocyte counts of <300 cells/mm^3. Infection involves respiratory (viral pneumonitis), gastrointestinal (colitis, including hemorrhagic colitis) tracts, and hepatitis;patients may present with posttransplant hemorrhagic cystitis. Adenovirus dissemination represents severity of underlying immune defect and is seen in 10–20% of patients with end-organ viral disease, except in patients with adenovirus cystitis, where disseminated adenoviral disease is seldom observed

[v]Long-term (>30 days) viral shedding is not uncommon in patients following allogeneic HSCT; RSV is notable RTVI in this regard. The 80 days of median duration of viral shedding may extend to just under a year in some allogeneic transplant recipients. This potential for pronged viral shedding warrants heightened awareness and strict adherence to appropriate precautions to prevent nosocomial RSV transmission to other vulnerable hospitalized patients. In the pediatric HSCT recipients, RSV infection within 60 days after transplant, patients given systemic corticosteroids within a week prior to the onset of RSV infection and the need for assisted mechanical ventilation were significant predictors for subsequent complications and death

[w]The BK virus was first isolated in 1971; after primary childhood infection, persistent BKV infection occurs within renal tubular cells and the urothelium. Viral reactivation in the recipients of kidney and allogeneic HSCT usually presents as allograft nephropathy and hemorrhagic cystitis, respectively. Presently, reduction in drug-induced immune suppression, when possible, and supportive care are the only viable treatment option; direct antiviral drug against BKV remains elusive

[x]EBV influence over B-cell malignant clones may act through different mechanisms of transcriptional regulation and possibly variance in genetic mechanisms that eventually determined viral latency during early EBV infection and EBV-host interaction

[y]The incidence of hMPV infection was similar to the incidence of RSV or parainfluenza virus UTRIs in patients undergoing HSCT. hMPV infections are notable for low risk of progression to the LRT. Serious systemic hMPV disease including viral encephalitis has been reported. Overall, these infections are well-tolerated, albeit hMPV pneumonitis in severely immunosuppressed stem cell allograft recipients may result in serious life-threatening lung disease

(continued)

Table 1.2 (continued)

[z]Parvo B19 infection may present as pure red cell aplasia after allogeneic HSCT

[aa]hCoV similar to hMPV is a common RTV. Serotypes associated with disease in transplant population include hCoV-OC43 followed by NL63, HKU1; 229E is less common. Unlike hMPV, these infections have a higher likelihood for progressing to the LRT, which often presents as subclinical, mild to moderate viral illness. In an observation among HSCT recipients, hCoV infection resulted in a notable number (~20%) of hospitalizations. In concert with hMPV infection, despite presence of severe immune suppression, hCoV-related confirmed deaths in allogeneic HSCT recipients remain less than 5%. Approximately one-third of transplant patients with hCoV infection may have infection due to other RTVs such as human bocavirus (HBoV). HBoV is an uncommon RTV in transplant patients and often (> 80%) seen with other RTVs. HBoV rarely causes LRTI; most infections are well-tolerated despite, transplant-related severe immune suppression

[ab]John Cunningham virus (JCV)-associated progressive multifocal leukoencephalopathy (PML) is an uncommon disease in patients undergoing allogeneic HSCT. In a report from Israel, 20 of 40 patients (24%) with JCV reactivation had persistent viremia after receiving myeloablative and nonmyeloablative pretransplant conditioning. PML was diagnosed in two patients with persistent JCV viremia, 96 and 127 days after HSCT. Advanced age was a significant predictor of JCV reactivation; 70% of these allogeneic HSCT recipients with persistent viral reactivation had died. Identifying high-risk patients with persistent JCV reactivation, especially those with incremental levels of viremia, may benefit from reduced drug-induced immune suppression for prevention of JCV leukoencephalopathy. PML continues to remain a devastating, albeit rare post-transplant infectious complication. *Artesunate*, an antimalarial drug that showed potent ex vivo activity against HHV-6, however, clinical response to artesunate in HSCT recipients with JCV-PML, has not been encouraging

[ac]Candidemia is seen in patients with severe pre-engraftment neutropenia (absolute neutrophil count <500 cell/microliter) that extends longer than 5 days. The increase in non-*albicans Candida* spp. is mainly due to *C. glabrata*, although patients following HSCT are also at risk for *C. krusei* infection. Emergence of echinocandin resistance among clinical *C. glabrata* isolates is concerning. For patients with *C. parapsilosis* infection, it is recommended to use antifungal drugs other than echinocandin class. The emergence of MDR *Candida auris* infections in transplant population makes selection of empiric anti-yeast therapy more challenging

[ad]Genetic susceptibility for IA include mutations in Dectin-1 and DC-SIGN among other well recognized risk factors such as high-risk allogeneic HSCT, CMV and respiratory virus infection, and positive *Aspergillus* PCR. It was recently noted that presence of three of the aforementioned factors generated a 57% probability for developing IA. In patients with no risk factors, the probability of IA was 2%, compared to ~80% in patients with four or more such risk factors

[ae]CMV reactivation after stem cell allograft transplantation increases the risk for IFD during the late transplant period. Unlike the risk factors for early IFD such as AML (HR 3), HLA antigen-mismatched donor graft (HR 3.4); HSCT recipients with lymphoma (HR 8.5), CMV reactivation (HR 5.5), and severe neutropenia (HR 3.5) are considered prominent risk factors for late-onset IFD. Patients with pretransplant IgG responses against *Aspergillus* proteins indicating significant fungal colonization or ongoing subclinical *Aspergillus* infections before preparatory conditioning regimen has commenced needs further clinical validation. Evaluation of 5589 HSCT recipients at a comprehensive cancer center between 1985 and 1999 showed increased incidence of IA after 1992 and remained high during that decade. The authors also reported increasing frequency of non-*Aspergillus* molds such as *Fusarium* spp. and mucormycosis in the late 1990s. These non-*Aspergillus* molds were prominent in patients undergoing multiple transplants. Most cases of mucormycosis were seen during the late transplant period, especially in patients with chronic GVHD. In patients undergoing nonmyeloablative HSCT, presence of severe acute GVHD, chronic extensive GVHD, and CMV infection are prominent risk factors for IFD

[af]Invasive aspergillosis is a complication seen in patients with delayed (>2 weeks) recovery of peripheral blood granulocyte count. Patients receiving high-dose systemic corticosteroids are also at an increased risk. *Aspergillus fumigatus* remains the most prevalent mold to cause invasive human disease, including in patients undergoing HSCT. Infections caused by *Scedosporium* and *Fusarium* spp. are occasionally seen in hematopoietic stem cell allograft recipients and commonly present during the period(s) of severe and prolonged neutropenia

[ag]Routine blood cultures have low sensitivity for diagnosis of fungemia. Carbohydrate biomarker (1, 3)-β-d-glucan has emerged as a useful laboratory test for the diagnosis of invasive yeast and mold disease. Furthermore, it may be used to monitor response to systemic antifungal therapy and infection relapse

[ah]Post-HSCT recovery of antigen-specific T lymphocyte-mediated immune response against CMV and *Candida albicans* is regarded as critical during the early and the late transplant period. Most patients develop antigen-specific T-cell response early in the transplant period which is derived from clones of both donor and recipient stem cell origin. Reconstitution of immune response via antigen-specific T lymphocytes of recipient origin is weakened in patients with GVHD. Incidence of IC during the 1st year after nonmyeloablative (5%) and myeloablative transplant conditioning is lower than that for IA (14%). Echinocandin nonsusceptible *Candida* spp. infection has been recently recognized as an emerging challenge in providing care for these highly vulnerable patients

[ai]PCP is a serious OI in transplant patients with severe cellular immune defect(s). Routine anti-PCP prophylaxis breakthrough infections are rare; although in patients receiving aerosolized pentamidine, atypical upper lung PCP may occasionally occur

[aj]Invasive zygomycosis or mucormycosis may occur disproportionally more frequently in patients on voriconazole prophylaxis and those with sinuorbital invasive mold disease. In transplant patients, the overall prevalence is less than 8% among all invasive fungal infections

[ak]Nearly half of the patients with disseminated fusariosis have evidence of fungemia, and close to 80% may exhibit multiple (>10–15) papular skin lesions with a necrotic center that is indistinguishable from ecthyma gangrenosum due to *Staphylococcus aureus* or disseminated *Pseudomonas* spp. infection

[al]Dematiaceous or melanin pigmented molds are associated with chronic localized infections and prevalent in certain geographic regions. In transplant patients, disseminated infections may occur; neurotropism is an important feature of these infections, and treatment with older antifungal drugs such as amphotericin B and early generation triazole-based compounds was associated with high rates of treatment failure

[am]The cumulative incidence of CNS infection following HSCT is <1% within first 30 days, 2% within 3 months, and 5% after 5 years following transplantation. Significantly high risk of CNS infection 5 years after CBT (8%) vs. matched related HSCT (2%) is important to note for the purpose of risk stratification. CNS fungal (35%) and viral (32%) infections are prominent, whereas toxoplasmosis and bacterial infection are seen in just over 10% of the patients. Aspergillosis is common (67%) followed by *Cryptococcus neoformans* (17%). CNS infection in transplant population is associated with high mortality (59%), and low (20%) 5-year overall survival

Table 1.2 (continued)

[an]Donor-derived toxoplasmosis has been reported along with cases of brucellosis in the endemic regions, along with West Nile virus infection, rabies, Chagas disease, and rare cases of lymphocytic choriomeningitis virus infection

[ao]*Strongyloides stercoralis* (pinworm or threadworms and *Enterobius vermiculari*) in the underdeveloped countries where fecal contamination of soil and water is common; evaluation of allogeneic transplant candidates requires serologic evaluation for exposure and if present, appropriate treatment should be completed for intestinal subclinical parasitic infestation prior to the trasnplantation procedure

[ap]In patients with extensive T-cell immune defects, *Strongyloides stercoralis* may cause accelerated autoinfection. Hyperinfection pulmonary syndrome in such patients is almost always fatal. Screening serology tests for the presence of strongyloidiasis by enzyme-linked immunosorbent assay after allogeneic HSCT may be falsely negative; and stool ova and parasite examination, in the absence of accelerated autoinfection during the pretransplant, is also riddled with low sensitivity

[aq]American trypanosomiasis caused by *Trypanosoma cruzi* needs to be assessed in patients planned to undergo allograft transplant procedure from endemic regions

[ar]Leishmania is transmitted by the bite of certain species of sand flies and presents as cutaneous (common) and visceral (uncommon and severe) disease; pretransplant evaluation should include serologic testing for prior exposure to these parasites in appropriate patients with high risk for prior exposure

Abbreviations: GVHD graft-versus-host disease, *HSV* herpes simplex virus 1 and 2, *CMV* cytomegalovirus, *VZV* varicella zoster virus, *HHV6* human herpesvirus 6, *EBV* Epstein-Barr virus, *CoNS* coagulase-negative *Staphylococcus*, *CDAD Clostridium difficile*-associated diarrhea, *GPB* gram-positive bacteria, *GNB* gram-negative bacteria, *HSCT* hematopoietic stem cell transplantation, *RSV* respiratory syncytial virus, *hMPV human metapneumovirus*, *hCoV* human coronavirus hypervirulent subtypes NL63 and HKU1, *PML* progressive multifocal leukoencephalopathy, *EBV-PTLD* Epstein-Barr virus-associated B-cell lymphoproliferative disorder, *HR* hazard ratio, *IFD* invasive fungal disease, *IA* invasive aspergillosis, *IC* invasive candidiasis, *SOT* solid organ transplant, *URTI* upper respiratory tract infection, *LRTI* lower respiratory tract infections, *RTV* respiratory tract virus, *RTVIs* respiratory tract viral infections, *hCoV* human coronavirus

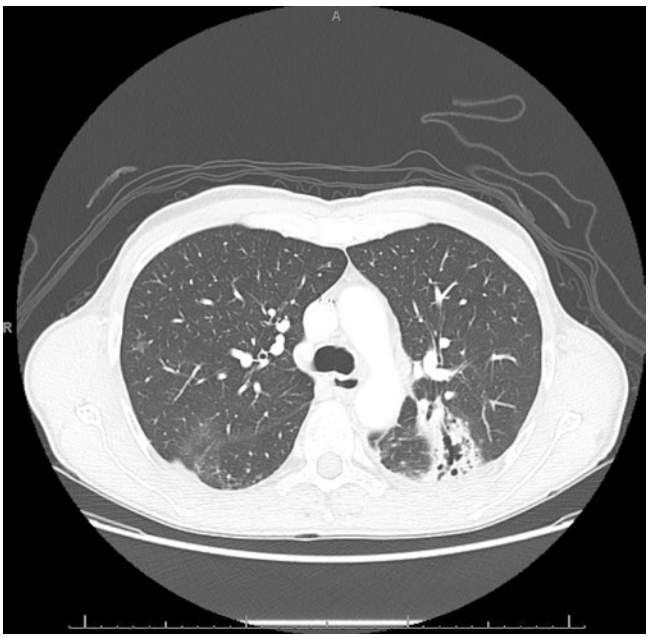

Fig. 1.1 CT scan of lungs without intravenous contrast showing necrotizing left lung *Pseudomonas* infection in a patient following HSCT. The differential for this thick-walled irregular cavitary lesion is broad and includes other bacterial infection such as *Klebsiella* spp., *Stenotrophomonas maltophilia*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Escherichia coli, Nocardia* spp.; *Mycobacterium tuberculosis* and nontuberculous mycobacterial infections. Cavitary rapidly growing cancers may have similar presentation, whereas viral infections including cytomegalovirus and adenovirus seldom present with such features. Other than suppurative necrosis of the lung, ischemic necrosis, i.e. pulmonary infarction, should also be considered. Tissue invasive mold lung disease may also have comparable radiographic presentation

Fig. 1.2 CT scan of lungs without intravenous contrast showing tree-in-bud appearance due to pulmonary *Mycobacterium avium* complex disease mostly involving the right lung demonstrating multiple areas of centrilobular nodules with a linear branching pattern. Endobronchial tuberculosis may present with such a radiographic finding, wherein patients with acutely developed tree-in-bud infiltrates bacterial or viral (CMV) etiology may also be entertained. It is important to note that bronchiectasis is the prominent radiographic presentation of *Mycobacterium avium* complex infection in patients undergoing transplantation. Rarely carcinomatous endarteritis due to breast or gastric cancer; bronchovascular interstitial infiltration due to lymphoma, leukemia, and sarcoidosis may have similar presentation. Scedosporium lung disease and pulmonary fusariosis may occassionally have nodular peribrochovascular distribution

Fig. 1.3 CT scan of lungs without intravenous contrast showing right lung *Mycobacterium kansasii* pneumonia with peribronchial thickening that could be mistaken for CMV pneumonitis and *Mycobacterium tuberculosis*, among other lung infections in a patients following allogeneic HSCT

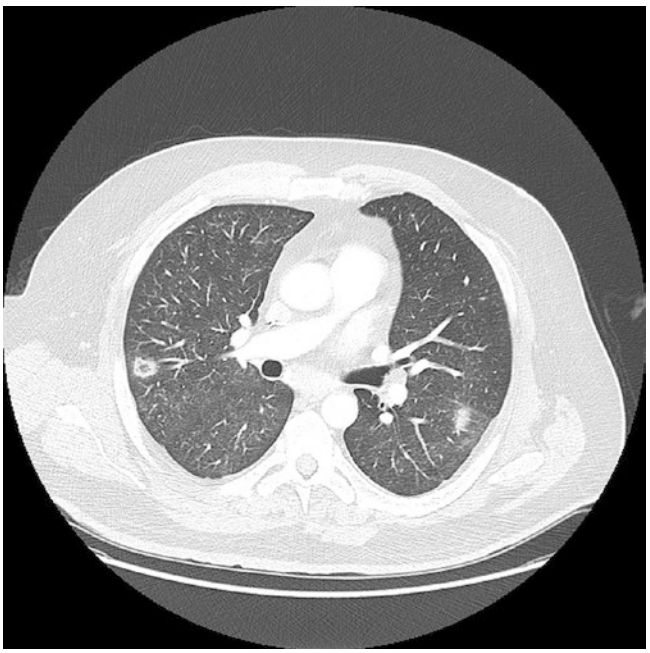

Fig. 1.4 CT scan of lungs without intravenous contrast showing bilateral nodular zygomycosis in a patient following allogeneic HSCT while receiving voriconazole prophylaxis. The right lung nodule with a central cavity cannot be radiographically excluded from other causes of nodular pneumonia such as invasive pulmonary aspergillosis, *Fusarium* spp., and other mold lung disease. Among bacteria, *Nocardia* spp. is a concern in allograft transplant recipients with such radiographic presentation. Primary lung lymphoma may have similar presentation. Rarely, patients with relapse acute leukemia in the post HSCT period may present with atypical pulmonary infiltrates

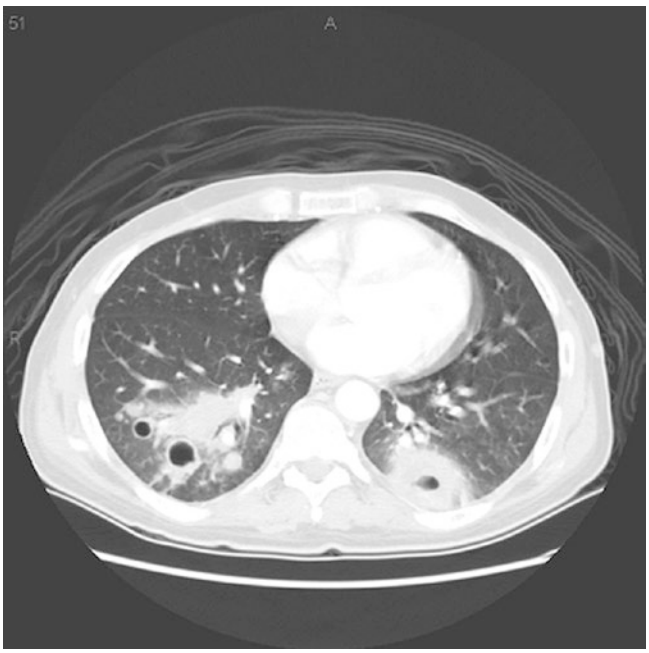

Fig. 1.5 CT scan of lungs without intravenous contrast showing cavitary pneumonia with dense consolidation involving both lower lobes in a patient with GVHD, who developed infection due to dematiaceous mold following allogeneic HSCT. In the differential diagnosis, necrotizing bacterial, clear (hyaline) and black (melanin pigmented) mold infections should also be considered along with multifocal pulmonary nocardiosis

at an additional risk for infections that are often seen in asplenic patients or those with functional hyposplenism. Patients with chronic GVHD are not only at an increased risk for systemic fungal disease like invasive aspergillosis or herpes virus reactivation herald by CMV viremia; additionally, encapsulated bacteria such as outlined in Table 1.1 may also be included in the risk profile during evaluation of such patients.

Patients receiving treatment for acute GVHD after allogeneic HSCT have heightened risk for invasive aspergillosis and infections due to other filamentous molds. Unlike the first risk period for invasive mold disease in allogeneic stem cell recipients, which coincides with the period of pre-engraftment severe neutropenia, patients with acute and chronic GVHD are seldom neutropenic.

Table 1.3 illustrates the salient features of infection risk and their association with the type of stem cell graft, pre-transplant conditioning preparatory regimens, and drugs commonly used in the prevention of GVHD. Cord blood stem cells are regarded as a major breakthrough for source that yields a steady supply of hematopoietic stem cells, especially among patients with difficult to find, immunologically (HLA-matched) compatible hematopoietic stem cell graft [18]. Cord blood stem cells have a limited number of nucleated cells that are adequate for children. In adults

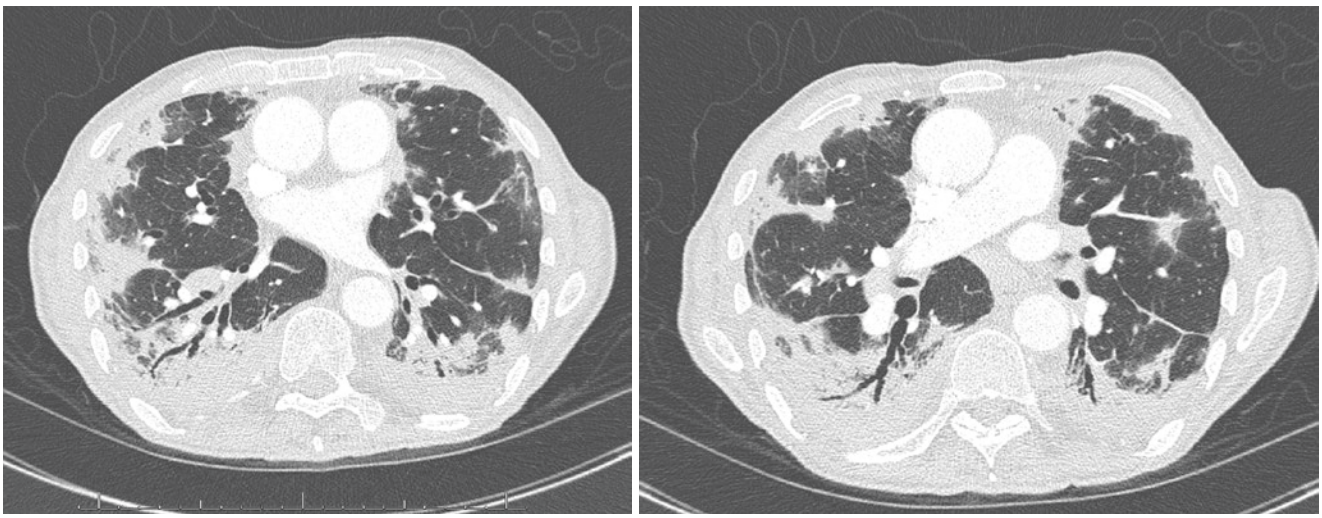

Fig. 1.6 CT scan of lungs without intravenous contrast showing cryptogenic organising pneumonia in a patient following allogeneic HSCT that may be mistaken for fibrosing subacute infection due to endemic mycosis among other causes of subacute lung infection

due to larger body surface area, transplantation with less than optimum number of stem cells complicate posttransplant period with issues such as inadequate and delayed neutrophil engraftment and peripheral blood cell count recovery, precarious graft stability, and, similar to recipients of T-cell-depleted grafts, a higher risk for infections associated with severe and prolonged neutropenia or those observed during GVHD (Tables 1.1 and 1.2). Various strategies are being explored to assuage this limitation including transplantation with cord blood grafts from more than one donor and ex vivo expansion of a single donor cord blood graft to increase the yield of nucleated cells [21]. In a review of 100 cord blood transplants at a comprehensive cancer center in Houston, Texas, the infection incidence rate ratio, which was total infection episodes per days at risk (survival after CBT) × 100, was 2.4 times higher in adult patients compared with children [22]. It was important to note that risk of infection was even greater (three times higher) in adults with neutropenia and was 1.9 times higher in patients with GVHD when compared with children undergoing CBT procedure [22].

It is considered essential to create a comprehensive infection assessment strategy that takes into account and recognizes the local issues at a particular transplant unit and its unique patient population. Such an approach requires cognizance of existing influences that may promote risk for infection including local and regional infection trends, patterns in pathogen prevalence and drug susceptibility profiles. Continued vigilance regarding emergent pathogens and ever-changing infection risk profile with advances in transplant procedures and drug-induced immune suppression are of paramount importance in providing care for the highly vulnerable transplant population.

A variety of noninfectious conditions may clinically and radiographically emulate an infectious process. Among these noninfectious maladies, those involving the skin and the lungs are the great imitators; when present, they are difficult to clinically distinguish from infections such as cellulitis or pneumonia. Two chapters in this volume are dedicated to provide an in-depth discussion on these topics.

An approach for establishing correct diagnosis for opportunistic infections is based on the maxim "when uncertain, obtain a tissue sample." A diligent adjudication is the central tenet in establishing accurate diagnosis for the immunologically vulnerable patients, in whom proclivity for atypical disease presentation further complicates ascertaining correct and timely diagnosis. Inaccurate diagnosis under the old dispensation of serologic and culture-based system may lead to inappropriate and ineffective treatment, worsening patients' morbidity, risk for further complications, and death. Therefore, focused yet comprehensive differential diagnoses, which encompasses etiology of infections and noninfectious causes that may mimic an infectious process including but not limited to drug toxicity; de novo malignancies or post transplant cancer recurrence; typical or atypical presentation of lymphoproliferative disorders; immune-inflammatory diseases like GVHD; and tissue infiltrative processes such as solid allograft rejection among others may greatly improve the guidance for an optimized management approach in patients undergoing lifesaving, stem cell and solid organ allograft transplantation.

Table 1.3 Relationship between infection risk and HSCT variables

Stem cell source, preparatory conditioning regimens, and GVHD prophylaxis	Immune defects	Infections
Allogeneic vs. autologous graft	Allograft recipient exhibits gradual recovery of cellular and adaptive immune function	Pre-engraftment neutropenia, if longer than 7–14 days, increases the risk for invasive candidiasis and IMD
	Innate immune function aided by cellular and acellular antimicrobial defense is to recover early after transplantation, especially in patients undergoing conventional autologous and nonmyeloablative HSCT. It is heralded by granulocyte engraftment and posttransplant resolution of neutropenia	IFD heightened risk coincides with the peak incidence of acute and chronic GVHD
	Complements and antimicrobial peptides reconstitute early after transplantation	Severe respiratory viral infections are also problematic in patients given systemic corticosteroids and immunosuppressive therapy for GVHD
	Patients with persistent severe thrombocytopenia that may follow in high-risk allogeneic stem cell recipients may continue to exhibit reduced host defense due to suboptimum thrombin-releasable antimicrobial peptides from platelets including platelet factor 4, RANTES, connective tissue-activating peptide 3, platelet basic protein, thymosin β-4, fibrinopeptide B, and fibrinopeptide A. The impact of depleted platelet-assisted immune defense and potentially higher susceptibility for infection in HSCT recipients with severe thrombocytopenia is not certain	CMV, less commonly HHV6, and disseminated adenovirus are encountered in patients with profound defects in anti-CMV and other antiviral pathogen-specific, effector cellular immune response
	Myeloid and plasmacytoid dendritic cells are recovered within 60 days after allogeneic HSCT to pretransplant levels, unless patients develop acute GVHD, in which case this recovery is significantly delayed. However, it may take a year or longer to achieve normal functional DC cell population after undergoing allogeneic stem cell transplantation. Plasmacytoid DCs are important for regulation and maintenance of immune tolerance and defense against viruses. The myeloid DCs serve as APCs that are pivotal in eliciting pathogen-directed cellular adaptive immune response	
	Recovery of NK cells in most patients undergoing allogeneic HSCT occurs usually 45 days after transplantation. These innate immune effector cells can directly lyse virus-infected cells and provide antineoplastic immune surveillance. NK cells are an important, readily available, albeit transient source of IFNγ and GM-CSF. The chemokines such as MIP-1α, MIP-1β, IL-8, and RANTES play a critical role in adaptive immune modulation. It was notable that lack of qualitative NK cell recovery in patients with T-cell-depleted transplant may render them less effective for prolonged periods	

Table 1.3 (continued)

Stem cell source, preparatory conditioning regimens, and GVHD prophylaxis	Immune defects	Infections
Unrelated donor or mismatched stem cell graft	Unrelated donor grafts are more frequently associated with severe GVHD and/or graft rejection compared with sibling donor stem cell allograft transplants	Mismatched and unrelated donor stem cell allograft transplants carry a significant risk for serious life-threatening infections seen in the late (6–18 months) post-transplant period. CMV infection and acute GVHD contribute significantly toward this risk. The late fatal infections include pneumonia, sepsis, central nervous system infection, and disseminated varicella
	Slow reconstitution of adaptive cellular helper and cytotoxic immunity, which is further delayed in patients requiring treatment for acute GVHD	IA 6 months after transplantation was associated with chronic GVHD and CMV disease
	Humoral immune response may not fully recover in patients with chronic GVHD	*Fusarium* spp. IFD is threefold higher in patients undergoing HLA-mismatched vs. HLA-matched HSCT; most cases occur 48 median days after transplantation. The trimodal distribution similar to IA coincides with pre-engraftment neutropenia; 60 days and over 1 year after transplant, corresponding with the incidence of acute and chronic GVHD, respectively
	Bone marrow as the source of stem cells and treatment with high-dose corticosteroids delay recovery of functional T-cell-based immunity for 3 months or longer after transplantation	Persistent neutropenia similar to that seen in cases with disseminated *Scedosporium* spp. infection and other invasive mold disease after allogeneic HSCT was the prominent prognosticator for death in patients with fusariosis
		It has also been recognized that subclinical CMV reactivation in patients while on ganciclovir prophylaxis or preemptive therapy appears to be a potent stimulator of T-cell function after transplantation
		Other serious infections include EBV-PTLD, disseminated HHV-6, and disseminated adenovirus infections
Peripheral blood stem cell graft vs. bone marrow stem cells	Faster neutrophil engraftment	The rate of severe and proven infections following stem cell engraftment was ≥twofold higher in patients in whom bone marrow SCT was given compared with those undergoing transplantation with PBSC allografts
	Blood stem cell grafts have higher lymphocyte subset counts, which, in most part, account for fewer infectious complications during the posttransplant period	HLA-matched, related-donor peripheral blood stem cells appear to lend protection against IA during early transplant period compared with those undergoing similar bone marrow stem cell allograft transplants
	Late transplant immune suppression due to chronic GVHD may occur	The greatest benefit of PBSC vs. BMSC has been noted in the risk profile for IFD, whereas for bacterial infections such benefit is intermediate, and it is least for viral infections

(continued)

Table 1.3 (continued)

Stem cell source, preparatory conditioning regimens, and GVHD prophylaxis	Immune defects	Infections
Cord blood stem cell graft	Slower neutrophil engraftment resulting in prolonged neutropenia in adult CBT recipients continues to be a serious limitation for this stem cell donor source	Cord blood stem cell transplantation increases the risk of early (<40 days) IAs
	Adult patients require a higher number of total nucleated cells and CD34+ progenitors than are often present in a cord blood unit, yielding to instability of the allograft even after successful engraftment. To mitigate these limitations, especially in adults, strategies to expand selected subpopulations of stem cell within the cord blood unit and transplantation of multiunit CB are currently being explored	CBT recipients had a higher incidence of severe bacterial infections within 100 days after transplantation; however, 3 years after CBT, risks of severe bacterial and other infections are comparable to patients undergoing BMT or peripheral blood allogeneic HSCT
	Slower restitution of T-cell pathogen-specific, cellular immune response as cord blood T-cells are predominantly naïve and exhibit suboptimum T-cell proliferation and IFN-gamma production in response to an insult or exposure to a foreign antigen. This inherent cellular dysfunction in CBS grafts appears to reflect defect(s) in signal transduction pathway(s)	CMV infection and/or presence of acute GVHD significantly increases the risk for IA
	Furthermore, T-cell dysfunction may also arise from prominence of Treg population in CBS with potent suppressor function compared with moderate Treg population in adult donor-derived stem cell grafts	Most (>90%) IFD similar to bacterial infections are seen within 100 days after transplantation
	Hypogammaglobulinemia and other B-cell dysfunction may occur in patients with chronic GVHD	Nearly half of the early fungal infections may be noted within the first 30 days after CBT
	Risk of graft rejection and severe acute GVHD have been comparable to that observed following PBSC or BMSC transplants; this is despite high degree of HLA antigen donor-recipient disparity in most adult patients undergoing CBT	CMV and varicella zoster virus infections after 100 days following CBT are mostly seen in patients with chronic GVHD
	Graft-versus-leukemia/lymphoma effect in CBT recipients has also been comparable to conventional stem cell graft transplants	Patients who recover peripheral blood lymphocyte count following successful CBT engraftment are at a significantly low risk for serious systemic infections
T-cell-depleted stem cell graft	Higher risk for graft rejection may be an issue	These patients have a higher risk of infections during the prolonged pre-engraftment neutropenia
	Slower reconstitution of cellular and humoral immunity	The risk factors for IA noted in allogeneic HSCT recipients include T-cell-depleted or DC34-selected stem cell grafts, treatment with systemic corticosteroids, GVHD, presence of severe lymphocytopenia, and neutropenia
	CD8 cells recover rapidly, whereas helper T-cells and B lymphocyte recovery remain significantly stunted for 1 year or longer after T lymphocyte-depleted stem cell graft transplantation	CMV infection and end-organ disease; LRTI due to RTVs are now recognized as important predictors for IA and other IFD during post-engraftment period
	Natural killer cells also make early and sustained recovery after transplantation	
	Despite T-cell-depleted PBSC grafts having higher numbers of mononuclear cells and granulocyte-macrophage units compared with BM grafts, recovery in B lymphocyte and T-cell subpopulations has not been dissimilar, in either group	
	These patients also exhibit a subnormal level of primed T-cell repertoire. Prominent lymphocyte population in such stem cell grafts is composed of naïve/unprimed T-cells. Primed T lymphocytes including activated helper T-cells that are an important and sustained source of IFN-gamma, a critical cytokine in targeted intracellular neutralization of various pathogens	
	Hypogammaglobulinemia has not been an issue in patients undergoing T-cell-depleted vs. conventional stem cell transplantation	

Table 1.3 (continued)

Stem cell source, preparatory conditioning regimens, and GVHD prophylaxis	Immune defects	Infections
Nonmyeloablative stem cell transplantation	Faster neutrophil engraftment following reduced intensive preparatory regimen	Patients with chronic lymphocytic leukemia (138 episodes/100 person-years) and recipients of matched unrelated donor graft (128 episodes/100 person-years) had higher risk of infection after NMT
	Blood stem cell recipients have higher lymphocyte subset counts and account for fewer infectious complications during posttransplant period	Nearly half of the CMV viremia is noted between 31 and 100 days after transplantation. CMV infection as expected is mostly encountered after the resolution of neutropenia
	Substantially reduced incidence of GVHD, especially severe grade III–IV acute GVHD	Close to 80% of IFI are late transplant infections that are diagnosed 100 days after NMT and associated with unacceptably high mortality (~80%). Presence of GVHD and treatment with systemic corticosteroids significantly increases the risk for IFD in such patients
	Late transplant immune suppression due to chronic GVHD may occur	
	B-cell dysfunction, when present, is often represented as deficiencies of immunoglobulin subclasses rather than severe hypogammaglobulinemia	The risk of IA after NMT appears to increase with time, while well-under 10% within 1 year after HSCT, the overall risk increases to around 10% at 2 years and close to 15% 3 years after transplantation. Patients with GVHD involving the intestinal tract show a significant risk for IA after NMT
	As in all transplant recipients including those undergoing autologous SCT, B-cell hyporesponsiveness is clinically demonstrated as reduced immunogenicity for convention vaccines. Response to protein conjugate vaccines tends to be superior compared with response elicited by pure polysaccharide and other complex sugar immunogens. Superior conjugate vaccine construct requires restitution of cellular immune response and a functional antigen presentation process	GVHD treatment with daclizumab further enhances the risk for IA. Daclizumab is a humanized monoclonal antibody that binds to CD25, the alpha subunit of the IL-2 T-cell receptor resulting in severe iatrogenic drug-induced cellular immune suppression
	Adults with rapid engraftment of NMT become full donor T-cell chimeras within 6 months after transplantation. In contrast to children, quantitative B-cell recovery in adults is usually delayed until 1 year after HSCT. It was interesting that immune reconstitution occurs faster in children undergoing NMT who exhibit extended duration of mixed hematopoietic chimerism, whereas in adults, reconstitution is more gradual despite rapid donor stem cell engraftment and T-cell chimerism	

(continued)

Table 1.3 (continued)

Stem cell source, preparatory conditioning regimens, and GVHD prophylaxis	Immune defects	Infections
Total body irradiation and chemotherapy-induced mucositis	Radiation exposure and highly active antineoplastic drugs kill rapidly proliferating cancer cells. The rapidly dividing normal orointestinal epithelial cells also sustain unintended damage that may clinically present in patients with severe and potentially life-threatening mucositis	Patients with severe mucositis, especially those with mucosal ulcerations, have threefold higher risk for α-hemolytic streptococcal bacteremia compared with those without ulcerative mucositis following HSCT. In such patients, presence of oral ulcerations significantly increases the length of hospitalization by nearly 1 week
	Various strategies including recombinant human keratinocyte growth factor among others are being explored to mitigate this serious debilitating complication commonly seen in the early posttransplant period	Similarly, presence of orointestinal mucositis has been associated with the risk for neutropenic enterocolitis or typhlitis and CDAD
	Initial phase of chemotherapy-induced stomatotoxicity is infiltration of tissue with inflammatory cells and vascular congestion, followed by epithelial cell damage resulting in ulceration; risk for bacterial and less often yeast invasion resulting in systemic infection. Patients who survive this phase are expected to make full recovery	The risk of fungemia due to *Candida* spp. may also be increased in such patients
	Divergent cytokine response plays an important role in the risk, severity, and duration of mucositis as does hosts' genetic predisposition	Patients with intestinal VRE colonization and mucosal disruption heighten the risk for systemic invasion and risk of VRE bloodstream infection
		Later TBI complication between 12 and 136 months after treatment is mostly noninfectious and includes restrictive lung disease (~8%) and altered pulmonary diffusing capacity (~12%); pulmonary complications had been statistically higher in patients with GVHD and those who underwent high-dose (15 MV vs. 9 MV) energy beam radiation therapy. Ocular complications are noted in nearly 30% of patients on long-term follow-up and include cataract and dry eye syndrome (~15% each), whereas keratitis is seldom seen
Antithymocyte globulin	ATG is polyclonal human antilymphocyte globulins that result in multifaceted immunomodulation and are shown to reduce the incidence of solid organ graft rejection and GVHD following allogeneic HSCT	The incidence of EBV-related complications was twice as high (~7%) in patients undergoing non-HLA-matched vs. HLA-matched allograft stem cell transplants. This risk was significantly higher (>20%) in patients given antithymocyte globulin versus those in whom this treatment was not given (<2%). In HSCT recipient with persistent EBV reactivation, just above 80% developed EBV-related PTLD suggested targeted surveillance
	ATG in vivo depletes proinflammatory cytotoxic T-cells in the peripheral blood via complement-dependent cell lysis, and peripheral lymphoid tissue T-cell depletion occurs via cell activation and apoptosis	Febrile illness, CMV infection, and hematologic abnormalities are known complications in patients treated with ATG
	ATG downregulates expression of the α-chain of the IL-2 receptor (CD25), which is expressed on activated T lymphocytes thereby interrupting an important signal for cell proliferation	
	Modulation of key cell surface molecules such as integrins and intercellular adhesion molecules that facilitate and regulate lymphocyte interactions with the endothelium. Chemotaxis is effected by interference with CXCR4 and stromal cell-derived factor-1α-driven lymphocyte migration	
	ATG induces apoptosis in B-cell lineages	
	It promotes and expands functionally immunosuppressive regulatory T-cells	

Abbreviations: *GVHD* graft-versus-host disease, *CMV* cytomegalovirus, *DC* dendritic cells, *NK* natural killer, *PML* JC virus-associated progressive multifocal leukoencephalopathy, *PTLD* Epstein-Barr virus-associated B-cell lymphoproliferative disorders, *IFD* invasive fungal disease, *CDAD Clostridium difficile*-associated diarrhea, *CBT* cord blood stem cell transplantation, *IA* invasive aspergillosis, *IC* invasive candidiasis, *Treg* regulatory T-cells, *HSCT* hematopoietic stem cell transplantation, *IMD* invasive mold disease, *HHV6* human herpes virus 6, *RANTES* regulated on activation, normal T-cell expressed and secreted, *APC* antigen-presenting cells, *IFNγ* interferon gamma, *NTM* nonmyeloablative transplant, NST, *GM-CSF* granulocyte-macrophage colony-stimulating factor, *CBS* cord blood stem cells, *BMSC* bone marrow stem cells, *PBSC* peripheral blood stem cells, *LRTI* lower respiratory tract infection, *SCT* stem cell transplant, *HLA* human leukocyte antigen

Infections in Heart, Lung, and Heart-Lung Transplantation

2

Andrés F. Henao-Martínez and José G. Montoya

Historical Perspective

We have conceived the human heart as the main source of our deep emotions and feelings. A place where our very conscious resides as portrayed by Edgar Allan Poe in his famous *The Tell-Tale Heart* short story: "I felt that I must scream or die! And now—again!—hark! Louder! Louder! Louder! Louder!" Dr. John Gibbon Jr. used for the first time in 1953 a heart-lung respirator to keep a patient alive while performing heart surgery. Dr. Norman Shumway at Stanford developed and perfected the first surgical technique leading to heart transplantation surgery. After Dr. Christian Barnard's first orthotopic heart transplant in December 1967, and Dr. Shumway first heart transplant in the United States in January 1968, heart transplantation became a standard therapeutic option for life-threatening congestive failure and started to be performed in the hundreds over the next following years at different centers. Heart transplant surgery faced complications due in part to rejection and infection. However, the development of more selective immunosuppressive therapy and improvements in prevention, detection, and treatment of infections allowed for heart transplant surgery to increase rapidly worldwide.

Four thousand and ninety six heart (3529 adults) transplants were reported to the International Society of Heart and Lung Transplant Registry (ISHL) in 2011 [1]. The landscape of infection affecting heart transplant patients has been shaped by different factors: (A) implementation of more selective calcineurin-based immunosuppressive protocols, (B) lessened immunosuppressive induction regimens, (C) the institution of antimicrobial prophylaxis resulting in a significant decrease or delay in the emergence of major infections episodes including *P. jirovecii* (PCP), *Nocardia* spp., *Listeria spp.*, *Toxoplasma gondii*, cytomegalovirus, toxoplasmosis, cytomegalovirus (CMV), herpes simplex virus (CMV), varicella zoster virus (VZV), and invasive fungal infections, (D) introduction of novel diagnostic technology facilitating earlier recognition and treatment of infections, (E) expansion in the criteria to select donors and recipients to include various scenarios dealing with HBV, HCV, and HIV infections [2], and (F) shift toward predominantly Gram-positive bacterial infections and multiresistant bacteria in recent years [3–5].

A Stanford team lead by Dr. Bruce Reitz performed a Lung transplantation as a combined heart-lung transplant procedure in 1981 [6]. Shortly after, thoracic surgeons optimized the single- and double-lung transplant procedures. Improvement of surgical techniques, especially bronchial anastomosis and evolution of flush perfusion lung preservation, decreased the perioperative bronchial complications substantially. Similarly to heart transplantation, improvements in immunosuppressive regimens, antimicrobial prophylaxis, and graft preservation led to enhancement in survival among lung transplant recipients. In contrast to cardiac, lung transplantation has faced the challenge of infections unique to the transplant of this organ. Mold infections of the anastomotic site, host versus graft disease, and serious infections with *Mycobacterium abscessus*, *Chlamydia* spp., bronchiolitis, and *Burkholderia cepacia* complex are among infectious complications rarely observed in other transplant patients [7].

Transplantation of thoracic organs has improved the quality of life and prevented the death of thousands of

individuals worldwide. Graft survival and life expectancy have been markedly improved in these patients due to the introduction of more optimal immunosuppression, antimicrobial prophylaxis, and diagnostic technology allowing the earlier diagnosis and treatment of infection and rejection. Finally, further control of infection is likely to result from implementation of new approaches to assess the net state of immunosuppression in these patients.

Epidemiology

Infection was recognized as a major threat to thoracic transplantation from the early inception days [8]. There are several factors predisposing thoracic transplant recipients to infections: (A) factors present before transplantation: age, presence of comorbidities (e.g., chronic kidney disease, diabetes mellitus, cancer, etc.), nutrition status, latent infections, colonization with healthcare-associated organisms, and occult community-acquired infections; (B) factors during the surgery: duration of the transplant procedure, graft injury including ischemic time, colonization or latent infection of the graft, surgical instrumentation (e.g., mechanical ventilation, invasive devices such as catheters, drains, Foley catheters, etc.), ICU stay, and need for re-interventions; and (C) factors present after transplant: degree of immunosuppression, CMV infection, and rejections (Table 2.1).

Table 2.1 Clinical features modifying infection risk in transplantation

Before transplantation
Age
Comorbidities: diabetes mellitus, chronic kidney disease, cancer, etc.
Nutrition status
Latent infections or occult community-acquired infections
Colonization with healthcare-associated organisms
During transplantation
Duration of the transplant procedure
Graft injury
Ischemic time
Anastomosis site in lung transplant
Denervation of allograft (e.g., diminished cough reflex)
Lymphatic drainage disruption
Colonization or latent infection of the graft
Surgical instrumentation (e.g., mechanical ventilation)
ICU stay
Need for re-interventions
After transplantation
Immunosuppression
CMV infection
Rejections

Heart Transplant Infections

A total of 4096 heart transplants were performed in 2011. Heart transplant recipients have an average age of 54 years and are predominantly man (76%). They have a significant history of smoking (46%) and hypertension (45%) and have cardiomyopathy (54%) followed by coronary artery disease (37%) as the leading causes of transplant [1]. The historical (pediatric and adult transplants between 1982 and 2011) 1-year, 5-year, and 10-year survival rates are 81%, 69%, and 50%, respectively. Overall median survival is 11 years, but it increases up to 13 years for those surviving the first year after transplantation. Although not associated with increased posttransplant mortality, infections before transplant can affect up to 25% of heart transplant candidates. Being bronchitis and soft tissue infections, the more commonly present [9]. Despite no major changes in the distribution of causes of death since 1994, infections remained a predominant factor of mortality during the first 3 years after transplant. It contributes with up to almost 20% of causes of death [3]. The global incidence of infections in heart transplant ranges between 30% and 60% and the associated mortality between 4% and 15% [10]. The incidence of infection measured as major infectious episodes per patient has steadily declined from 2.83 in the early 1970s to 0.81 in the early 2000s [3, 8, 11]. The most frequent type of infection is bacterial (44%), followed by viral (42%), fungal including *Pneumocystis jirovecii* (14%), and protozoa (0.6%). Unfavorable functional outcomes are observed in patients who developed infections in the first year of transplant, mainly associated with bloodstream, CMV, and lung infections [12]. Pulmonary and central nervous system (CNS) infections are independent predictors of mortality among heart transplant recipients. Reactivation of latent parasitic infections residing in extra-cardiac tissues in the host or transmitted in the transplanted heart is an important consideration. The classic example is the reactivation of *Trypanosoma cruzi*. Chagas disease is a vector-borne illness transmitted by triatomine bugs, and it is endemic in Latin America. The ethnicity or origin of either the donor or the recipient from these regions should raise the concern for possible reactivation. Chagas reactivation was documented in 38.8% of cases in a cohort of Brazilian heart transplant recipients, where Chagas cardiomyopathy was the second most common indication for transplant (34.9%) [13]. Chagas can also reactivate from the transplanted heart procured from a seropositive donor and transplanted into a seronegative recipient. Although with a substantial decreased on its prevalence in the most recent eras, toxoplasmosis is another important consideration in this setting. Similarly to Chagas, *Toxoplasma gondii*—also

with a predilection to invade the myocardium—can be transmitted by reactivation of quiescent cysts in the recipient or the transplanted heart [14].

Lung and Heart-Lung Transplant Infections

By 2011, 3640 adults received lung transplantation, the highest reported number of procedures up to that date, driven mainly by the increase of double-lung transplants. Double-lung transplant is indicated for septic lung diseases (e.g., cystic fibrosis). Around 66% of recipients were aged 45–65 years old. The most frequent indications for transplant were COPD (34%), followed by interstitial lung disease (ILD) (24%), bronchiectasis associated with cystic fibrosis (CF) (17%), and α1AT deficiency-related COPD (6%) [15]. The overall (from 1994 to 2011) 1-year, 5-year, and 10-year survival rates among lung recipients are 79%, 53%, and 31%, respectively. Overall median survival is 5.6 years. Lung transplants from CMV seronegative donors have better survival rates than from CMV seropositive donor. Thirty-day mortality was led by graft failure (24.7%) and non-CMV infections (19.6%). During the remainder of the year, non-CMV infections were the leading cause of death (35.6%). Infection is still prominent as the cause of death following the first year of transplant after bronchiolitis obliterans syndrome (BOS)/chronic lung rejection or graft failure [15]. Other infections complications historically present among the ten primary causes of death within the first year include sepsis, pneumonia, and fungal infections [16]. High lung allocation score (LAS) at the time of transplantation is associated with a lower 1-year survival and higher rates of infections among lung transplant recipients [17].

Sixty-three adult Heart-Lung transplantations were reported to the ISHL registry in 2011. Sixty-six percent of recipients were in the group range from 18 to 49 years old. Sixty-three percent of the indications were for congenital heart disease and idiopathic pulmonary arterial hypertension. Heart-lung transplant for CF was higher in Europe and other centers compared to North American. When compared to lung only transplants, short-term survival was worse, but long-term survival was better for the heart-lung transplant recipients. Their 1-year, 5-year, and 10-year survival rates were 63%, 44%, and 31%, respectively. The median survival was 3.3 years and 10 years for those surviving the first year. Similarly, they have graft failure (27%), technical complications (21.9%), and non-CMV infections (17.8%) as leading causes of death during the first 30 days posttransplant. Non-CMV infections (35.1%) were the top cause of death after 1 month and within 1 year of transplant. After the first year, BOS/late graft failure and non-CMV infections were the predominant causes of death [15]. Among other risk factors for mortality in lung transplantation are cystic fibrosis, nosocomial infections, and mechanical ventilation before transplant [18].

Infections in lung transplant recipients are predominantly bacterial (48%), viral (35%), fungal (13%), and mycobacterial (4%) [19]. In 60%, the infection site is pulmonary. Risk factors for infection vary by the type of organism. Mechanical ventilation (MV) for >5 days immediately following transplant surgery and isolation of *Staphylococcus aureus* (SA) from airway cultures in the recipient were considered risk factors for invasive SA infections in a retrospective study of patients with lung and heart-lung transplants [20]. Likewise, risk factors for the development of healthcare-associated infections with Gram-negative organisms, *Aspergillus*, *Legionella*, and MRSA (methicillin-resistant *Staphylococcus aureus*), include prolonging MV, renal failure, use of ATG (antithymocyte globulin), and recurrent rejections episodes [21]. Additionally, α-1-antitrypsin deficiency and repeat transplantation are also risk factors for nosocomial infections. *Mycobacterium tuberculosis* transmission from lung donors with latent infection has been documented in highly endemic areas [22]. Colonization with MDR organisms (*Pseudomonas aeruginosa*, *Burkholderia*, *Acinetobacter*, nontuberculous mycobacteria (NTM), and *Scedosporium*) before transplant—especially important in CF patients—can predict the development of challenging infections to treat after transplant [23].

Pretransplant Evaluation of Recipients and Donors

Pretransplant Screening of Recipients

Patients should undergo a comprehensive evaluation of potential infectious complications associated with transplantation. A detailed medical history including previous vaccinations, history of past infections, exposures (geographical, occupational, animal, etc.), travel, and foreign-born status among others should be obtained.

Clinicians shuold perform routine serologies for the detection of pathogen-specific IgG for CMV, HSV, EBV (VCA), VZV, hepatitis B (HBsAg, HBsAb, HBcAb), HIV, hepatitis C, and syphilis. Toxoplasma IgG should also be performed in heart and heart-lung transplant candidates. Additionally, we recommend to obtain UA, urine culture, CXR, and tuberculin skin test (TST), or a Quantiferon assay. In lung and heart-lung transplant candidates, sputum should be cultured for bacterial, fungal, and AFB studies.

Some centers advocate the screening of patients for colonization with MDR (multidrug resistant) bacteria such as MRSA and VRE (vancomycin resistant *Enterococci*),

which it may have an impact on the type of antibacterial prophylaxis used preoperatively or the empirical antibiotics should sepsis develop in the immediate postoperative period. In potential lung recipients, previous respiratory colonization with MDR *Pseudomonas*, especially in CF patients, should not exclude them from transplant [24]. On the other hand, if colonization with *B. cenocepacia* (genomovar III) in CF is present transplant is relatively contraindicated [25, 26].

Checking for endemic fungi such as *Coccidioides immitis* or for the parasites *Trypanosoma cruzi*, *Strongyloides stercoralis*, and *Leishmania* spp. is indicated in the presence of the appropriate risk factors [27–31].

Histoplasma capsulatum has reactivated during immunosuppressive therapy [32]. Infections after solid organ transplantation (SOT) are rare and attributable to transmission from the donor [33]. Furthermore, latent histoplasmosis can be present with negative serologies and treatment after transplant carries a good outcome. Therefore the role of screening for histoplasmosis is of questionable significance [34].

Pretransplant Screening of Donors

The type of evaluation may change if the donor is alive or deceased depending on the available time to collect the samples. Similarly to recipients, donors should undertake a comprehensive assessment including a complete history, assessment of risk factors, exposures, immunizations, and previous or current infections. Donors should be screened for HIV, hepatitis B/C, syphilis, and tuberculosis. Furthermore, we recommend to obtain serologies for CMV, EBV, HSV, VZV, and *Toxoplasma gondii*, and for HTLV-1/HTLV-2 in endemic areas. In high-risk donors, the use of nucleic acid amplification tests (NAAT) for HBV, HCV, and HIV should be considered. Additionally, blood cultures to document an occult bacteremia are recommended. In lung transplant donors, we recommend obtaining respiratory cultures through bronchoscopy to detect colonizing organisms and target them to prevent invasive infections in the donor. Culturing the media of the allograft during acquisition or processing have been advocated to reduce the risk of mycotic aneurysms among kidney transplant recipients, which may apply to other SOT [35]. Screening of donors for endemic mycosis is not well established. On the other hand, heart transplant donors should be screened for Chagas if the donor was born in Latin America [29]. Finally, it is important to highlight the increase recognition of emerging, unusual viral infections such as West Nile virus, lymphocytic choriomeningitis virus, rabies, and different human coronaviruses [34, 36]. Testing for those organisms should be done based on individual assessments. Table 2.2 describes and summarizes the diagnostic workup recommend among donors and recipients.

Table 2.2 Infectious screening during transplantation

Diagnostic workup among donors and recipients
Routine tests obtained among donors and recipients:
Viral test: HIV Elisa, hepatitis C antibody, HBV (HBsAg, HBcAb total, HBsAb), IgG antibody for CMV, HSV, EBV VCA, VZV
Bacterial: Treponemal antibody (e.g., EIAs, FTA-ABS), QFN assay or PPD
Parasite: Toxoplasmosis IgG (routinely indicated for heart transplant patients)
Other screening to consider among donors or recipients in the presence of specific risk factors:
Viral: NAAT for HIV, HCV, HBV in high-risk donors. HTLV-1/HTLV-2 in donors from endemic areas
Bacterial:
Recipients: UA, urine culture, CXR, and sputum culture. *Optional*: To consider screen for colonization with MDR organisms (MRSA or VRE)
Donors: Blood cultures, allograft media culture, and bronchoscopy with culture from respiratory specimens in lung donors
Parasite: Ortho EIA and Abbott Prism Chagas test to screen for *Trypanosoma cruzi* in donors or recipients from Latin America. *Strongyloides stercoralis* and *Leishmania* spp. serologies should be obtained in recipients in the presence of appropriate geographic risk factors
Fungal: EIA for coccidioidal antibodies or complement fixing antibodies for cocci

Abbreviations: NAAT Nucleic acid amplification test, *CXR* chest X-ray, *MDR* multidrug resistant, *EIA* enzyme-linked immunosorbent assay

Prevention of Infections

Immunizations

Immunization should be optimized before transplantation since the recipient will have better chances to mount an adequate immune response [37]. The advisory committee on immunization practices (ACIP) [38] and the guidelines for immunizations in solid organ transplantation [39] recommend inactivated influenza vaccine annually. Tetanus, diphtheria, and acellular pertussis (Tdap) should be administered to all adults who have not previously received Tdap or have an unknown status. Varicella vaccination with two doses in patients without evidence of immunity or a single dose of zoster vaccination, inactivated polio vaccine, hepatitis A/B, HPV (three series through 26 years of age), and meningococcal and pneumococcal vaccines should be administered [38]. It is remarkably important to vaccinate all household members as well. BCG and rabies vaccines can be considered under some extenuating or exposure-related indications. See Table 2.3.

Avoidance of Exposures

Education of the patient and the family members is a cornerstone to establishing effective preventive measures. Emphasis should be enforced about hand hygiene and food handling.

Table 2.3 Immunizations recommendations during transplantation

Recommended vaccines among heart, lung, and heart-lung recipients
Annual inactivated influenza vaccine
Tdap (should be administered to all adults who have not previously received Tdap or have an unknown status)
VZV (two series) in patients without evidence of immunity
Zoster vaccine should be given in varicella-positive candidates age ≥60 years and considered in candidates aged 50–59 (>4 weeks before transplant)
Inactivated polio
Hepatitis A series
Hepatitis B series
HPV (three series through 26 years of age)
Pneumococcal: Pneumococcal conjugate 13-valent (PCV13) followed by pneumococcal polysaccharide 23 (PPSV23) vaccine 8 weeks later (If PPSV23 was received first; PCV13 should be given at least 1 year after)
Meningococcal conjugate vaccine
Under special circumstances: Rabies and BCG

Additionally, potential sources of bacteria, fungi (e.g., *Aspergillus*), and toxoplasmosis such as plants and flowers, cleaning pet's litter or cages, eating uncooked meat, acquiring new pets, construction areas, farming, barnyard activities, and smoking marihuana should be avoided. If those recreational or occupational exposures are unavoidable; appropriate gear, such gloves, must be worn. Education about possible community exposures is also important. Close contacts with persons with fevers or rash potentially infected with VZV, herpes zoster, or influenza should be circumvented as well. Patients should cook all meals thoroughly, wash all fruits and vegetables, and shun all unpasteurized products. Safe sex practices are recommended. If any foreign travel is planned, seeking evaluation in a specialized travel clinic is advisable.

Prophylaxis

Guidelines for the management of surgical antimicrobial prophylaxis list cefazolin (2 g, 3 g for patients with weight >120 Kg every 4 h) as the recommended regimen for heart, lung, and heart-lung transplantation surgery. Clindamycin (900 mg every 6 h) or vancomycin (15 mg/kg) can be substituted as alternative agents in beta-lactam allergic patients [40, 41]. This recommendation can be adjusted individually, based on local hospital surveillance data or previous knowledge of colonizing organisms (e.g., addition of aztreonam, gentamicin, or a single-quinolone dose). However, the widespread use of quinolones may increase the resurgence of antimicrobial resistance. The antibiotic should be administered within 60 min before surgical incision (within 120 min for vancomycin or quinolones) and to be continued for 24–48 h in heart transplants and 48–72 h and no longer than 7 days in lung and heart-lung transplant recipients. Recommendation to continue antibacterial prophylaxis until chest and mediastinal tubes are removed lacks sufficient evidence. Redosing will depend on the procedure duration and associated blood loss.

The recipient does not need treatment if a localized infection was present in the donor, except during meningitis where concomitant bacteremia often coexist. In meningitis and bacteremia, it is prudent to treat the recipient for 2–4 weeks [34].

Indications for antifungal prophylaxis in heart transplant recipients are not clear. A systemic review showed no benefit of antifungal therapy to prevent invasive fungal infections in transplants recipients other than liver [42]. Although a prospective cohort of heart transplant recipients showed targeted prophylaxis—an echinocandin for a median of 30 days with the presence of at least one risk factor for invasive aspergillosis (IA) (reoperation, cytomegalovirus disease, posttransplantation hemodialysis, and another patient with IA in the program 2 months before or after the procedure)—was highly effective and safe in preventing IA episodes [43], no consensus exists for universal antifungal prophylaxis in heart transplant recipients. Most centers have adopted antifungal prophylaxis including inhaled amphotericin B, oral itraconazole, or IV targeted echinocandin prophylaxis.

In lung and lung-heart transplant recipients, fungal prophylaxis should be considered, especially if pretransplantation respiratory cultures either from the donor lung or recipient airways shows *Aspergillus* or *Candida*. One approach is to use inhaled amphotericin B (50 or 100 mg in extubated or intubated patients, respectively) daily until 4 days after transplant and then weekly until hospital discharge in patients with no known colonization [44, 45]. If a mold has been isolated, voriconazole is recommended up to 4 months after transplant. Although evidence and efficacy need to be confirmed, combination antifungal prophylaxis therapies is used at some centers [46].

Pneumocystis jiroveci prophylaxis is done with trimethoprim-sulfamethoxazole (TMP-SMX) for 6 months, up to 1 year. Some centers extend the PJP prophylaxis to lifelong. TMP-SMX also confers protection against *Toxoplasma*, *Nocardia*, and *Listeria* species infections. Alternatively, dapsone, inhaled pentamidine, or atovaquone can be used in patients with a history of sulfa allergy. TMP-SMX is recommended at many centers for lifelong in toxoplasmosis seronegative recipients of seropositive cardiac donors (*Toxoplasma* D+/R−) [11].

CMV prevention is recommended to all D+/R− and R+ patients. There are two common strategies for CMV prevention: antiviral prophylaxis and preemptive therapy. Both approaches possess similar success rate and their advantages and disadvantages [47]. Guidelines recommend valganciclovir or intravenous ganciclovir as the preferred antivirals. Oral ganciclovir is an option in heart transplant patients, although it possesses a low oral bioavailability and therefore the theoretical risk of increased resistance. Often, CMV immune globulin is used as an adjunctive agent. In heart recipients, prophylaxis is recommended for 3–6 months in D+/R− and 3 months in R+. In lung and heart-lung recipients, the duration of prophylaxis is 12 months and 6–12 months in D+/R− and R+ recipients, respectively [48]. In D−/R− patients, otherwise not receiving CMV active

agents, antiviral prophylaxis against other herpes viruses, such as HSV and VZV, should be considered. Use of oral CMX001 (oral liposomal formulation of cidofovir) in hematopoietic-cell transplants reduced CMV-related events and may have a potential role in preventing CMV in other transplant settings [49]. Refer to Table 2.4 for a list of prophylaxis recommendations.

Table 2.4 Antimicrobial prophylaxis

Prophylaxis in heart, lung, and heart-lung transplant
Bacterial[a]:
Preferred: Cefazolin 2 g (3 g for patients with weight >120 Kg). Redose every 4 h for extended procedure time and significant blood loss
Alternative: Vancomycin 15 mg/kg or clindamycin, 900 mg IV
CMV prophylaxis[b]:
Valganciclovir, 900 mg PO once daily
IV ganciclovir, 5 mg/kg IV once daily
Oral ganciclovir (heart transplant), 1 gr PO three times a day
Consider adjuvant therapy with CMV immune globulin
Pneumocystis jiroveci:
TMP-SMX, one single tablet a day or one double-strength tablet three to seven times a week for 6–12 months
Alternatively, dapsone (100 mg PO daily); inhaled pentamidine (300 mg/dose monthly) or atovaquone (1500 mg PO once daily) can be used
Other: In D−/R− patients, otherwise not receiving CMV prophylaxis, consider acyclovir to prevent HSV/VZV reactivation
Prophylaxis in heart transplants
Parasitic:
Consider lifelong TMP-SMX in toxoplasmosis mismatch recipients (D+/R−)
CMV prophylaxis:
Doses as above. Duration: 3–6 months in D+/R− and 3 months in R+ recipients
Fungal (optional):
IV echinocandin daily for 30 days in the presence of IA risk factors
Prophylaxis in lung and heart-lung transplants
Bacterial:
Consider the addition of aztreonam, gentamycin, or a single-quinolone dose in the presence of previous respiratory cultures positive for Gram negatives
CMV prophylaxis[b]:
Doses as above. Duration: 12 months in D+/R− and 6–12 months in R+ recipients
Fungal:
Negative pretransplant respiratory cultures: Inhaled *amphotericin B*, 50 or 100 mg in extubated or intubated patients, respectively, daily until 4 days after transplant and then weekly until hospital discharge
Positive pretransplant respiratory cultures for *Aspergillus*: *voriconazole*, 6 mg/kg every 12 h for 2 doses; followed by maintenance dose of 4 mg/kg every 12 h, is recommended up to 4 months after transplant. Maintenance dose can be achieved with oral voriconazole 200 mg PO every 12 h

Abbreviation: IA Invasive aspergillosis

[a]The antibiotic should be administered within 60 min before surgical incision (within 120 min for vancomycin or quinolones) and to be continued for 24–48 h in heart transplants and 48–72 h and no longer than 7 days in lung and heart-lung transplant recipients

[b]Doses of valganciclovir, ganciclovir, and other antibiotics may require adjustment for renal function

Risk of Infection Posttransplantation

<1 Month

This period is characterized more commonly for nosocomial, bacterial infections. Thus, the bacterial organisms present are often MDR (e.g., VRE, MRSA). In heart transplant recipients, skin and soft tissue infections (SSTI), surgical site infection, and mediastinitis are of concern during this period. Likewise, lung and lung-heart transplant recipients may develop infections related to previous respiratory colonization (*Pseudomonas, Aspergillus*). Other significant infections include aspiration pneumonitis, healthcare- and ventilator-associated pneumonia, catheter-related bloodstream infections (CRBSI), nosocomial UTIs, and *Clostridium difficile* colitis. Donor-derived infections during this period can be present and will include HSV, lymphocytic choriomeningitis virus (LCMV), rhabdovirus (rabies), West Nile virus (WNV), and HIV. *Toxoplasma gondii* and *Trypanosoma cruzi* are also serious donor-derived infections in heart transplant recipients that can develop within the first 6 months posttransplantation [50].

1–6 Months

During this period, reactivation of latent infections usually occurs. Hence, bacterial infections such as those caused by *Nocardia asteroides*, *Listeria monocytogenes*, and *Mycobacteria tuberculosis* typically occur. Additionally, fungal infections by *Aspergillus* spp., *Cryptococcus neoformans*, and *P. jirove*ci and parasitic by *Toxoplasma gondii*, *Leishmania* spp., *Strongyloides*, and *Trypanosoma cruzi* can also be seen. Viral infections present during this period include herpesviruses (HSV, VZV, CMV, and EBV) and adenovirus.

>6 Months

Development of infections after 6 months are predominantly community-acquired pneumonia and urinary tract infections. Other diseases include *Aspergillus* and *Mucor* species, *Nocardia*, *Rhodococcus*, and late viral infections including CMV, hepatitis B and C, JC polyomavirus infection, post-transplant lymphoproliferative disorder (PTLD), HSV encephalitis, and viral community-acquired infections (e.g., coronavirus, West Nile virus, influenza).

Monitoring

Infections

It is important to recognize transplant recipients as a patient population with increased susceptibility to infections and

have a low threshold to perform diagnostic workup in the presence of any concerning signs or symptoms. Infections monitoring is also done in a structured way when preemptive therapy for CMV is in place (as opposed to universal prophylaxis). Protocols vary by the transplant center but, usually, implies a weekly CMV PCR or pp65 Ag monitoring [51]. Likewise, monitoring of cell-mediated immunity (CMI) using a Quantiferon-CMV assay may be useful predicting late-onset CMV disease once CMV prophylaxis has been stopped [52]. CMI also have been monitored for EBV using an enzyme-linked immunoSpot assay [53].

Immunoglobulin G (IgG), C3, IgG2 levels, and NK cell counts have been proposed as an attempt to identify the risk of infection in heart transplant recipients within the first year [54].

Drug-Drug Interactions

Significant drug-drug interactions exist among antimicrobial and immunosuppressive agents. Patient medication list should be reviewed carefully. CTP3A4 strong inducers such as nafcillin reduce tacrolimus serum concentrations. In contrast, azoles such as fluconazole can result in increased levels of tacrolimus or cyclosporine. For voriconazole, the dose of tacrolimus needs to be reduced by two-thirds [55] and the cyclosporine dose by 50% [56]. Rifamycins can have an opposite drug-drug interaction by decreasing the concentrations of prednisone, cyclosporine, tacrolimus, sirolimus, and mycophenolate mofetil (MMF) [57, 58]. Likewise, tacrolimus administration along with quinolones may cause QT prolongation [59].

Infections in Heart Transplantation

Infecting Microbial Agents

Bacterial

In heart transplant patients, bacterial infections have similar clinical manifestations commonly observed in other patient populations. However, clinical signs may be subtle or absent (e.g., afebrile). They are the most frequent type of infections in this setting, reaching up to 50% of all infections [3]. The most common are pulmonary infections followed by bacteremias, mediastinal, and skin infections. *Staphylococcus aureus*—predominantly methicillin-resistant—can cause SSTI, ventilator-associated pneumonia, mediastinitis, CRBSI, other forms of bacteremia, and osteomyelitis. In contrast, coagulase-negative *Staphylococcus* is more commonly associated with CRBSI. Among Gram-negative bacteria, *Pseudomonas aeruginosa* is common, usually of pulmonary origin. *Escherichia coli* is the primary causal organism of UTIs. Extended-spectrum β-lactamase (ESBL)-producing *Klebsiella pneumoniae*, *Escherichia coli*, *Klebsiella oxytoca*, and *Citrobacter freundii* are also found in 2.2% of heart transplant recipients [60].

Nocardia species are well recognized as an opportunistic pathogen in this setting. Although relatively rare in heart transplant recipients (frequency <1%), *Nocardia* is only second in frequency in heart transplant after lung transplant recipients [61–63]. Pertinent-independent risk factors associated with the development of this infection in SOT include high-dose steroids, history of CMV disease, and high levels of calcineurin inhibitors [62]. With the almost universal prophylaxis with TMP-SMX, *Nocardia* infection is less common and often present late, usually after 1 year posttransplant [63]. When they occurred, they affect the lung predominantly, which is the port of entry for disseminated infections and CNS invasion. Also, it can cause skin nodules and abscesses. *Listeria monocytogenes* can also be seen in heart transplant recipients and can count for a significant proportion of the bacterial meningitis cases in this setting [64]. Additionally, myocarditis and myocardial abscesses with this organism have also been documented [65]. *Mycobacterium tuberculosis* and nontuberculous mycobacteria (NTM), although, documented to occur in heart transplantation, are rare in the United States [66, 67]. However, it is important to recognize that the development of tuberculosis (TB) can be more prevalent in some endemic regions and often present with extrapulmonary involvement [68, 69]. *Legionellosis* and *Rhodococcus equi* with mainly pulmonary manifestations (pneumonia, pulmonary infiltrates, or cavitation) are another significant infections among heart transplant recipients [70].

Fungal

Fungal infections excluding PCP represent around 4.0% of all the infections. From them, invasive mold infections (IMI) are a significant contribution to morbidity and mortality among heart transplant recipients. The incidence in this population can reach 10 per 1000 person-years, and its associated mortality is approximately 17% [71]. *Aspergillus* represents up to 65% of all IMI. Its median time of onset is about 46 days, although late presentation (>90 days) has been more recently recognized associated with receipt of sirolimus in conjunction with tacrolimus for refractory rejection or cardiac allograft vasculopathy [72]. The most common clinical presentation for aspergillosis includes fever, cough, and single or multiple pulmonary nodules [73]. Extrapulmonary manifestations include spondylodiscitis, infective endocarditis, mediastinitis, endophthalmitis, and brain and cutaneous abscesses [74–78]. Dissemination tends to affect the CNS in a good proportion of the cases. Mucormycosis is the second most frequent mold affecting heart transplant recipients. *Mucor*, along with other non-*Aspergillus* molds (e.g., *Scedosporium*, *Ochroconis gallopava*), are associated with disseminated infections, CNS involvement, and poorer outcomes [79, 80]. *Pneumocystis jiroveci* (PCP)—although with a marked reduction in inci-

dence with the introduction of universal prophylaxis—is still a significant pathogen and cases may occur late after heart transplant. Cryptococcosis, although infrequent among SOT patients, has its higher incidence in heart transplant recipients [81]. Usually, its manifestations present late and affect the lungs and the CNS predominantly. Histoplasmosis and coccidioidomycosis occurred typically in the first year after transplant. Antigenuria was the most sensitive diagnostic test in SOT for histoplasmosis [82]. Finally, *Candida* infections are an important cause of morbidity and mortality as well. Rate of colonization is higher than in the general population [83]. *Candida* most commonly causes an oral mucosa infection. Although there has been a decline of invasive infections over time, these do occur and typically in the form of bloodstream infections secondary to catheter-related infections, tracheobronchitis, or disseminated disease [84]. Additionally, other confined end-organ injuries such as endophthalmitis and esophagitis can also be seen.

Viral

CMV infection is of critical importance among SOT. In heart transplant recipients, CMV has been inconsistently associated with cardiac allograft vasculopathy [85]. Furthermore, CMV leads to upregulation of pro-inflammatory cytokines, increase procoagulant response, left ventricular dysfunction, allograft rejection, and an increase of opportunistic infections [86]. The greatest risk for developing CMV disease is CMV-negative recipients of CMV-positive organs (D+/R−), followed by D+/R+ and D−/R+. A clinical report estimated that the rate of *infections* in heart transplant ranges between 9% and 35%, and *disease* is present in around 25% of patients [87]. The clinical manifestations are not unique to heart transplant recipients and include a CMV syndrome (fevers, myalgias, arthralgias, malaise, leukopenia, and thrombocytopenia). CMV-associated end-organ injury in this setting includes most frequently pneumonitis and gastrointestinal disease [10]. Other manifestations comprise myelosuppression, hepatitis, and pancreatitis. In contrast to the high frequency observed in AIDS patients, chorioretinitis in heart transplant patients is relatively rare [87]. Guidelines on CMV diagnosis and managements are discussed in more detail in Chap. 55 and also have been published elsewhere [88]. Other herpes viruses are of important consideration as well. EBV-associated T-cell PTLDs are more frequent in heart transplant recipients (0.4%) than in other SOT patients [89]. PTLD is a significant contributor to morbidity and mortality in the pediatric heart transplant population [90]. Human T-lymphotropic virus type I (HTLV1), human herpes virus (HHV)-6, HHV-7, and HHV-8 might play a role in EBV(−) T-cell PTLDs as well. Herpes viruses can manifest, as in other hosts, as mucocutaneous lesions for HSV, herpes zoster for VZV, infectious mononucleosis in the case of EBV, Kaposi sarcoma for HHV-8, and encephalitis for HHV-6/7. Hepatitis, colitis, pneumonitis, and gastrointestinal disease have also been attributed to dissemination with certain herpes viruses. Herpes viruses can present with disseminated skin lesions (with or without vesicle formation) and fever of unknown origin.

Adenovirus has been associated with rejection, ventricular dysfunction, coronary vasculopathy, and the need for retransplantation. The current standard treatment for adenovirus is cidofovir, but outcomes are not optimal [91].

Chronic hepatitis without an identifiable cause should prompt testing for hepatitis E virus (HEV). Chronic HEV infection leads to the rapid development of fibrosis. HEV testing should be done with RNA PCR due to a delay in the antibody response. We recommend decreased immunosuppression and ribavirin therapy for 3 months [92, 93]. Other less common manifestation that should be considered under the correct epidemiologic risk factors include HTLV-1/HTLV-2-associated myelopathy, rabies, lymphocytic choriomeningitis virus, subacute measles encephalitis, mumps (associated parotitis, orchitis, vestibular neuritis, and allograft involvement), dengue virus, orf virus, human coronavirus, and influenza [36].

Parasitic

Cardiac transplant itself is one the predictors for development of toxoplasmosis [94]. Other associated risk factors include negative serum status before transplant, diagnosis of cytomegalovirus (CMV) infection, and high-dose prednisone. Toxoplasmosis can be transmitted by the donor heart (D+/R−, especially during the first 3 months) or can reactivate from the recipient (>3 months). Most of the infections developed during the first 6 months posttransplant and are predominantly primary infections. About 22% of infected patients had a disseminated infection carrying an estimated 17% mortality. Toxoplasmosis can manifest otherwise with myocarditis, encephalitis, pneumonitis, or chorioretinitis. Diagnosis requires identification of tissue cysts surrounded by an abnormal inflammatory response, detection of *Toxoplasma* DNA in body fluids by PCR, or positive *Toxoplasma*-specific immunohistochemistry in affected organs. Posttransplant serological tests are not helpful for diagnosis and may be misleading since results may change or not regardless of the presence of toxoplasmosis [95]. The preferred treatment regimen is a combination of pyrimethamine with sulfadiazine [96].

Advanced Chagasic cardiomyopathy is a primary indication for heart transplantation in some centers [13]. *Trypanosoma cruzi*, the causal organism of Chagas disease, can be transmitted up to 75% of the time from infected heart donors (D+/R−) [97]. Additionally, Chagas disease can reactivate from the donor once immunosuppression is

in place (R+). The reactivation rate can range between 22% and 90% in recipients with chronic chagasic cardiomyopathy undergoing heart transplant [98–100]. Additional risk factors for reactivation include rejection episodes, neoplasms, and use of MMF [98]. The mean onset of symptoms is approximately 112 days [101]. Once manifested, Chagas can present with nonspecific symptoms such as fever, malaise, anorexia, hepatosplenomegaly, and lymphadenopathy. Myocarditis, pericarditis, and encephalitis are also seen. Reactivation can mimic rejection and exhibits congestive heart failure, AV block and skin manifestations such as nodules and panniculitis. Increased eosinophil count and anemia can be indirect indicators of reactivation [102]. Diagnosis is made with the visualization of circulating trypomastigotes in peripheral blood. Additionally, blood and tissue PCR can be used. Tissue amastigotes can be seen in biopsy H&E preparations (Fig. 2.1). Finally, serologies are a crucial aspect in the diagnosis especially if seroconversion have been documented. In asymptomatic individuals, when the diagnosis of Chagas has been established in the donor, monitoring should be instituted with weekly blood *T. cruzi* PCR and microscopy [29]. Preferred antitrypanosomal therapy consists on benznidazole. Nifurtimox is an alternative treatment option. Posaconazole has anti-parasitic activity but carries high failure rates [103, 104]. GI disease with *Isospora* (*Cystoisospora*) *belli*, *Cryptosporidium*, *Cyclospora*, and *Microsporidia* has been reported to affect SOT recipients. Microsporidiosis can manifest with disseminated disease: fever, keratoconjunctivitis, CNS involvement, cholangitis, cough, and thoracic/abdominal pain [94]. Other rare parasitic infections affecting heart transplants include leishmaniasis, strongyloidiasis, and free-living amoebas [94, 105].

Sites and Types of Infection

Skin, Soft Tissue, and Bone

The rate of surgical site infections (SSI)—sternal wound infections—in patients receiving antimicrobial prophylaxis ranged from 5.8% to 8.8% following heart transplant procedures [41]. Heart transplantation itself is an independent risk factor for SSIs. Other risk factors include age, prophylaxis with ciprofloxacin alone, positive wire cultures, female gender, previous left ventricular assist device (VAD) placement, BMI >30 kg/m^2, previous cardiac procedures, and inotropic support for hemodynamic instability [41, 106]. Similarly to other hosts, *Staphylococcus* species are the predominant organism causing SSTIs. MRSA can reach up to 21% of the cases. Gram-positive organisms: VRE (*E. faecalis*), coagulase-negative staphylococci, and other *Enterococcus* species are other etiologic agents. Candida and selected gram negatives such as *Enterobacteriaceae*, *P. aeruginosa*, and *Stenotrophomonas maltophilia* can cause SSIs as well [107]. Sternal osteomyelitis often complicates deep SSI. Additionally, sternal wound infections by NTM and fungi such as *Aspergillus* and *Scedosporium* have been documented [108, 109]. Herpes zoster is also an important consideration and source of morbidity. Herpes zoster (HZ) is found as a complication in 19–22% of the patients with a median time of presentation ranging from 0.73 to 2.10 years [64, 110]. Close to half may develop postherpetic neuralgia. Multi-dermatome involvement, zoster ophthalmicus, and meningoencephalitis are also described. Exposure to MMF is an independent risk factor. Conversely, CMV prophylaxis reduces the risk for HZ.

Bloodstream

Bloodstream infections (BSIs) are a risk factor for mortality among heart transplant recipients. Likewise, SOT recipient status is an independent risk factor for developing bacteremia [111]. In heart transplant recipients; the rate of BSI ranged between 16% and 24%. The median onset is about 51–191 days, and the sources are in order of frequency: lower respiratory tract, urinary tract, and CRBSI. Gram-negative bacteria were more commonly isolated. They are in order of appearance *E. coli*, *P. aeruginosa*, and *K. pneumoniae*. More common Gram-positive bacteria were *S. aureus*, *S. epidermidis*, *E. faecalis*, and *L. monocytogenes*. Directly attributable mortality is 12.2%. Among the identifiable independent risk factors to develop BSI are hemodialysis, prolonged intensive care unit stay, and viral infections [112, 113]. Infective endocarditis (IE) is seen more frequently among heart transplant recipients than in the general population. With IE occurred, it most commonly involves the mitral and tricuspid valves and *Staphylococcus aureus* and *Aspergillus* are the main etiologic organisms. The main predisposing factors in this setting are believed to be the frequent use of vascular indwelling cathe-

ters and the frequency of endomyocardial biopsies [114]. *Staphylococcus aureus* bacteremia in heart transplant recipients ranges from 10% to 38% [11, 115]. The sources of SA bacteremia in SOT are CRBSI (30%), pneumonia (24%), wound (14%), endocarditis (10%), intra-abdominal infections (9%), bone and joint (7%), cardiac devices (3%), UTI (1%), and SSTI (1%) [115].

Chest

Immediately following heart transplant and during the 1st month, patients are more susceptible to develop pneumonia, most of which are healthcare or ventilator associated and therefore caused by nosocomial organisms such as MRSA, *Pseudomonas aeruginosa*, and other Gram negatives including *Acinetobacter* and ESBL-*Enterobacteriaceas*. Pneumonia is one the major contributors to mortality in the early postoperative period. Pneumonia-related mortality approaches 15% [116]. After the 1st month, interstitial pneumonia and pneumonitis can develop, and the differential includes herpesviruses (HSV, CMV, VZV) and respiratory syncytial virus (RSV), *Toxoplasma gondii* and *Pneumocystis jiroveci.* Pulmonary nodules with or without cavitation can be caused by fungi such as coccidioidomycosis, aspergillosis, mucormycosis, cryptococcosis; bacterial including actinomycosis, tuberculosis, atypical mycobacterial infections, *Nocardia*, *Rhodococcus equi*, and Gram-negative bacilli; and noninfectious causes like pulmonary infarction or lymphoproliferative disorders [117, 118]. Pulmonary nodules are seen in about 10% of the patients, and the median detection time is about 66 days. The associated symptoms are fever and cough. The most frequent etiology is *Aspergillus* followed by *Nocardia*, and *Rhodococcus*. CMV is an exceedingly rare cause of pulmonary nodules. The diagnostic approach with the higher yield is transthoracic fine needle aspiration followed by bronchoalveolar lavage and transtracheal aspiration [118]. Community-acquired pneumonia caused by *Streptococcus pneumonia*, *Legionella* spp., mycoplasma, and influenza is another source of morbidity [10].

Mediastinitis is a common complication in this setting. In patients receiving antimicrobial prophylaxis, mediastinitis develops in 3–7% of the patients [107, 119]. A CT scan is usually necessary to determine the extension of the infection. MRSA *Staphylococcus epidermidis*, Gram-negative bacteria, and *Aspergillus fumigatus* are frequently found as the causal organisms [120]. Antimicrobial therapy should be accompanied by aggressive surgical debridement [121].

Abdominal/Genitourinary

There are not distinctive abdominal-pelvic complications among heart transplant recipients. *Clostridium difficile* is a common hospital-related cause of diarrhea associated with the use of antimicrobials. Other etiology for diarrhea secondary to acute gastroenteritis can present in a protracted way in this setting. Listeria infection can present as a febrile gastroenteritis illness as well. Nontyphoid *Salmonella* infection has been described to complicate the early postoperative period in a center in Taiwan [122]. Acute cholecystitis can affect heart transplant recipients advocating to have a low threshold to use ultrasound as a screening method [123]. Acute pancreatitis with abscess formation has also been described [124]. As pointed above, hepatitis E can present with persistently abnormal liver tests.

Although less frequent than in kidney transplant recipients, urinary tract infections are an important cause of morbidity. UTIs are predisposed by Foley catheters. The organisms most commonly involved are Gram-negative bacteria, *Enterococcus*, and *Candida*. Polyomavirus nephropathy by BK virus has been described in heart transplant recipients and might be a contributor to chronic kidney disease [125].

Central Nervous System

The need for urgent transplantation and multiple transfusions are independently associated with infectious, neurologic complications. Its overall mortality can reach 12% [64]. Donor-derived meningoencephalitides affecting heart transplant recipients usually manifest within the first 30 days. These infections include West Nile virus, arenaviruses (e.g., LCMV), and rabies. WNV can manifest with a Guillain-Barré-like axonopathy with cerebrospinal fluid (CSF) pleocytosis. In addition to meningitis or encephalitis, ataxia, myelitis, optic neuritis, polyradiculitis, and seizures can also be observed [126]. WNV can be also acquired by the recipient in the community or through blood transfusions and present at a later time [127]. Other infectious forms of meningitis and encephalitis that can present after the 1st month include listeriosis, *Streptococcus pneumoniae*, *Trypanosoma cruzi*, *Toxoplasma*, HHV-6, and disseminated herpes virus infections (CMV, VZV, HSV, and EBV) [128–130]. The absence of appropriate primary prophylaxis or monitoring increases their risk. *Aspergillus* causes the majority of brain abscess. Additionally *Toxoplasma*, tuberculosis, *Listeria* spp., *Cryptococcus neoformans*, *Scedosporium* spp., and *Nocardia* can also be causative agents [129]. Concomitant pulmonary involvement is common, particularly for those whose portal of entry is the respiratory tract.

Progressive multifocal leukoencephalopathy (PML), a demyelinating disease caused by the reactivation of JC virus, has a usual median onset of 27 months. It carries a marked high case fatality rate and a median survival of 6.4 months in SOT [131]. The use of rituximab as an antirejection treatment seems to confer an increased risk for PML [132]. HTLV-1-associated myelopathy (HAM) has been described as well in SOT.

Infections in Lung and Heart-Lung Transplantation

Infecting Microbial Agents

Bacterial

Bacterial infections are the most common type of infections among lung and lung-heart transplant recipients. The anatomic site most frequently affected is the respiratory tract, usually manifested with pneumonia, sinusitis, or tracheobronchitis. Previous colonization, healthcare associated, and procedures related are the primary sources. For patients with cystic fibrosis (CF), knowledge of previous colonization results may provide some diagnostic and therapeutic advantages. *Pseudomonas aeruginosa* is a predominant colonizing pathogen in CF. However, *Acinetobacter baumannii*, *Burkholderia* species, *Stenotrophomonas maltophilia*, *Achromobacter xylosoxidans*, NTM, *Pandorea*, and *Ralstonia* are also observed [23]. Furthermore, pathogens that are known to cause nosocomial pneumonia during the 1st month include *Staphylococcus aureus*, *Pseudomonas aeruginosa*, other Gram negatives (*Klebsiella pneumoniae*, *Enterobacter cloacae*, *Serratia marcescens*, *Escherichia coli*, *Acinetobacter* species), and anaerobes.

Gram-positive bacteria are a common source of infections making up to 40% of them [133]. The most common sites affected were the respiratory tract, followed by bacteremia, skin, wound, and catheter related. The pathogens more frequently identified are *Staphylococcus* species (77%), *Enterococcus* species (12%), *Streptococcus* species (6%), *Pneumococcus* (4%), and *Eubacterium lentum* (1%). *Staphylococcus aureus* infection can develop up to 20% of lung recipients. SA commonly causes pneumonia, followed by tracheobronchitis, bacteremia, intrathoracic infections, and SSTIs [20]. *Streptococcus pneumoniae* is community acquired and present with pneumonia, usually after 6 months posttransplant. *Pseudomonas aeruginosa* has high rates of colonization (up to 40%) and disease (30%) [134]. Other significant bacterial infections that may present after the 1st month are *Mycobacterium tuberculosis*, NTM, *Nocardia*, *Rhodococcus*, and *Legionella*. Isolation of NTM in lung transplant recipients without evidence of disease is not associated with increased mortality [135]. Nocardiosis can occur in about 2% of the lung transplant recipients. The median time of onset ranges from 14.3 to 34.1 months [136, 137]. *Nocardia asteroides*, *N. farcinica*, *N. nova*, and *N. brasiliensis* have been reported. *N. farcinica* appears to carry worse outcomes. This infection can present as a breakthrough in the presence of trimethoprim-sulfamethoxazole for *P. jiroveci* prophylaxis, although the isolates may remain susceptible. Mortality has been reported to range between 18% and 40%. The native lung is more frequently affected in single-lung transplant recipients. Nodules are the more prevalent radiographic finding. Extrapulmonary involvement affecting the skin and brain can be seen. Hypogammaglobulinemia and neutropenia seem to confer additional risk factors for nocardiosis in this setting [137].

Fungal

Fungal infections are frequent complications in lung and lung-heart transplant. They present in about 15–35% and carry an overall mortality close to 60% [138]. *Aspergillus* and *Candida* are the most frequent causative agents. Other important fungi include *Cryptococcus* spp., mucormycosis, endemic fungi (*Histoplasma*, *Coccidioides*, and *Blastomyces* spp.), *Scedosporium* spp., *Fusarium* spp., and dematiaceous molds. Candida infections are prominent during the 1st month after transplantation. It can be one of the most common causes of BSI in this setting [139]. Although colonization of the upper airways and gastrointestinal tract is common, *Candida* additionally can cause mucocutaneous disease, tracheobronchitis, anastomosis site infections, CRBSI, and disseminated disease. *Aspergillus* spp. lead as the cause of invasive fungal infections. Its attack rate of infection is almost ten times compared to that in other SOT patients (estimated incidence of 6% among lung transplant recipients) [140, 141]. *A. fumigatus* is the most common species, but *A. terreus*, *A. flavus*, and *A. niger* have been described as well. The main predisposing risk factors in this setting are intense immunosuppression, previous colonization with *Aspergillus* spp., airway ischemia, and BOS. Single-lung transplant possesses the greatest risk to developing an invasive *Aspergillus* infection carrying a higher mortality than double-lung and heart-lung transplant recipients. Single-lung recipients are usually older and more likely to have COPD as the indication for transplantation [140]. *Aspergillus* infections can present as tracheobronchitis, pneumonia, or disseminated disease. Extrapulmonary involvement includes sinusitis, CNS or orbits infections, and vertebral osteomyelitis. Aids in the diagnosis can include surveillance bronchoscopies (bronchoalveolar lavage stain and culture; biopsy), chest CT and serum/BAL galactomannan, beta-D-glucan, and PCR. The presence of pulmonary nodular lesions in invasive infections can carry better outcomes [142]. Voriconazole is the treatment of choice. It is important to note that immune reconstitution inflammatory syndrome (IRIS) can develop at a median of 56 days in 7% of treated lung transplant recipients [143]. In *Aspergillus* tracheobronchitis, nebulized amphotericin B and debridement of the bronchial anastomosis are important adjuvant measures to systemic antifungal therapy [144, 145]. *Pneumocystis jirovecii* pneumonia manifests from 1 to 6 months. Its incidence has been reduced dramatically with universal TMP/SMX prophylaxis. Cryptococcosis with a rate of 2% in lung transplant recipients presents with pulmonary involvement, but dissemination with meningitis can occur. Furthermore, *Cryptococcus* skin manifestations

like cellulitis and *Cryptococcus*-associated IRIS have been documented [146, 147].

Viral

Viral infections are a common cause of morbidity among lung transplant recipients. The most common viruses are (1) CMV among the herpes viruses and (2) community-acquired respiratory viruses. As in other SOT recipients, the higher risk to develop CMV infection is among D+/R−, followed by D+/R+, D−/R+, and D−/R−. This last scenario carries less than 5% of risk [48, 148]. Lung transplant recipients possess higher risk for CMV than other SOT with an estimated incidence of 30–86% [87]. The lung is considered a primary reservoir for CMV latency, and abundant lymphocytic tissue surrounds the transplanted organ. Additionally, the use of antilymphocyte antibodies to treat rejection or for immunosuppression and other herpesviruses infections are additional risk factors for CMV disease [149]. Interferon (IFN)-γ (+874T/T) polymorphism increases IFN levels and may be a predisposition for CMV disease [150]. CMV is significantly associated with BOS, which reduces survival after the first year posttransplant [151]. CMV disease is most commonly manifested by pneumonitis or viral syndrome and less frequently with gastrointestinal disease. Among lung transplant recipients, ganciclovir-resistant CMV carries an increased morbidity and mortality [152].

Infections with community-acquired respiratory viruses ranged from 7.7% to 64%. These infections are associated with increased risk to develop pneumonia, graft dysfunction manifested by lung function loss, BOS, high calcineurin inhibitor blood levels, and increase mortality [153–155]. These viruses include influenza, parainfluenza, respiratory syncytial virus (RSV), coronaviruses, human rhinovirus, adenovirus, human metapneumoviruses, and bocaviruses. The hospitalization rates are higher for influenza and parainfluenza (50% and 17%, respectively) [154]. Symptoms are usually nonspecific. Diagnosis often requires detection of viral nucleoprotein antigens in nasopharyngeal swabs or bronchoalveolar lavage (BAL) by enzyme immunoassay or fluorescent antibody or the amplification of nucleic acid by PCR. Ribavirin may possess activity against *Paramyxoviruses* (RSV, *Metapneumovirus*, and parainfluenza). Ribavirin is administered inhaled, orally, or intravenously. Oseltamivir or zanamivir is the treatment choice of influenza A or B [156]. Adamantanes (amantadine and rimantadine) are not active against influenza B, and there is a marked increase resistance among influenza A strains [156]. Similarly to other SOT recipients, DNA viruses like non-CMV herpesviruses (HSV-1,-2), VZV, HHV-6,-7,-8, and EBV are a source of significant morbidity including but not limited to CMV-negative viral syndrome, rash, pneumonitis, hepatitis, and encephalitis [157]. Lastly, polyomavirus such as BK virus (BKV), JC virus (JCV), and simian virus 40 (SV40)—although frequently encountered in lung transplant recipients with an unclear causality—may cause worsening renal function or survival [158]. PTLD is also a well-recognized complication. A trend toward late PTLD presentation (>1 year) has been documented where B symptoms are more predominant as well as extra-graft involvement [159].

Parasitic

As other immunosuppressive states, certain parasitic infections can complicate lung and heart-lung transplants recipients. It is critical to elicit a detailed history and geographic risk factors to determine the risk of acquisition and the potential etiologic agent. Toxoplasmosis can result from primary infection or reactivation of previous latent infections. Toxoplasmosis can develop in patients with negative epidemiological history for cat ownership or consumption of undercooked meat. In patients with primary toxoplasmosis, nonspecific symptoms such as fever, lymphadenopathy, or organ injury may be present. Reactivation can cause encephalitis with or without space-occupying brain lesions, seizures, chorioretinitis, fever of unknown origin, pneumonitis, myocarditis, and rash. Although cases of the lung fluke, *Paragonimus westermani* have not been reported in lung transplantation, it can be a potential threat in endemic areas where this organism is endemic. Other parasites that can target the lung in immunosuppressive states include *Echinococcus*, *Schistosoma*, and *Strongyloides stercoralis* [160]. Strongyloidiasis can present as hyperinfection syndrome [161]. *Leishmania*, although infrequently seen, has been reported among lung and lung-heart recipients [30]. Free-living amoebas can affect this population as well. Amoebic granulomatous dermatitis and disseminated infection presenting with ulcerative skin lesions, respiratory failure, and seizures have been described in lung transplant recipients [162, 163]. Finally, alimentary protozoa, including *Cryptosporidium*, which present with diarrhea and may elevate tacrolimus levels [164], and microsporidia, which present with unusual manifestations like myositis or granulomatous interstitial nephritis, affects lung transplant recipients [165, 166].

Sites and Types of Infection

Skin, Soft Tissue, and Bone

The overall rate of SSIs is about 13% with a significant proportion of infections being organ or space occupying (72%), deep incisional (17%), and superficial (10%) [18, 41]. Independent risk factors to develop SSI are diabetes, female donor, prolonged ischemic time, and the number of red blood cells transfusion during the perioperative period [167]. SSIs are associated with a 35% mortality within the first year of transplantation. The most common organisms found to cause

SSI or mediastinitis are *P. aeruginosa*, *Candida* species, *S. aureus* (including MRSA), *Enterococcus*, coagulase-negative *Staphylococci*, *Burkholderia cepacia*, *E. coli*, *Proteus mirabilis*, *Serratia marcescens*, *Acinetobacter baumannii*, *Enterobacter cloacae*, and *Klebsiella* species. There is a correlation in up to 33% of the patients' SSI causative organisms with previous pathogens colonizing recipients' native lungs at the time of the transplant [167]. The median onset is 25 days after lung transplant [167]. Although rare, NTM can cause SSI infections among lung transplant recipients. The most frequently encountered are *Mycobacterium avium* complex followed by *Mycobacterium abscessus* and *Mycobacterium gordonae*. NTM SSI infections can be complicated by progressive disseminated disease or requirement of lifelong suppressive therapy [135]. Other organisms such as *Mycoplasma hominis* and *Lactobacillus* spp. have also been described. Deep infections can affect up to 5% of the patients. Sternal osteomyelitis can reach up to 6% of these deep infections. Causative organisms for sternal osteomyelitis include *Pseudomonas aeruginosa*, *Serratia marcescens*, and *Scedosporium*. Non-sternal osteomyelitis affecting the calcaneus bone has complicated a disseminated infection with *Aspergillus fumigatus* [168].

Bloodstream

Bloodstream infections (BSIs) occur with an estimated rate of 25% among lung transplant recipients. A major proportion of BSIs occur in the early posttransplant period. BSIs infections are significantly associated with worse survival [139, 169]. The most common organisms encountered are *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Candida* [139]. *Pseudomonas aeruginosa* BSI—predominantly present during the transplant hospitalization period and more commonly affecting CF patients—is followed in frequency by *Burkholderia cepacia* and *Candida albicans*. Conversely, *Staphylococcus aureus* was the predominant organism after transplantation discharge. In an estimated 70% of BSI, the source was pulmonary, followed in frequency by CRBSI, gastrointestinal infection, peritonitis, and UTI. A pulmonary source of bacteremia in SOT often develops into septic shock [170]. Although unusual, cases of *Aspergillus fumigatus* endocarditis have been described following lung transplantation [171]. Often patients had CF as the underlying lung disease and a median of 8 ± 6 months presentation. This complication carries a high mortality and often requires a combination of antifungal therapy with valvular replacement surgery.

Chest

Infectious complications related to the chest cavity include mediastinitis, cardiac (pericarditis and myocarditis), lung parenchyma infections (nodular infiltrates, cavitation, or pneumonia), bronchial anastomosis infections, and pleural space infections (bronchopleural fistula and empyema). Empyema followed by mediastinitis and pericarditis, in addition to surgical wound infections and sternal osteomyelitis, is the most frequent deep SSI complications affecting the chest cavity. Empyema presents in around of 3.6% of cases. It occurs during the first 6 months after transplantation (median 46 ± 39 days) carrying an estimated mortality of 28.6% [172]. Most common organisms found are *Staphylococcus* spp., *E. coli*, *Enterobacter* spp., *Klebsiella* spp., *Mycoplasma hominis*, VRE, and *Candida*. Furthermore, *Mycobacterium abscessus* was isolated as a rare causative agent of empyema as well [173]. The degree of immunosuppression, reduced renal function, previous sternotomy, and re-exploration due to bleeding are listed as potential risk factors for mediastinitis [119]. There is an increased prevalence of mediastinitis caused by Gram negatives and fungi among lung transplant recipients. Causative organisms for mediastinitis are similar to SSI and are listed above. Infectious pericarditis can be present up to 6% of the patients (isolated organisms include MSSA, *Mycoplasma hominis*, and *Scedosporium prolificans*) [167, 174, 175]. Due to their high fatal rate, fungal bronchial anastomotic infections are critical to recognize.

Pneumonia is believed to affect around 21% of lung recipients and 40% of heart-lung recipients. Nosocomial organisms cause early pneumonia as in other posttransplant settings. The donor's lung seems to be the primary source for pneumonic infections, although the recipients' upper airways or sinuses are also potential sources. Preoperative colonization with Gram-negative rods and colonized infected donor bronchus or perfusate are recognized risk factors for pneumonia. Likewise, pretransplantation colonizing microorganisms from suppurative lung disease are associated with pneumonia development posttransplant [176]. The most common causal organisms are *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Aspergillus* spp. Other pathogens include bacteria such as *B. cepacia*, *Enterobacter* species, *S. maltophilia*, *Klebsiella* species, *S. epidermidis*, and *E. coli*, and fungi such as *Fusarium* spp., *Cryptococcus neoformans*, and *Paracoccidioides brasiliensis* [176]. After the 1st month, pneumonia can present as local infiltrates, diffuse interstitial infiltrates, and nodules with or without cavitation. This type of presentation may aid in the possible causative microorganism. The list of potential pathogens is extensive and includes in addition to the already mentioned *Nocardia*, *Chlamydia pneumonia*, *Legionella*, TB, NTM, *Pneumocystis jirovecii*, *Rhodococcus*, herpesviruses (CMV, HSV, and VZV), respiratory viruses, endemic fungi (e.g., histoplasmosis), mucormycosis, and *Scedosporium* spp. [177–179].

Abdominal/Genitourinary

Similarly to other SOT, common infectious complications affecting the gastrointestinal or genitourinary tract include *Clostridium difficile* colitis and UTIs. Intra-abdominal com-

plication carries an overall increase mortality [180]. Frequent GI symptoms presenting posttransplant are diarrhea which can affect almost 30% of lung transplant recipients and abdominal pain. Abdominal pain should prompt further investigation for potential intra-abdominal causes. In the pediatric population, the possibility of PTLD should be investigated since it carries a high mortality [181]. Other described infectious intra-abdominal complications include digestive perforation (seen in 6%) [182], retroperitoneal abscesses, cholecystitis, perianal abscesses, esophagitis, pancreatitis, pancreatic abscesses, hepatitis, diverticulitis, appendicitis, CMV colitis, megacolon, and colon rupture [180, 183, 184]. In developing countries, persistently abnormal liver enzymes should prompt testing for HEV. HEV RNA should be used for screening. Oral ribavirin seems to be safe and effective in this setting [185].

Central Nervous System (CNS)

CNS symptoms developing during the 1st month following lung or heart-lung transplantation should trigger the concern for donor-derived viral infections. LCMV often is accompanied by CSF normal to low glucose, marked elevated protein, and mild pleocytosis [36]. Although with unclear benefit, ribavirin has been used. Donor-transmitted rabies is an uncommon but neurologic devastating complication that occurs within the first 30 days of transplant. Lung transplantation has been described as a potential causal mechanism [186]. Other organisms known to cause meningitis in lung transplant recipients are *Cryptococcus*, tuberculosis, WNV, and herpesviruses [187, 188]. Diagnosis of WNV in this setting requires nuclear acid amplification due to the unreliability of serologic testing. *Scedosporium apiospermum* infections often cause dissemination including CNS abscesses in addition to pulmonary involvement among lung transplant recipients [189]. It is important to differentiate from other molds, since amphotericin B is ineffective against *Scedosporium* spp. In severe cases or refractory disease without an appropriate surgical debridement, the addition of terbinafine to voriconazole may prove to be useful [190]. Other recognized organisms causing occupying brain lesions are *Fusarium*, *Nocardia*, *Aspergillus*, toxoplasmosis, *Cryptococcus neoformans*, *Listeria*, and *Cladophialophora bantiana* [191–193]. PML, a late manifestation, can be associated with intensified immunosuppression or rituximab. Cidofovir followed by mirtazapine can be considered as a form of therapy for PML.

Conclusions

Infections in heart, lung, and heart-lung transplant recipients are a complex, dynamic, and evolving process. Many factors such as demographics, timing, type of transplant, anatomy, and microbiology, among others, interplay in the development of these fatal complications. Pertinent recognition and treatment of these infections improve transplantation outcomes.

Infections in Liver Transplantation

3

B. Sharmila Mohanraj, Amol S. Rangnekar, and Joseph G. Timpone Jr.

Indications for Liver Transplantation

Orthotopic liver transplantation (LT) is most commonly offered to patients with end-stage liver disease. However, this lifesaving therapy can also be used to successfully treat patients with acute liver failure, primary and some metastatic liver tumors, and selected metabolic conditions (Table 3.1).

Decompensated cirrhosis is defined by the presence of specific complications including jaundice, hepatic encephalopathy, ascites, spontaneous bacterial peritonitis, hepatorenal syndrome, or variceal hemorrhage. Once a patient develops complications of portal hypertension, 5-year survival is <50%. Additionally, patients with cirrhosis may develop life-threatening pulmonary complications such as hepatopulmonary syndrome (HPS) or portopulmonary hypertension (PPH).

The Child-Turcotte-Pugh (CTP) score helps to stratify severity of illness according to a combination of five physiologic and laboratory variables: ascites, hepatic encephalopathy, bilirubin, albumin, and prothrombin time. Patients in CTP class B or C have less than a 60% 2-year survival and should be considered for OLT. The Model for End-Stage Liver Disease (MELD) score is a more simplified and objective method designed to characterize the degree of illness of patients with end-stage liver disease. The MELD score incorporates serum bilirubin, prothrombin time, and creatinine values [1]. Based on its ability to predict survival, the MELD score has been used to prioritize patients on the OLT wait list. It is generally accepted that patients with a MELD score greater than 10 should be referred for liver transplant evaluation, and those with a MELD score of 15 or higher are most likely to derive benefit from OLT [2]. Despite its simplicity, the MELD score does disadvantage a subset of patients who have severely decompensated liver disease but minimally abnormal laboratory results. Recently, serum sodium has been incorporated into the MELD score, i.e., MELD-Na. Hyponatremia is an independent predictor of mortality in patients with decompensated cirrhosis, and diminished serum sodium levels may be a surrogate marker of advanced portal hypertension [3, 4].

Table 3.1 Indications for liver transplantation

Decompensated hepatic cirrhosis
Biliary cirrhosis (primary biliary cholangitis, primary sclerosing cholangitis, biliary atresia, Alagille syndrome, cystic fibrosis, progressive familial intrahepatic cholestasis)
Hepatocellular carcinoma
Hepatoblastoma
Hemangioendothelioma
Metastatic neuroendocrine tumors
Glycogen storage disease
Neonatal hemochromatosis
Amyloidosis
Hyperoxaluria
Urea cycle defects
Disorders of branch chain amino acids
Acute liver failure
Budd-Chiari syndrome
Polycystic liver disease

Acute liver failure (ALF) is a rare but life-threatening condition, which is manifested by evidence of hepatic injury, coagulopathy, encephalopathy, and absence of underlying cirrhosis in most patients. In Western countries, nearly half of all cases are attributed to acetaminophen overdose. Other less common etiologies include drug injury, viral hepatitis, autoimmune hepatitis, and fulminant Wilson disease. Mortality exceeds 30% with death often occurring within 1 week of presentation. Although a majority of patients with ALF due to acetaminophen toxicity may recover spontaneously, those with ALF due to other etiologies often require OLT to survive [5, 6].

Certain patients with liver-based metabolic conditions and systemic complications may also benefit from OLT. Examples of these conditions include familial amyloidosis, glycogen storage disease, and primary hyperoxaluria. Although underlying liver synthetic function is preserved, hepatic allograft transplant allows for correction of a specific metabolic deficit in these patients.

As the incidence of hepatocellular carcinoma (HCC) continues to rise, patients with this disease now represent a substantial proportion of liver transplant recipients. Patients with cirrhosis and portal hypertension are unlikely to tolerate hepatic resection of their HCC and are offered OLT in order to improve their recurrence-free survival. Typically, patients with tumor burden within the Milan criteria are considered good candidates for OLT and are typically awarded MELD exception points [7]. More liberal tumor burden criteria have been proposed for transplant, although larger tumor size and number seem to correlate with a higher risk of recurrence [8].

Most patients with cholangiocarcinoma have traditionally not been candidates for liver transplants due to high post-transplant recurrence rates and poor survival. However, recent data suggest that carefully selected patients with isolated unresectable hilar tumors who are treated with neoadjuvant chemotherapy and radiation therapy may have acceptable survival rates after transplant [9]. In general, patients with known intrahepatic cholangiocarcinoma may be candidates for resection but are not typically considered for OLT.

In the USA, patients are prioritized for liver transplantation on the basis of the MELD score. In selected cases, patients with specific complications of liver disease may be eligible for MELD exception scores. MELD exception scores may be standardized, as is the case presently in patients with HCC within Milan criteria, certain pulmonary complications of cirrhosis, and selected metabolic disorders. In specific cases, some patients may be granted MELD exception on an individual basis by the regional review board after taking into account extenuating circumstances.

Contraindications to Liver Transplant

Life-threatening conditions such as severe cardiopulmonary disease or sepsis are generally major contraindications to OLT. Although patients with human immunodeficiency virus (HIV) infection can successfully undergo transplant, those with AIDS are thought to be poor candidates based on their poor health and the risk of additional post-transplant immune suppression. Patients actively using drugs or alcohol are often excluded as well. Many transplant centers have traditionally required abstinence from alcohol for a minimum of 6 months prior to listing, although this requirement has been evolving recently after a significant post-transplant survival benefit was demonstrated in selected patients with severe alcoholic hepatitis [10]. Patients with extrahepatic malignancy, metastatic HCC, or intrahepatic cholangiocarcinoma should not undergo transplant. Patients may also be denied liver transplant on the basis of certain psychosocial factors such as persistent noncompliance with medical care or lack of adequate social support. Relative contraindications to liver transplantation include advanced age, severe obesity, prior abdominal surgeries, and significant mesenteric vascular thromboses.

Pre-transplant infectious disease work-up includes serologic testing to diagnose infectious causes of acute or chronic liver disease such as hepatitis A virus (HAV), hepatitis B virus (HBV), and hepatitis C virus (HCV) and to identify latent infections, which may reactivate in the setting of post-transplant immunosuppression. These include cytomegalovirus (CMV), Epstein-Barr virus (EBV), varicella zoster virus (VZV), rapid plasma regain test for syphilis, and interferon gamma release assay or tuberculin skin test for latent tuberculosis. All patients are screened for HIV. Selected high-risk individuals may undergo testing for coccidioidomycosis, *Trypanosoma cruzi*, or *Strongyloides stercoralis*, depending upon geographic location, travel history, and/or history of exposure to various endemic infections. Pre-transplant dental evaluation is typically mandatory in order to identify and manage potential oral sources of infection after undergoing transplantation. Dental extractions, if warranted, should occur prior to liver transplantation. Immunizations for HAV, HBV, pneumococcus, influenza, diphtheria, tetanus, and pertussis should be administered to appropriate transplant candidates at the time of the pre-transplant evaluation. As there is a contraindication to live vaccines after transplantation, immunization status for measles, mumps, and rubella (MMR) and varicella should also be obtained. The American Association for the Study of Liver Diseases (AASLD) has published online guidelines in 2013 for the evaluation of potential liver transplant recipients which can be found at https://www.aasld.org/publications/practice-guidelines-0.

Based on reasonable short- and long-term outcomes, patients with HIV infection can successfully undergo OLT. Typically, these patients should have well-controlled disease on antiretroviral therapy, with undetectable HIV RNA and absence of active AIDS-associated opportunistic infections or malignancies. CD4+ counts >100 may be a reasonable cutoff in patients with leukopenia due to portal hypertension and splenic sequestration. Other contraindications to liver transplantation may include a history of AIDS-defining opportunistic infection that requires chronic secondary prophylaxis or has limited treatment options such as progressive multifocal leukoencephalopathy (PML), disseminated *Mycobacterium avium* complex, chronic cryptosporidiosis,

EBV and human herpesvirus-8-related lymphoproliferative disorders such as non-Hodgkin's lymphoma and visceral Kaposi's sarcoma (KS), or significant cervical or anal neoplastic disease due to human papillomavirus. Some centers have performed transplants in patients with cutaneous KS. Although recurrence of the malignancy can occur after undergoing transplant surgery, these patients may be managed with mechanistic target of rapamycin (mTOR) inhibitor-based immunosuppressive regimens after OLT based on the antineoplastic effects of these agents.

Several factors may increase the risk for graft loss in HIV+ patients undergoing liver transplants including older donor age, HCV-positive donors, low recipient BMI, and simultaneous liver and kidney transplantation [11]. Of note, these outcomes and predictors of graft loss were identified in older studies of HIV- and HCV-coinfected patients undergoing transplant. Additional studies are needed to determine outcomes in an era of improved HCV therapy and specifically in non-coinfected patients requiring transplant.

Types of Liver Transplantation

The majority of liver transplants in the Western world utilize whole organ allografts from deceased donors. However, alternative options such as split deceased donor grafts or partial living donor grafts are used occasionally. In the USA, living donor liver transplantation (LDLT) currently accounts for less than 5% of all liver transplants, although in other parts of the world, LDLT is utilized more frequently.

Most deceased donors are considered on the basis of donation after brain death (DBD). Occasionally donation after circulatory death (DCD) can be considered. DCD donors are characterized by the absence of systemic circulation along with irreversible apnea and unresponsiveness. The main risk associated with DCD is organ ischemia and the potential for biliary epithelial injury. Initial results of the experience with DCD OLT were marked by increased rates of ischemic cholangiopathy, a condition which can lead to recurrent cholangitis, graft loss requiring retransplantation, or death [12, 13]. However, some centers have reported similar patient and graft survival with DCD and DBD donors, particularly with the use of donors less than 40 years old, and minimization of cold and warm ischemia times [14, 15].

LDLT offers the advantage of allowing for expedited access to transplantation at a time before the recipient develops advanced liver failure while simultaneously increasing the donor pool. However, these benefits must be balanced against the potential risks of morbidity and death for the donor.

In order to be considered for LDLT in the USA, patients must already be listed for deceased donor liver transplantation (DDLT). Selected recipients with low MELD score and significant hepatic decompensation, HCC, or other complications of advanced liver disease such as primary sclerosing cholangitis with recurrent episodes of ascending cholangitis or polycystic liver disease are typically good candidates for LDLT. Conversely, patients with higher MELD scores and severe hepatic decompensation usually have limited survival and a shorter anticipated waiting time for transplant. As compared to patient undergoing DDLT, LDLT recipients may have a significantly higher rate of complications and need for retransplantation, although adjusted long-term survival appears to be similar [16, 17]. As such, careful recipient selection is critical. Contraindications to LDLT may include significant mesenteric vascular thrombosis, severe portal hypertension, need for simultaneous renal transplantation, or retransplantation. An additional consideration is matching donor and recipient body size. Specifically, a graft weight-to-body weight ratio of 0.8% is recommended to avoid the development of small-for-size syndrome, a condition marked by the development of hyperbilirubinemia, intractable ascites, coagulopathy, renal failure, and extended duration of hepatic encephalopathy. Biliary complications tend to occur with higher frequency in LDLT recipients, although rates are lower in centers with higher volume living donor, partial hepatic graft transplantation [18].

Deceased donor livers may also be split to maximize yield for recipients. As with LDLT, adequate graft weight for the recipient must be determined prior to transplant. Most commonly deceased donor livers are split so as to offer the left lateral segment to a pediatric recipient and the remaining allograft to an adult recipient.

Donor Selection

In the USA, the majority of liver donation occurs after brain death. The criteria to determine initial DBD donor eligibility include complete apnea, brainstem areflexia, cerebral unresponsiveness, and evidence of irreversible and permanent loss of central nervous system function [19, 20]. The diagnosis can often be determined based on clinical examination and noninvasive testing such as electroencephalography, evoked cerebral potentials, and transcranial Doppler ultrasonography [21, 22].

Absolute contraindications to organ donation include most extrahepatic malignancies and transmissible infections associated with high risk of mortality. Specifically, donors with active extracranial or hematologic malignancies are not considered suitable for organ donation. However, patients with primary brain tumors without extracranial metastases may be considered as donors for transplant. Donors with fungemia, mycobacterial disease, disseminated resistant bacterial infections, and prion disease are typically excluded from donation.

Once a donor is considered suitable based on these preliminary criteria, additional information is required. Initial donor-recipient matching is determined based primarily on blood type and graft size, although multiple other factors are evaluated prior to transplantation. An ideal donor would meet the following criteria: age less than 50 years, hemodynamic stability, absence of significant chronic disease, systemic infection, malignancy, or abdominal trauma.

However, since only a limited number of donors meet these parameters, transplant providers have liberalized exclusion criteria in an effort to increase the donor pool. Extended criteria donor grafts refer to those from donors with older age, higher degree of hepatic steatosis, history of malignancy, active viral or bacterial infection, or history of trauma. Traditionally, older donor age was considered a risk factor for graft failure, primarily based on increased risk for chronic vascular disease, significant comorbidities, and potentially more hepatic steatosis in elderly donors. However, more recent experiences suggest that donor age alone may not be a predictor of graft outcome. In fact, older donors even greater than 80 years old may be used with reasonable success if other donor risk factors such as hepatic steatosis and cold ischemia time can be minimized [23–25]. The use of older donors in recipients with HCV infection has traditionally correlated with increased graft loss. This finding may become less relevant in the modern era of improved HCV direct antiviral therapy, as HCV infection can be successfully eradicated in the majority of HCV-seropositive recipients either before or soon after liver transplantation.

Hepatic steatosis can be quantified by biopsy of the donor liver. Grafts with mild macrovesicular steatosis (<30%) are routinely used with good graft outcomes. In contrast, severe macrovesicular steatosis (>60%) within the donor graft increases the risk of primary nonfunction and is usually a contraindication for use of the organ [26, 27]. The donor risk index (DRI) predicts liver graft failure based on specific donor characteristics and transplant factors including age, race, height, cause of death, partial or split organ, DCD status, cold ischemia time, and sharing outside of a local donor service area [28].

All organ donors undergo nucleic acid testing (NAT) to rule out specific transmissible viral infections such as HIV, HBV, or HCV. In general there is a finite, albeit low, risk of viral transmission from the average donor. A study of organ procurement organizations in the USA has reported HIV and HCV prevalence rates of 0.1% and 3.5%, respectively, in donors with normal risk. Among high-risk donors, the prevalence of HIV and HCV was higher (0.5% and 18%, respectively). A model based on these known prevalence numbers estimates the incidence of undetected viremia as being 1 in 60,000 for HIV and 1 in 5000 for HCV in normal-risk donors. Among high-risk donors, the incidence may rise to 1 in 12,000 for HIV and 1 in 1000 for HCV [29].

The US Public Health Service (PHS) has developed specific criteria to classify donors as being at increased risk for recent HIV, HBV, or HCV infection [30]. These criteria include factors such as high-risk sexual behaviors and prior injection drug use. The specific PHS criteria for high-risk donors established in 2013 include:

1. High-risk sexual behavior within the preceding 12 months (people who have had sex with a person known or suspected to have HIV, HBV, or HCV infections, men who had sex with men [MSM], women who have had sex with an MSM, people who have had sex in exchange for money or drugs, people who have had sex with a person who had sex in exchange for money or drugs, people who have had sex with a person that has injected drugs by intravenous, intramuscular, or subcutaneous route for nonmedical reasons)
2. High-risk children (a child who is ≤18 months of age and born to a mother known to be infected with or at increased risk for HIV, HBV, or HCV infections, a child who has been breastfed within the preceding 12 months and a mother known to be infected with, or at increased risk for, HIV infection)
3. People who have injected drugs by intravenous, intramuscular, or subcutaneous route for nonmedical reasons in the preceding 12 months
4. People who have been in lockup, jail, prison, or a juvenile correctional facility for more than 72 h in the preceding 12 months
5. People who have been newly diagnosed with or have been treated for syphilis, gonorrhea, chlamydia, or genital ulcers in the preceding 12 months
6. People who have been on hemodialysis in the preceding 12 months (increased risk for recent HCV infection only) [30]

Recipients of organs from PHS high-risk donors typically receive separate counseling about the potentially increased risk of viral transmission. All transplant recipients undergo pre-transplant testing for HIV, HBV, and HCV. Post-transplant serologic surveillance within the first year after transplant is recommended to exclude new infections in recipients of organs from PHS high-risk donors.

While patients with positive hepatitis B surface antigen are excluded from donation, selected patients with isolated positive hepatitis B core antibody (HBcAb+) may be considered as suitable donors. Initial evaluation requires excluding underlying hepatic fibrosis in case the donor had prior hepatitis B infection. If the graft is found to be suitable for donation, there is still a risk of viral transmission to the recipient. Risk of HBV infection in the recipient depends largely on whether the recipient has immunity against HBV. Specifically, although infection rates are low in hepa-

titis B surface antibody (HBsAb) positive/HBcAb+ recipients, they may be as high as 76% in recipients with both negative HBsAb and HBcAb [31]. As such, the recipient of a liver allograft from a HBcAb+ donor will usually receive oral antiviral medication with or without hepatitis B immune globulin (HBIG) for prophylaxis. The use of lamivudine for prophylaxis has reduced the risk of infection to less than 4%, and the use of newer agents such as tenofovir and entecavir with lower rates of resistance may result in even lower infection rates among OLT recipients from isolated HBcAb+ donors. The addition of HBIG to oral antiviral agents may not provide additional benefit in this setting [32].

HCV-seropositive (+) donor livers are used in HCV-seropositive recipients. Assuming the absence of significant hepatic fibrosis in the donor liver, the use of HCV+ donors for HCV+ recipients can be considered and does not appear to affect patient survival, graft survival, or severity of HCV recurrence following transplantation [33].

Experience with HIV-seropositive (+) donors in organ transplantation is limited at this time. In 2013, the USA enacted the HIV Organ Policy Equity Act which allowed for the transplantation of HIV+ organs into HIV+ recipients. Initial reports of liver transplantation with HIV+ donors suggest good short-term outcomes.

Surgical Approaches to Liver Transplantation

The abdomen is typically opened with a bilateral subcostal incision with midline extension. To begin the recipient hepatectomy, the falciform and gastrohepatic ligaments are divided. The liver can then be lifted to expose the porta hepatis. Subsequently the hepatic artery, bile duct, and portal vein are sequentially divided. The patient is often placed on veno-venous bypass during this time. The suprahepatic and infrahepatic vena cava are clamped, and the recipient's liver is removed en bloc with the excluded portion of the vena cava. The gallbladder is removed along with the liver. Back-table preparation of the allograft typically occurs during the recipient hepatectomy. The allograft is then placed into the recipient, and the vena cava and portal venous anastomoses are created. The allograft is reperfused, and systemic bypass is discontinued. After reperfusion of the allograft, the arterial and biliary anastomoses are completed.

In certain cases, variant anatomy may require alteration in the creation of vascular or biliary anastomoses. An arterial conduit can be used if the recipient hepatic artery is insufficient. Roux-en-Y hepaticojejunostomy is considered in select cases such as when the recipient common duct is diminutive or large biliary collateral veins are present. Patients with primary sclerosing cholangitis typically require Roux-en-Y hepaticojejunostomy. In the past, T tubes were used in the case of donor-recipient duct size mismatch. However, their use has declined significantly in recent years due to the risk of complications including bile leak. Many centers will now consider closing a portion of the larger duct with suture prior to creating the biliary anastomosis.

An alternative to vena cava exclusion is the piggyback technique. In this situation, the hepatic artery, common duct, and portal vein are divided in the typical fashion. However, instead of clamping the vena cava and removing the liver en bloc with the vena cava, the surgeon instead dissects the liver surface off of the vena cava. The hepatic veins are clamped and divided, and the recipient liver is removed without disrupting the recipient vena cava. Longitudinal incisions are made in the recipient and donor vena cavas to allow for creation of a cavo-caval anastomosis. Potential benefits of the piggyback technique include decreased warm ischemia time, reduced blood transfusions requirements, and less need for veno-venous bypass. Piggyback reconstruction may increase the risk of developing hepatic venous outflow obstruction and subsequent Budd-Chiari syndrome.

Surgical Complications Resulting in Infection

Multiple surgical complications after LT may predispose to the development of infection. Hepatic artery thrombosis (HAT) is the most common vascular complication after OLT, with a 4% incidence reported in adult recipients [34]. HAT can be classified as early or late occurring before or after 4 weeks following transplantation. Early HAT may present in three distinct ways. The most severe presentation is fulminant hepatic failure, which is marked by acute rise in liver enzymes, encephalopathy, coagulopathy, and often sepsis. Other patients with HAT can present subacutely with ischemic injury to the bile ducts which predominantly rely on perfusion by the hepatic artery. These patients will subsequently develop biliary complications including strictures, acute cholangitis, hepatic abscesses, or recurrent episodes of bacteremia. A final group of patients with HAT may be asymptomatic and diagnosed incidentally.

HAT can be identified on Doppler ultrasound, although either radiographic or conventional angiography is often required to confirm the diagnosis. Patients with HAT and fulminant hepatic failure require management of sepsis including broad-spectrum antibiotics and prompt retransplantation. Less symptomatic patients can be taken to the operating room for hepatic artery revision and possible thrombectomy or managed non-operatively with catheter-directed thrombolysis. Patients who present with biliary complications of late HAT typically will develop a progressive course marked by recurrent cholangitis and other complications of biliary obstruction. In the short term, they can be managed with endoscopic or percutaneous biliary drainage and antibiot-

ics during episodes of acute cholangitis. However, many of these patients will ultimately require retransplantation.

Biliary complications occur frequently with an average incidence of up to 25% reported in some series. Many types of complications may occur including anastomotic and non-anastomotic biliary strictures, bile leak, biliary abscess, obstruction due to stones or casts, or acute cholangitis. The majority of biliary complications occur in the first 3 months after transplant, although biliary strictures may present several years post-LT. Approximately 80% of biliary strictures are at the site of anastomosis, but later presentations of non-anastomotic strictures may occur as a consequence of DCD organ use, older donor age, technical factors at the time of arterial anastomosis, HAT, hepatic artery stenosis, prolonged cold ischemia time, CMV infection, ABO blood group mismatch, or recurrent primary sclerosing cholangitis [35–37]. LDLT and split liver recipients are at increased risk for biliary complications as compared to DDLT recipients due to the cut surface of the liver and potentially more delicate biliary anastomoses. Most biliary structures are managed with endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous biliary drainage. In patients with persistent anastomotic strictures despite repeated endoscopic therapy, surgical revision may be considered.

Intra-abdominal hemorrhage can occur in the early post-transplant period with a reported prevalence as high as 20%. Preexisting coagulopathy and diminished hepatic synthetic function are associated with a higher risk of bleeding. Initial management is typically supportive, but reoperation may be required in up to 15% of cases if bleeding persists. However, a source of hemorrhage may be identified in only half of such cases [38].

Immunosuppressive Regimens in Liver Transplantation

The alloimmune response after LT is primarily T-cell mediated. The role of donor-specific antibodies and the concept of antibody-mediated rejection require further study but generally appear to be rare. Currently, induction immunosuppression with T-cell-depleting agents, such as thymoglobulin, is not used routinely after OLT. On Day 1, liver transplant recipients receive 500–1000 mg of methylprednisolone followed by a taper and conversion to prednisone. Initially, recipients are maintained on a multidrug regimen including a calcineurin inhibitor (CNI) such as tacrolimus, an antimetabolite agent such as mycophenolate, and corticosteroids.

CNIs serve as the backbone of immunosuppression regimens for most patients after liver transplantation. Most centers use tacrolimus as the preferred CNI. Direct comparisons between tacrolimus and cyclosporine after OLT have revealed lower rates of acute rejection and improved patient and graft survival with the use of tacrolimus [39–41]. CNIs are associated with nephrotoxicity, neurotoxicity, hypertension, and hyperlipidemia. Alopecia and hyperglycemia are more often seen with tacrolimus use, while hirsutism and gingival hyperplasia are more commonly associated with cyclosporine. Patients with acute liver failure and decompensated cirrhosis with severe hepatic encephalopathy may be more prone to neurotoxicity from these agents. As such, introduction of the CNI may be delayed until the patient is awake. CNIs are metabolized by the cytochrome p450 system; therefore, their serum concentration may be affected by several other commonly used medications. CNI levels and drug exposure will decrease with concurrent use of certain antiepileptic medications, rifampin, alcohol, and St. John wort. In contrast, CNI levels and drug exposure will increase with the use of macrolide antibiotics, azole and triazole-based antifungals, verapamil, and grapefruit juice.

In selected patients, mTOR inhibitors such as sirolimus or everolimus may also be used, often to minimize potential toxicities from a CNI-based regimen. Everolimus is FDA approved for use with a low-dose CNI in patients after liver transplantation, while sirolimus is not approved by FDA for use in patients undergoing liver transplants, and occasionally used off-label in select patients. The use of mTOR inhibitors within the first 30 days after liver transplant is discouraged due to the risk of hepatic artery thrombosis and impaired wound healing. Some studies suggest that early initiation of mTOR inhibitors within 90 days of OLT may lead to increased preservation of renal function [42–44]. The recommendation for concurrent use of a low-dose CNI is based on a higher risk of acute rejection for patients on mTOR monotherapy. Additionally, mTOR inhibitors do exhibit some antineoplastic activity and have been shown to reduce the risk of recurrent cutaneous squamous cell carcinoma after renal transplantation [45]. It is not clear that mTOR inhibitors improve long-term post-transplant recurrence risk in regard to HCC [46, 47]. Besides the risk of hepatic artery thrombosis and impaired wound healing, other common adverse effects associated with mTOR inhibitors include oral ulcers, edema, proteinuria, hyperlipidemia, and bone marrow suppression.

Mycophenolate, an antimetabolite agent, is commonly used in conjunction with a CNI in patients after liver transplantation and allows for more rapid discontinuation of corticosteroids. In many patients, mycophenolate is withdrawn within the first year after transplant; however, prolonged use may be indicated in order to minimize adverse effects of CNIs, such as nephrotoxicity [48]. Additionally, some centers maintain patients transplanted for autoimmune liver diseases on mycophenolate for a longer duration given the increased risk of acute rejection or recurrent autoimmune disease after OLT. The use of mycophenolate in pregnancy is contraindicated based on an increased risk of pregnancy loss and congenital malformations. Azathioprine may be a substitute for mycophenolate at some centers.

Glucocorticoids, usually prednisone, have multiple inhibitory effects on hosts' immune responses mediated by both innate and adaptive T and B cells. Due to their numerous side effects, most centers attempt to rapidly taper and wean patients off prednisone as soon as possible, often within the first 6 months after transplantation. Long-term low-dose prednisone has been utilized in patients with pre-transplant autoimmune liver disease. Since steroids increase HCV replication, abrupt changes in steroids, such as rapid withdrawal or bolus dosing for rejection, may be associated with worse outcomes [49].

Humanized monoclonal antibodies against the IL-2 receptor can be used in order to delay initiation of a CNI, particularly to avoid the immediate risk of nephrotoxicity or neurotoxicity. The use of daclizumab has demonstrated low rejection rates and improved renal function without an increase in CMV or other infections [50]. In 2009, daclizumab was removed from the market for commercial reasons. Basiliximab is commercially available and occasionally used clinically, although published data regarding the use of this immune modulator in liver transplant recipients are limited.

Management of Rejection in Liver Transplantation

Acute cellular rejection (ACR) occurs in up to 25% of OLT recipients, with the majority of cases occurring within the first month after transplant [51]. Antibody-mediated rejection is thought to be an uncommon phenomenon in this solid organ allograft transplant population. The risk of ACR after 1-year post-transplant declines to 10% and is potentially associated with poor compliance with antirejection medication. Early ACR does not seem to affect graft survival, but late ACR has been associated with an increased risk of developing chronic rejection and graft loss [52]. In many cases, the initial suspicion for ACR arises when elevated liver enzymes are discovered. Symptoms including fever or jaundice are less common, particularly if ACR is identified early. Liver biopsy is required to make the diagnosis of ACR, which is defined by a triad of mixed cell portal inflammation, endotheliitis, and ductulitis [53]. The majority of cases of ACR can be managed with corticosteroid therapy. Typically a high dose of methylprednisolone 500–1000 mg daily is given intravenously for 1–3 days with a subsequent taper. Patients with refractory ACR can be managed with either a second course of steroids or less often thymoglobulin. Thymoglobulin, a polyclonal antibody preparation directed against lymphocytes, is administered intravenously for up to 5 days with careful monitoring of white blood cell and platelet counts. All patients generally receive oral antimicrobial prophylaxis for CMV and *Pneumocystis jirovecii* when treated for ACR.

Chronic rejection (CR) occurs in less than 5% of OLT recipients in the modern era. Prior ACR, autoimmune liver disease, and CMV infection all may predispose to development of CR. Patients with CR typically present with laboratory evidence of cholestasis and may be jaundiced. As opposed to in ACR, steroid therapy is not beneficial in the management of CR. Options for management include increasing the dose of tacrolimus or the use of additional immunosuppressants such as mycophenolate mofetil or an mTOR inhibitor. Despite maximal medical therapy, many patients with CR will ultimately require retransplantation [54].

Infectious Complications in Patients with Chronic Liver Disease and Cirrhosis

Cirrhosis represents a state of progressive hepatic fibrosis with marked distortion of the hepatic architecture and development of regenerative nodules. The liver plays an important role in the hosts' immunity against bacterial pathogens; therefore, the development of chronic liver disease and cirrhosis renders such patients to an increased risk for infections. Thus, liver transplant candidates represent a unique patient population that is highly vulnerable to multiple infectious complications affecting the pre-transplant course. In addition, chronic liver disease and cirrhosis are associated with increased morbidity and mortality, due to gastrointestinal and variceal bleeding, severe and recurring ascites, hepatic encephalopathy, hepatorenal and hepatopulmonary syndromes, bile secretion impairment, and severe coagulopathy. Infections play an important role in the overall morbidity and prognosis for persons with chronic liver disease including cirrhosis and may contribute to 30–50% mortality [55]. Bacterial infections are noted at the time of hospitalization or during the course of hospital stay in 25–35% of patients with cirrhosis [56]. It is estimated that there is a 15% hospital mortality for cirrhotic patients who develop an infection episode [55]. In patients with cirrhosis, it is estimated that 30% are community-acquired infection, and the remainder are healthcare-onset infections. Approximately 35–40% of these healthcare-acquired infections will occur >48 h after hospital admission, which places these patients at an increased risk for infections due to multidrug-resistant organisms (MDROs) [56, 57].

Overview of Liver Function and Its Contribution to Host Defense

The liver is an organ that plays an important role in the metabolism, synthesis, and the storage of nutrients and proteins. The liver produces the majority of the body's proteins and therefore has pivotal synthetic functions such as metab-

olism and synthesis of amino acids, carbohydrates, fatty acids, lipoproteins, plasma proteins like albumin, transport proteins, protease inhibitors, fibrinogen, clotting factors, and complements. The liver also serves as a center of detoxification, removing or degrading toxic components from the circulation. In order for the liver to accomplish these functions, the hepatocyte must extract nutrients, waste, and toxic products from the blood that circulate through the liver within its sinusoids. The liver is continuously exposed to dietary ingredients consisting of exogenous molecules and micronutrients, environmental products, and byproducts of the gastrointestinal microbiota. The blood from the gastrointestinal and mesenteric circulation enters the liver via the portal vein and mixes with oxygen-rich blood from the systemic circulation via the hepatic artery and ultimately drains into the liver sinusoids. It is estimated that 80% of the hepatic blood flow within the liver arises from the gastrointestinal tract through the portal circulation [58]. Therefore, hepatocytes are exposed to a mixture of portal venous and arterial blood. The sinusoids are lined with liver sinusoidal endothelial cells that contain fenestrations to facilitate passage of the blood to reach the hepatocytes [58]. The hepatocytes are constantly exposed to foreign and immunogenic antigens and environmental toxins and those produced by the endogenous orointestinal microbiota. This constant exposure could result in untamed systemic immune activation; however, the liver plays a critical role in regulation and maintenance of immunologic and inflammatory homeostasis [58].

In addition to metabolism and synthesis, the hepatocytes play an important role in host defense. Their contribution to host immunity includes the production of complement and antimicrobial proteins, acute phase proteins in response to infection, and antigen presentation to T cells [58]. The liver is also a lymphoid organ with unique immunological properties. The liver-specific macrophages, known as Kupffer cells, line the luminal surface of the hepatic sinusoids and are an important part of the reticuloendothelial system (RES). The Kupffer cells in the liver comprise 90% of the body's tissue macrophages and make up one-third of the parenchymal cells in the liver [59]. Both the Kupffer cells and the hepatocytes contain pattern recognition receptors (PRR) which can bind to microbe-associated molecular patterns and damage-associated molecular patterns that originate from the gastrointestinal tract through the portal circulation [60–62]. These molecular patterns are then phagocytized by the Kupffer cells or hepatocytes and are removed and cleared from the circulation. These local processes of removal and degradation by the Kupffer cells and the hepatocytes serve a protective role to prevent systemic immune activation as a result of antigens and byproducts from the gastrointestinal tract [58]. These properties ensure an efficient innate defense against intestinal organisms and toxins and confer a particular capacity for preservation of immune tolerance. The normal liver is therefore considered to be immune tolerant or "tolerogenic." This is best supported by the observations that liver transplant recipients can reduce and also wean their immunosuppressive therapy in up to 20% of the patients, compared to recipients of other solid organ transplant [63].

On the other hand, with regard to host defense, the Kupffer cells of the liver play a key role in the removal of bacteria and their endotoxins from the bloodstream, as well as producing local inflammatory cytokines. Their presence within the vascular sinusoids provides an effective first line of defense against infections via the hematogenous route and bacterial translocation from the gastrointestinal tract.

Immunologic Dysfunction in Cirrhosis

In patients with cirrhosis, this crucial hepatic immunologic homeostasis is severely disrupted. Additionally, a milieu of dysregulated systemic pro-inflammatory cytokine response can result in further organ damage, especially in cirrhotic patients with systemic infection or sepsis [57]. The immunopathogenesis seen in cirrhosis is quite complex and is outlined in Fig. 3.1. In general, the clearance of bacteria and bacterial endotoxins by the Kupffer cells is impaired in patients with cirrhosis due to portosystemic shunting. The immunologic dysfunction associated with cirrhosis is further augmented by compromised liver synthetic function, malnutrition, stress catabolism, and also lifestyle factors, such as alcohol consumption. Chronic liver disease and cirrhosis are associated with alterations and/or deficiencies in all of the host defense mechanisms. In addition to depressed host immunity, these patients are at increased risk for exposure to healthcare-acquired infections due to their frequent need for hospitalization to manage the many complications associated with chronic and end-stage liver disease.

The key host factors that contribute to an increased risk of infection in patients with cirrhosis include (1) alterations in the intestinal microbiota and the intestinal mucosal barrier; (2) depression of activity by Kupffer cells and RES; (3) suboptimum opsonic activity in serum and the ascitic fluid; (4) neutrophil dysfunction with decreased phagocytosis and chemotaxis; and (5) decreased production and abnormalities in complement pathways, pattern recognition receptors, and C-reactive protein [57].

In recent years there has been an increased appreciation of the importance of the normal gut microbiota which contributes to both the host's metabolic and immunologic functions. The majority of the gut microbiota is comprised of obligate anaerobes within the phylum *Firmicutes* (specifically *Clostridia* spp. and Gram-negative anaerobes such as the *Bacteroides* spp.). In the bowel of healthy subjects, Gram-negative bacteria are present in relatively low numbers as compared with the obligate anaerobes, whereas

Fig. 3.1 Immunologic dysfunction associated with cirrhosis. PRR, pattern recognision receptors. SBP, spontaneous bacterial peritonitis. HRS, hepato-renal syndrome

with cirrhosis, the proportion of Gram-negative bacteria is more prominent. Alterations in the composition of the gut microbiota are well recognized in patients with cirrhosis, with an increase in colonization by the Proteobacteria that are predominantly Gram-negative enteric bacteria [64]. Spontaneous infections with Gram-negative bacilli are common in patients with cirrhosis, and it is proposed that this is mainly due to bacterial translocation from the gastrointestinal tract that has undergone alteration in the gut microbiota. Bacterial translocation occurs when bacteria or yeast migrate to the mesenteric lymph nodes and into the portosystemic circulation [57]. In animal experiments, oral administration of radiolabeled *E. coli* was detected within the intestinal lumen, mesenteric lymph nodes, and the ascitic fluid in mice with cirrhosis [65], supporting the possible mechanism of enhanced bacterial translocation

that may also occur in patients with cirrhosis. Additionally, Gram-negative bacilli are demonstrated to be more efficient in translocating across bowel lumen when compared to obligate anaerobes in a murine experimental model [66], providing further evidence for clinical observations that Gram-negative enteric bacilli are the most common cause of infection in patients with chronic end-stage liver disease and systemic infections due to anaerobes are seldom seen. Other factors that contribute to the bacterial translocation of pathogenic bacteria in cirrhosis include intestinal bacterial overgrowth and increased intestinal permeability [64]. Intestinal overgrowth and alterations in the gut microbiota appear to correlate with the Child-Pugh score; higher prevalence of bacterial overgrowth has been observed in patients with Child-Pugh classes B and C compared with patients having class A liver disease [67, 68]. Moreover, intestinal bacterial overgrowth has been associated with a diagnosis of minimal hepatic encephalopathy and supports the use of nonabsorbable rifaximin in the treatment and prevention of hepatic encephalopathy in such patients [68]. It has also been shown that there is a higher bacterial burden of pathogenic *E. coli* in stool cultures in patients with cirrhosis and those with early-stage hepatic encephalopathy [69]. Normal hosts have tight junctions between mucosal and epithelial cells, which limit translocation of bacteria and bacterial products. Patients with cirrhosis have alterations in tight junction or desmosome proteins that compromise the physiologic barrier and may result in increased bacterial translocation [70, 71]. Additionally, intestinal bacterial access to the gut epithelial cells may be facilitated by deficiencies in IgA, bile lipids, and antimicrobial peptides that are notably observed in patients with advanced cirrhosis [64, 72, 73]. Therefore, changes in the gut microbiota, coupled with the increased intestinal permeability, particularly in cirrhotic patients with ascites greatly enhance the risk for bacterial translocation due to aerobic Gram-negative bacteria resulting in spontaneous bacterial peritonitis and bloodstream infections.

Cirrhosis is associated with both sinusoidal and septal fibrosis which results in portosystemic shunting. Patients with cirrhosis have depressed RES-Kupffer cell function, which can further promote translocation of bacterial pathogens and their endotoxins, thus reducing immune surveillance by the Kupffer cells/RES and allowing these pathogens access to the bloodstream [74]. Toll-like receptors (TLRs) are expressed on the surface of macrophages including Kupffer cells and can recognize and bind to bacterial products including endotoxins. Alterations in the TLRs and nucleotide-binding oligomerization domain (NOD) 2 gene via minor genetic polymorphisms may result in decreased affinity of TLR for Gram-negative bacilli lipopolysaccharide further enhancing the risk for bacterial infections in patients with cirrhosis [75, 76]. Furthermore, it has been demonstrated that simultaneous variations in the NOD 2 and TLR genes are associated with increased risk for spontaneous bacterial peritonitis, as well as an increase in surrogate markers for intestinal permeability in patients with cirrhosis [77]. It appears that genetic polymorphisms may contribute to the risk of spontaneous bacterial peritonitis and other bacterial infections in patients with chronic liver disease and cirrhosis.

Patients with cirrhosis experience both generalized immunodeficiency and systemic immune activation with the production of pro-inflammatory cytokines, also referred to as cirrhosis-associated immune dysfunction (CAID) [77]. There are numerous immunologic deficits that contribute to CAID and ultimately risk of systemic infection. In patients with cirrhosis, there is an overall reduction of circulating immune cells, and this is most notable for neutrophils, naïve T cells, and memory B cells [78]. In addition to reduced numbers of immune cells, there is a cellular dysfunction, including reduced phagocytic and chemotactic properties of neutrophils, reduced phagocytic activity of monocytes, hypoproliferative response to mitogens by T and B cells, and reduced natural killer cell cytotoxic activity [79–82]. Stunted TNFα production and HLA-DR expression have also been noted in cirrhotic patients with acute decompensation, such as sepsis, and referred to as "immune paralysis" [83].

Finally, as cirrhosis affects the synthetic function of the liver, the production of both complement and pattern recognition receptors (PRRs) are diminished [84]. Several important soluble PRRs produced by the liver include C-reactive protein, lipopolysaccharide-binding protein, peptidoglycan recognition protein, and soluble CD14, which activate complement associated opsonization cascade [85, 86]. Reduction in complement and PRR synthesis decreases bactericidal function of phagocytic cells in patients with cirrhosis [87]. Specifically, decreased concentrations of C3, C4, and CH50 result in suboptimal opsonic activity in both serum and ascitic fluid and have been recognized as an important risk factor that is associated with increased susceptibility to bacterial infections [88, 89]. Bactericidal functions of neutrophils are compromised resulting from decreased circulating cells in the peripheral blood due to splenic sequestration, decreased chemotaxis, and phagocytosis [88]. In patients with cirrhosis, neutrophils have reduced microbicidal activity owing to diminished intracellular superoxide production and myeloperoxidase activity [90]. Additionally, neutrophil dysfunction can be further exacerbated by alcohol consumption further suppressing phagocytosis and increasing the risk of bacterial infection [91].

In summary, the immunologic and synthetic function of the liver plays an important role in immune surveillance and immunologic homeostasis. Patients with advanced liver disease awaiting liver transplantation are a vulnerable population due to hepatic structural abnormalities, reduced production of critical immuno-protective proteins, reduced circulating immune cells, and impaired function of these

cells. This overwhelming acquired immunodeficiency in patients with end-stage liver disease is further augmented by the frequent exposure to the healthcare setting, placing these patients at risk for numerous infectious complications prior to undergoing hepatic allograft transplantation.

Clinical Aspects of Infections in Patients with Chronic Liver Disease and Cirrhosis

As a result of CAID, infectious complications are extremely common in patients with chronic liver disease and may be the cause of mortality in up to 50% of these patients [92–94]. The most common types of infections are spontaneous bacterial peritonitis (SBP), UTI, pneumonia, bloodstream infections, and skin and soft tissue infections [95, 96]. The bacteriologic causes of these infections are predominantly (~75%) due to Gram-negative bacilli (GNB); Gram-positive organisms and anaerobes account for 20% and 3%, respectively [97]. It is estimated that 64% of these infections may be due to drug-resistant bacteria [98]. Infection in patients with cirrhosis can exacerbate liver failure and precipitate end-organ damage at other sites [99]. Due to the dysregulation of the pro-inflammatory cytokine response in patients with cirrhosis, sepsis carries a mortality rate of 26–44%. Infection can cause acute decompensation in individuals with chronic liver failure, which can result in worsening hepatic encephalopathy. Acute kidney injury with hepatorenal syndrome, acute lung injury with ARDS, and severe coagulopathy with gastrointestinal bleeding can all be precipitated by bacterial infections in patients with cirrhosis [62].

Spontaneous bacterial peritonitis is a common infection in cirrhotic patients with ascites. Severe, potentially life-threatening SBP that requires hospitalization often noted in patients with advanced liver disease may be associated with 31% mortality [59]. SBP is characterized by the spontaneous infection of ascitic fluid in the absence of an intra-abdominal source of infection. The pathogenesis of SBP is caused by bacterial translocation from the intestinal tract in the setting of portosystemic shunting. The most common organism isolated from peritoneal fluid is *Escherichia coli*. In a large series of 519 patients with SBP, the prevalence of culture-positive organisms included *E. coli* (43%), *Klebsiella pneumoniae* (11%), *Streptococcus pneumoniae* (9%), other streptococcal species (19%), other *Enterobacteriaceae* (4%), *Staphylococcus* species (3%), and *Pseudomonas aeruginosa* (1%), and 10% were miscellaneous organisms [100]. Another study noted that in the setting of norfloxacin prophylaxis for SBP, viridans group streptococci were prominent streptococcal isolates followed by group B *Streptococcus*, *Streptococcus pneumoniae*, and *Streptococcus bovis*, emphasizing the increasing importance of streptococcal species breakthrough infection as a cause of SBP in patients receiving fluoroquinolone prophylaxis [101]. Guidelines and recommendations for the diagnosis, management, and prevention of SBP have been published and are updated by the American Association for the Study of Liver Diseases (AASLD) [102]. After SBP, UTIs are the next common site of infection in patients with cirrhosis. As in other patient populations, urinary catheters are an important risk factor for such infections, and as expected, GNB are common causative pathogens.

Patients with cirrhosis are at increased risk for community-acquired pneumonia (CAP), healthcare-acquired pneumonia (HCAP), and aspiration pneumonia. As patients with cirrhosis have both complement and B-cell defects, they are at increased risk for infections due to encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Klebsiella pneumoniae*. Additionally, these patients are more likely to have concurrent bacteremia and have multilobar involvement compared with CAP in the general population [103]. The depressed cellular immune response associated with cirrhosis also places these patients at increased risk for legionellosis. These patients require frequent hospitalization, and therefore they are at increased risk for HCAP. Hepatic encephalopathy is a risk factor for HCAP, because these patients have decreased mental status and are at risk for aspiration of oropharyngeal contents that often are colonized by Gram-negative enteric bacilli. Empiric treatment for HCAP should include coverage for *Pseudomonas aeruginosa* and other drug-resistant GNB, as well as MRSA. Patients with cirrhosis are at increased risk for aspiration events in the setting of altered mental status due to hepatic encephalopathy or excessive alcohol consumption, which places them at risk for lower respiratory tract infections [104]. Additionally, the periodontal disease that is seen in alcoholic patients provides a favorable environment for both anaerobes and *Klebsiella pneumoniae* colonization, which can lead to lower respiratory tract infection during aspiration events [67, 105]. It is well recognized that patients with chronic alcoholism are at an increased risk for community-acquired pneumonia due to *S. pneumoniae*; a study reported that alcohol abuse was also a risk factor for CAP and septic shock due to *Pseudomonas aeruginosa* and *Acinetobacter* species [106]. It is important to note that the latter two infections are uncommon in patients with alcoholic cirrhosis unless these patients have extensive prior healthcare exposure including stays in the intensive care unit or need for mechanical ventilatory support; other risk factors include leukopenia or neutropenia.

Bloodstream infections can occur as a result of bacterial translocation from the gastrointestinal tract; Gram-negative enteric bacilli, enterococci, and *Streptococcus* spp. are common pathogens [58, 107]. It has been reported that bacteremia or SBP can complicate gastrointestinal bleeding in 17–45% of the episodes [108]. The management of esopha-

geal varices involves esophageal variceal ligation (EVL) and esophageal variceal sclerotherapy (EVS); both of these procedures may increase the risk for transient bacteremia. In a meta-analysis, the overall rate of bacteremia following these procedures was 13%; bacteremia was significantly more common after EVS (17%) compared with EVL (6%) [109]. The most common cause of transient bacteremia associated with EVS and EVL includes alpha-hemolytic *Streptococcus* and coagulase-negative staphylococci [110, 111]. As with other hospitalized patients, invasive procedures such as indwelling central venous catheters place these patients at increased risk for bloodstream infections due to *Staphylococcus aureus* including MRSA and coagulase-negative staphylococci. Presence of cirrhosis was noted as an independent risk factor for the development of spontaneous bacteremia due to group B *Streptococcus* [112].

Hepatic hydrothorax is another complication of cirrhosis, and this can evolve into spontaneous bacterial empyema. Spontaneous bacterial empyema may be seen in 10–20% of patients with hepatic hydrothorax, and like SBP, these infections are primarily due to Gram-negative enteric bacilli [113–115].

Skin and soft tissue infections including necrotizing fasciitis have been reported in patients with cirrhosis. In patients with end-stage liver disease, generalized edema, especially involving the lower extremities, is not uncommon; furthermore, suboptimal personal hygiene and malnutrition place these patients at increased risk for relapsing skin and soft tissue infections. The common causative agents are *Staphylococcus aureus*, including CA- and HA-MRSA, and β-hemolytic *Streptococcus* including group B *Streptococcus*; GNB infections have also been reported [62]. Other rare causes of skin and soft tissue infections due to *Vibrio vulnificus* and *Aeromonas hydrophila* may be seen more often in patients with cirrhosis compared with the general population.

Specific Pathogens

Patients with chronic liver disease exhibit CAID due to decreased complement levels, less effective phagocytic activity and chemotaxis, "bypass" of the reticuloendothelial system due to portosystemic shunting, and availability of free iron that promotes growth of particular organisms.

Iron is bound to proteins such as hemoglobin, ferritin, transferrin, and lactoferrin, which maintain a low level of free iron that inhibits sustained bacterial growth. The liver plays a key role in iron metabolism, and this can be significantly disrupted in patients with chronic liver disease and cirrhosis. While this disruption in iron homeostasis is most notable in hemochromatosis, it has also been reported in patients with alcoholic liver disease, nonalcoholic fatty liver disease, and chronic hepatitis C infection. Cirrhosis is associated with decreased synthetic function, including the production of hepcidin, an important regulatory peptide for iron metabolism. In response to infection and inflammation, there is increased production of hepcidin, which decreases the availability of free iron, resulting in induced hypoferremia. The decreased levels of free iron by hepcidin have important antimicrobial properties, by creating an environment that does not support bacterial growth. Animal models of hepcidin-deficient mice showed increased susceptibility to infection with *Vibrio vulnificus*. Therefore, suggesting that reduced production of hepcidin in patients with chronic liver disease and cirrhosis contributes greatly to their susceptibility to specific pathogens [116–118].

Noteworthy pathogens that are more common in patients with chronic liver disease and cirrhosis, as compared to the general population, include *E. coli*, *Vibrio* spp., *Aeromonas hydrophila*, *Plesiomonas shigelloides*, *Yersinia* spp., *Salmonella* spp., *Listeria monocytogenes*, *Mycobacterium tuberculosis*, and the invasive molds like *Aspergillus fumigatus* and *Rhizopus* spp. These organisms are able to take advantage of the immunodeficiency associated with chronic liver disease and cirrhosis; additionally high free iron levels provide favorable growth environment for such organisms [62, 79, 119].

The *Vibrio* spp., including *V. vulnificus*, *V. cholera*, and *V. parahaemolyticus*, can cause severe infection in patients with chronic liver disease and those with cirrhosis. *Vibrio vulnificus* is a Gram-negative, halophilic noncholera *Vibrio* species that is a common organism isolated from estuarine and marine environments and has been associated with gastroenteritis, skin and soft tissue infections with hemorrhagic bullae, and bacteremia resulting in severe sepsis and death. Impaired iron metabolism and increased iron availability appear to underlie the pathogenicity of *V. vulnificus* invasive disease [120–122]. Common coastal sites where *V. vulnificus* is endemic include the Chesapeake Bay and the Gulf Coast. Most patients (90%) with *V. vulnificus* bacteremia have a history of consuming raw or undercooked shellfish specifically oysters, whereas skin and soft tissue infections are associated with the handling of raw seafood or direct inoculation due to recreational exposure to marine environment [84, 123, 124]. Gastroenteritis is the most common clinical manifestation, cellulitis with hemorrhagic bullae, and less commonly seen necrotizing fasciitis has also been reported. Patients with chronic liver disease or cirrhosis can present with primary *V. vulnificus* bacteremia associated with multiple hemorrhagic bullae and septic shock. In case series, *V. vulnificus* bacteremia carries a mortality of 40%, with an extremely poor prognosis in patients with septic shock at the time of presentation [83–86, 125]. Therefore, it is recommended that persons with chronic liver disease should avoid consuming raw undercooked shellfish and exposure to marine water.

Aeromonas species are GNB that are isolated predominantly from fresh water. *Aeromonas hydrophila* is the most common species and mainly presents as gastroenteritis. A rapidly progressive cellulitis or necrotizing fasciitis may rarely occur in such patients following exposure to fresh water. Bacteremia due to *Aeromonas* spp. is more common in patients with underlying cirrhosis and was associated with a 36% crude mortality [126]. In the same series, *Aeromonas* bacteremia, cirrhosis was the common underlying disease. *Aeromonas* SBP is an uncommon illness that may be observed during the summer months and associated with a diarrheal illness [127]. *Plesiomonas shigelloides* is also a GNB which can be acquired by the ingestion of raw or undercooked shellfish. It has been associated with gastroenteritis and in rare instances SBP [128, 129]. It may have a propensity to cause severe disease in iron overload conditions such as hemochromatosis.

The *Yersinia* spp., *Y. enterocolitica*, and *Y. pseudotuberculosis* are Gram-negative enteric bacilli that are also ferrophilic. Therefore, patients with cirrhosis and hemochromatosis are at risk for these gastrointestinal pathogens, which can be transmitted by undercooked pork products. In rare instances, *Yersinia enterocolitica* bacteremia has been associated with blood transfusions [130].

Listeria monocytogenes are Gram-positive bacilli that may be acquired via the ingestion of infected processed and canned food products or unpasteurized milk and products made from raw milk such as certain variety of cheese. The most important risk factor for invasive *L. monocytogenes* infection is depressed cellular immunity; availability of free iron in the hosts has been recognized as an important determinant of *Listeria* pathogenicity and virulence. Hence *L. monocytogenes* infections have been described in patients with hemochromatosis and cirrhosis [131–133]. Bacteremia and meningitis are the common clinical presentations of *L. monocytogenes* invasive disease.

Infections due to *Mycobacterium tuberculosis*, *Aspergillus fumigatus*, and *Rhizopus* spp. can rarely complicate the course of patients with chronic liver disease and cirrhosis due to the underlying immunodeficiency coupled with the alteration in iron homeostasis [62, 79, 80, 82].

Infectious Complications in Liver Transplant Recipients

Epidemiology

The incidence of infection after liver transplantation (LT) is particularly high compared to other solid organ transplants, likely due to the complexity of the procedure, risk of abdominal contamination, and especially due to poor medical status of many allograft recipients with end-stage liver disease. Although mortality has markedly improved post-LT (), it is estimated that up to two-thirds of all LT patients suffer at least one episode of infection [134].

The risk of infection post-transplant is primarily determined by epidemiologic exposures including donor-derived, recipient-derived, healthcare-acquired, and community-acquired pathogens – and the patient's net state of immunosuppression. The net state of immunosuppression is based on multiple factors and includes the level of pharmacologic immunosuppression, underlying host factors, surgical procedures and other medical interventions, and viral infections (such as CMV). This is a complex interaction, and it generally varies predictably over time, based on typical protocols for antirejection immunosuppressive therapy and prophylactic strategies. Consequently, the risk of infection post solid organ transplant is traditionally subdivided into three distinct intervals: from surgery to 1 month post-transplant, 1 month to 6–12 months post-transplant, and beyond 6–12 months post-transplant [135, 136].

Pre-transplant Screening for Infections

Pre-transplant screening of both potential donors and recipients can help prevent infectious complications in multiple ways: by identifying contraindications to transplant, by detecting latent or occult active infections, and by stratifying risk for future infections and allowing appropriate preventive steps such as prophylactic antimicrobials or vaccination. Historically, screening approaches have differed widely between organ procurement organizations within the USA and internationally [137, 138]. With greater experience and ability to diagnose transplant-related infections, there is now an established subset of infections that are routinely screened for in most cases. Most transplant centers' screening protocols require and perform the following tests in donors and recipients prior to transplantation and include human immunodeficiency virus (HIV) antibody, HSV (herpes simplex) IgG antibody (at some centers), cytomegalovirus (CMV) IgG antibody, hepatitis C virus (HCV) antibody, hepatitis B virus (HBV) surface antigen (HBsAg), hepatitis B core antibody (HBcAb IgM and IgG, or total core antibody), hepatitis B surface antibody (HBsAb), rapid plasma reagin (RPR), toxoplasma antibody (especially in heart recipients), Epstein-Barr virus (EBV) antibody (EBV VCA IgG, IgM), varicella zoster virus (VZV) antibody, purified protein derivative (PPD) or interferon gamma release assay (IGRA) for latent TB infection in recipients, *Strongyloides* serology (for recipients from endemic areas), *Coccidioides* serology (for recipients from endemic areas), *Trypanosoma cruzi* serology (for donors and recipients from endemic areas), serologies for tetanus, diphtheria, measles, mumps, and

pneumococcal titers as an aid to pre-transplant immunization (at some centers).

Some optional screening measures include West Nile virus serology or NAT HHV-8 serology and BK serology in kidney donor and recipients. NAT for HIV, HCV, and HBV is also performed and is of increasing importance especially in donors with high-risk social behaviors.

However, screening practices can still vary by transplant center [139]. Caregivers may choose to expand screening tests based on epidemiological or clinical factors on a case-by-case basis. Presurgical testing for LT is generally similar to protocols for other solid organ transplants; however, addressing potential latent *Mycobacterium tuberculosis* infection (LTBI) in candidate recipients raises some specific challenges.

Immunocompromised states may confer a weakened ability to react to tuberculin skin tests (TSTs) and interferon gamma release assays (IGRAs), decreasing the sensitivity of these tests when screening for *Mycobacterium tuberculosis* (MTb) [140, 141]. Individuals with cirrhosis are known to have impaired immune responses, including altered T-cell-dependent functions, which may affect the sensitivity of MTb testing [142]. There is no gold standard for latent MTb diagnosis, and all current tests have questionable accuracy for immunocompromised hosts. However, they do have high specificity and, thus, are still a valuable tool for minimizing the risk of active tuberculosis infection for many patients after undergoing transplantation [143–145]. Although there is limited research on the use of these tests specifically in individuals prior to transplantation, 2013 guidelines from the American Society of Transplantation recommend standard TST for all transplant candidates, with consideration of a second boosting TST 2 weeks later for those who initially test negative; this can potentially reveal a positive test for patients with remote exposure [146]. IGRAs are also recommended as an alternative to TST and may be preferable for convenience at most transplant centers. The use of an IGRA for screening for LTBI is favored in the setting where a patient has received a prior BCG vaccine, as an IGRA is more specific than a TST in this instance. The QuantiFERON-TB Gold In-Tube test (QFT) (Cellestis, Australia) has been compared to the TST for diagnosis of latent tuberculosis infection in candidates being considered for LT, and of note, indeterminate QFT results were more likely in patients with higher MELD scores [145]. There is some evidence that the T-SPOT TB test (Oxford Immunotec Ltd) may have slightly higher sensitivity than the QuantiFERON-Gold In-Tube test [147].

Treatment for LTBI also poses a unique challenge for pre-LT candidates, given the hepatotoxic potential of the treatment options. Completion of treatment before transplantation is ideal to best minimize the risk of developing active tuberculosis infection. With careful monitoring, even compensated cirrhotic individuals can complete the treatment safely [148, 149]. If exposure to MTb is suspected to be recent (i.e., if the candidate had recent conversion of their TST or IGRA from negative to positive), early treatment is especially favored, as risk for MTb activation is highest during the initial 1–2 years post exposure [150]. However, for candidates with advanced decompensated liver disease, it is usually advisable to defer treatment till after transplant when the patient is deemed stable from a liver function standpoint, to minimize the risk of fulminant hepatotoxicity.

There are two standard treatment options for LTBI in pre-liver transplant candidates: isoniazid for 9 months or rifampin for 4 months. The risk for hepatotoxicity has not been shown to be significantly different between the two drugs for this population [145]. Due to the contraindicated drug interactions between rifampin and many immunosuppressants, rifampin is not recommended following transplantation. The coadministration of rifampin with tacrolimus results in decreased drug exposure of tacrolimus. Twelve weeks of directly observed therapy with isoniazid and rifapentine is a third approved regimen for LTBI in the general population; however, as it has not been studied in the LT population, it is not recommended in these cases. Additionally, rifapentine is similar to rifampin in its effect on tacrolimus drug exposure. A randomized prospective study sought to investigate the efficacy and safety of 9 months of levofloxacin prophylaxis in LT candidates; however, the study was terminated early due to an 18% rate of severe tenosynovitis in the levofloxacin arm [151].

Timeline for Infectious Complications from Transplant Procedure to 1 Month After Transplantation

Bacterial and Healthcare-Acquired Infections

In the first month post-LT, infections are most often healthcare associated and bacterial in origin, similar to the infection risks for immunocompetent hosts undergoing other hepatobiliary procedures. A variety of factors are associated with an increased risk for bacterial infection. These factors include older age, length of preoperative stay, CMV infection, duration of surgery, retransplantation, volume of transfused blood products, preoperative MELD and CTP scores, bilioenteric anastomosis, technical complications (e.g., biliary leak, HAT), renal replacement therapy, and hyperglycemia [152]. Intra-abdominal infections are most common due to the technical nature of the surgery. The bile duct has no natural collaterals, being supplied only arterially, as opposed to the liver, which has dual circulation through the portal system. The biliary epithelium is thus more vulnerable to hypoperfusion during transplantation or resulting from hepatic

artery thrombosis (HAT). A 30-year review at one center found a 14% rate of biliary complications post-LT, including anastomotic and non-anastomotic strictures, bile leaks, and cholangitis. Elevated MELD, HAT, and elevated donor creatinine suspected to reflect altered metabolic factors at the site of anastomosis, which may impair healing, were all significant risk factors for anastomotic biliary complications [153]. Biliary complication may in turn lead to further infectious complications, such as hepatic and intra-abdominal abscesses. A 10-year retrospective study at a large transplant center diagnosed hepatic abscess post-LT at a rate of 4.8 per 1000 transplant patient-years [154]. In the same study, HAT was confirmed to be a significant predisposing factor for hepatic abscess. Management of infectious biliary complications warrants antibiotic coverage for enteric Gram-negative organisms and anaerobes, as well as healthcare-associated bacteria based on the patient's history. Source control may necessitate drainage, endoscopic intervention, surgical repair or in severe cases, retransplantation.

After intra-abdominal infections, the lungs are the second most frequent site of infectious complication post-LT. A retrospective study of deceased donor hepatic allograft recipients found an incidence of 10 episodes of ventilator-associated pneumonia per 1000 days of mechanical ventilation. *Enterobacteriaceae* accounted for 79% of bacterial etiologic agents. Both intra-abdominal infection and pneumonia can be complicated by concurrent bacteremia. A multicenter retrospective study found bloodstream infections complicated 29% of LT recipients in the first year after transplantation, with 52% of infections occurring within the first 100 days [155].

Surgical wound infections are third common infectious complications during this period, followed by urinary tract infections and other healthcare-associated infections (HAIs) [150]. Risk factors identified for surgical site infection include prolonged operative time, large-volume blood transfusion, biliary leak, retransplantation, dialysis, and CMV infection [156, 157].

Antibiotic resistance has become an increasing problem for treating HAIs. In 2014, the CDC found that 14% of HAIs in short-term acute care hospitals were caused by 1 of 6 major antibiotic-resistant threat bacteria [158]. The most recent survey of HAIs from the National Healthcare Safety Network from 2011 to 2014 further showed that resistance patterns continue to change over time [159]. Antibiotic resistance is particularly a concern for liver transplant recipients who are likely to have had prior antibiotic exposures as a result of numerous hospitalizations associated with the complications of chronic liver disease in the pre-transplant period. A study of 300 liver transplant recipients found 88 suffered at least 1 infection in the early 30-day post-transplant period; and of these, 78 (89%) were due to drug-resistant bacteria [159]. The multidrug-resistant organisms (MDROs) most commonly encountered in LT recipients include extended β-lactamase-producing *Enterobacteriaceae* (ESBL), MDR *Pseudomonas aeruginosa*, carbapenem-resistant *Acinetobacter baumannii* (CR-AB), carbapenem-resistant *Enterobacteriaceae* (CRE), vancomycin-resistant *Enterococcus* (VRE), and methicillin-resistant *Staphylococcus aureus* (MRSA) [160].

The most common MDROs associated with ESBL production are *Klebsiella pneumoniae* and *E. coli*. Although it appears that ESBL-producing organisms may be more common in kidney transplant recipients, often as an etiology for UTIs, LT recipients are also at risk for these organisms and have been reported in 5.5–7% [161–163]. In a large solid organ transplant cohort, 53% of the *Klebsiella pneumoniae* isolates were ESBL producing, and the highest risks were seen in kidney transplant recipients, especially those requiring post-transplant renal replacement therapy [162]. Infections due to ESBL-producing organisms in solid organ transplant recipients have been noted to be associated with mortality that ranged from 5% to 20% [162, 164, 165]. Carbapenems are the preferred treatment of choice for serious infections due to ESBL-producing *Klebsiella pneumoniae* and *E. coli*.

Pseudomonas aeruginosa has many resistance mechanisms and therefore demonstrates lack of susceptibility to a variety of antibiotics in liver transplant recipients. MDR *Pseudomonas* was the causative pathogen for healthcare-associated pneumonia (HCAP) in 18% of LT recipients [166]. Bloodstream infections due to *P. aeruginosa* have occurred in up to 10% of LT recipients, and 50% of these isolates are multidrug resistant. Treatment of MDR *Pseudomonas aeruginosa* can be quite challenging in LT; clinicians may often need to resort to nephrotoxic agents such as the aminoglycosides and the polymyxins. The role of cephalosporin ß-lactamase combinations such as ceftolozane/tazobactam and ceftazidime/avibactam may offer additional options for MDR *Pseudomonas*; however, data in the solid organ transplant patient population for these newer antimicrobial drugs is lacking.

Infections due to carbapenem-resistant Acinetobacter baumannii have been reported with increasing frequency in LT recipients, and appear to predominantly occur in the setting of HCAP and bloodstream infections. Bloodstream infections due to *Acinetobacter baumannii* have been reported to be as high as 24% in LT recipients, with over 50% of these isolates being caused by carbapenem-resistant *A. baumannii* [167–169]. *Acinetobacter* infections in LT recipients can carry a poor prognosis with inhospital mortality rates that may exceed 50% [168, 170, 171]. As with MDR *Pseudomonas*, treatment options are limited and include the polymyxins, such as colistin, and addition of aminoglycosides. Other options include minocycline, tigecycline, and ampicillin/sulbactam, as the β-lactamase inhibitor, sulbactam, has intrinsic activity against *A. baumannii*.

Recently, infections due to carbapenem-resistant *Enterobacteriaceae* (CRE) have been identified in solid organ transplant centers. Although there are multiple patterns of carbapenem resistance, the majority of cases in the USA are due to type A carbapenemases – specifically carbapenem-resistant *Klebsiella pneumoniae* (CRKP). Rates of CRKP have been reported between 6.6% and 12.9% in patients undergoing liver transplantation, although 1 transplant center has noted a rate as high as 23% [172–174]. In general, the most common sites of infections due to CRKP in LT recipients include surgical site, organ space, HAP, and UTI [172]. Mortality associated with CRKP infections in LT recipients ranges from 18% to as high as 80% [172, 174–176]. Another cohort of solid organ transplant patients found that infection with CRKP was independently associated with higher mortality (HR 5.562 [CI 95% 1.186–26.088]) [177]. In addition to traditional risk factors associated with CRKP infections in other patient populations, pre-transplant colonization with CRKP can place such patients at an increased risk for CRKP infections following transplantation [175, 176]. Despite this risk, there are currently no absolute contraindications to exclude donors that are colonized with CRKP. Treatment of LT recipients who developed CRE or CRKP infections is quite complicated, often requires combination antimicrobial therapy, and can also be associated with drug toxicity. Agents that have been used include the polymyxins such as colistin, aminoglycosides, and tigecycline along with or without a carbapenem agent. Although fosfomycin can be considered for treatment of uncomplicated UTIs due to CRE, the intravenous formulation is not available in the USA. One case report of complicated extensively drug-resistant (XDR) *Klebsiella pneumoniae* bacteremia during early post-transplant period necessitated addition of IV fosfomycin as an investigational drug to a multidrug regimen [178]. The role of the newer β-lactamase agents such as ceftazidime/avibactam and meropenem/vaborbactam is yet to be defined for the management of serious infections due to CRE and CRKP.

Infection and colonization by vancomycin-resistant *Enterococcus* (VRE) have been well characterized in pre-liver transplant candidates and in patients following liver transplantation. In the USA, the estimated rates of VRE colonization, prior to and after transplantation, were 16% and 22%, respectively [179]. There is wide variation in the prevalence of VRE colonization in LT candidates and liver transplant recipients, depending upon the transplant center and the patient population studied, and ranges from 0% to 44% [180–182]. In a prospective surveillance study, pre-transplant VRE colonization was found to be associated with an increased risk for VRE infections after transplantation and associated with higher morbidity as measured by ICU stay and length of hospitalization; however, VRE colonization did not result in increased mortality. On the other hand, the acquisition of VRE colonization post-LT was associated with increased morbidity and mortality compared with LT recipients with no evidence of VRE colonization [183]. The risk factors that are associated with VRE infection include prior antibiotic exposure, prolonged hospitalization, interventional procedures or complications of the biliary tract, and surgical re-exploration [161]. Common sites of VRE infection in the LT recipient include intra-abdominal, organ space, hepatobiliary, surgical site, bloodstream, and the urinary tract. Mortality due to VRE infections in LT recipients has previously been reported to be as high as 82%; this was, however, at a time when limited treatment options for VRE were available [184]. The use of linezolid and daptomycin, agents that have activity against such drug-resistant bacterial strains, has improved patient outcomes, although a 37.6% mortality has been reported in solid organ transplant recipients treated with linezolid for VRE infections [185].

Infections due to MRSA have been declining in the LT population, likely because of improved infection prevention practices such as strict implementation of hand hygiene, development of bundles for central venous catheter insertion and management, perioperative surgical site antiseptic policies, the use of daily chlorhexidine washes for select group of patients, and adherence to contact isolation policies [186]. A meta-analysis noted that there was 8.5% and 9.4% prevalence of MRSA colonization in pre- and post-liver transplant recipients, respectively. Additionally, pre- and post-transplant colonization was associated with six- to eleven-fold higher probability for subsequent development of MRSA invasive disease [179]. A single-center study reported 23% MRSA infection in LT recipients over an 8-year period; central vascular catheters, surgical wound, intra-abdominal space, and the lung were the most common sites of infection. Furthermore, the authors noted a 21% 30-day mortality in patients with MRSA infections [187]. Vancomycin continues to be the mainstay of treatment against MRSA; daptomycin and linezolid are being used with increasing frequency in select high-risk patients. Ceftaroline, the first cephalosporin with activity against MRSA, is approved for skin and soft tissue infections, and bacterial pneumonia, and may offer an alternative treatment option for MRSA infections in the LT patient population pending further clinical data.

The growing threat of MDRO infections in LT recipients can certainly affect patient outcomes. Therefore, emphasis on infection prevention and antibiotic stewardship is vital to limit further increases in antibiotic-resistant HAIs in patients undergoing a transplantation procedure [188]. This multidisciplinary approach has been shown to decrease surgical site infection rates by 52% in solid organ transplant recipients [189].

Infection due to *Clostridium difficile* has become an important healthcare-acquired pathogen with high morbidity and risk of death. The combined effect of potent immunosuppression and broad-spectrum antibiotic exposure increases

the risk of *Clostridium difficile*-associated colitis during the early post-LT period. In a retrospective study of 1340 solid organ transplant recipients, the cumulative incidence of *C. difficile* colitis was highest (3%) in liver allograft recipients [190]. In a series of 467 LT recipients, incidence was 8%, with the majority of cases occurring within the first month following transplantation [191]. Another single-center retrospective study observed an incidence of 14% for *C. difficile* infection over a mean follow-up time of 1.8 years after LT; 41% of these cases occurred within 1 week after transplantation. The authors reported that most patients with *C. difficile* colitis had fever, whereas white blood cell count was less than 12,000 cells per μL [192].

Fungal Infections

In addition to bacterial infections, C*andida* spp. are a significant pathogen in the early post-transplant period. In a prospective multicenter investigation of invasive fungal infections following solid organ transplantation, 639 such cases among nearly 17,000 patients under surveillance were observed during the 6-year study period. Liver allograft recipients were at a high risk (41%) among this large cohort of SOT recipients. Fungemia was prominent (44%) disease presentation followed by intra-abdominal infection (14%). *Candida albicans* and *Candida glabrata* species constituted the majority of infections (46% and 24%, respectively) [193].

In the general population, the known risk factors for developing invasive *Candida* infection include extended treatment with broad-spectrum antibiotics, presence of central venous catheter, use of total parenteral nutrition, presence of severe neutropenia (ANC <500 cells per μL), diabetes mellitus, renal replacement therapy, mechanical ventilation, and intensive care stay. In transplant patients, recent CMV infection, primary graft failure, early surgical re-exploration, and colonization with *Candida* spp. during pre- and early post-transplant period are additional risk factors of invasive candidiasis. In LT recipients specifically, choledochojejunostomy is associated with a higher risk of invasive candidiasis compared to a choledochocholedochostomy anastomosis, as the former requires opening of the bowel [194]. Also, prophylaxis for spontaneous bacterial peritonitis with fluoroquinolones has been found to be an independent risk factor for invasive candidiasis in patients undergoing LT [195].

Diagnosis of invasive *Candida* infection is definitive when cultured from a sterile site; however, routine blood cultures lack optimal sensitivity, and often diagnosis can be missed or delayed. Detection of β-D-glucan, a polysaccharide component of fungal cell walls, can be a useful adjunctive test. However, in a multicenter analysis among LT recipients, β-D-glucan was not a reliable test for the diagnosis of invasive fungal disease [196]. Treatment for *Candida* spp. infection in liver transplant recipients is similar to the general population [197]. Source control, including removing central venous catheters when determined as the source of fungemia, remains important for successful clearance of fungemia.

Given the high frequency of invasive *Candida* infection in LT population, antifungal prophylaxis after transplant surgery may be considered among patients at increased risk for fungal disease. A randomized, double-blind, placebo-controlled trial of fluconazole prophylaxis vs. no antifungal prophylaxis after LT demonstrated a decreased rate of fungal colonization and both superficial and invasive fungal infection, although no difference in mortality was found [198]. Current guidelines recommend stratification based on specific risk factors. Patients are deemed high risk for invasive candidiasis, if they have ≥2 of the following conditions: prolonged or repeat operation, retransplantation, renal failure, ≥40 units of cellular blood products, choledochojejunostomy, or *Candida* spp. colonization in the perioperative period [188]. In one series including 30 pre-LT candidates, 81% were found to have *Candida* carriage in gastrointestinal tract [199]. High-risk patients are recommended to be treated with an antifungal medication. Fluconazole 400 mg daily is sufficient for most *Candida* spp. coverage, though, notably, prevalence of non-*albicans Candida* spp. have increased and such infections are associated with higher mortality in the immunosuppressed host [194]. Duration of antifungal prophylaxis may vary by transplant center; however, 4-week duration is common. Prophylaxis may be extended based on ongoing risk factors. Recipients at low risk for invasive fungal infection may be observed without antifungal prophylaxis [200].

While *Candida* spp. constitute the majority of fungal infections during early post-LT period, *Aspergillus* spp. infections are rare, albeit a significant, pathogen. In case series and retrospective reviews, the incidence of invasive aspergillosis (IA) after LT may vary from 1% to 10% [201–203]. A multicenter surveillance network of transplant patients found an 11% incidence of IA over 5 years post-LT [204]. Multiple factors have been correlated with an increased risk of IA after transplantation. Retransplantation and the need for renal replacement therapy have the highest association [205]. It is theorized that injury to the hepatic reticuloendothelial phagocytes and alteration of platelet-mediated inflammation seen in patients with hepatic dysfunction increase susceptibility to tissue-invasive *Aspergillus* spp. infection [206, 207]. Renal failure may directly impact granulocyte and macrophage function or may be a marker for other predisposing factors in critically ill patients. Other factors that increase risk for IA in the initial 90 days post-LT include urgent transplantation, CMV infection, prolonged intensive care unit stay, additional surgery, and multiple invasive bacterial infections [208].

Historically, IA was most common in the first 90 days post-LT and may occur within 30 days after transplant surgery in patients at particularly high risk. However, recent

analysis has found a slight shift in the diagnosis of IA to later post-transplantation period (>90 days) [209]. This is speculated to be due to improved overall management of transplant patients, ranging from surgical techniques to improved infection prevention and surveillance protocols. In addition, CMV infection is a known risk factor for IA, and prophylaxis against CMV may have also contributed to shift the timing of IA. Recent cases also demonstrated significantly lower mortality than in the past from >90% down to 60%; however, IA associated with early retransplantation still carries a high mortality [205, 210].

Clinically, pulmonary IA is the most common manifestation followed by disseminated disease. Diagnosis can be challenging, as cultures have low sensitivity, since isolation of *Aspergillus* spp. in respiratory tract culture samples in most patients represent fungal colonization. Serum fungal assays such as galactomannan and β-D-glucan are increasingly utilized to help confirm or rule out IA; however, accuracy and reliability of these assays remain uncertain [195]. Positive *Aspergillus* antigen from bronchoalveolar fluid has been shown to have high specificity in lung transplant recipients [211]. A combination of clinical, microbiological, and radiographic findings along with hosts' susceptibility for these infections should be considered in making diagnosis of IA in patients following LT.

Treatment of IA in liver transplant recipients is similar to the general population, as outlined in the Infectious Diseases Society of America guidelines [212]. Given the high mortality and difficulty in ascertaining correct IA diagnosis in highly susceptible transplant patients, it is recommended to initiate anti-mold therapy when IA is strongly suspected, while work-up including tissue biopsy is in progress. Voriconazole is the drug of choice for primary IA; drug interactions may warrant modified dosing for certain antirejection drugs. Concomitant reduction of immunosuppression is ideal if feasible. Adjunctive surgery may be warranted in select cases. Duration is variable, but a minimum of 12 weeks is typically recommended; however, this should be extended based on clinical and radiographic treatment response, extent of the disease, and level of net immune suppression.

While universal prophylaxis for IA is not routinely recommended following solid organ transplantation, high-risk LT recipients have been shown to benefit from it [179, 200]. This targeted prophylaxis is correlated with decreased rates of IA and appears to be cost-effective. One retrospective single-center review found administering 90 days of voriconazole prophylaxis to high-risk patients post-LT had an institutional cost of 5.6% of the predicted cost for treating IA [213]. The best choice of prophylactic antifungal is not clear. Prior studies have investigated echinocandins, liposomal amphotericin B, and voriconazole [214–216]. Echinocandins are a common choice, given their ease of single daily dosing, minimal toxicity, and drug-drug interaction. The most suitable choice for anti-mold prophylaxis may vary depending on the clinical context.

Donor-Derived Infections

Unexpected donor-derived infections are a rare occurrence with an estimated incidence of 0.2% in solid organ transplant recipients [217]. As a result of current screening and prophylaxis practices, many viruses such as HIV, CMV, EBV, HBV, and HCV are identified early during the procurement period of the donor, and therefore, appropriate graft acceptance, infection surveillance, and when applicable treatment can ensue in the recipient. Unexpected donor-derived infections, although uncommon, can be an important complication particularly in the early post-transplant period. In addition to routine pre-transplant screening of the donor whether living or cadaveric allografts by history and laboratory screening, the procuring surgeon should carefully inspect the organ and donor for signs of infection by thorough physical examination. Surveillance cultures are typically sent that include blood, urine, and sputum samples. Peritoneal cultures may be warranted in cases of enterotomy and ascitic contamination to guide postsurgical antibiotic coverage [218]. Active infection in the cadaveric donor is not necessarily an absolute contraindication for transplantation; targeted antibiotics often can mitigate the risk. However, decisions are made on a case-by-case basis. Liver transplant recipients are particularly vulnerable to acquire bacterial infections via the allograft harvested from a donor with bacteremia; this possibly is related to the large tissue and vascular volume of the liver compared to other solid organ transplants [219]. Antibiotic prophylaxis may need to be extended in high-risk scenarios, such as donors with infective endocarditis and meningitis [220]. If an active bacteremia is diagnosed in the donor, the liver may still be used safely, provided that the donor has received appropriate treatment for the infection for 48 h and that the recipient receives at least 14 days of targeted treatment against that infection following transplantation [217, 221]. Guidelines suggest that for virulent pathogens that can cause endovascular infections such as *Staphylococcus aureus* and *Pseudomonas aeruginosa*, 2–4 weeks of antibiotic therapy should be considered although prolonged course of antibiotic therapy in recipients of such allografts has not been clinically validated [222]. Isolation of bacteria at a distant tissue site, such as in sputum or urine, usually does not necessitate antibiotic therapy in recipients of such donor allografts, with the exception of liver grafts from donors with confirmed or suspected bacterial pneumonia or pyelonephritis [222]. In some infections, such as severe encephalitis of unclear etiology, allografts are typically excluded outright [223].

In addition to bacterial etiologies, reported donor-transmitted infections in LT have run the gamut and have included viruses, fungi, and parasites [224]. Uncommon

diseases may be challenging to diagnose, and donor origin among other possible exposure and potential infection transmission history should be considered for atypical post-transplant infection. Some less common viral infections that have resulted in allograft infection transmission include West Nile virus, lymphocytic choriomeningitis virus (LCMV), and rabies; these viruses have been associated with devastating neurologic morbidity and mortality in recipients of solid organ transplantation [139, 225, 226].

The most common fungal pathogens that can be transmitted from donor to recipient are *Candida* species, *Coccidioides immitis*, and *Cryptococcus neoformans* [222]. *Candida* can be derived from the organ donor, although transmission of *Candida* spp. to recipients occurs more typically from contamination during the organ procurement and preservation process [227–229]. Although donor transmission of any endemic mycoses is possible, donor screening for *Coccidioides immitis* is the only fungal serology that is routinely obtained in donors from endemic regions. Prophylaxis with an azole antifungal agent is recommended for LT recipients whose donor has a documented positive *Coccidioides* serology [226]. Recently, reports of infections due to *Cryptococcus neoformans* occurring in the early post-transplant period have raised possibility of potential donor transmission of the dimorphic fungal infection [226, 230–232]. Donor transmission of *Mycobacterium tuberculosis* has been well documented in the solid organ transplant population [217, 233]. Patients with active tuberculosis infection should not be considered for organ donation; however, latent tuberculous infection in a donor is not considered contraindication for organ procurement and transplantation. In this setting, treatment of latent tuberculous infection in the recipient will mitigate the risk of developing active tuberculosis after LT.

Strongyloides stercoralis and *Trypanosoma cruzi*, the causative agents of Chagas disease, are the most common parasites that have been associated with donor-transmitted parasitic infections. In the solid organ transplant recipient, *Strongyloides* can lead to accelerated intestinal infection increasing the risk for polymicrobial bacteremia and bacterial meningitis due to enteric Gram-negative bacilli (GNB) or the rare devastating *Strongyloides* hyperinfection syndrome, which is associated with rapidly progressive respiratory failure and death. As a result, donor screening with *Strongyloides* serology should be performed in donors from endemic regions such as tropics, subtropics, and Appalachia, USA; if serology is positive, recipients should be treated with ivermectin [234, 235]. *Trypanosoma cruzi* donor-derived infection is more problematic in patients undergoing heart transplantation; donor serologic screening for *T. cruzi* should be considered for liver allograft donors from endemic regions including Mexico and Central and South America. If a donor is positive for *T. cruzi* serology, there is no clear contraindication for liver transplantation, as long as the LT recipient undergoes regular surveillance for parasitemia. Preemptive treatment with benznidazole is initiated for patients with a positive *T. cruzi* PCR assay [236, 237].

Stored pre-transplant serum from both donor and recipient can be used to test and help confirm allograft-transmitted infection. Close collaboration with the national transplant authorities, the local organ procurement organizations, and appropriate public health agencies is vital for tracking these infections and to notify all other organ recipients from such donors.

Opportunistic Infections 1 to 6–12 Months After Liver Transplantation

After the first month, surgical recovery is well underway, and nosocomial infections become less prevalent. However, iatrogenic antirejection drug-induced immunosuppression is still high, and thus opportunistic infections are considered especially common from 1 month to 6–12 months after LT. Without prophylaxis, herpesviruses such as herpes simplex virus 1 and 2, varicella zoster virus, and cytomegalovirus, and environmental fungi like *Pneumocystis jirovecii* are important pathogens.

Cytomegalovirus (CMV) is the most important viral infection in LT recipients and contributes to significant morbidity and mortality in this patient population. CMV can manifest from asymptomatic viremia, to a syndrome associated with fevers and pancytopenia, to invasive target organ disease. In LT recipients, the gastrointestinal tract is the most common site of CMV involvement and can present as esophagitis, gastritis, and enterocolitis but can also involve other sites such as the lungs [238]. CMV has a predilection to involve the allograft, and therefore CMV hepatitis is an extremely common manifestation in LT recipients and can sometimes be confused with allograft rejection [239]. The incidence of CMV infection in LT recipients varies depending upon the risk group studied, with rates of 18–29% overall; however, it has been reported to be as high as 65% in the high-risk donor-recipient mismatch (D+/R−) [240–243]. The use of CMV prophylaxis with ganciclovir or valganciclovir in LT recipients for at least 3 months post-transplantation has reduced the incidence in the D+/R− subgroup to 12–30% [241, 243–246]. Historically, in LT recipients who do not receive CMV prophylaxis, CMV infection occurs within 3–6 months from the time of liver transplantation, which correlates with the period of maximal immunosuppression. However, in the setting of CMV prophylaxis, LT recipients can experience delayed-onset (also referred to as late-onset) CMV disease – after CMV prophylaxis has been discontinued – often occurring >6 months from the time of transplant [247, 248]. Delayed-onset CMV infection in LT recipients is

more likely to cause tissue-invasive disease as compared to early-onset disease [248].

As CMV is an immunomodulatory virus, it has numerous indirect effects on the liver allograft. CMV can upregulate alloreactive T cells, and it can precipitate allograft rejection. In LT recipients, it has been thought to be associated with the vanishing bile duct syndrome, chronic ductopenic allograft rejection, cholestasis, and ultimately allograft failure [249–252]. Chronic CMV infection, in the setting of immunosuppression, may be related to atrophy of the biliary ducts and the development of allograft arteriopathy that is seen with chronic allograft failure [253]. It is also postulated that as CMV can invade the vascular endothelium, it may be responsible for hepatic artery thrombosis [254, 255]. Finally, CMV infection can further augment the immunosuppression of transplant patients and places LT recipients at increased risk for bacterial, viral, and fungal infections, as well as increased risk for EBV-associated post-transplant lymphoproliferative disorder (PTLD) [256–258].

Risk factors for CMV infection include CMV D+/R− mismatch, lymphocyte-depleting agents such as thymoglobulin and alemtuzumab, high-dose mycophenolate mofetil, genetic polymorphisms in the toll-like receptor 2 gene, allograft rejection, and retransplantation [259, 260]. Initial infection is significantly more likely to cause symptomatic illness than reactivation [261]. There are two accepted strategies for prevention. Universal prophylaxis with valganciclovir is one approach and has the added benefit of prophylaxis against other herpesviruses. A duration of 3–6 months of prophylaxis is typical but may be extended based on clinical factors [262]. Alternatively, a preemptive approach utilizes weekly monitoring for CMV antigenemia or PCR, with prompt initiation of treatment for early replication; this strategy may be preferable for avoiding drug toxicity. There is no definitive recommendation of one approach over the other, although universal prophylaxis is preferred in high-risk transplantations – specifically CMV D+/R− allograft mismatches. A meta-analysis comparing the two in the LT population found no difference in the incidence of CMV disease. Using indirect comparison, there was also no difference in acute cellular rejection or mortality between the two groups, but a decreased incidence of graft loss with universal prophylaxis was found [263]. Treatment of CMV infection with either oral valganciclovir or intravenous ganciclovir in LT recipients is similar to other SOT recipients. Resistance to ganciclovir is rare, but more likely in patients with past prolonged use of ganciclovir [264].

Pneumocystis jirovecii is ubiquitous in the environment but transforms to a common respiratory pathogen for the immunosuppressed. Without prophylaxis, the incidence of infection in LT recipients has been found to vary from 1% to 11% [265]. Clinical presentation in SOT recipients is similar to individuals with human immunodeficiency virus (HIV), though the acuity of symptoms is typically thought to be more severe in non-HIV patients. Treatment approach is also similar to HIV patients, with trimethoprim-sulfamethoxazole (TMP/SMX) being the drug of choice and adjunctive steroids a consideration based on hypoxemia [266]. Prophylaxis against *Pneumocystis* is routinely recommended for the first 6–12 months in all SOT patients and may be extended as needed based on ongoing risk [267]. TMP/SMX is the first choice for prophylaxis and has the added benefit of helping to prevent other opportunistic pathogens, such as *Toxoplasma gondii*, *Listeria monocytogenes*, *Nocardia* spp., *Isospora*, *Cyclospora*, and some bacterial agents.

With prophylaxis for the most prevalent infections being standard, their incidences have overall been reduced, but can still occur, typically after the prophylactic course has ended. Endemic fungi and *Mycobacterial* spp. including *M. tuberculosis* are also not uncommon pathogens during this post-transplant period. During the time of maximal immunosuppression (1–6 months after transplantation), reactivation of endemic mycoses can occur but oftentimes present later after transplantation and may be due to exogenous infection. *Cryptococcus neoformans* is the third most common fungal infection in solid organ transplant recipients, with an incidence that ranges from 0.2% to 5% [268, 269]. In general, cryptococcosis is a late infectious complication, occurring a median of 16–21 months after transplantation, although in liver and lung transplant recipients, it can present earlier – within 12 months post-transplantation [269–271]. The most common sites of infection are the lungs and the central nervous system, although cutaneous, liver, kidney, and osteoarticular involvement can also occur. Disseminated and extrapulmonary cryptococcosis has been reported in 50–75% of solid organ transplant recipients [271–273]. Liver transplant recipients have a sixfold increase risk for disseminated disease as compared to other types of transplant recipients [269]. The diagnosis and management of cryptococcosis in solid organ transplant recipients have been extrapolated from other patient populations (such as HIV) and retrospective/observational experience and are available as practice guidelines from the Infectious Diseases Society of America and the AST Infectious Diseases Community of Practice. Initial treatment with a lipid preparation of amphotericin B and flucytosine, followed by fluconazole maintenance treatment, is recommended [269, 274].

The true incidence of endemic mycoses in the solid organ transplant population is not well defined, but infections due to *Histoplasma capsulatum*, *Coccidioides immitis/posadasii*, and *Blastomyces dermatitidis* have been well recognized. All of these infections can occur as a result of reactivation or as an exogenous new infection. *Histoplasma capsulatum* is a soil-based pathogen which has been well recognized to be endemic in the Ohio-Mississippi River Valley region of the USA. Histoplasmosis is a relatively uncommon infection in

solid organ transplant recipients, with an incidence of <1%, even in endemic regions. Histoplasmosis usually presents within the first 2 years after transplant, but there can be wide variability regarding the time of presentation [275–278]. In solid organ transplant recipients, it presents as progressive disseminated histoplasmosis that includes pulmonary and extrapulmonary manifestations such as hepatosplenomegaly, pancytopenia, and gastrointestinal and mucosal involvement. Coccidioidomycosis is endemic in the southwestern states including Southern California, as well as Mexico, and Central America. Most cases occur within the first year of transplant, with a reported incidence of 1.4–6.9% in endemic regions [279]. Due to depressed cellular immunity in solid organ transplant recipients, severe pneumonia, as well as dissemination to skin, bones, joints, meninges, and organ allograft can occur [280–283]. Patients with a prior history of coccidioidomycosis or a positive *Coccidioides* serology prior to transplantation should receive fluconazole prophylaxis after transplantation [280]. The endemic regions for blastomycosis include the Midwest, south central and southeastern regions of the USA, and provinces of Canada along the waterways. Blastomycosis is rare in solid organ transplant recipients, and an incidence of only 0.14% was noted over a 16-year observational period [284]. The treatment for the endemic mycoses includes a lipid preparation of amphotericin B and the azoles, and recommendations and guidelines for the diagnosis and management have been established [280].

Overall, a range of opportunistic infections may occur during this time of high immunosuppression post-LT, warranting a broad differential for patients presenting with infectious symptoms [285].

Community-Acquired/Late Infections

Beyond 6–12 months, graft function has ideally stabilized, and immunosuppressive medications can slowly be minimized. This decreases the net state of immunosuppression and consequently the risk of opportunistic infections; however, there is always some ongoing risk. Infections during this phase are typically community-acquired. A 5-year study at a large transplant center found a prevalence of 183 hospitalizations for infectious complications post-LT, with 145 (79%) occurring in the post-6-month period. The same study found respiratory infections to be the most frequent etiology overall for solid organ recipients, accounting for 26.9% of late infections. The next most common etiologies were sepsis/bacteremia (13.1%), liver/biliary tract (12.4%), genitourinary (12.2%), CMV (7.5%), and fever of unknown origin (8%) [286]. Community-acquired infections in post-transplant patients may also present with more severe clinical manifestations [287]. Less common pathogens, such as fungi, parasites, and mycobacteria, are also seen in the post-6-month period, sometimes related to diminished vigilance for environmental exposure prevention over time. Infections due to *Nocardia* spp. are relatively uncommon, with an overall incidence of 0.7–3.5% in solid organ transplant recipients and only a reported incidence of 0.1% in LT recipients [288–290]. The median time to the onset of *Nocardia* infection in a European cohort was 17.5 months after transplantation, and infection was associated with corticosteroid use, tacrolimus use, and elevated calcineurin trough levels within the preceding month; interestingly, the use of TMP/SMX was not protective [291]. Recently there has been an emergence of non-*Aspergillus* mold infections in the solid organ transplant patient population. The occurrence of these mold infections can have a bimodal distribution, and in one study, 37.8% occurred within 6 months of diagnosis, and 33% occurred >2 years from the time of transplantation. In that same study, the median time to development of an invasive mold infection in the LT recipients was 81 days [292]. The most common non-*Aspergillus* molds were the *Mucorales*, *Fusarium* spp., and *Scedosporium* spp. The most common sites of infection for these molds were the lungs, sinuses, skin, and dissemination to the central nervous system. The dematiaceous molds that include *Exophiala*, *Alternaria*, *Dactylaria*, *Curvularia*, *Cladophialophora*, *Verruconis gallopava*, and others have been reported in the solid organ transplant populations as case reports and small case series [293]. This group of molds most often manifests as skin and soft tissue infections but can disseminate to the central nervous system. In one case series, the median time to onset was 22 months after transplantation, and the cutaneous presentation was associated with a good outcome [294].

Viral infections associated with the presence of chronic immunosuppression can also occur and include late-onset CMV infection, EBV-associated PTLD, JC virus infection associated with progressive multifocal leukoencephalopathy (PML), and HHV-8 infection associated with Kaposi's sarcoma. Liver transplant recipients have an intermediate risk for the development of EBV-associated PTLD as compared to other solid organ transplant recipients. One center reported an incidence of PTLD in 6.3% of their pediatric LT recipients and an incidence of 1.2% in the adult LT recipients [295]. The cumulative incidence of PTLD in LT recipients has been estimated to be 1–2% over 5 years [296]. The highest risk factors for EBV-associated PTLD is due to primary infection as a result of an EBV D+/R− mismatch, in addition to a higher level of immunosuppression [297]. While the majority of cases occur within 1 year of transplantation, a 0.25% incidence has been noted in LT recipients at 1 year. Guidelines and recommendations have been established for the monitoring, diagnosis, and management of EBV-associated PTLD [298].

Infection with *Mycobacterium tuberculosis* (MTb) can occur during the period of maximal immunosuppression and well beyond that time period. Treatment of active MTb in all solid organ recipients poses a challenge for drug dosing, due to the strong interaction between rifampin (and other rifamycins) and calcineurin inhibitors or rapamycin. For LT recipients in particular, the likelihood of drug-induced hepatotoxicity is increased, warranting careful medication management [298]. Substitution of one or more first-line drugs may be needed, based on the liver function at baseline and during the course of treatment; frequent lab monitoring and consultation with a MTb expert is advised [143]. Directly observed therapy is generally preferred for transplant recipients and is vital when alternative regimens are employed. Some experts recommend a minimum 9-month treatment course for all solid organ transplant patients, due to a concern for increased mortality with shorter courses [299].

Individuals with chronic allograft dysfunction requiring higher maintenance immunosuppression should be considered at ongoing high risk for opportunistic disease and thus continued on appropriate prophylaxis as necessary.

Prophylaxis/Prevention of Infections

As detailed above, there are standard screening recommendations and protocols for prophylaxis against the most common opportunistic pathogens, particularly *P. jirovecii*, *CMV*, and *Candida* spp. Vaccination is another crucial prevention strategy. Despite the clear preventive benefits, vaccination rates have been suboptimal in LT recipients [300]. Due to chronic immune dysfunction, patients with advanced liver disease may have diminished antibody response to vaccination [301]. Consequently, it is advisable to administer vaccines as early as indicated [302]. Live vaccines are generally contraindicated post-transplant.

National guidelines for perioperative antibiotics recommend piperacillin-tazobactam or cefotaxime plus ampicillin as standard prophylaxis in liver transplantation; however, individual centers may vary their protocol [303]. A 4-year single-center review found that 53% of surgical site infections were caused by multidrug-resistant bacteria, emphasizing the need for a tailored prophylactic approach, based on patients' histories and local antibiotic resistance patterns [157].

Relapse of HBV and HCV Post-liver Transplantation

HBV reinfection rates of the allograft were previously reported to range between 80% and 100% in the 1980s. Based on 2-year graft survival of only 50%, many centers discontinued offering OLT in this population for a time [304]. Additionally, in the absence of antiviral therapy, some patients have developed fibrosing cholestatic hepatitis, a rapidly progressive and often fatal condition [305]. However, the introduction of HBIG and antiviral medications in the late 1980s has significantly improved post-transplant survival in such patients.

There are several risk factors for HBV reinfection after liver transplant. Patients at higher risk include those with positive hepatitis B e antigen (HBeAg), negative HBeAg but high HBV DNA level, or history of pre-transplant antiviral drug resistance. Patients at lower risk include those with cirrhosis and low HBV DNA level with or without antiviral medication, coinfection with hepatitis delta virus (HDV), or fulminant HBV infection [306].

Subclinical HBV reactivation has been reported in HBsAg-negative and HBcAb-positive recipients who have received livers from HBsAg-negative and HBcAb-negative recipients. However, this low-grade viral replication has not been associated with the development of positive HBsAg or active viral hepatitis. Therefore, antiviral therapy is not indicated in this scenario [307].

HCV infection recurs in the allograft in greater than 95% of HCV+ liver allograft recipients [308]. Advanced donor age and high-intensity immunosuppression such as the use of bolus steroids or thymoglobulin can influence the severity of HCV recurrence after OLT [309, 310]. Although the course of HCV recurrence may be variable after liver transplant; up to 20% of patients develop allograft cirrhosis within 5 years of transplantation [311]. HCV+ recipients have demonstrated lower patient and graft survival when compared to patients transplanted for other indications. HIV coinfection has also correlated with diminished post-transplant survival. Fibrosing cholestatic hepatitis is a rapidly progressive condition that develops in 5–10% of HCV+ liver transplant recipients, at times within the first year after transplant, and often leads to diminished survival [312]. Differentiating recurrent HCV from ACR can be difficult due to overlapping histologic features, but certain findings such as lobular or interface hepatitis and lymphoid follicles may be more suggestive of HCV infection.

HBV Prophylaxis

All patients with HBV infection prior to transplantation should be continued on antiviral therapy after undergoing OLT. Additionally, patients without HBV infection who receive livers from isolated HBcAb+ donors should also be started on antiviral therapy. Most often either entecavir or tenofovir are utilized, and the choice of a specific agent is made based on prior treatment history and side effect profiles of individual antiviral drug.

The role of HBIG in the current era remains unclear. Prior to the discovery of potent antiviral agents, HBIG was often used long-term as standard prophylaxis with reduction in the risk for HBV recurrence [313]. However, high-dose intravenous HBIG is expensive and may not provide additional benefit compared to the use of oral antiviral agents alone, especially in low-risk patients. In high-risk patients, HBIG may be discontinued after 1 year following transplantation.

HCV Treatment Post-liver Transplantation

Ideally, most patients with HCV should be treated with antiviral therapy prior to transplant. However, pre-transplant antiviral therapy may be difficult to tolerate and less effective in patients with decompensated cirrhosis. Specifically, the use of protease inhibitors for HCV is generally not recommended in patients with decompensated cirrhosis.

Currently, there are several options for treatment of genotype 1 HCV in post-OLT patients. Ledipasvir/sofosbuvir combination therapy after OLT with weight-based ribavirin for 24 weeks has been associated with a 96% SVR12 rate in patients with Metavir fibrosis stage F0 to F3 or those with compensated cirrhosis. In patients with decompensated cirrhosis, SVR rates range between 60% and 88% depending on degree of hepatic impairment [314]. Simeprevir and sofosbuvir with or without ribavirin for 12–24 weeks has been associated with SVR12 rates greater than 80% in both cirrhotic and non-cirrhotic patients [315, 316]. Daclatasvir in combination with sofosbuvir with or without ribavirin for 24 weeks after OLT demonstrated a 91% SVR12 rate in patients with severe recurrent HCV infection. The SVR12 rate was notably lower when daclatasvir was administered with simeprevir with or without ribavirin for 24 weeks [317]. The fixed-dose PrOD combination (paritaprevir, ritonavir, ombitasvir, dasabuvir) with ribavirin for 24 weeks resulted in a 96% SVR24 rate in patients with mild fibrosis, in whom the treatment commenced after transplantation [318]. CNI troughs must be monitored carefully with the use of simeprevir or paritaprevir. Newer regimens including elbasvir/grazoprevir and sofosbuvir/velpatasvir have yet to be studied in liver transplant population with HCV infection.

There are limited data for non-genotype 1 HCV infection in patients undergoing OLT. Daclatasvir in conjunction with sofosbuvir with or without ribavirin can be used in patients with genotype 2 or 3 HCV infection. Patients with genotype 4 HCV can be managed with either ledipasvir/sofosbuvir given with or without ribavirin or daclatasvir and sofosbuvir along with or without ribavirin. Sofosbuvir/velpatasvir has pangenotypic coverage and may be another option, although data in OLT recipients have yet to be reported.

Other Hepatitis Virus Infections After Transplantation

Hepatitis A Infection After Liver Transplant

Hepatitis A virus (HAV) is contracted through a fecal-oral route. Although most patients with HAV experience a self-limited course, acute liver failure may develop in less than 1% of infected individuals. Patients over 50 years of age and those with other chronic liver diseases are at higher risk to develop fulminant liver failure [319]. Accordingly, it is generally recommended that patients with chronic liver disease, including cirrhosis, should be vaccinated in the pre-transplant setting. Despite vaccination, a subset of anti-HAV IgG+ patients may lose anti-HAV IgG antibodies within the first 2 years after liver transplantation [320]. Whether loss of the anti-HAV IgG antibodies correlates with true loss of immunity and need for booster immunization(s) remains unclear. HAV vaccine is safe to administer in the post-transplant setting, although serologic response is often lower than seen in patients vaccinated prior to undergoing allograft transplantation [321]. Assuring receipt of two vaccine doses and deferring vaccination to a later time when the patient is on a lower level of immunosuppression may improve serologic response in patients requiring further vaccine doses after transplantation [322, 323]. The specific implications of HAV infection in patients undergoing liver transplantation are not well described. However, as this patient population tends to be older, and may develop chronic liver disease following OLT, the risk for severe HAV infection may be greater. Additionally, chronic drug-induced immunosuppression may promote HAV replication by subverting hosts' immune surveillance.

Hepatitis E Infection After Liver Transplant

Infection from the hepatitis E virus (HEV) was previously thought to be an uncommon disease in Western countries. Past reports had described a self-limited illness, which is noted more often in developing regions in Asia and Sub-Saharan Africa. However, HEV is being increasingly diagnosed in Europe and the USA, particularly over the past decade. Complications such as fulminant liver failure or severe hepatic decompensation have been described in a small minority of patients, particularly those who are pregnant or have chronic liver disease [324–326].

Traditionally, HEV transmission has been attributed to consumption of contaminated water and/or food, including pork products or venison. Due to its perceived rarity, most Western countries have not routinely tested blood or organ donors for HEV. However, a case of HEV transmission during blood transfusion was described in a patient following

liver transplantation [327]. Additionally, there have been reports of potential cases of liver allograft-transmitted HEV infection with subsequent development of chronic hepatitis and cirrhosis of the transplanted allograft [328, 329].

In most immunocompetent individuals, HEV tends to cause an acute infection that resolves spontaneously. In contrast, chronic HEV infection defined as persistence of viral infection for greater than 3 months has been described in greater than 60% of solid organ transplant recipients following a primary HEV infection during the post-transplant period [330]. Among solid organ transplant (SOT), recipients of liver allografts are considered at highest risk for chronic HEV infection. Most infections are due to HEV genotype 3. In such patients, persistent HEV infection after transplantation may increase the risk for rapidly progressive hepatic fibrosis which may ultimately result in graft failure [331]. Extrahepatic manifestations of HEV infection such as cryoglobulinemia have also been reported in patients, including those who have undergone solid organ transplantation [332].

Studies from France have shown that incidence of HEV in patients undergoing OLT ranges between 2.8 and 4.8 per 100 person years [333, 334]. Due to the variable sensitivity of HEV-IgM assays and delayed IgG response after transplantation, HEV RNA may be a more useful test for the diagnosis of chronic HEV infection in such patients [335]. Furthermore, it is important to note that SOT recipients may still contract new HEV infection despite the presence of pre-transplant anti-HEV seropositivity [126].

Diagnosis of new HEV infection after transplantation should prompt a reduction in antirejection drug-related immune suppression; nearly a third of transplant recipients may resolve HEV chronic infection with this measure alone [123]. Specific immunosuppressive medications may correlate with risk of HEV persistence in transplant patients. In vitro studies have demonstrated increased HEV replication in the setting of tacrolimus, cyclosporine, and mTOR inhibitors [336, 337]. However, in one clinical study, liver or kidney transplant recipients who developed chronic HEV infection were more likely to have been on tacrolimus rather than cyclosporine [123]. In contrast, in vitro studies have demonstrated that mycophenolate mofetil reduces HEV replication, and this finding has been correlated in a clinical study where heart transplant patients taking mycophenolate mofetil were more likely to clear post-transplant HEV infection [338]. Corticosteroid use does not appear to affect HEV replication [129].

Patients with persistent HEV infection even after reduction of immunosuppression are candidates for antiviral therapy. In solid organ transplant recipients, ribavirin at a dose of 8 mg/kg given for at least 3 months can lead to sustained virologic response in the majority of patients [339]. Dose adjustments may be necessary based on renal function and during the course of therapy if patients develop medication-induced anemia. Smaller studies have demonstrated that PEG-interferon alpha over a 3–12 month period may lead to viral clearance, although treatment is associated with significant adverse effects and may precipitate graft rejection [340, 341].

Acknowledgments The authors express their deepest appreciation to Jonathan Kumar for his assistance with manuscript preparation.

Infections in Kidney and Pancreas Transplantation

4

Megan K. Morales, Matthew Cooper, Peter Abrams, and Joseph G. Timpone Jr.

Abbreviations

AB	Asymptomatic bacteriuria
ATG	Antithymocyte globulin
BKPyV	BK polyomavirus
CDI	Clostridium difficile infection
CMV	Cytomegalovirus
CNI	Calcineurin inhibitors
CRAB	Carbapenem-resistant *Acinetobacter baumannii*
DAA	Direct-acting agent
EBV	Epstein-Barr virus
eGFR	Estimated glomerular filtration rate
EIA	Enzyme immunoassay
FDA	Food and Drug Administration
FQ	Fluoroquinolone
HBV	Hepatitis B virus
HCV	Hepatitis C virus
HIV	Human immunodeficiency virus
HLA	Human leukocyte antigen
HRD	High infectious risk donor
HSV	Herpes simplex virus
ICU	Intensive care unit
IGRA	Interferon-gamma release assay
INH	Isoniazid
IPA	Invasive pulmonary aspergillosis
IVIG	Intravenous immunoglobulin
KDIGO	Kidney disease: improving global outcomes (clinical practice guidelines sponsored by the National Kidney Foundation)
KPC	Klebsiella pneumoniae carbapenemase
KS	Kaposi sarcoma
MDR	Multidrug resistant
MDRO	Multidrug-resistant organism
mTOR	Mammalian target of rapamycin
NAT	Nucleic acid testing
OI	Opportunistic infection
OKT3	Muromonab-CD3
OPO	Organ procurement organization
OPTN	Organ Procurement and Transplantation Network
PAK	Pancreas after kidney
PCP	Pneumocystis pneumonia
PCR	Polymerase chain reaction
PEP	Postexposure prophylaxis
PF	Perfusion fluid
PPFC	Peripancreatic fluid collection
PTA	Pancreas transplant alone (i.e., not combined with renal transplantation)
PTLD	Posttransplant lymphoproliferative disorder
QALY	Quality-adjusted life year
RNA	Ribonucleic acid
SOT	Solid organ transplant
SPK	Simultaneous pancreas-kidney transplant
SRTR	Scientific Registry of Transplant Recipients
SVR	Sustained virologic response
TB	Tuberculosis
TMP-SMX	Trimethoprim-sulfamethoxazole
UNOS	United Network for Organ Sharing
UTI	Urinary tract infection
VZV	Varicella-zoster virus
WNV	West Nile virus

Introduction

The primary indication for kidney transplantation is end-stage renal disease (ESRD) severe enough to require renal replacement therapy (RRT; e.g., dialysis) to sustain an individual's life. Kidney transplantation results in improved patient survival and improved quality of life when compared to patients who remain on renal replacement therapy. Unfortunately, the demand for organs greatly outweighs kidney availability, a trend which has persisted over the past several decades. In 2015, the national Organ Procurement and Transplantation Network/Scientific Registry of Transplant Recipients (OPTN/SRTR) reported that 97,680 patients were on the waiting list, of which 61,234 were active [1]. The SRTR estimates that approximately 50% of listed patients have been on dialysis for at least 4 years [1]. Briefly, there are three types of kidney transplants which include (1) deceased donor kidney transplant, (2) living-related donor kidney transplant, and (3) living-unrelated donor kidney transplant. A total of 18,597 adult and pediatric kidney transplants including multi-organ transplantation occurred in 2015, of which 5626 were living donor transplants [1]. Regardless of the kidney transplant type, kidney transplantation offers a survival benefit as compared to patients on either hemodialysis or peritoneal dialysis. This survival advantage is likely due to the incorporation of better immunosuppressive regimens, improved management of the medical comorbidities in the posttransplantation period, and improved preventive and treatment strategies for infectious complications during the posttransplantation period. Renal allograft and patient survival statistics can be found at https://optn.transplant.hrsa.gov/data/view-data-reports/national-data/#. In general, renal allograft and patient survival rates are better for living-related donor type versus deceased donor type renal allograft. Deceased donor 5-year renal allograft and patient survival are 74.3% and 82.9%, respectively, while living donor 5-year renal allograft and patient survival are 85.5% and 91.9%, respectively.

More than 40% of ESRD in the United States is secondary to diabetes mellitus (DM)-related nephropathy, for which select patients are candidates for pancreas transplantation. The three forms of pancreas transplantation include simultaneous pancreas kidney (SPK), pancreas after kidney (PAK), and pancreas transplant alone (PTA); all achieve similar endpoints of curing an individual's insulin-deficient DM, preventing diabetic nephropathy and halting and often reversing the secondary complications of DM including retinopathy, neuropathy, gastroparesis, ketoacidosis, and hypoglycemic unawareness. Most candidates for pancreas transplantation suffer from long-standing type 1 diabetes with risk for severe secondary complications. Select patients with type 2 DM who are insulin-deficient and demonstrate phenotypic features of type 1 DM can also benefit from pancreas transplantation.

A large number of patients whose progressive chronic kidney disease (CKD) eventually meets criteria for kidney transplantation will experience many years of medical decline. This clinical deterioration includes constitutional symptoms such as increasing fatigue and malaise associated with CKD-related anemia. Other comorbidities of CKD include progressive cardiovascular disease, peripheral and autonomic neuropathy, bone disease, and sexual dysfunction. The social and emotional toll of CKD is extensive and profound, affecting not just patients but also their dependents and extended family. The transplant center assessment, therefore, focuses on the spectrum of morbidity associated with CKD, including the medical, surgical, immunologic, nutritional, and psychosocial condition of each candidate for the purpose of discerning the risks of surgery and the introduction of immunosuppression versus the potential benefit that may be achieved through transplantation.

Transplantation Options

It is increasingly appreciated that an individual's overall state of health prior to transplantation is an important factor in determining their subsequent clinical outcome. Accordingly, understanding transplant surgical complications resulting in infection often requires a consideration of the underlying medical condition of the kidney or kidney/pancreas transplant recipient prior to surgery. The same risk factors for surgical site infection (SSI) that have been well enumerated by organizations such as the National Healthcare Safety Network (NHSN) similarly apply to kidney and kidney/pancreas transplant patients. These risk factors include age, obesity, malnutrition, prolonged preoperative hospitalization, infection at distal sites, cancer, hyperglycemia, immunosuppression, and duration of surgery [2]. Beyond these general risk factors, the immediate period after transplantation is critical in determining surgical risk of infection as the allograft organ(s) is recovering from perioperative ischemia-reperfusion injury and the recipient is receiving peak level immunosuppression therapy. Furthermore, the details of the surgical technique itself used in the transplant operation are highly relevant to surgical infectious complications.

The multidisciplinary team will determine which of the kidney transplant categories is most appropriate for a potential recipient and may include deceased donation from brain-dead deceased donor, donation after cardiac death, or high kidney donor profile index kidney or living donation from a related or unrelated donor. Based on projections of survival benefit following transplantation, an individual candidate may be suited for one or more of these transplant options. Of the three types of pancreas transplants noted above, SPK is performed most commonly to address the multiple morbidities of the diabetic transplant candidate

and shows superior survival compared to kidney transplant alone in this population [3].

Surgical Approaches and Complications

Except for one critical difference, the surgical approach is similar between kidney transplant and kidney/pancreas transplant. Both operations involve either midline or curvilinear incisions in the lower abdomen, with dissection and ligation of the inferior epigastric vessels, mobilization of the ipsilateral rectus muscle and gonadal structures, ligation of proximal and distal lymphatics in the ipsilateral iliac fossa, and mobilization of the ipsilateral common, external, and occasionally internal iliac arteries and veins. Both kidney and pancreas are connected to the iliac vessels for perfusion and venous drainage. The kidney transplant ureter is usually connected to the extraperitoneal portion of the bladder; rarely, the transplant ureter is insufficient in length to reach the bladder and is therefore connected to the recipient's native ureter. It is important to note that a standard kidney transplant does not involve opening the peritoneum and avoids contact with the bowel or other intraperitoneal organs. The kidney allograft is transplanted into the retroperitoneal space in either the right or left lower abdominal quadrants. There is preference to transplanting the kidney allograft on the left side in patients receiving an SPK or in anticipation of a PAK transplant. Conversely, in pancreas transplantation, the duodenal segment surrounding the head of the pancreas allograft is commonly connected intra-abdominally to the recipient's jejunum in a side-to-side configuration to accomplish enteric exocrine drainage. A minority of transplant surgeons prefer to connect the transplant duodenum to the recipient bladder.

When evaluating or risk-stratifying pancreas transplant recipients for surgical infectious complications, it is critical to know whether the pancreas transplant involves bladder or enteric exocrine drainage. The incidence of urinary tract infections (UTIs) is significantly higher with bladder drainage [4]. It is thought that the highly alkaline, bicarbonate-rich exocrine drainage of the pancreas leads to injury to the mucosal lining of the recipient bladder and the alterations in acid-base balance of the urine combine to cause higher rates of UTIs. The incidence of peritonitis is higher with bowel drainage, as leakage of pancreatic enzymes into the abdomen together with enteric leakage can lead to peritonitis and intra-abdominal abscess [5]. It is likewise critical to ascertain whether the pancreas transplant has encountered any technical complications. A high-volume pancreas transplant group reported a much higher incidence of bacterial and fungal complications in the cohort of patients who experienced any significant surgical complication [6]. For example, complications including hematuria and urethral stricture following bladder drainage may lead to UTIs, prostatitis, epididymitis, and pyelonephritis [7]. Furthermore, the readmission rate for pancreas transplant recipients is well-known to be much higher than for kidney recipients. This increased incidence results from higher rates of dehydration, increased rates of rejection, and increased rates of infection. Higher rates of hospitalization in the pancreas transplant population place these patients at higher risk for healthcare-associated infections (HAI).

Similar to pancreas transplant, recipients of kidney transplants with postoperative complications are at an increased risk of infectious complications. Well-described complications of kidney transplant include lymphocele, subcutaneous hematoma, peri-allograft hematoma, urine leak, and ureteral stricture. If not addressed in a timely fashion, all of these surgical complications can lead to allograft kidney dysfunction, and also secondary systemic infection in recipients can be life-threatening. An important factor that may affect initial allograft function is the cold ischemic time in deceased donor kidney allografts. After surgical removal of a kidney from a donor, it is placed in cold preservation fluid, prior to transplantation into the recipient; this period of time is known as the cold ischemic time (CIT). Prolonged CIT has been associated with delayed graft function and allograft failure. There is a proportional increase in allograft failure for each additional hour of CIT. There is a low rate of allograft failure of 4% within first year after transplantation with CIT of <36 h [8, 9]. While a threshold CIT has not been established, a typical cutoff time is 24 h but may be extended up to 48 h at the discretion of the transplant center.

An important factor that could contribute to early risk of infection, specifically UTI or allograft pyelonephritis, is the placement of a ureteral stent. Ureteral stents may be selectively placed at the time of surgery to prevent a ureteral stricture occurring from a prolonged CIT in a deceased donor kidney allograft. Ureteral stents in the absence of persistent urinary leak are typically removed via cystoscopy 3–4 weeks following transplantation procedure.

Prompt diagnosis and intervention to correct the complications noted above is critically important, requiring ongoing close collaboration between the medical and surgical teams.

Immunosuppressive Regimens

A primary reason for the improved allograft survival of kidney and pancreas transplants in the modern era is the broad adoption of induction therapy at the time of transplantation of either organ. Compared to conventional immunosuppressive agent therapy alone, a large number of controlled-randomized trials demonstrate that induction therapy involving biologic antibodies in addition to conventional immunosuppression is superior in decreasing kidney and pancreas transplant rejection and allograft failure rates

[10]. An exception to this general rule is made for genetically identical donor-recipient transplants due to the significantly reduced immunologic risk for graft rejection in this relatively small cohort of patients. Induction agents can be classified as either depleting or nondepleting antilymphocyte agents. The optimal prophylactic induction therapy for kidney and kidney/pancreas transplantation remains controversial. In general, transplant centers in the United States use alemtuzumab or rabbit antithymocyte globulin (rATG) as first-line induction, both of which are lymphocyte-depleting agents but have very different mechanisms and side-effect profiles. Patients who cannot tolerate, or have mitigating circumstances that preclude, first-line induction will generally receive basiliximab induction, a nondepleting interleukin-2 receptor antagonist.

In addition to induction therapy, all recipients of kidney and kidney/pancreas transplants receive maintenance immunosuppressive therapy with a combination of agents including corticosteroids such as prednisone; calcineurin inhibitors like cyclosporine A, tacrolimus; mTOR inhibitors, everolimus, sirolimus; antiproliferative agents such as mycophenolate mofetil, mycophenolate sodium, or belatacept, a costimulation inhibitor. Although the optimal maintenance regimen remains unclear, well over 90% of solid organ transplant recipients in the modern era are discharged home on a regimen including tacrolimus as the primary maintenance drug. Tacrolimus is a calcineurin-inhibitor (CNI) drug that decreases organ rejection rates by inhibiting production of interleukin-2, a molecule that promotes development and proliferation of T cells in response to the detection of a foreign antigen. Maintenance immunotherapy is required in kidney and kidney/pancreas transplant recipients to prevent acute rejection and the loss of the allografts over the long term. The first year following transplantation is generally the period of highest immunosuppression levels. The overall level of immunosuppression is slowly reduced overtime, with many factors influencing this gradual taper including allograft function as well as history of rejection or infection.

Pretransplantation Issues Concerning End-Stage Renal Disease and Dialysis Patients

Of the approximately 120,000 people awaiting transplantation in the United States, the vast majority, over 99,000, await kidney transplants [11]. The majority of patients who undergo renal transplantation will have been on dialysis prior to transplantation, leaving them vulnerable to infection in the pretransplant setting that may impact their eligibility for transplantation or the course of the transplant itself. In 2014, 4761 patients died while waiting for a kidney transplant, and another 3668 people became too sick to receive a transplant [11, 12]. The median wait time for an individual's first renal transplant was 3.6 years and may be longer in certain regions of the country [12, 13]. Wait time continues to accrue if a patient is inactivated, as may happen while being treated for infection or completing pretransplantation evaluation; inactive patients now make up approximately 40% of those listed for transplant [14].

Infectious Complications of Hemodialysis and Peritoneal Dialysis

The major bacterial infections in patients on hemodialysis include catheter-related bloodstream infections and respiratory tract infections; infection is the second leading cause of death after cardiovascular causes in patients undergoing maintenance hemodialysis [15]. The rates of bloodstream infections vary, depending upon the type of hemodialysis catheter used, with arteriovenous fistulas having the lowest rates of infection. Catheter-related bloodstream infections have been reported to occur in 0.3/100 patient-months for native arteriovenous fistula, 0.7/100 patient-months for arteriovenous grafts, 4.6/100 patient-months for cuffed hemodialysis catheters, and 7.3/100 patient-months for non-cuffed hemodialysis catheters [16]. In the HEMO study, the authors noted that 21% of the first infection-related hospital admission was due to a vascular access infection [17]. The authors also noted that while only 7.6% of the study population had hemodialysis catheters for vascular access, these catheters accounted for a disproportionate amount of vascular access infections (32%), as compared to arteriovenous fistulas/grafts [17]. It has been estimated that there is a tenfold increase in the relative risk of bloodstream infections with tunneled hemodialysis catheters as compared to arteriovenous fistulas [18]. One prospective study of 472 patients who had a recently placed hemodialysis catheter reported that 35% of patients experienced a catheter-related bloodstream infection at 3 months, and 54% experienced a catheter-related bloodstream infection at 6 months [19]. Despite these increased rates of infection associated with tunneled hemodialysis catheters, the prolonged maturation time for arteriovenous fistulas necessitates temporary use of such catheters for most patients initiating hemodialysis. The most common causative organisms for bloodstream infections in hemodialysis patients are due to staphylococcal species, specifically *Staphylococcus aureus*, and coagulase-negative staphylococci such as *Staphylococcus epidermidis* [15]. Bloodstream infections due to *S. aureus* occur as a result of infection with a person's own endogenous strain, as >50% of patients on hemodialysis are carriers of *S. aureus* [20, 21]. The high rate of *S. aureus* carriage and colonization, or both, the presence of indwelling vascular access catheters, and uremia-related neutrophil dysfunction, contribute greatly to the high rates of *S. aureus* infections in this patient population [20]. It has been estimated

that in patients on hemodialysis who are colonized with *S. aureus*, 65% of these isolates were resistant to methicillin [22]. Methicillin-resistant *Staphylococcus aureus* (MRSA) is common among hemodialysis patients, and therefore empiric treatment with vancomycin is warranted in patients with suspected bloodstream infections [23]. Infections due to enterococci and Gram-negative rods can occur, although such infections are less common [15]. In addition to bloodstream infections, metastatic foci of infection may be seen, most typically with bloodstream infections due to *S. aureus*. The common types of infections associated with metastatic foci from bloodstream infection include endocarditis, osteomyelitis especially involving the vertebral column, epidural abscesses, septic arthritis, and septic pulmonary emboli [15, 22]. Persons receiving hemodialysis are 17.8 times more likely to develop endocarditis than the general population, *S. aureus* accounting for 57.9% of cases [24, 25]. Furthermore, the rates of metastatic foci of infection were noted to be more common with *S. aureus* and have been reported to occur in 10–40% of patients with *S. aureus* bacteremia [26, 27].

Patients on hemodialysis are also at increased risk for respiratory tract infections [15] due to community-acquired pathogens such as *Streptococcus pneumonia*, as well as healthcare-associated pathogens, given their frequent exposure to the healthcare setting. Seasonal influenza is also common among persons on hemodialysis; therefore, annual influenza vaccine is indicated for this high-risk population. It is extremely important that patients on hemodialysis be vaccinated for both influenza and pneumococcus, because pneumonia-associated death rates are 14–16 times higher as compared to the general population [28]. *Mycobacterium tuberculosis* is another important pulmonary pathogen in the hemodialysis population, and screening for latent tuberculosis infection is routinely preformed during pretransplant evaluation of potential renal allograft recipients.

The most common infectious complication of chronic peritoneal dialysis is peritonitis. It is estimated that the rate of peritonitis in patients initiating peritoneal dialysis is 42 per 100 patient-years [29]. Another study observed that 37% of patients on peritoneal dialysis developed peritonitis with an annual rate of 0.37 episodes of peritonitis per year at risk [30]. Infections at the exit site of peritoneal dialysis catheters have also been reported. Several large observational studies have reported that Gram-positive cocci account for 50–60%, Gram-negative rods accounted for approximately 15%, and fungi accounted for approximately 2% of cases of peritonitis due to peritoneal dialysis [31, 32]. The majority of Gram-positive cocci infections are due to coagulase-negative staphylococci and *S. aureus* [32], although *Enterococcus* species including vancomycin-resistant *Enterococcus* (VRE) have been reported. Gram-negative enterics and *Pseudomonas aeruginosa* are also associated with peritonitis in peritoneal dialysis patients. It has been reported that non-pseudomonal Gram-negative rods have a worse outcome than peritonitis due to coagulase-negative staphylococcus or *S. aureus* [33]. Peritonitis due to *Pseudomonas aeruginosa* can result in significant morbidity and is often associated with catheter exit-site infections [34]. Fungi are a relatively rare cause of peritonitis in this setting; however, the most common cause is *Candida* species – most often due to *Candida albicans*, *Candida parapsilosis*, and *Candida glabrata* [35]. Other unusual fungal pathogens have been reported and include *Aspergillus* species, *Paecilomyces*, *Penicillium*, *Zygomycetes*, and *Rhodotorula* [35, 36]. Overall, fungal peritonitis is associated with high mortality rates of 20–30% as well as marked inflammation of the peritoneal membrane resulting in dropout from peritoneal dialysis [35]. In patients on peritoneal dialysis who undergo kidney transplantation, there appears to be an ongoing risk for the development of peritonitis, and therefore many authors recommend the immediate removal of the peritoneal dialysis catheter as opposed to waiting for the establishment of renal allograft function [37]. While good outcomes for kidney transplantation in patients on peritoneal dialysis have been reported, Martins et al. found less favorable results among patients undergoing simultaneous pancreas-kidney transplants who utilized peritoneal dialysis, as compared to those on hemodialysis at the time of transplantation, including higher rates of thrombosis-driven relaparotomy, pancreatic loss due to infection, thrombosis-related kidney loss, and inferior survival with infection as the leading cause of death [38].

The management of bloodstream infections due to hemodialysis vascular access catheters and peritonitis associated with peritoneal dialysis is beyond the scope of this chapter. Treatment guidelines are available at: http://cid.oxfordjournals.org/content/49/1/1.full and http://www.pdiconnect.com/content/30/4/393.full.pdf, respectively [23, 39].

Viral Infections in Hemodialysis Patients and Considerations for Kidney Transplantation

Blood-borne pathogens due to viruses are important clinical aspects in the management of patients receiving hemodialysis. The most important viruses include hepatitis B virus (HBV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV). HBV and HCV transmission have also been documented in peritoneal dialysis patients, albeit at a significantly lower rate [40]. The prevention and management of these viruses are crucial in patients being considered for kidney and kidney-pancreas transplantation.

The transmission of viral hepatitis is a real concern for hemodialysis patients and staff. As recently as 2013, a patient acquired novel hepatitis B virus (HBV) infection through contamination in her dialysis center from a source patient who had failed renal transplantation and reactivated quiescent HBV infection [41]. Guidelines target both prevention

of infection via available vaccinations as well as routine testing and infection prevention measures to prevent nosocomial transmission and can be fully reviewed at the CDC website for Dialysis Safety – http://www.cdc.gov/dialysis/guidelines/index.html [42].

A national surveillance study of US dialysis centers in 2002 showed a 1% prevalence of dialysis patients who were seropositive for hepatitis B surface antigen (HBsAg) and an annual infection incidence of 0.12% [43]. Although most HD patients who acquire HBV infection will not develop severe or fulminant hepatitis, only a minority will clear the infection converting to HBsAg negative. These patients are more likely then patients without kidney disease to have persistent antigenemia and chronic elevation of liver enzymes [44]. Once additionally immunosuppressed after transplantation, even those who seemingly cleared infection previously may reactivate, particularly if they never developed surface antibodies (HBsAb) [45].

Hepatitis B vaccination is recommended for susceptible dialysis and CKD patients as well as healthcare workers, including those at dialysis centers [46]. In the same 2002 survey, approximately half of hemodialysis patients and 90% of staff received vaccination, and both groups had increasing vaccination rates over the 5-year period [43]. Ideally, HBV vaccination, which occurs at intervals of 0, 1, and 6 months, is administered prior to the initiation of dialysis, as well as for peritoneal and home dialysis patients who may require in-center hemodialysis in the future. Vaccination prior to dialysis has been shown to result in higher immunogenicity or antibody titers [47]. Hemodialysis and immunocompromised patients require a "double dose" (40 μg) of HBV vaccine and should have follow-up serologic testing to confirm vaccine response. If titer response 1–2 months following completion of the vaccine series is not ≥10 mIU/mL, a second vaccination series should be administered. Hemodialysis patients should undergo yearly HBsAb testing with administration of a booster dose if titers subsequently decline to <10 mIU/mL [48]. The list of recommended vaccines for patients on dialysis being considered for kidney transplantation is outlined in Table 4.1.

Table 4.1 Recommended vaccinations for adults with renal disease – 2016 CDC Guidelines [49]

[a]Yearly influenza (inactivated only for renal transplant recipients)
Tdap (once in adulthood, then Td booster every 10 years)
Pneumococcal (PCV13, then PPSV23 at least 8 weeks later)
Hepatitis B (higher 40 μg dose)
[a]Zoster (Shingrix, age >50 or taking/anticipating immunosuppressive therapy)
Human papilloma virus (females up to age 26, males up to age 21)
[a]MMR (born after 1957 if not already vaccinated or having immunity)
[a]Varicella (born after 1980 not already vaccinated or having immunity)

[a]Live virus vaccinations are not recommended for transplant recipients

Risk factors for HBV infection among hemodialysis patients in non-endemic regions include [43, 50, 51]:

- Lack of a protocol for HBV-infected patients
- Patients in the same center positive for HBsAg
- Lack of separate space and dialysis machines for HBsAg-positive patients
- Low (<50%) HBV vaccination rates within a dialysis unit
- Preparation of injectable medications outside of a dedicated medication room, such as on a cart or in a treatment area
- Longer duration on hemodialysis, with 4% higher odds ratio of HBV prevalence per year

Those patients known to be chronically infected with HBV should be treated, with the goal of maintaining undetectable viral loads and normal transaminases. Patients both with and without cirrhosis are at risk for hepatocellular carcinoma so should undergo regular liver cancer screening. Entecavir (Baraclude®, Bristol-Myers Squibb, Princeton, NJ) and tenofovir (Viread®, Gilead Sciences, Foster City, CA) are the most commonly used agents and have a high barrier to resistance in HBV. For patients on hemodialysis, either agent should be administered once every 7 days after dialysis. Lamivudine (Epivir®, ViiV Healthcare, Quebec, Canada) is an alternative option administered at a decreased daily dose but has a lower barrier to resistance. After transplantation, doses must be adjusted with improvement of renal function. Of note, due to the recognized potential nephrotoxicity of tenofovir, alternative agents may be considered in some cases. Tenofovir alafenamide (TAF, Gilead Sciences, Foster City, CA) was approved as a part of combination antiretroviral therapy in HIV patients and provides a more favorable toxicity profile with regard to renal and bone laboratory measurements. Early studies using TAF show promise for the treatment of chronic HBV and may be another option during post-kidney transplantation period [52, 53]. It is important to confirm HIV negativity when treating for HBV to avoid development of HIV resistance as these agents are active against both viruses, and treatment of HIV would require at least two additional antiretroviral agents.

Reported hepatitis C virus (HCV) prevalence of US and European dialysis centers ranges from 2.6% to 22.9%, with a mean of 13.5% [54]. HCV infection is associated with an increased relative risk for all-cause and cardiovascular mortality in dialysis patients [55]. Nosocomial HCV transmission may be influenced by prevalence of HCV within a dialysis unit, low personnel-to-patient ratio, or dialysis in close proximity to HCV-infected patients [56, 57] although this may largely be avoided with strict adherence to infection control practices. Increased HCV prevalence was associated with longer duration on hemodialysis, male gender, Black race, diabetes, coinfection with HBV, prior renal

transplant, or alcohol or substance abuse in the preceding 12 months. Whereas, HCV seroconversion was associated with longer time on dialysis, HIV/AIDS or HBV infection, and recurrent cellulitis or gangrene, at the patient level and an increase in facility HCV prevalence, at the center level [54]. Approximately half of centers reported a seroconversion during the 2–4-year study period. An increase in highly trained staff was associated with both lower HCV prevalence and risk of seroconversion.

HCV infection has been identified as an independent risk factor for graft loss and mortality in renal transplant patients [58–60]. It should be noted that these studies were conducted before the widespread use of direct-acting agents (DAAs) against HCV infection. While combinations of DAAs such as sofosbuvir (Sovaldi®, Gilead Sciences, Foster City, CA)/simeprevir (Olysio®, Janssen Therapeutics, Titusville, NJ) and ombitasvir/paritaprevir/ritonavir/dasabuvir (Viekira Pak®, AbbVie Inc., North Chicago, IL) have revolutionized the treatment of chronic HCV infection, data on the use of these agents in patients with chronic kidney disease is still evolving. The approval of fixed dose elbasvir and grazoprevir combination Zepatier (Merck & Co. Inc., Whitehouse Station, New Jersey) in January 2016 marked the first DAA therapy approved for patients with HCV genotypes 1, the most common in the United States and genotype 4 infections in patients on hemodialysis [61]. In the C-SURFER study, genotype 1 patients with eGFR less than 30 mL/min per 1.73 m^2, (76% of whom were on hemodialysis, 20% treatment experienced and 6% with hepatic cirrhosis) experienced 94% sustained virologic response (SVR) after 12 weeks of therapy [62]. Genotypes 2, 3, 5, and 6 still require the use of sofosbuvir-based regimens which is renally excreted and has limited data in patients on hemodialysis. A small series including 11 hemodialysis patients and 1 peritoneal dialysis patient found lower SVR rates in the dialysis group but reported only minor adverse events including fatigue, rash/itching, anemia, diarrhea, and decreased appetite with a regimen of half-dose sofosbuvir plus simeprevir [63]. Another study involving pre- and post-kidney or kidney/liver transplant recipients included ten patients on dialysis who were treated with daily sofosbuvir with good tolerability and SVR rates [64]. In the United States, use of sofosbuvir is currently approved for patients with eGFR >30 mL/min. The 2008 Kidney Disease Improving Global Outcomes (KDIGO) guidelines, sponsored by the National Kidney Foundation, recommend treatment prior to renal transplantation as sustained virologic response (SVR) before transplant reduces the risk of hepatic and extrahepatic complications after transplantation [65]. In certain regions with very high organ demand, however, transplantation of a HCV-positive donor kidney will drastically shorten wait times, and therefore many providers may choose to delay treatment until after transplantation. Data supports the use of renal graft from HCV-positive kidney donors showing improved survival in recipients of such grafts versus remaining on the transplant waitlist and continued dialysis [66].

Lee et al. published a multicenter cohort study comparing HBV-mono-infected or HCV-mono-infected to seronegative kidney transplant recipients and found that patients with HBV had worse survival but no difference in graft function as compared to HBV-negative patients [67]. Hepatic complications constituted the primary cause of increased mortality. There was improved patient survival on entecavir compared to lamivudine. While HCV infection did not lower patient survival, it was associated with an increased incidence of renal allograft failure and acute rejection.

As a result of the widespread use of effective combination antiretroviral therapy for the treatment of HIV infection, morbidity and mortality due to opportunistic infections and neoplasms has declined dramatically. Therefore, the major morbidity and mortality has now shifted to other causes such as cardiovascular etiologies, chronic kidney disease, end-stage liver disease, and non-opportunistic malignant neoplasms [68]. Chronic kidney disease and the need for renal replacement therapy in HIV-infected patients are multifactorial; the common causes include HIV-associated nephropathy, immune complex disease, coinfection with HBV and HCV, HIV-associated thrombotic microangiopathy, drug toxicity, and medical comorbidities such as hypertension and diabetes that are often encountered in patients receiving antiretroviral medications. Several HIV cohort studies have observed that 3.1–6% of HIV-infected patients have chronic kidney disease and 1.7% of patients have end-stage renal disease [69, 70]. HIV prevalence in the hemodialysis population varies between 0.67% and 20%, which reflects the overall prevalence of HIV within that region [71, 72].

Stock et al. led a multicenter prospective study of renal transplantation in HIV-infected persons which found 3-year patient and graft survival rates of 88% and 74%, respectively, which fell between national rates for recipients 65 years and older and all comers [73]. Additionally, there was no evidence of accelerated HIV disease progression or virologic failure in the posttransplantation period [73]. However, there were surprisingly higher rates of allograft rejection, up to 33% [73]. Risk factors for acute allograft rejection in the multivariate model included transplant from a deceased donor and cyclosporine use, whereas a higher posttransplantation CD4+ T-cell count was marginally protective. More recently, using the Scientific Registry of Transplant Recipients (SRTR) data of 510 HIV-positive adult kidney recipients, Locke et al. found that HIV-negative and HIV mono-infected kidney transplant recipients had similar graft survival and patient survival, whereas HIV/HCV coinfected patients had worse outcomes [74]. They identified several risk factors to predict higher rates of graft loss among HIV-positive kidney transplants that should be taken into account

Table 4.2 Common infections in the prerenal transplant (dialysis-dependent) period

System	Infection	Organisms
Bloodstream (hemodialysis)	Catheter-related bloodstream infection	*Staphylococcus aureus*, coagulase-negative staphylococci
		Less commonly enterococcus species, Gram-negative bacteria
	Metastatic foci of bloodstream infection: endocarditis, osteomyelitis (especially vertebral), epidural abscess, septic arthritis, septic pulmonary emboli	Same as that causing bloodstream infection
Respiratory tract	Pneumonia, upper respiratory tract infection	Community acquired pathogens, especially *Streptococcus pneumoniae*
		Healthcare acquired pathogens
		Seasonal influenza
	Tuberculosis	*Mycobacterium tuberculosis*
Intra-abdominal (peritoneal dialysis)	Peritonitis	Gram-positive cocci, especially coagulase negative staphylococci and *Staphylococcus aureus* (50–60%)
		Gram-negative bacilli, including *Pseudomonas aeruginosa* (15%)
		Fungi, especially *Candida albicans*, *C. parapsilosis*, *C. glabrata*; also reported *Aspergillus* species, *Paecilomyces*, *Penicillium*, *Zygomycetes*, and *Rhodotorula* (2%)
	Catheter exit site infection	Gram-positive cocci, especially *S. aureus* and Streptococcus spp.
Hepatic	Viral hepatitis	Hepatitis B virus, Hepatitis C virus

in the pretransplantation process: HCV coinfection increased risk by 2.72-fold; >3 human leukocyte antigen (HLA) mismatches increased risk by 1.80-fold in coinfected recipients plus 3 HLA mismatches having an amplified 3.86-fold risk of graft loss [59]. These very encouraging findings support the role of kidney transplantation as a viable option for HIV-infected persons with chronic kidney disease on dialysis.

As for all solid organ transplant recipients, potential candidates for kidney or kidney-pancreas transplant should have HIV virologic control before proceeding to transplantation. While transplant protocols may vary by hospital, generally recipient criteria for potential HIV-positive recipients include a CD4+ T-cell count of 200 cells per cubic millimeter or greater, undetectable HIV plasma RNA level, a stable antiretroviral regimen, and no active opportunistic infection, which were the selection criteria for the prospective multicenter HIV kidney transplant study [73].

Dr. Elmi Muller was the first surgeon to transplant HIV-positive recipients with kidneys from aviremic HIV-positive donors at the Groote Schuur Hospital in Cape Town, South Africa in 2008 [75]. The results of this case series of 27 HIV recipients who received kidneys from deceased HIV-infected donors noted 5-year posttransplant patient and allograft survival rate of 74% and 84%, respectively, among individuals with well-controlled HIV disease [75]. Beginning in 2016, select centers in the United States have begun performing HIV-positive to HIV-positive renal transplants in addition to positive-to-positive liver transplants as part of a multicenter research trial (ClinicalTrials.gov identifier number: NCT02602262).

Mittal et al. reported the first pancreas transplant alone in an HIV-positive recipient with good outcomes [76]. Reported outcomes of SPK transplants in HIV-positive patients have been mixed with two of four patients in a review series experiencing graft failure including one death [77].

Common infections in the pretransplantation period are summarized in Table 4.2.

Pharmacologic Considerations in Patients with Chronic Kidney Disease Undergoing Kidney Transplantation

Patients on hemodialysis also require careful titration of renal-dosed medications before and after transplant. In the pretransplant setting, this may translate to limited HCV treatment options or difficulty optimizing a pretransplant HIV regimen. In the posttransplant setting, this may lead to resistance or failure of virologic suppression if antiretrovirals are underdosed, for instance, or breakthrough opportunistic infections if prophylactic antimicrobials are underdosed. Specifically, antiretroviral agents which require dose modification in patients with chronic kidney disease include reverse transcriptase inhibitors emtricitabine, lamivudine, and tenofovir. In general, the protease inhibitors, non-nucleoside reverse transcriptase inhibitors, and integrase inhibitors do not warrant dose adjustment in the setting of chronic kidney disease [78]. However, in managing HIV-infected patients in the pretransplant period, consideration should be given to selecting a regimen that avoids drug interactions with anticipated immu-

nosuppressives introduced after transplantation. Specifically, protease inhibitors are potent inhibitors of CYP3A4 isoenzymes and can result in increased drug exposure of the calcineurin inhibitors [78]. Conversely, the NNRTIs can result in decreased drug exposure of the calcineurin inhibitors [78]. Regimens that include integrase inhibitors such as raltegravir lack drug interactions with the CYP450 system and may be a preferred regimen for appropriate patients [79]. More recently, cobicistat, a potent inhibitor of CYP3A4 isoenzyme, has been complexed to several antiretrovirals in order to improve drug exposure. It can be anticipated that cobicistat will also interact with the antirejection immunosuppressive regimen, and therefore avoidance of these agents should be considered when constructing an antiretroviral regimen for an HIV-infected kidney transplant candidate. Maraviroc, which is an HIV CCR5 entry inhibitor, may show promise in the posttransplantation setting, as this may provide the added benefit of improved allograft survival, as loss or blockade of the CCR5 receptor has been associated with reduced allograft rejection rates [80].

Conversely, overdosing of certain antimicrobials or antiretrovirals in the setting of pretransplant declining renal function or posttransplant acute or chronic allograft rejection may negatively impact graft function, as may be seen with the use of tenofovir or trimethoprim-sulfamethoxazole (Table 4.3). Other important anti-infective agents that could result in significant drug interactions with the immunosuppressive regimen due to CYP 450 isoenzyme inhibition include the triazole antifungal agents such as fluconazole and voriconazole (Table 4.4). These agents can cause increased drug exposure of immunosuppressives such as the calcineurin inhibitors.

Table 4.3 Commonly used anti-infectives in the renal transplant recipient requiring dose adjustment for renal function

Medication	Indication/use
Acyclovir/valacyclovir	HSV prevention and treatment
Aminoglycosides (amikacin, tobramycin, gentamicin)	Gram-negative bacterial infection
Amphotericin B	Fungal infection, especially *Aspergillus* spp. and *Zygomycetes*
β-lactam and cephalosporin classes	Bacterial infection
Ciprofloxacin, levofloxacin	Treatment of bacterial infections, treatment of Polyoma BK Virus (PyBKV) infection
Colistin	Gram-negative bacterial infection
Daptomycin	Gram-positive bacterial infection
Emtricitabine, lamivudine, tenofovir	HIV therapy
Ertapenem, meropenem, imipenem	Resistant Gram-negative bacterial infection
Fluconazole	Candida prevention and treatment
Foscarnet	Resistant CMV and HSV infection
Ganciclovir/valganciclovir	CMV prevention and treatment
Trimethoprim-sulfamethoxazole	Urinary tract infection and *Pneumocystis* prevention and treatment
Vancomycin, intravenous	Resistant Gram-positive bacterial infections

Table 4.4 Anti-infectives modulating cytochrome P450 drug metabolism (anti-infectives and immunosuppressants metabolized via CYP450 isoenzyme)

Inducers	Inhibitors	
Will accelerate substrate metabolism and decrease drug effect	Will slow substrate metabolism and increase drug effect	Post-transplant maintenance immunosuppressants that are CYP450 substrates
Nevaripine (CYP3A4, CYP2B6)	Ciprofloxacin (CYP1A2)	Cyclosporine (CYP3A4)
Efavirenz (CYP3A4)	Clarithromycin (CYP3A4)	Everolimus (CYP3A4)
Etravirine (CYP3A4)	Cobicistat[a] (CYP3A4, CYP2D6)	Prednisone (CYP3A4)
Rifampin, Rifabutin (CYP1A2, CYP2C9, CYP2C19, CYP3A4)	Erythromycin (CYP3A4)	Sirolimus (CYP3A4)
	Etravirine (CYP2C9, CYP2C19)	Tacrolimus (CYP3A4)
	Fluconazole (CYP2C9, CYP2C19, CYP3A4)	
	Isavuconazole (CYP3A4)	
	Isoniazid (CYP2C19)	
	Itraconazole (CYP3A4)	
	Ketoconazole (CYP3A4)	
	Metronidazole (CYP2C9)	
	Posaconazole (CYP3A4)	
	Ritonavir (as part of a boosted protease inhibitor regimen)[b] (CYP2C9, CYP2C19, CYP2D6, CYP3A4)	
	Terbinafine (CYP2D6)	
	Trimethoprim-sulfamethoxazole (CYP2C9)	
	Voriconazole (CYP3A4, CYP2C19, CYP2C9)	

[a]As part of a boosted HIV regimen with atazanavir, darunavir, elvitegravir

[b]Boosted protease inhibitor regimens: Atazanavir, darunavir, or lopinavir with ritonavir

Pretransplantation Screening for Potential Recipients

Routine screening testing to be done for renal transplant candidates mirrors that of other solid organ transplant candidates and includes serologic testing for immunity to vari-

Table 4.5 Infectious screening for the pre-renal transplant recipient

Laboratory testing
HIV Ag/Ab (4th generation) assay and Nucleic Acid Test (NAT)
Hepatitis serologies:
Hepatitis A antibody
Hepatitis B surface antigen, surface antibody, core antibody, and NAT
Hepatitis C antibody and NAT
Vaccination titers: measles, mumps, rubella, varicella
Syphilis screen – either treponemal or nontreponemal test
Latent TB screen – generally interferon gamma release assay preferred over tuberculin skin test
CMV IgG antibody
EBV antibodies
Based on regions of endemicity
Strongyloides antibody
Coccidioides serology
T. cruzi serology
Imaging
Chest radiography
Should be performed for any patient with a positive TB screening test
May warrant further evaluation if pulmonary nodules suggest infectious etiology, such as fungal or mycobacterial infection

cella, measles, mumps and rubella, serologic and nucleic acid testing (NAT) for HIV, HBV, and HCV, and screens for syphilis and latent tuberculosis. Patients from endemic regions may additionally undergo screening for latent strongyloidiasis, coccidioidomycosis, and, rarely, histoplasmosis, HTLV, or trypanosomiasis. The recipient's CMV and EBV serostatus should be established by serology [81]. Patients may remain listed for years awaiting deceased donor renal allograft transplantation, and screening for viral infections such as HBV and HCV should be kept up to date. Serologic screening tests and recommended imaging are summarized in Table 4.5.

As with other solid organ transplant recipients, renal transplantation places recipients at an increased risk of developing tuberculosis (TB), estimated at 20–74 times higher risk among solid organ transplant recipients, so testing for latent tuberculosis should be included as part of routine pretransplantation screening [82]. It has been well established that patients on hemodialysis are 6–25 times more likely to develop tuberculosis as compared to the general population [83]. Moreover, latent tuberculous infection (LTBI) has been reported to be as high as 20–70% in the hemodialysis population [83]. Therefore, screening for LTBI, and treatment of LTBI, is warranted in all patients on hemodialysis and of particular importance for those who are being considered for listing for kidney transplantation. Most dialysis centers routinely perform annual tuberculin skin testing (TST). Presence of uremia in patients with chronic kidney disease undergoing HD alters macrophage and T-cell functions; the resulted anergy has been noted in as many as 44% of such patients compared with 16% anergy in the general population, making TST less optimal screening tool for this population [83]. A retrospective study of dialysis patients found the two-step, or boosted, TST to have a sensitivity of 14% and specificity of 88% among dialysis patients using an abnormal chest X-ray as a proxy [84]. Two studies demonstrated that a single-step TST had a sensitivity of 11.3% and 14.7%, and an additional 12.1% and 13.1% of the hemodialysis patients, respectively, had a positive TST using the two-step method [83]. Given concerns for poor sensitivity of TST in the dialysis population, most transplant centers now rely on serum interferon-gamma release assays (IGRA) using QuantiFERON-TB Gold in tube (Qiagen, Victoria, Australia) or T-SPOT.TB (Oxford Immunotec, Oxfordshire, England). In hemodialysis patients, the sensitivities of IGRAs for the diagnosis of LTBI have ranged from 22% to 71.4%, and the specificity was noted to be as low as 41.9% and as high as 100% [83]. In renal transplant patients, TST and IGRA results may have only fair agreement, but TST induration size may correlate with positive IGRA [85]. In a prospective study following potential kidney transplant recipients after TST or IGRA testing, Kim et al. found that 13% of 312 patients had positive TST or clinical risk factors requiring pretransplant isoniazid (INH) therapy and none of these patients developed active tuberculosis. In the remaining 272 patients, 71 had a positive T-Spot alone and a negative TST; these patients did not receive INH, and four patients went on to develop active tuberculosis infection after undergoing kidney transplantation. This study demonstrates that T-spot is a more effective method for screening latent tuberculosis in patients being evaluated for kidney transplantation [86]. Based on the high rates and heightened risk of active tuberculosis disease in patients with chronic kidney disease on dialysis, screening for latent and active TB is an essential part of the pretransplant evaluation. While it appears that IGRAs may be the preferred screening modality for LTBI, if TST is the only available modality, then a two-step TST should be performed. Active TB needs to also be ruled out based on a careful assessment of signs and symptoms, and a chest X-ray should be performed as part of the pretransplant evaluation. In high-risk patients, or patients with indeterminate results, high-resolution CT imaging of the thorax may be warranted. Recommendations for the screening, diagnosis, and management of TB in solid organ transplant recipients are available and should be implemented as part of the pretransplant evaluation [87].

Though not a routine part of pretransplant screening, an abnormal pretransplant urodynamic assessment is associated with more frequent urinary complications [88]. Other screenings have been proposed to estimate the risk for bacterial and opportunistic infections (OIs) during posttransplant setting require further validation studies. It was interesting to note that a measured immune risk phenotype prior to trans-

plantation defined as +CMV serology plus CD4/CD8 ratio <1 and/or CD8 T cell count >90th percentile was associated with higher risk for severe bacterial infections and OIs after transplantation [89].

Living Donor and Deceased Donor Screening for Occult Infection

In 2014, 5537 of 17,107 kidney transplants came from living donors [12], and an increasing number are donated via paired exchange in which potential recipients with willing donors may be matched in a larger pool to those with more compatible kidneys. Five hundred forty-four such unrelated paired donations were performed in 2014 [11]. Any potential living kidney donor must undergo their own screening evaluation for occult infection prior to transplantation including clinical history and laboratory evaluation for HIV, HBV, HCV, CMV, and Epstein-Barr virus (EBV) serostatus, syphilis screen, and TB screening. At-risk live donors, defined by regional and seasonal infection-risk variation, may additionally require screening for coccidioidomycosis, strongyloidiasis, West Nile virus, and latent or subclinical *Trypanosoma cruzi* infection [90]. Although there is currently no data regarding Zika virus screening among solid organ graft donors, living kidney donors from Zika virus endemic areas may have prior infection. The Organ Procurement and Transplantation Network (OPTN)/United Network for Organ Sharing (UNOS) Ad Hoc Disease Transmission Advisory Committee does not recommend prior Zika virus infection as a strict exclusion criteria from organ donation; however, the risk of donor-derived infection should be balanced with benefits of transplantation [91]. As the Zika virus outbreak continues in Central and South America, the Caribbean, Mexico, and now parts of Florida and Texas, this will likely be an evolving area of research and guidelines as Zika-infected donors are assessed for organ donation and renal or other transplant recipients travel to the evolving endemic regions and develop new Zika virus infection after undergoing transplantation.

There is an increasing number of deceased donor renal allografts coming from high infection-risk donors (HRD), in part driven by an ongoing epidemic of recreational drug use and overdose deaths. The US Public Health Service currently defines 12 criteria for being at increased risk of recent HIV, HBV, and/or HCV infection, with concern of transferring infection via allograft during a "window" period where recently acquired viremia is not yet detectable by antibody or nucleic acid testing [92] (see Tables 4.6 and 4.7). Actual risk of HIV acquisition during the window period has been estimated between 0.04 and 4.9 per 10,000 donors based on NAT testing. The window for highest HIV infection risk exists in injection drug users (4.9 per 10,000 donors), men who have sex with men (4.2 per 10,000), commercial sex workers (2.7 per 10,000), incarcerated donors (0.9 per 10,000), donors exposed to HIV through blood (0.6 per 10,000), donors engaging in high-risk sexual activities (0.3 per 10,000), and hemophiliacs (0.035 per 10,000) [93]. Pooled risk of window period HCV transmission from

Table 4.6 Special situation donor criteria

High-risk donor criteria	Extended criteria donor
People who have had sex with a person known or suspected to have HIV, HBV, or HCV infection in the preceding 12 months	Donor aged >60 years
	Donor aged >50 years, plus two of the following:
Men who have had sex with men (MSM) in the preceding 12 months	History of hypertension
	Serum creatinine ≥1.5
Women who have had sex with a man with a history of MSM behavior in the preceding 12 months	Death resulting from a stroke
People who have had sex in exchange for money or drugs in the preceding 12 months	
People who have had sex with a person who had sex in exchange for money or drugs in the preceding 12 months	
People who have had sex with a person who injected drugs by intravenous, intramuscular or subcutaneous route for nonmedical reasons the preceding 12 months	
A child who is ≤18 months of age and born to a mother known to be infected with, or at an increased risk for, HIV, HBV or HCV infection	
A child who has been breastfed within the preceding 12 months and the mother is known to be infected with, or at increased risk for, HIV infection	
People who have injected drugs by intravenous, intramuscular, or subcutaneous routes for nonmedical reasons in the preceding 12 months	
People who have been in lockup, jail, prison, or a juvenile correctional facility for more than 72 consecutive hours in the preceding 12 months	
People who have been newly diagnosed with, or have been treated for, syphilis, gonorrhea, *Chlamydia*, or genital ulcers in the preceding 12 months	
People who have been on hemodialysis in the preceding 12 months – *at increased risk for recent HCV infection only*	

Table 4.7 Window period lengths

	Serology	Nucleic acid test (NAT)
HIV	Third-generation/standard serology: 19–20 days	5–6 days
	Fourth-generation/combined Ag/Ab serology	
	7–15 days	
HCV	58–65 days	3–5 days
HBV	36–44 days	20–25 days

HRDs ranges from 0.027 to 32.4 per 10,000 donors, with the highest risk categories being injection drug users (32.4 per 10,000), commercial sex workers and donors exhibiting high-risk behavior (12.3 per 10,000), men who have sex with men (3.5 per 10,000), incarcerated donors (0.8 per 10,000), donors exposed to HIV-infected blood (0.4 per 10,000), and hemophiliacs (0.027 per 10,000) [93].

As of 2010, approximately 9% of deceased kidney donors were classified as HRD [94]. A decision analytic Markov model of renal failure treatment modalities estimated that use of HRD kidneys as compared to discarding these organs would result in higher patient survival, a greater number of quality-adjusted life years (QALY) (5.6 vs. 5.1 years per patient), more kidney transplants, and lower cost of care ($60,000 vs. $71,000 per QALY). They estimated a lower total number of infections, 13.1 vs. 14.8 infections per 1000 patients over 20 years occurring in recipients of HRD organs because of the increased time on hemodialysis if HRD organs are discarded, which in turn carries higher HCV incidence [95]. Because HRDs tend to be younger with less medial comorbidities, recipients of HRD renal transplants have a significantly improved 5-year graft survival compared with non-HRD expanded criteria donor kidney recipients of 84% vs. 78%, respectively ($p < 0.001$) [96].

Infectious Diseases Considerations for Incompatible Kidney Transplant Recipients

Some potential kidney transplant recipients may have otherwise acceptable donors except for the presence of preformed human leukocyte antigen (HLA) antibodies or ABO blood group incompatibility. Similarly, some patients on the wait list for a deceased donor may be highly sensitized, often due to previous blood product transfusion, pregnancy or prior transplantation, and subsequently have longer wait times and decreased likelihood of finding a suitable donor. These patients may be candidates for HLA or ABO-incompatible kidney transplant. Recipients of incompatible kidney transplants have a survival benefit over patients who do not undergo transplantation or wait for a deceased donor allograft, with an 8-year survival benefit significant across all levels of donor-specific antibody [97]. To prevent antibody-mediated rejection and graft loss in these cases, patients undergo pretransplantation desensitization with rituximab, intravenous immunoglobulin (IVIG), and/or plasmapheresis, although specific protocols vary by center. Rituximab is associated with numerous potential adverse events, including cytopenias/hypogammaglobulinemia and increased infectious risks (see Table 4.8). In the United States, rituximab carries a boxed warning for HBV reactivation which may lead to fulminant hepatitis, liver failure, or death [98]. Patients should be screened for HBV typically as part of routine pretransplant screening; see the section above entitled Pretransplantation Screening for Potential Recipients prior to treatment. Those with positive surface antigen should start treatment, and patients with negative HBsAg and a positive core antibody (HBcAb) should have ongoing monitoring for reactivation [98, 99]. HBV reactivation has been reported greater than a year after rituximab therapy [98, 100]. Other newly acquired or reactivated viral infections at increased risk following rituximab use include CMV, herpes simplex virus (HSV), parvovirus B19, varicella zoster virus (VZV), West Nile virus, and HCV [98]. Rituximab also carries a boxed warning against progressive multifocal leukoencephalopathy (PML) due to JC polyomavirus [98]. Data has been mixed as to increased risk of infection after incompatible kidney transplant but generally shows at least a trend toward increased viral infection and surgical complications [101–103]. However, actual increased risk may be impacted by immunosuppressive regimen, splenectomy, or preconditioning regimen all of which may vary between centers, making it difficult to standardize risks across the population as a whole [103]. Overall patient and allograft survival and acute rejection are comparable to HLA and ABO compatible kidney transplants [101, 102].

Table 4.8 Infectious risks associated with rituximab use [98, 104]

Bacterial/ mycobacterial	Sepsis, sinusitis, nasopharyngitis, bronchitis, pneumonia, cellulitis, urinary tract infection, colitis
	Mycobacterium avium, *Mycobacterium kansasii*
Viral	Hepatitis B reactivation
	Cytomegalovirus (CMV)
	Herpes simplex virus (HSV)
	Parvovirus B19
	Varicella zoster virus (VZV)
	West Nile virus (WNV)
	Hepatitis C
	Progressive multifocal leukoencephalopathy (PML) caused by JC virus
	BK virus
Fungal	Pneumocystis pneumonia
Parasitic	Babesiosis
Non-infectious	Infusion reaction (fever, rigors, nausea, pruritus, angioedema, hypotension, headache, vomiting, rash, and other symptoms) may mimic acute infection

Infections in the Posttransplantation Period: An Overview

Infections contribute significantly to the morbidity and mortality that is experienced in the solid organ transplant recipient. It is estimated that infections account for 15–20% of the causes of mortality in kidney transplant recipients, although this has been declining over the past several years due to

improvements in anti-infective prophylaxis strategies [105]. Candidates for kidney and kidney-pancreas transplantations carry with them their own "baggage" that places them at risk for infectious complications, specifically uremia which is associated with depressed T-cell functions, as well as diabetes mellitus which contributes to hosts' suppressed immune response, and the potential hyperglycemia that places patients at risk for infection after surgery. Several factors contribute to infections following transplantation and include (1) environmental and external factors such as pathogens acquired from the healthcare environment including Gram-negative enteric bacteria or the external environment like endemic mycoses or molds; (2) reactivation of prior infections in the recipient such as HSV, VZV, and CMV; (3) donor-derived infections; (4) iatrogenic complications associated with surgery or hospitalization; and (5) overall state of immunosuppression due to antirejection regimen and infection with immunomodulatory viruses such as CMV, EBV, HBV, HCV, or HIV or both [106, 107]. Another factor that is unique to kidney transplant recipients is the type of renal replacement therapy that precedes transplantation. Postoperative infection rates are notably higher in patients on peritoneal vs. hemodialysis prior to undergoing transplantation (67.5% vs. 25.9%; $p < 0.00001$) [108]. A timeline has been proposed by several authors [107] to categorize the types of infections that are encountered in the posttransplantation period and will be addressed here.

Early Infections Following Kidney and Kidney-Pancreas Transplants

The immediate posttransplantation period has been defined as <30 days from the time of transplantation and is most typically due to healthcare-acquired pathogens, although donor-derived infections can also occur in rare situations.

Early Infections: Risk Factors

There are numerous risk factors associated with the development of infectious complications in the initial posttransplantation period. The majority of these early infections are healthcare acquired, and are related to the risk of exposure to the healthcare setting, and risk of complications of the actual surgical procedure. Other unique factors also contribute to infection risk and are reviewed below.

A Cochrane analysis found insufficient evidence to link early (<14 days) or late (>14 days) steroid withdrawal or steroid avoidance to risk of infection in the postoperative period [109]. They identified only one trial in which significantly more urinary tract infections (UTIs) were reported in the late withdrawal group compared to steroid avoidance, with a relative risk of 0.41 [110].

Markers reported to be independent predictors of infection in the kidney transplant population include elevated ferritin, magnesium deficiency, and vitamin D deficiency, although they may be altered by other illness or physiologic stressors, therefore warranting further study [111–113].

Hypogammaglobulinemia, defined as IgG level <350 mg/dL, has also been identified as a risk factor for severe opportunistic infection and higher number of infections in the first 3 months after transplantation compared to patients with normal serum immunoglobulin levels and may be modifiable with immunoglobulin infusions and monitoring of levels [114, 115].

Approximately one in three renal transplant recipients will have an early readmission occurring within the first 30 days after renal transplantation [116]. Infectious complications appear to be an important cause for early readmission. A large retrospective review identified surgical site problems as the primary cause of early readmission, which may include superficial wound infection or symptomatic perinephric fluid collection. The second most common reason for readmission was UTI with or without bloodstream infection, followed by pneumonia and fever of unknown origin. Other nonsurgical complications leading to readmission included colitis, epididymitis, neutropenia, leukocytosis, pancreatitis, cholangitis, lower extremity cellulitis, and PD catheter infection. Discharge-level factors associated with readmission included electrolyte abnormalities and delayed graft function. Previously published data has also cited older age, black race, low educational level, and medical comorbidities such as hypertension, obesity, diabetes mellitus, cardiovascular disease, HCV, stroke, chronic obstructive pulmonary disease, prior transplant, and frailty as risk factors for early readmission. Donor risk factors associated with recipient readmission include age, expanded criteria donor status, donation after circulatory death, and cold ischemic time. Transplant risk factors include HLA mismatch, length of stay, lack of induction therapy, waitlist time, delayed graft function, and, in one study, weekend discharge [117–120].

Early Infections: Surgical Complications

Renal transplant recipients are at risk for the typical postoperative complications and infections of immunocompetent surgical patients. The most common infections include surgical site infections, urinary tract infections, hospital-acquired pneumonia, and central line-associated bloodstream infections (CLABSI) [106]. The typical causative bacterial organisms are those that are most commonly associated with the particular site of infection. Therefore, it can be anticipated that surgical site infections are predominantly due to Gram-positive cocci, in particular *Staphylococcus aureus*, whereas UTIs are commonly due to enteric Gram-negative bacilli.

UTIs are the most common infection in renal transplant recipients, with US Renal Data System reporting a cumulative incidence of 17% within the first 6 months following transplantation [121]. Ureteral stents placed at the time of renal allograft transplantation confer increased risk for UTI within the first month following transplant (11.4% vs. 0.3% of non-stented allograft recipients; $P < 0.001$) [122].

In addition to the typical postsurgical infectious complications, there are risks unique to the kidney transplantation procedure. Perfusion fluid (PF) used following deceased donor nephrectomy, if contaminated, may lead to serious infection in the recipient [123]. Use of empiric antifungal agents in the perioperative period is routinely given in case of yeast contamination of PF [123]. Ranghino et al. analyzed recipients with bacterial contamination of PF and found an overall incidence of 38.4%, with half being staphylococci and 9.9% *Candida albicans*. Targeted preemptive therapy of PF contamination did not reduce the rate of PF-related allograft infection, which were low despite high frequency of such contamination. The authors suggest a reasonable reduction in the use of antibiotic therapy can be considered along with close monitoring.

As many as 10–34% of pancreas transplant recipients experience complications requiring relaparotomy [124–126], most commonly due to vascular graft thrombosis and intra-abdominal infection but also pancreatitis, bleeding, and stump and anastomotic leaks [125, 126]. Approximately half of those undergoing relaparotomy require graft pancreatectomy [126], but this may be performed in as many as 70% of patients when done for leaks or abscesses [125, 126]. Risk factors for early relaparotomy include donor age >40 years and recipient obesity [125] as well as bladder drainage versus enteric drainage (18.2% vs. 5.8%; $p < 0.05$). Relaparotomy did not significantly affect patient survival consistently between studies, but relaparotomy is consistently associated with significantly lower graft survival [125–127].

Clinically significant peripancreatic fluid collections (PPFC) were found in 16% of pancreas-kidney transplant recipients in a study by Singh et al. [128]. The majority of PPFCs occurred within the first month and may occur up to 3 months after undergoing transplantation. Most patients required relaparotomy except for two in this series who underwent drainage by interventional radiology. Over half (56%) of PPFC were infected; all had bacterial infection with the most common organisms being *Enterococcus faecalis*, coliform/enteric pathogens, *Staphylococcus* spp., and lactobacillus, and 10% of these patients' cultures additionally isolated *Candida*. Multidrug-resistant (MDR) bacteria were isolated in 11%. Similar patient and kidney graft survival was seen in patients with and without PPFC; however, significantly lower total pancreas graft survival resulted (68% vs. 85%), and a greater incidence of infection was also observed (75% vs. 46%; $P < 0.05$) during 5 years following transplantation. Patients with PPFCs had significantly greater incidence of recurrent UTI (58% vs. 36%), bacteremia (31% vs. 3%), and fungal (28% vs. 1%) and viral infection (28% vs. 14%) compared to patients without the evidence of PPFC ($p < 0.001$) [128].

Early Infections: Healthcare-Acquired Infections

As noted above, kidney and pancreas-kidney recipients are at risk of typical postoperative and nosocomial infectious complications in the early posttransplantation period, as well as unique infectious risks related to their transplantation.

In addition to the healthcare-acquired pathogens noted above, a growing problem in hospitals is the increased incidence of *Clostridium difficile* infection (CDI) colitis. Higher CDI incidence has been reported in the solid organ transplant population [129]. Unique CDI risk factors in the kidney and kidney-pancreas transplant population include male gender (82% vs. 48%; $p = 0.003$), deceased donor recipients (84% vs. 64%; $p = 0.045$), leukopenia (18% vs. 4%; $p = 0.038$), recent gastrointestinal procedure within the preceding 3 months (18% vs. 4%; $p = 0.038$), and more days of cumulative and restrictive antimicrobial exposure and more cephalosporin use (43% vs. 16%; $p = 0.008$).

Infection with MDR and extensive drug-resistant organisms is also of increasing concern worldwide and in patients undergoing allograft transplantation. In transplant recipients, exposure to prolonged stays in intensive care units, extensive preemptive and empiric use of broad-spectrum antibiotics and immunosuppressive antirejection therapy, and systemic corticosteroids may be the harbingers of these severe infections. Extended-spectrum beta-lactamase (ESBL)-producing *Enterobacteriaceae* such as *Escherichia coli* and *Klebsiella pneumoniae* have become increasingly prevalent. In SOT recipients with *Klebsiella pneumoniae* infection, over half may be ESBL producers [130]. ESBL-producing *Enterobacteriaceae* have been isolated in up to 11% of urinary cultures in one hospitalized kidney transplant cohort [131]. The urinary tract is the most commonly infected site in renal transplant recipients with MDR infection [132–134], and MDROs accounted for 69% of isolates in symptomatic renal transplant recipients with UTI [132]. Comparison of bacterial species and susceptibilities in a renal transplant population over 10 years has shown a significant increased presence of *Klebsiella pneumoniae* (9.5% vs. 15.6%), *Pseudomonas aeruginosa* (1.8% vs. 7.9%), and *Enterobacter cloacae* (0.6% vs. 3.1%) as well as higher drug non-susceptibility rates for all antibiotic classes with the exception of fosfomycin [132]. Routine perioperative antimicrobial prophylaxis may be ineffective against resistant bacteria or yeast that may have been present in the donor allograft or bloodstream at the time

of procurement [135]. In deceased liver donors, risk of donor allograft infection with any bacterial organism is increased if the donor received vasopressors ($p = 0.22$) or cardiopulmonary resuscitation ($p = 0.036$) or had a prolonged intensive care unit stay of 7 days or more ($p \leq 0.0001$) [136], although as little as 2 days may be sufficient for the donor to acquire an MDR organism (MDRO) [137]. Transmission of resistant pathogens leads to high morbidity and mortality. In a tertiary care hospital outbreak with *Klebsiella pneumoniae* carbapenemase (KPC)-producing *K. pneumoniae*, the incidence of KPC infection in renal transplant recipients was 26.3%, and overall 30-day mortality among the SOT recipients was 42% [133]. A prolonged outbreak of carbapenem-resistant *Enterobacter gergoviae* involving renal transplant recipients identified flaws in infection prevention practices of cleaning and handling urinary devices as a contributing factor for the infection risk [134]. Recipient risk factors for acquisition included advanced age, ureteral stent use, retransplantation, and male gender. A kidney-pancreas recipient with donor-derived carbapenem-resistant *Acinetobacter baumannii* (CRAB) with blaOXA-23 carbapenemase gene who died less than 1 week following transplant had developed widespread and deep-seated infection including acute mitral valve endocarditis with splenic and renal septic emboli, myocarditis, peritonitis, and pneumonia which were confirmed on postmortem examination [138].

The above data demonstrates that MDR organisms such as ESBL producing *Enterobacteriaceae*, carbapenem-resistant *Enterobacteriaceae* (CRE), *Pseudomonas*, and *Acinetobacter* spp. substantially contribute to morbidity and mortality in recipients of solid allograft transplant. Therefore, clinicians caring for these patients will need to be aware of their local hospital antibiograms when making empiric antibiotic selection for suspected infection in this high-risk patient population.

Early Infections: Donor-Derived Infection

Huaman et al. analyzed UNOS data on all primary, single organ deceased donor kidney transplants from 2008 to 2013 and found an incidence of donor blood culture positivity in 8.1% of cases [139]. Donor blood culture positivity was associated with delayed graft function but did not impact graft or patient survival. Although bacterial colonization at a distant site, such as the respiratory tract, in a renal allograft recipient does not warrant uniform use of antibacterial therapy, it may rarely signify unrecognized bacteremia [135]. Return of positive donor blood cultures after transplantation may warrant treatment in the recipient. The most common pathogens include coagulase-negative staphylococci and *Staphylococcus aureus*, although Gram-negative infections are being seen in increasing numbers. The exact duration is unknown, but it is recommended to treat the recipient with targeted antibiotics for a minimum of 7–10 days [140, 141]. Use of a kidney allograft from a donor with respiratory colonization of KPC or CRAB may still be considered with close follow-up, but urine culture positivity with these resistant organisms should be considered a contraindication to use of that kidney unless infection is eradicated prior to transplantation [135]. Donor bacteremia with an MDRO should likewise be avoided if recognized prior to transplantation [135].

The risk of donor-derived viral hepatitis and HIV is low, but donor-derived transmissions have been documented. A quantitative review of the literature including 9 studies with 1385 kidney recipients found only 45 had seroconversion of hepatitis B markers [142]. Hepatitis B core antibody accounted for the majority of those who tested positive after receiving a core antibody positive graft. Only 0.28% of recipients converted to surface antigen positivity, and there was no symptomatic hepatitis nor were patient or graft outcomes worse with seroconversion [135, 142]. Both HCV and HIV have been inadvertently transmitted when donors had unrecognized infection. The first known transmission of HIV and HCV to four recipients- two kidneys, liver, and heart- resulted in two deaths and allograft failure in the other two recipients [143]. Human error has been a factor in other instances of transplantation of HIV-positive organs into negative recipients. In Taiwan, miscommunication by phone between a transplant coordinator and laboratory technician with regard to an HIV test resulted in five recipients being transplanted with HIV-positive organs, including heart, liver, lungs, and two kidneys [144]. Patients were started on postexposure prophylaxis (PEP) within 36 h after transplant, and reportedly, follow-up testing of the recipients was negative for HIV; the duration and exact PEP regimen as well as interval to follow-up testing were not defined. Three Italian patients also received HIV-positive organs as the result of an error in documentation after misreading of a computer printout [145]. Further testing from a tissue bank laboratory was faxed on a weekend without verbal communication and resulted in a delay of 5 days until the donor's status was recognized by the transplanting institution. These patients also received HIV medication and have had negative HIV NAT testing and functioning grafts reported at 7 years after transplantation [135]. In both situations, neither donor's family was aware of their HIV status. Transmission and accidental use of HIV-positive renal allografts has not been limited to deceased donors. In 2009, an adult male potential donor tested negative for HIV 79 days before transplant but had unprotected sex with a male with unknown HIV status in the interval before transplantation [146]. The kidney recipient had a posttransplantation course complicated by hospitalizations for febrile illness, renal insufficiency and possible

rejection and then tested positive for HIV and had a CD4 cell count <100 cells/μL when hospitalized with refractory oral and esophageal candidiasis.

Human T-cell lymphotropic virus type 1 (HTLV-1) is another retrovirus that has had documented transmission via organ transplantation [147]. HTLV-1 has pockets of endemicity worldwide, but seroprevalence is extremely low in the United States, accounting for 0.0034% among blood donors [148]. It is largely asymptomatic, but in a minority of patients (2–5%), it may cause adult T-cell leukemia- lymphoma or, even more rarely, HTLV-1-associated myelopathy, also known as tropical spastic paraparesis [149]. Twelve published cases of HTLV-1-associated myelopathy from Spain and Japan, including nine kidney recipients, reviewed by Ramanan et al., have resulted from reactivation, primary infection, and donor-derived infection [147]. The first donor-derived case in the United States, reported in 2014, occurred after deceased donor renal transplantation from a donor who emigrated from the Dominican Republic in childhood and resulted in recipient myelopathy at 5 months after transplant [147]. The low seroprevalence in the United States led to a high degree of organ wastage due to false-positive results as well as a lack of FDA-licensed testing in many organ procurement organization (OPO) labs, so in 2009 the OPTN ceased to recommend universal donor screening [149].

In the early posttransplantation period, clinicians should be aware of the rare possibility of donor-derived neurotropic viruses. Transmission of West Nile virus (WNV) has also occurred as a donor-derived infection after transplantation [135]. The kidney may be the site of prolonged WNV replication and shedding, and testing of urine instead of blood has been proposed [135]. The first two clusters of rabies transmission via SOT to non-vaccinated recipients reported development of symptoms and death within 6 weeks of transplantation [135, 150]. Recently a renal allograft recipient developed delayed donor-derived rabies at 18 months after transplantation; however, three other recipients from the same donor survived [151]. Clusters of donor-derived lymphocytic choriomeningitis virus (LCMV) have been reported with poor survival outcomes in the recipients [152].

Donor-derived infections due to other miscellaneous causes have occurred. Immunosuppression is a risk factor for dissemination of latent *Strongyloides* infection, which may persist for decades after leaving an endemic area, typically subtropical climates but also portions of the Southeastern United States. Hyperinfection syndrome from massive larval proliferation and autoinfection after SOT immune suppression carries a mortality rate of greater than 50% [153]. Kidney recipients may reactivate in the setting of profound immunosuppression, but donor-derived infection has also occurred, with the majority of reported cases in the United States occurring in renal transplant recipients [154]. While Chagas disease due to *Trypanosoma cruzi* is endemic in Central and South America, it is estimated that 300,000 persons living in the United States are infected with *T. cruzi* [155]. Transfusion-related and donor-derived infections have occurred predominantly in heart transplant recipients. In 2001, donor-derived Chagas disease from a cadaveric donor from Central America occurred in three recipients: one kidney transplant, one kidney-pancreas, and one recipient of hepatic allograft. The recipient of kidney-pancreas transplant was febrile and diagnosed after a finding of trypomastigotes on a peripheral blood smear; the other recipients were later found to have positive culture for Chagas disease parasite. Despite treatment with nifurtimox, the kidney-pancreas and liver recipients died of myocarditis and hepatic and renal failure, respectively [156]. Primary infection and reactivation have also been documented, most typically in cardiac transplant recipients, however rarely a cause for renal allograft failure [157].

Common infections in the early postoperative period are summarized in Table 4.9.

Opportunistic Infections in Kidney and Pancreas-Kidney Transplant Recipients, First 6 Months Following Transplantation

Opportunistic Bacterial Infections

Solid organ transplant recipients as a whole are at greatly increased risk of TB infection, usually reactivation of latent infection, and carry a 20- to 74-fold higher rates than the general population [82, 158]. The cumulative incidence in renal transplant recipients is 5%, with approximately 40% of cases occurring in the first year [159]. Pulmonary TB represented 78% of cases, including disseminated disease. Predictably, active tuberculosis infection has an unfavorable impact on graft and patient survival, particularly in patients with disseminated disease [158, 159]. Therefore, IGRA testing for latent TB infection should prompt treatment for latent TB in renal transplant recipients and has shown to reduce the risk for serious TB active infection in this group (RR 0.31) [158]. Those treated with isoniazid (INH) have no significant difference in the incidence of hepatitis. Most centers elect to treat with INH to avoid the drug-drug interactions between rifampin and steroids, as well as its effect on decreased CNI drug exposure and serum levels. However, there is data to support the use of rifampin-based regimens; they were well tolerated, without untoward effect on allograft function or increased risk for rejection [160].

Nontuberculous mycobacterial (NTM) infections are rare in renal transplant patients. A single-center study over a 7-year period identified 34 cases of NTM disease in SOT recipients, with only three episodes noted in kidney or kidney-pancreas recipients [161]. *Mycobacterium abscessus* and *Mycobacterium avium intracellulare* were the most

Table 4.9 Common infections in the early (≤30 day) post-kidney or kidney-pancreas transplantation period

Route of acquisition	Infection	Organisms	Risk factors
Surgical	Urinary tract infection	Gram-negative bacilli (especially *Enterobacteriaceae* and *Pseudomonas aeruginosa*), *Enterococcus* spp.	Placement of ureteral stents (kidney recipients), bladder drainage method (pancreas recipients)
			Candiduria: contamination of perfusion fluid
	Surgical site infection	Gram-positive cocci, less commonly Gram-negative bacilli	Obesity, older age, impaired glycemic control
	Pyelonephritis due to contamination of perfusion fluid	Staphylococci (50%), *Candida* species (10%)	
	Anastomotic leaks and peripancreatic fluid collections (pancreas recipients)	Enteric Gram-negative bacilli	Enteric drainage method
		Enterococcus spp., *Staphylococcus* spp., *Lactobacillus*, *Candida* spp.; multidrug-resistant organisms (11%)	
Healthcare acquired	Urinary tract infection	*Enterococcus* spp., enteric Gram-negative bacilli especially *E. coli*	Presence of urinary catheter
	Pneumonia	Gram-negative bacilli, *S. aureus*	Mechanical ventilation especially if prolonged, aspiration, chronic lung disease
	Central line-associated bloodstream infection (CLABSI)	*Staphylococcus* spp., *Enterococcus* spp.	Indwelling central vascular catheter
		Gram-negative bacilli	
	Colitis	*Clostridium difficile*	Deceased donor, leukopenia, recent gastrointestinal procedure in the preceding 3 months, more days of cumulative and restrictive antimicrobial exposure, more cephalosporin use
	Multidrug resistant organism (MDRO) infection, most commonly in the urinary tract	ESBL-producing *Enterobacteriaceae* (especially *E. coli* and *Klebsiella pneumoniae*), *P. aeruginosa* and *Enterobacter cloacae*; carbapenemase-producing *K. pneumoniae* (KPC); carbapenem-resistant *Acinetobacter baumannii* (CRAB); vancomycin-resistant enterococci (VRE)	Prolonged intensive care/hospital stays, extensive antibiotic exposure
Donor-derived	Urinary tract infection (donor bacteriuria)	Enteric Gram-negative bacilli	
	Bloodstream infection (donor bacteremia)	Coagulase-negative staphylococci, *Staphylococcus aureus*, less commonly Gram-negative bacilli	
	Viral hepatitis	Hepatitis B virus, hepatitis C virus	High-risk donor
			Human error (such as in testing or reporting donor serologies)
	Retrovirus infection	HIV, HTLV	HTLV: Donor from endemic region
			HIV: High-risk donor
			Human error (such as in testing or reporting donor serologies)
	Neurotropic virus	West Nile virus, rabies virus, LCMV	
	Parasitic infection	Strongyloides stercoralis, Trypanosoma cruzi	Donor from endemic region

common pathogens, and the lung was the most common site of disease. Lung transplant recipients had the highest risk of infection. Infections due to *Nocardia* species are a relatively uncommon cause of infection in kidney and pancreas allograft recipients.

Fungal Infections

The risk of reactivation of endemic dimorphic fungal infections depends on individuals' exposure to the specific geographic locations. *Histoplasma capsulatum* is the most widely prevalent endemic dimorphic fungi causing human illness (see Fig. 4.1). Assi et al. reviewed over 150 histoplasmosis cases occurring in solid organ transplant recipients over a 7-year period, 67% of which occurred in kidney, kidney-pancreas, and pancreas recipients [162]. The median time to diagnosis was 27 months after transplantation; however, one-third of cases were diagnosed in the first year. Disseminated disease was present in 81% of the cases, and approximately one-third had severe disease requiring care in ICU. A 10% attributable mortality was observed with *Histoplasma* infec-

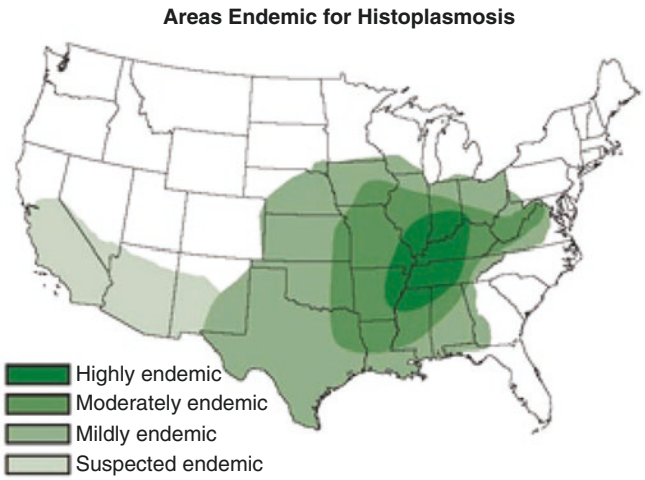

Fig. 4.1 Areas endemic for histoplasmosis [163]. (Reprinted from National Center for Emerging and Zoonotic Infectious Diseases, Centers for Disease Control and Prevention (CDC). 21 Nov 2015. http://www.cdc.gov/fungal/pdf/histoplasmosis-lifecycle508c.pdf)

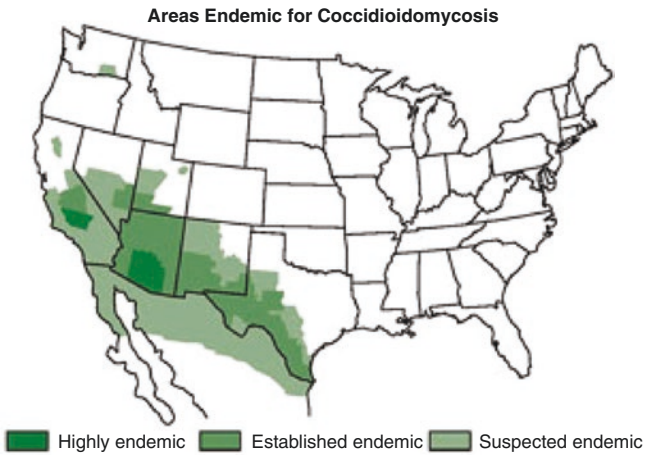

Fig. 4.2 Areas endemic to coccidioidomycosis. Known and suspected areas where the fungus that causes Valley fever lives in the United States [165]. (Reprinted from National Center for Emerging and Zoonotic Infectious Diseases, Centers for Disease Control and Prevention (CDC). Aug 2016. http://www.cdc.gov/features/valleyfever/)

tion and most deaths occurring within 1 month of infection diagnosis. Older age and severity of fungal disease were risk factors for death in these high-risk patients with histoplasmosis. Urinary histoplasma antigen was the most sensitive diagnostic test and was positive in 93% of the cases.

Coccidioidomycosis, caused by the dimorphic fungi *Coccidioides immitis* and *Coccidioides posadasii*, is endemic to the Southwestern United States, particularly Arizona and Southern California, as well as Northern Mexico and Central America [164] (Fig. 4.2). Coccidioidomycosis typically causes a self-limiting febrile illness with respiratory features; however, dissemination with multi-organ involvement may occur in immunocompromised patients and carries a substantial morbidity and mortality [164, 166, 167]. Dissemination rates in dialysis and renal transplant recipients are high between 25% and 75%; the spleen, kidneys, skin, pancreas, bone marrow, thyroid, lymph nodes, and CNS are the common extrapulmonary sites involved [166, 167]. The median time between transplantation and infection was 6 months, although infections have been seen 4 years after transplantation. Prophylaxis against coccidioidomycosis may be targeted in renal transplant recipients with recent infection or positive serology at the time of transplantation.

Cryptococcus neoformans is an encapsulated yeast found in soil, frequently associated with contamination by bird feces, and may be inhaled by a human host. It is the third most common invasive fungal infection in SOT recipients, following *Candida* and *Aspergillus* [168]. Cryptococcosis may manifest as meningitis, pulmonary infection, skin disease, or dissemination infection. Cryptococcosis may present with greater delay than other fungal infections; the median time to onset was 575 days in a large surveillance study of invasive fungal infection in SOT recipients [168]. Kidney transplant recipients may present with cryptococcal disease even later than liver or lung recipients [169]. A recent single-center survey found 1.2% incidence of cryptococcosis, which included disseminated, meningeal, and cutaneous disease [170]. Half of their cases occurred within the first 6 months following transplantation. Additional immunosuppression risk factors were noted in half of these patients including concurrent CMV infection with leukopenia or increased drug-induced immunosuppression preceding the cryptococcal infection. Blood cultures were positive in only half of cases. Cryptococcal immune reconstitution inflammatory syndrome (IRIS) is an increasingly recognized complication in SOT recipients, and clinical presentation may not be too dissimilar to what has been extensively reported in patients with AIDS receiving highly active antiretroviral therapy [169].

The incidence rate of invasive aspergillosis (IA) is lower in renal allograft recipients compared with other solid organs transplantation. Since renal transplants are the most frequently performed transplants, the overall burden is highest [171]. The estimated incidence of IA in renal transplant recipients is <0.5% [172, 173]. Approximately half of episodes occur in the first 3–6 months after transplantation although late IA 6 months after undergoing transplantation procedures occurs more commonly in renal than other SOT recipients [171, 173]. Risk factors for early IA seen within 3 months of transplant procedure include a longer duration of renal replacement therapy pretransplant and the presence of leukopenia [174] as well as acute rejection and the need for dialysis in the first weeks [171]. Risk of late IA is associated with donor CMV seropositivity [174]. Underlying lung disease and chronic heart failure also increase the risk

for IA [171, 173]. The patients with IA were also more likely to have had a bloodstream infection, CMV disease, HCV, or low lymphocyte counts in the immediate postoperative period, although these may be surrogate markers of overall profound immunosuppression or healthcare exposures [171]. Mortality ranges from 40% to 60%, most of which is attributable to IA [171, 174]. Positivity of serum galactomannan correlates with increased mortality [173, 174]. Of survivors, 25% experienced graft loss. Renal allograft aspergilloma has been reported occurring late after transplantation. Graft aspergilloma typically requires a surgical approach in addition to systemic mold-active antifungal drug therapy although successful medical treatment alone has been reported [175]. Treatment of aspergillosis in any SOT recipient requires careful adjustment of CNI dosage in conjunction with azole use, typically voriconazole. Intravenous voriconazole contains cyclodextrin for solubility and may accumulate in the setting of renal dysfunction and dialysis, although it does not cause profound toxic effects. The liposomal formulation of amphotericin B (AmBisome®, Gilead, Foster City, CA) does not achieve adequate penetration for fungal pyelonephritis, and the nonliposomal formulation (amphotericin B deoxycholate) must be used, which carries higher risk of renal dysfunction, electrolyte abnormalities, as well as infusion-related reactions and discomfort.

Prophylaxis against *Pneumocystis jiroveci*, formerly *P. carinii*, pneumonia (PCP) is universally recommended in solid organ transplant recipients. The incidence of PCP in renal transplant recipients ranges from 0.6% to 14%, and the period of greatest risk occurs between 2 and 6 months after transplantation [176, 177]. PCP is the most common opportunistic infection leading to ICU admission in renal transplant recipients, and approximately one-half require mechanical ventilation [178]. Trimethoprim-sulfamethoxazole (TMP-SMX) is the prophylactic agent of choice as it is the most effective and also prophylaxes against additional pathogens, including *Toxoplasma gondii*, *Listeria monocytogenes*, *Nocardia* spp., and urinary pathogens. TMP-SMX may also prevent infection with *Nocardia*, although breakthroughs have been reported while on PCP drug prophylaxis. Concerns specific to renal transplant recipients include the need for dose adjustment in the setting of delayed graft function or fluctuating renal function. Hyperkalemia and a mild increase in serum creatinine level, though not truly reflective of an actual decrease in renal dysfunction, may occur during TMP-SMX therapy, which may be difficult to manage in some renal allograft recipients. For patients with sulfa allergy or an inability to tolerate TMP-SMX, dapsone, inhaled pentamidine, or atovaquone are alternative therapies that are less effective and do not provide additional prophylaxis against the aforementioned pathogens. PCP coinfection with CMV is common, and definitive diagnosis should be pursued to ensure treatment of all active pathogens [176]. Any late allograft dysfunction and subsequent use of T-cell depleting immunosuppression and corticosteroids should prompt resumption of PCP prophylaxis.

Outbreaks of pneumocystis pneumonia have also occurred among renal transplant recipients in Europe, Japan, and Canada [179–181]. The Canadian outbreak represented the first such in North America in recent decades [179]. All patients had received 1 year of TMP-SMX prophylaxis after transplantation. The median time between transplant and PCP infection was over 10 years. Affected patients had lower eGFR (29.3 mL/min vs 66.3 mL/min, $p = 0.028$) and lymphopenia (0.51×10^9/L vs 1.25×10^9/l, $p = 0.002$). Four patients who had genotyping done had an identical fungal strain. Overlapping ambulatory care visits were identified as the potential source of transmission. Genotyping done in the Canadian and other cohorts has identified a predominant strain being responsible for outbreaks, presumably from a common human or environmental source [179, 180]. After an outbreak, the entire renal transplant population should resume prophylaxis for 6–12 months [179–181].

Viral Infections

BK Polyomavirus Virus

BK polyomavirus (BKV) is a small double-stranded DNA virus in the polyomavirus family with four serologic groups and genotypes, each of which may elicit specific, non-cross-reactive antibody responses [182]. It was discovered in 1971 and named for the index patient's initials [183]. Infection is thought to be acquired in childhood via oral and respiratory secretions, and initial infection is generally mild in patients with intact immune function [183]. Among the general population, seroprevalence is estimated between 60% and 80% with highest seroprevalence of 91% between the ages of 5 and 9 years [184, 185]. Age and BKV titers have a significant association with linearly declining titers at a rate of 8.7% per 10 years [184, 185]. BKV infects proximal tubule epithelial cells, where it persists and, when reactivated by immune suppression, replicates and produces infectious virus particles within the cells [186]. While immunosuppression likely plays a role in reactivation of the virus, mouse models also show mechanical and chemical injury contributing to newly acquired infection or BKV infection reactivation [187].

BKV infection is an important cause of renal allograft dysfunction and graft loss. The most common presentations include asymptomatic rise in creatinine, nephropathy, and ureteral stenosis. Hemorrhagic cystitis is an uncommon manifestation in renal transplant recipients but is the most common presentation of BKV infection in hematopoietic stem cell transplant recipients [183]. In kidney transplant

recipients who develop an unexplained rise in creatinine, BKV PCR in urine and serum should be obtained as part of the evaluation.

Incidence has been increasing since the mid-1990s, thought to be due to the use of more intensive immunosuppression regimens [188]. Incidence of BKV infection peaks around 1 and 3 months following transplantation; infections do occur later within the first year after transplantation [189–192]. Asymptomatic BKV shedding may be found in up to 10% of the general population and approximately 20–32% of renal transplant candidates [184, 185, 191–194].

Because the BKV seroprevalence is so high in the general population, it is not considered an exclusion criterion for donors, although seronegative recipients may acquire donor-derived BKV infection. In a study of 20 donor-recipient pairs, sequencing was consistent with donor derivation of BK infection [195]. Measurable presence of BKV pretransplant is considered a risk factor for posttransplant BK virus replication, higher rates of graft dysfunction, and higher serum creatinine levels [192–194], although no association was found between pretransplant BK viruria and posttransplant BK viruria or viremia in a 2016 prospective study by Bicalho et al. [191].

Fluoroquinolone (FQ) prophylaxis against BKV showed promise in in vitro and observational studies and was proposed to inhibit host topoisomerase used by the virus for replication but failed to prevent infection in prospective and randomized controlled trials [182, 196–198]. Lebreton et al. completed a 3-month prospective study of ciprofloxacin prophylaxis in patients who had additional pretransplantation immune suppression and found that neither rates of BKV infection nor bacterial infection differed [197]. Knoll et al. performed a double-blinded placebo controlled trial with 3 months of levofloxacin prophylaxis, which did not prevent BK viruria [196]. The levofloxacin prophylaxis was associated with an increased risk of adverse events such as bacterial resistance and nonsignificant increased risk of suspected tendonitis. A systematic review concluded that FQ prophylaxis is ineffective in preventing BKV infection and found no significant differences in FQ-resistant infection [198]. Brennan et al. found that randomized use of tacrolimus versus cyclosporine A did not impact the incidence of future BK viruria or viremia, although in patients who did develop viruria, levels were highest in tacrolimus and lowest in cyclosporine A treated patients [199].

BKV infection progresses to nephropathy in 1–10% of kidney transplant recipients [190]. Preemptive PCR monitoring of viral DNA in urine or blood is recommended, usually at least monthly immediately after transplant, and then at 3 months' interval (Fig. 4.3). Elevated BKV DNA levels in blood should trigger further evaluation and an early reduction in drug-induced immunosuppression to prevent progression to nephropathy [190]. BKV viruria typically precedes viremia by 6–12 weeks and may be present in 10–40% of renal transplant recipients without any clinical or histological evidence of BK nephropathy [183, 190, 199, 200]. Persistent high-level viruria for more than 2 months or viremia PCR ≥10,000 copies/mL in the setting of renal dysfunction have an increased positive predictive value for BKV nephropathy [190, 200]. Because of the frequency of viral shedding in the urine, some centers use viremia as a screening methodology, which may be more predictive and identify a narrower group of patients for closer monitoring. The advantages of screening for viruria or urine decoy cells include a high negative predictive value and less invasive testing [190]. Renal biopsy remains the gold standard for diagnosis and should be pursued if viruria or viremia is present in high sustained levels or is seen in conjunction with elevated creatinine or persistent urine cytologic changes, although some centers will elect to make changes in immunosuppression and treat based on high sustained viremia alone.

"Decoy cells" are epithelial cells with typical cytopathic effects including enlarged nuclei and basophilic nuclear inclusions and are characteristic for BKV infection that can be seen in urine cytology. JC virus is another human polyomavirus that may cause the presence of decoy cells in urine. However, infection with JC virus is more likely to be asymptomatic and less likely to result in polyomavirus nephropathy [200]. Risk factors for graft loss in recipients with BKV infection include serum creatinine >2 mg/dL, early BK virus nephropathy within the first 6 months following transplant, and presence of microvascular inflammation including glomerulitis and peritubular capillaritis [201]. Other identified risk factors can be further classified as donor-related, recipient-related, and transplant-related, although there is some discordance between studies, such as preceding CMV infection as a potential risk factor, indicating an area of evolving understanding [183, 190, 202–210]. (Table 4.10) Protective factors include centers with higher transplant volume and living kidney donation [203].

Standard of care involves reduction of immunosuppression which is typically sufficient to clear viremia and viruria plus decoy cells or both. Reduction of immunosuppression is less likely to clear decoy cells due to JC virus infection, with <50% clearance versus 93% clearance in patients with BKV-associated decoy cells; this being said, the observed risk of graft loss is minimal even in those who fail to clear decoy cells in the urine following reduced antirejection-associated immune suppression [200]. The mTOR (mammalian target of rapamycin) inhibitors have in vitro antiviral activity, therefore replacing CNIs with these agents have been suggested for select patients with immunological risk for BK nephropathy [188, 189]. Use of cyclosporine A in place of tacrolimus has also been suggested in patients with persistent BK viremia [190]. The proposed adjuvant therapies include fluoroquinolones, leflunomide, cidofovir, and intravenous immunoglobulin (IVIG) [183, 190].

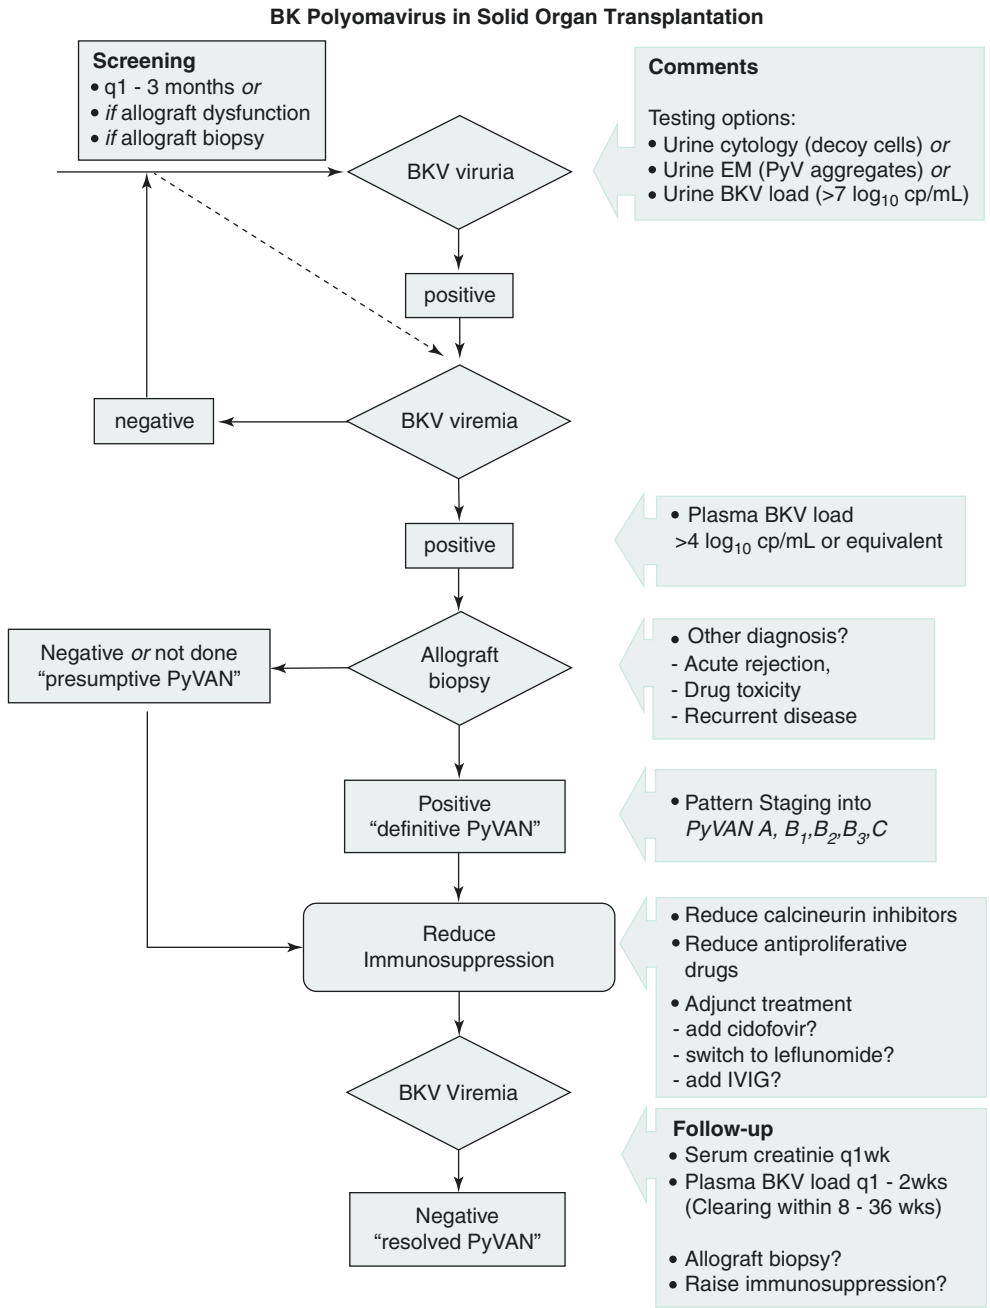

Fig. 4.3 BK polyomavirus screen. Screening and management of kidney transplant patients for BKV replication and polyomavirus-associated nephropathy (PyVAN) [190]. (Reprinted with permission from Hirsch and Randhawa [190] with permission from John Wiley and Sons)

Table 4.10 Risk factors for BK polyomavirus nephropathy

Donor-related risk factors	Recipient-related risk factors	Transplant-related risk factors
HLA-mismatch	Pediatric recipients or older age	Ureteral stents or trauma
Deceased donor	Male gender	Delayed graft function
High BK virus-specific antibody titers (suggesting more recent exposure and possibly higher burden in the kidney)	Low or absent BK virus-specific antibody titers	Acute rejection
	White or African American ethnicity	Antirejection treatment
Female gender		Steroid exposure
Ischemia-reperfusion injury		Lymphocyte-depleting induction
Advanced donor age		Higher immunosuppressive drug levels
		Tacrolimus-based suppression regimen
		Diabetes mellitus
		Cytomegalovirus infection

After clearing plasma BKV DNA and nephropathy by histology, a cautious increase in maintenance immunosuppression can be considered [190]. Cases of IRIS have been described with BKV infection [190, 211]. With close monitoring, re-transplantation may be considered and carries a 93% graft survival rate 3 years after transplantation [212]. Dharnidharka et al. found that 17.5% would require intervention for recurrent infection [212].

Brincidofovir is an oral form of cidofovir that shows promise as a future therapeutic option [182]. Research focused on ELISPOT assay may also help to better define the immune response to BKV in individualized treatment decisions [213]. Rare but increasing reports of long-standing PV nephropathy and renourinary neoplasms also warrant ongoing evaluation [214].

Human Adenovirus

Human adenoviruses (AdV) are non-enveloped double-stranded DNA viruses within the *Adenoviridae* family [215] which have also been seen with increasing frequency due to use of more potent immunosuppression [215]. There are 7 species (A–G) which are further subdivided into serotypes, of which 52 have been identified [215]. Certain serotypes are associated with particular disease manifestations [215, 216]. In immunocompetent patients, it causes self-limited respiratory, gastrointestinal, and conjunctival disease year-round and is most commonly seen in children or military recruits [215]. In renal transplant recipients, it causes hemorrhagic cystitis or tubulointerstitial nephritis [216] and may lead to acute graft rejection and systemic dissemination [217–221]. Species B serotypes 7, 11, 34, and 35 are particularly associated with hemorrhagic cystitis. In addition to gross hematuria, patients may present with dysuria and fever as well as coinfection with bacterial UTI, BK virus infection, or concurrent AdV viremia [217]. Time to onset following transplantation may vary widely from days to a year or more, but most will fall in the first 1–3 months after transplantation [215, 217, 220].

Humar et al. detected plasma adenovirus DNA in 6.5% of kidney recipients over a 1-year study period [222]. Among all SOT recipients, over half (58%) were asymptomatic, while another 21% had vague or nonspecific symptoms. The remaining patients experienced gastrointestinal or respiratory symptoms at equal rates of 10.5% each. No effect on acute graft rejection was observed; however, subsequent CMV infection rates were higher in kidney transplant recipients with adenovirus viremia.

Unlike preemptive CMV and BK screening following renal transplantation, adenovirus screening is not routinely performed. If disease is suspected, the diagnosis can be established with PCR or with rapid antigen tests such as immunofluorescence assays in respiratory samples or by enzyme immunoassay, immunochromatography, or latex agglutination in stool samples [216]. While most serotypes grow well in cell cultures, with the exception of serotypes 40 and 41, viral culture may take up to 28 days for viral growth and ex vivo cytopathic changes to appear in the cell line cultures [215, 216]. Typical cytopathic effects seen in tissue include nuclear enlargement, peripheral condensed chromatin, and basophilic nuclear inclusions representing viral particles [216, 218], and renal biopsy may additionally show tubular cell necrosis. Many patients may continue to shed virus for a prolonged period of time after recovery from an infection or in asymptomatic patients without the evidence of viral disease.

The U.S. Food & Drug Administration (FDA) has not approved any agent for the treatment for AdV infection. Cidofovir is active against all AdV serotypes and widely used for treatment of AdV disease in the immunosuppressed population [215]. Cidofovir undergoes intracellular conversion to become the preferred substrate for the AdV DNA polymerase, leading to viral DNA chain termination [223]. For mild cases a reduction in drug-induced immune suppression alone may be sufficient, although no standardized algorithm exists. Cidofovir carries a significant risk of nephrotoxicity, which can be seen in up to half of patients, and neutropenia and uveitis may occur [216]. It requires renal dose adjustment and should be given with probenecid and intravenous hydration to mitigate the risk of nephrotoxicity. Thrice-weekly dosing may be less nephrotoxic however may result in breakthrough of CMV or HSV infections [216]. CMX001, or brincidofovir, the lipid conjugate of cidofovir, achieves higher intracellular levels compared with cidofovir, does not carry the same nephrotoxicity risk and shows promise as a potentially safe and effective treatment for AdV infection [223].

Serial quantitative PCRs are useful in monitoring the course of disease and defining the end of therapy [220]. Median duration of AdV infection in the urinary tract is 15 days [217]. Use of IVIG for patients with hypogammaglobulinemia may also be helpful as an adjunctive therapy [114, 216].

Cytomegalovirus (CMV)

Like BKV, CMV seroprevalence is common in the general population, typically following a primary infection in childhood that then establishes lifelong latency. Human CMV is a β herpes virus and the largest virus to infect humans [224]. Seroprevalence rates in the United States reach 60–70% and rates are near 100% in parts of Africa [224, 225]. In healthy adults, infection may be asymptomatic or present with features of acute infectious mononucleosis. Similar to HSCT, in solid organ transplant recipients CMV is associated with serious and potentially life-threatening illness. The virus itself additionally encodes genes that downregulate the host immune system [224].

CMV infection in renal transplant recipients may present as asymptomatic viremia, CMV syndrome typically consisting of fever, malaise, leukopenia and thrombocytopenia, or end-organ, tissue-invasive disease. The most common site of CMV organ disease in renal transplant recipients involves the upper or lower gastrointestinal tract presenting as esophagitis, enteritis, and/or colitis [226, 227]. CMV disease involving the lungs, retina, pancreas, and liver is less common in these patients. In general, tissue-invasive CMV disease has a predilection to involve the allograft of solid organ transplant recipients [228]. The renal allograft may be the site of subclinical or latent CMV disease, viruria being not uncommon in renal transplant recipients [229]. However, among viremic renal transplant recipients, viral inclusions are found in <1% of biopsies performed for increasing serum creatinine levels [230]. In an observational study, the majority of these biopsies showed interstitial nephritis with tubulitis, although a wide spectrum of histopathology has been associated with CMV in the renal allograft [230]. In this select subgroup of patients with CMV viral inclusions, treatment with ganciclovir and documented clearance of virus had not resulted in normalization of serum creatinine levels. In patients receiving a pancreas or pancreas-kidney transplant, gastrointestinal disease is the most common manifestation of tissue-invasive CMV disease [231].

Donor and recipient CMV serostatus is an important determinant in prevention strategies for CMV infection following transplantation. In early prophylaxis trials using valacyclovir, between 48% and 67% of patients in the control group developed CMV disease within the first year after transplant [232, 233]. CMV seronegative recipients (R−) had a far higher incidence of CMV disease than their seropositive counterparts (48% vs. 6%) [232]. Biopsy-confirmed acute graft rejection 6 months after transplantation occurred in more than half of patients in whom antiviral prophylaxis was not given [232, 233]. A large prospective study of 609 kidney and kidney-pancreas recipients, who received standardized universal CMV prophylaxis, found 17.7% developed CMV viremia over a 4-year period of which 88% were asymptomatic [210]. Those with symptomatic CMV disease presented with either CMV syndrome or tissue-invasive disease [210]. Infection occurred at a median of 5.6 months after transplant. Multivariate analysis identified D+/R− serostatus ($p \leq 0.0001$), donor age >50 years ($p = 0.013$), higher mean tacrolimus dose ($p = 0.0009$), and higher mean mycophenolic acid blood level ($p = 0.01$) to be risk factors for CMV infection. D−/R− status is the lowest risk for CMV infection. Authors found symptomatic CMV infection, when compared with asymptomatic viremia or no viremia, to have a significantly negative impact on graft survival, conferring a 3.5 times higher risk for graft loss ($p = 0.04$) [210]. A pooled analysis of randomized controlled trials found patients receiving mTOR inhibitors were significantly less likely to have CMV viremia, infection, or end-organ disease as compared to those receiving mycophenolate [234].

Disease rates are similar among pancreas transplant recipients. A study of 130 simultaneous pancreas-kidney (SPK) or pancreas after kidney (PAK), all of whom received antiviral prophylaxis for a median duration of 49 days, had an overall CMV infection rate of 24%, which diverged when classified by recipient serostatus to 44% in D+/R− and 8.2% in R+ group [235]. Another large retrospective study of pancreas and pancreas-kidney recipients found CMV infection in 17.1%; asymptomatic viremia was noted in 4.8%, and CMV disease including CMV syndrome or tissue-invasive disease was present in 10.2% of patients [231]. The cumulative incidence of CMV infection was 20% within 10 years after transplantation [231]. Risk factors for the total cohort included D+/R− status (OR = 16.075), preceding non-CMV infections such as bacterial, fungal, or other viral infections (OR = 6.362), and duration of antiviral prophylaxis (OR = 0.984) [235]. Among the D+/R− group, only non-CMV infection was identified as a risk factor for CMV disease (OR = 10.7). In another large group of 407 pancreas recipients, the incidence of CMV infection was 20.2% in D+/R−, 16.5% in D+/R+, 5.0% in D−/R+, and 2.8% in D−/R−; most of these infections occurred 3 months and beyond after transplantation [236]. Infection was less common in SPK. Immune suppression was not reduced in 72%, and no CMV-related deaths or graft loss were noted.

Valganciclovir prophylaxis after renal transplantation is protective against CMV, HSV, and varicella zoster virus (VZV). Nevertheless, routine monitoring should be done with pp65 antigen or quantitative CMV PCR at regular intervals or if there is clinical suspicion of CMV disease. The longest duration of prophylaxis is recommended for those at highest risk of CMV infection – those with D+/R− status. The American Society of Transplantation (AST) Infectious Diseases Community of Practice regularly updates CMV guidelines, including recommendations for prophylaxis [228] (Table 4.11). Universal prophylaxis may be more

Table 4.11 Risk, recommended prophylaxis, and duration by donor/recipient CMV serostatus

Donor/recipient CMV status	Degree of relative risk	Prophylaxis agents and dosing, assuming normal renal function	Minimum duration of prophylaxis
D+/R−	Highest risk	Valganciclovir[a] 900 mg oral daily	6 months
D+/R+, D−/R+	Moderate risk	Valganciclovir[a] 900 mg oral daily	3–6 months
D−/R−	Lowest risk	Acyclovir 400 mg oral twice daily or valacyclovir 500 mg oral twice daily[b]	3 months

[a]Oral ganciclovir 1gram three times daily may be substituted
[b]D−/R− prophylactic approach may vary by transplant center

cost-effective than a preemptive monitoring strategy, which employs regularly scheduled CMV PCR monitoring [234]. In the setting of acute rejection and treatment with lymphocyte-depleting agents or high-dose corticosteroids, resumption of valganciclovir prophylaxis for 1–3 months is warranted. A preemptive strategy may alternatively be considered [228].

Treatment is twofold, including reduction of immunosuppression and targeted inhibition of the viral DNA polymerase with intravenous ganciclovir or oral valganciclovir. Oral valganciclovir can be used in patients with mild to moderate disease, whereas intravenous ganciclovir is indicated for patients with severe or life-threatening disease and high CMV viral loads or in patients with unpredictable enteric drug absorption [228]. Induction treatment should be maintained for a minimum of 2 weeks but should be extended until resolution of symptoms and virologic suppression has been documented using antigenemia or PCR [228].

Treatment options for drug-resistant CMV include high-dose intravenous ganciclovir (7.5–10 mg/kg every 12 h), foscarnet, and cidofovir. Both ganciclovir and valganciclovir require intracellular phosphorylation into ganciclovir monophosphate via phosphotransferase, a product of the UL97 gene of CMV. Monophosphate is then phosphorylated by cellular enzymes to ganciclovir triphosphate [224]. Mutation in the UL97 gene results in ganciclovir-resistant virus and may be seen in patients requiring repeated treatment courses and following long-standing low drug level exposure. Viral resistance to ganciclovir may vary depending on the site of mutation [228]. In this setting, high-dose ganciclovir or foscarnet may be considered, based on individual genotypic assays. The addition of the UL54 gene mutation can confer cross-resistance to ganciclovir, foscarnet, and cidofovir [228].

Potential toxicities from CMV treatment in renal transplant recipients are considerable. Myelosuppression may be seen with ganciclovir and valganciclovir, compounded by concurrent use of trimethoprim-sulfamethoxazole prophylaxis in many cases. Additionally, as renal function may improve or fluctuate in the posttransplantation setting, dose adjustments of valganciclovir prophylaxis may lag, leading to inadequate intracellular levels and breakthrough infection or development of de novo drug-resistant viral isolates. Use of either foscarnet or cidofovir carries risk for significant nephrotoxicity, making management of resistant virus in the renal transplant recipient additionally challenging. Foscarnet therapy requires close electrolyte monitoring as hypocalcemia, hypomagnesemia, and hypophosphatemia may also result [224]. Cidofovir undergoes uptake by the proximal convoluted renal tubular cells, leading to cell degeneration and necrosis which may be irreversible and require patients to receive renal replacement therapy [237]. Adequate intravenous hydration should be maintained, and coadministration of probenecid reduces cidofovir reuptake by renal tubular cells.

Epstein-Barr Virus

Epstein-Barr virus (EBV), another of the human herpes viruses, causes acute infectious mononucleosis among immunocompetent individuals and lymphoma in HIV-infected individuals. It is transmitted through saliva, body fluids such as with sexual contact, blood transfusion, or via organ transplantation. Within the SOT population, EBV infection may cause posttransplant lymphoproliferative disorder (PTLD). PTLD incidence varies by type of SOT and occurs at the lowest rates in renal transplant recipients, with an approximate incidence of 0.46% in the first year and then 1.1–1.4% cumulative incidence by 5 years after undergoing transplantation [238–240]. However, as renal transplants are by far the most commonly performed among the solid organs, kidney transplant recipients make up the highest absolute number of PTLD cases [238]. Using the UNOS database, the PTLD rate among pancreas transplant recipients was estimated at 1% with a mean follow-up time of 5 years [241]. Risk factors for development of PTLD in the pancreas allograft recipients were similar to those identified in renal allograft patients.

Identified risk factors for development of PTLD in renal transplant recipients include history of pretransplant malignancy, fewer HLA matches, or treatment with antithymocyte globulin (ATG) or muromonab-CD3 (OKT3) [239]. A 10-year single-center prospective trial, however, found no significant association between induction or maintenance immunosuppression regimens and occurrence of PTLD [238]. Recipient age has had conflicting impact on development of PTLD between American and French registry data [239, 240]. Recipient EBV serostatus is considered to be the most important factor in development of PTLD. Use of mycophenolate and azathioprine are associated with a lower risk of PTLD, whereas IL2-receptor inhibitors and sirolimus use do not appear to impact the risk for PTLD [239]. Monthly EBV PCR testing has a low positive predictive value of 16.7%, although a 95.2% negative predictive value is appealing [238]. Nevertheless, regular monitoring is standard of care in most centers, and KDIGO guidelines suggest monitoring high-risk (EBV D+/R−) kidney transplant recipients for EBV with NAT testing, and that any patients with increasing EBV load have a reduction in immunosuppression [242] (Table 4.12).

Table 4.12 Epstein-Barr virus monitoring in high-risk* renal transplant recipients [242]

Time after transplantation	Recommended frequency of monitoring
First week	Once
3–6 months	At least monthly
6–12 months	Every 3 months

Additional monitoring is recommended after treatment for acute rejection

**High risk is considered EBV seropositive donor and seronegative recipient (D+/R−)*

The role of prophylaxis in preventing PTLD remains ill-defined. Although antiviral prophylaxis is not generally given to target EBV or prevent the development of PTLD specifically, when routine antiviral prophylaxis became widespread both acyclovir prophylaxis for HSV and ganciclovir or valganciclovir for CMV prophylaxis demonstrated a decline in PTLD rates [243–245]. This was first observed in a cohort of pancreas-kidney recipients receiving different anti-CMV prophylactic regimens including oral acyclovir or intravenous ganciclovir followed by oral acyclovir [244]. A multicenter, case-control study of renal transplant recipients assessed the impact of immunosuppressive and antiviral therapy on PTLD in this population and found that prophylactic antiviral use was associated with up to 83% PTLD risk reduction [246]. For every 30 days of ganciclovir use, risk of PTLD during the first year was 38% lower, with an odds ratio of 0.62. Acyclovir was less effective but still resulted in reduced risk for PTLD (odds ratio 0.83). Results were strongest within the first year following transplantation. A retrospective registry study of over 44,000 deceased-donor kidney transplants found nearly identical rates of lymphoma during the first year after transplant among patients who did and did not receive ani-CMV prophylaxis [247]. They did, however, find a complete absence of lymphomas in patients who had received anti-CMV immunoglobulin in the first year following transplantation. This protection did not extend beyond 1 year, and all three groups developed lymphoma at similar rates in the subsequent 5 years. A prospective randomized trial with EBV D+/R−solid organ recipients found no difference in (1) incidence of detectable EBV viral load within the first year posttransplant, (2) time to first detectable viral load, or (3) time to high-level viral load between patients given ganciclovir for 3 months or ganciclovir plus immune globulin therapy [248]. Three of these 34 patients developed PTLD, all of whom were in the immune globulin treatment group.

The treatment of PTLD is complicated and involves reduction in iatrogenic antirejection drug-mediated immune suppression, antiviral therapy, and rituximab-based chemotherapy regimens. Five-year survival of renal transplant recipients with PTLD is just over 60% [239, 240]. Graft PTLD has an improved 5-year survival rate of approximately 80% [240]. Older age, pretransplant malignancy, OKT3 use, HBV or HCV infection, late-onset PTLD, and multiple site involvement or high Ann Arbor staging have been identified as risk factors for death [239]. Good prognostic markers include mycophenolic acid use which was associated with improved survival [239, 240]. Among pancreas allograft recipients with PTLD, 1-, 3-, and 5-year survival rates were 91%, 76%, and 70%, compared to 97%, 93%, and 88% in patients without PTLD [241].

Community-Acquired/Late Infectious Complications in Kidney and Pancreas-Kidney Transplant Recipients

As renal transplant recipients approach 1 year and beyond after transplantation, they are more likely to acquire community-based infections. Up to 6% of renal recipients will have a life-threatening complication requiring ICU admission, most at or beyond the 6-month posttransplant mark [178]. The most common ICU diagnoses for these admissions are cardiac pulmonary edema, bacterial pneumonia, acute graft pyelonephritis, and bloodstream infection. The most common opportunistic infection is PCP, with approximately half needing mechanical ventilation. The most common immune suppression-associated systemic toxicities include drug-related neutropenia, sirolimus-related pneumonitis, and posterior reversible encephalopathy syndrome (PRES). Acute kidney injury is common with 40% requiring renal replacement therapy. Hospital mortality ranges up to 30%, while half of patients are discharged free from dialysis.

In a matched, case-control propensity-adjusted study of SOT and non-SOT controls with blood culture proven sepsis, of which approximately 40% of the SOT were kidney or pancreas-kidney transplants, those with SOT were more likely to have:

- A higher number of comorbidities [OR 8.2]
- Higher sepsis-related organ failure assessment scores [OR 1.2]
- Presence of nosocomial infection [OR 36.3]
- Appropriate initial antibiotics [OR 0.04]
- Lower white blood cell count [OR 0.93] [249]

Interestingly, after adjustment for clinical presentation, severity of illness, and types of infection, SOT recipients with sepsis had a significantly lower risk of death at 28 days and 90 days when compared with non-SOT patients [249]. The authors suggest that immune suppression for transplantation may account for this survival benefit due to modulation of the inflammatory response. These patients were also, however, more likely to receive initial appropriate antibiotics, and it was not reported if these patients received earlier or more infectious disease consultations to assist with treatment of sepsis although presumably most SOT recipients are well-linked to care and counseled to call their center early on for any sign or symptom of possible infection [250]. A large retrospective study using University Health System Consortium ICD coding data found SOT recipients hospitalized with sepsis or severe sepsis were more likely to be younger and insured by Medicare and found a similar lower in-hospital mortality compared to non-SOT patients for those with kidney, liver, and kidney-pancreas transplants but not those with heart or lung transplant who in fact had higher mortality rates [251].

For patients with pancreas or pancreas-kidney transplants, urinary tract infections are the most common urological complications, followed by hematuria, bladder calculi, reflux pancreatitis, and urine leaks related to the pancreatic graft [252]. The urinary bladder drainage method in pancreas transplantation is associated with a higher frequency of urologic complications and rarely requires conversion to enteric diversion [252–254]. Flow issues should be considered in any kidney or pancreas-kidney recipient as abnormal or blocked flow may increase risk for infection and may complicate success in achieving cure or preventing recurrence.

Asymptomatic bacteriuria is common and may account for approximately half of diagnosed UTIs in renal transplant recipients [255]. The bulk of asymptomatic bacteriuria occurs in the early posttransplantation period – particularly the first month – with enteric pathogens such as *Enterococcus faecalis* and *Escherichia coli* [255, 256]. Identified risk factors for asymptomatic bacteriuria include female gender, induction with ATG, presence of comorbidities, acute rejection, and CMV infection. Treatment in renal transplant recipients has ranged from 30% to 100% in series, but evolution to symptomatic UTI is similar between treated and untreated patients, and in both groups, it is typically not the same bacterial pathogen to cause the asymptomatic bacteriuria and the UTI [255, 256]. El Amari et al. found persistent bacteriuria in nearly half of treated episodes with selection of a resistant pathogen in 78% [256]. Conversely, more than half of untreated patients (59%) may have spontaneous bacterial clearance in the urine, particularly if they have low-grade bacteriuria without pyuria. Traditionally, however, asymptomatic bacteriuria was treated in the posttransplantation period with the intent of preventing future UTI or development of graft pyelonephritis; this approach continues to be controversial. In a randomized controlled trial, kidney transplant recipients underwent systematic screening for asymptomatic bacteriuria beyond the second month after transplant and found no differences in the frequency of pyelonephritis, lower UTI, acute rejection, graft function, and all-cause mortality up to 24 months among the antibiotic treatment group vs. patients randomized to no antibiotic control group [257]. There were no additional complications of antibiotic use including *Clostridium difficile* colitis or colonization or infection with drug-resistant organisms in the antibiotic treatment group.

Pyelonephritis in the renal transplant recipient has distinct clinical characteristics. It is defined as the presence of fever plus urinary culture growth with greater than 10^5 CFU/mL and/or bacteremia along with at least one of the following symptoms: pain over the allograft site, chills, cystitis with dysuria, increased urinary frequency, or urgency [258, 259]. The incidence rate of acute graft pyelonephritis is 4.4 episodes per 100 patient-years [258]. In this study, risk factors for the development of acute graft pyelonephritis included the presence of glomerulonephritis as the underlying disease and the previous occurrence of at least two episodes of asymptomatic bacteriuria, and odds ratio was higher with increasing number of episodes of asymptomatic bacteriuria. As mentioned above, the relationship between asymptomatic bacteriuria and the development of acute graft pyelonephritis remains unsettled. In the 3-year follow-up, there was no significant difference in levels of serum creatinine, creatinine clearance, or 24-h proteinuria between patients with and without acute graft pyelonephritis.

Candiduria may represent asymptomatic colonization or, less commonly, true infection. Generally, it does not warrant treatment in adults unless they are neutropenic or will be undergoing urinary tract instrumentation. Ureteral stents remaining in place after transplantation may become colonized and make candiduria difficult to clear. Echinocandins do not achieve adequate levels in the urine to be used for treatment, whereas fluconazole and nonliposomal amphotericin B may be used. In challenging cases of azole-resistant candiduria or fungal pyelonephritis, flucytosine may be added but is generally not used alone due to a low barrier for development of resistance during or following monotherapy. Surgical evaluation may be needed in some cases of pyelonephritis, particularly due to *Aspergillus* spp. [175].

Rejection often mimics infection and should be included in the differential diagnosis of patients presenting with renal allograft dysfunction and fever. Nearly half of patients with allograft failure are hospitalized with fever within 6 months of failure [260]. Patients weaned off immunosuppression after failure have less documented infection than those patients maintained on immunosuppression (38% vs. 88%, $p < 0.001$), although they are at risk for increased alloimmunization. In both groups, the most common infection is dialysis catheter-related bloodstream infection. Hospitalized patients with documented infection are less likely to have allograft nephrectomy performed (30% vs. 81%; $p < 0.001$). Mortality was higher in simultaneous pancreas-kidney recipients and those hospitalized with documented infection.

Emerging fungal pathogens in the renal transplant population tend to occur late after 18 months following transplantation [261]. Relevant pathogens include *Scedosporium*, *Pseudallescheria* spp. and *Fusarium* spp., Zygomycetes such as *Rhizopus*, *Mucor*, and dermatiaceous molds like *Ochroconis, Verruconis, Cladophialophora, Bipolaris, Rhinocladiella,* and *Fonsecaea* species. The most common sites of infection include respiratory tract and paranasal sinuses, skin, and central nervous system.

Dermatophytosis is common in renal transplant recipients, occurring in 42% of patients in one screening study [262]. Infection was chronic lasting more than a year in 40% of the patients. Tinea cruris and tinea corporis were the most common infections observed, with *Trichophyton rubrum* being a common pathogen.

Post-kidney or kidney-pancreas transplant recipients are at risk for malignancies which occur later posttransplantation and are associated with the use of chronic immunosuppressive therapy. A malignancy of infectious origin is Kaposi Sarcoma (KS), due to reactivation or donor-derived acquisition of human herpes virus 8 (HHV-8) [263]. Incidence ranges from 0.5% in Western and Northern countries to approximately 5%

in Mediterranean regions, the Middle East, and South Africa. The skin is the primary site of KS, but visceral organ involvement can occur as well; involvement of the allograft is rare. An approach to treatment may involve reduction of immune suppression, change of regimen to include an mTOR inhibitor such as sirolimus, which has an antiviral effect, local treatments including laser, surgery, cryotherapy or radiotherapy, or systemic chemotherapy in severe cases.

As patients get farther out from transplant, they may engage in more outdoor activities or travel with the potential for exposure to infection, and the risk of acquiring severe travel-related illness is higher in immunocompromised persons [264]. An increasing number of parasitic infections are reported in SOT recipients, including intestinal giardiasis in a SPK recipient [265] and strongyloidiasis, of which kidney recipients constitute the majority of donor-derived infections [154]. Travel-related Chikungunya has been reported in an HIV-positive renal transplant as well [264]. West Nile virus is another mosquito-borne illness but endemic to parts of the United States. Transplant recipients have a higher risk of neurological complications from WNV [135, 266], as seen in three kidney and pancreas-kidney recipients in the 2012 epidemic, two of whom survived after treatment with IVIG [266]. Transmission of WNV has also occurred as a donor-derived infection after transplantation [135]. The kidney may be the site of prolonged WNV replication and shedding, and testing of urine instead of blood has been proposed [135].

Common infections beyond the first month posttransplantation are summarized in Table 4.13.

Table 4.13 Common infections in the intermediate and late (community phase) post-kidney or kidney-pancreas transplantation period

Category	Infection	Organisms	Route of acquisition	Risk factors
Bacteria and mycobacteria	Asymptomatic bacteriuria (AB), urinary tract infection, acute graft pyelonephritis	Enteric Gram-negative bacilli (especially *E. coli*), *Enterococcus* spp.	Community acquired, healthcare associated	For AB: female gender, induction with antithymocyte globulin, presence of comorbidities, acute rejection, CMV infection
				Acute graft pyelonephritis: ± recurrent asymptomatic bacteriuria
				In pancreas-kidney transplant: vesicular drainage method
	Bacterial pneumonia	*S. pneumoniae*, *S. aureus*, Gram-negative bacilli, atypical bacteria	Community acquired, healthcare associated	
	Bloodstream infection	*S. aureus*, coagulase-negative staphylococci	Community acquired, healthcare associated	Graft failure with resumption of hemodialysis, particularly via temporary catheter
	Tuberculosis, most commonly pulmonary and disseminated	*Mycobacterium tuberculosis*	Primary: Reactivation	Positive IGRA test, from an endemic region, increased immunosuppression
			Secondary: Donor-derived, community acquired	
Fungus	Endemic mycoses	*Histoplasma capsulatum*, *Coccidioides immitis*, *C. posadasii*, less commonly *Blastomyces dermatitidis*	Reactivation, primary community acquisition	Living in region of endemicity
	Cryptococcosis (meningitis, pulmonary infection, cutaneous disease, dissemination)	*Cryptococcus neoformans*, *Cryptococcus gattii*	Environmental (inhalation)	
	Pneumocystis pneumonia	*Pneumocystis jiroveci*, formerly P. carinii	Primary: Environmental (inhalation)	Use of T-cell depleting immunosuppression including steroids
			Secondary: Healthcare-associated outbreak	
	Aspergillosis	*A. fumigatus*, *A. niger*, other species	Environmental (inhalation)	Renal replacement therapy, leukopenia, allograft rejection, comorbid lung disease or heart failure, CMV
	Other mold infection (respiratory tract infection, sinusitis, skin/dermatophytosis or central nervous system infection)	*Zygomycetes*, dematiaceous molds, *Scedosporium/Pseudallescheria*, Fusarium species	Environmental	
		Dermatophytosi: *Trichophyton rubrum*		
	Urinary tract infection, pyelonephritis	Candida species, Aspergillus species	Endogenous, environmental, healthcare associated	Candiduria: presence of ureteral stents

(continued)

Table 4.13 (continued)

Category	Infection	Organisms	Route of acquisition	Risk factors
Viral	Polyomavirus nephropathy	BK virus, JC virus (rare)	Primary: Reactivation Secondary: Donor-derived in a seronegative recipient	HLA mismatches, deceased donor, high donor BK virus-specific Ab titers, low or absent recipient BK virus-specific Ab titers, higher overall immunosuppressed state, allograft injury (delayed graft function, ischemia-reperfusion injury), ureteral stents, CMV infection
	Asymptomatic viremia, CMV syndrome (fever, malaise, cytopenias), tissue-invasive disease (esophagitis, enteritis/colitis, pneumonitis, hepatitis, viruria, or rarely renal allograft involvement)	Cytomegalovirus	Primary: Reactivation Secondary: Donor-derived in a seronegative recipient, transfusion related with non-leukoreduced blood products, or rarely new community acquisition	Donor positive/recipient negative serostatus, allograft rejection
	Adenovirus hemorrhagic cystitis, allograft rejection, respiratory tract disease, gastroenteritis, hepatitis, myocarditis, dissemination	Adenovirus	Reactivation, primary community acquisition	
	Posttransplant lymphoproliferative disorder (PTLD)	Epstein-Barr virus	Primary: Donor-derived Secondary: Reactivation	Recipient EBV-negative serostatus, history of pretransplant malignancy, fewer HLA matches, overall higher immunosuppressed state
	Hepatitis	Hepatitis B virus, hepatitis C virus	Reactivation, donor derived	Chronic HBV or HCV infection in recipient, high-risk donor
	Progressive multifocal leukoencephalopathy (PML)	JC virus	Reactivation	
	Kaposi sarcoma (KS) of skin or viscera	Human herpes virus 8 (HHV8)	Primary: Reactivation Secondary: Donor-derived in a seronegative recipient	Regionality (Mediterranean, Middle East, South Africa)
Parasitic	Disseminated strongyloidiasis	Strongyloides stercoralis	Reactivation, primary community acquisition	History of residence in or travel to an endemic region

Use of Antimicrobial Prophylaxis in the Kidney and Pancreas-Kidney Transplant Recipient

The use of antimicrobial prophylaxis is a vital tool in preventing infection and complications in kidney and pancreas-kidney transplant recipients. Infection rates have improved with the introduction of standardized antimicrobial prophylaxis after transplant [267]. The ideal prophylaxis targets diseases that are either common or carry significant morbidity and mortality and confers little toxicity. Cost-effectiveness may be a consideration when comparing prophylactic modalities as well. If a patient has significant allergies to antibiotics that are known before transplant, consultation with an allergist may be considered for allergy testing to better delineate options for treatment in the event of infection after transplant.

Trimethoprim-sulfamethoxazole (TMP-SMX) is the cornerstone of antimicrobial prophylaxis in renal transplant recipients, with the aim at preventing urinary tract infections, pyelonephritis, urosepsis, and pneumocystis pneumonia. Prior to its routine use in renal transplant recipients, 30–40% of recipients developed UTIs within the first 4 months following transplantation, and they were often associated with Gram-negative bacteremia, significant graft dysfunction, and relapse [267]. KDIGO guidelines recommend its use for at least 6 months after transplantation with the indication of preventing urinary tract infections and pneumocystis; prophylaxis should be extended or reinstituted for at least 6 weeks after treatment for acute rejection [242]. TMP-SMX carries potential added benefits as it also confers protection against additional pathogens, such as *Toxoplasma gondii*, *Listeria monocytogenes*, and *Nocardia* spp., among others [268, 269]. TMP-SMX is inexpensive and easily accessible but may cause significant adverse reactions in some patients, including cytopenias, hepatic necrosis, and drug rashes ranging from urticaria to Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) [269]. While the sulfamethoxazole may be nephrotoxic at high doses, the trimethoprim may cause a minor, generally ≤0.4 mg/dL increase in serum creatinine without truly impacting glomerular fil-

tration rate as it inhibits tubular creatinine secretion [270, 271]. This effect is more pronounced in patients with chronic kidney disease or higher serum creatinine prior to use [270]. It must be dose adjusted in the setting of renal allograft dysfunction if creatinine clearance falls below 30 mL/min [269]. Hyperkalemia and GI upset may also be dose-limiting side effects in some patients. Other options for pneumocystis prophylaxis include dapsone, which may have cross-allergenicity with TMP-SMX and may rarely cause life-threatening hemolysis in patients with or without glucose-6-phosphate dehydrogenase (G6PD) deficiency or methemoglobinemia. Atovaquone is administered as an oral solution and may cause gastrointestinal upset. Inhaled pentamidine should be used with caution in patients prone to bronchospasm and is the least effective agent against PCP as it may not prevent upper lobe pneumocystis or the rare extrapulmonary pneumocystis infection. These alternative agents do not confer protection against the broader range of pathogens covered by TMP-SMX.

Despite TMP-SMX broader antimicrobial coverage, however, retrospective data is conflicted as to its effectiveness in preventing asymptomatic bacteriuria or UTI and trends toward increased amoxicillin and TMP-SMX resistance within 30 days of use [272, 273]. Conversely, it has been shown to reduce the incidence of sepsis in renal transplant recipients as compared to those without prophylaxis [274]. Randomized controlled trials, however, have shown efficacy of TMP-SMX prophylaxis. Renal transplant recipients randomized to receive TMP-SMX had fewer hospital days with fever and bloodstream infections when receiving high-dose prophylaxis (320/1600 mg daily, compared to 160/800 mg daily). Both doses, however, were effective in preventing urinary tract infection after, but not before, catheter removal. TMP-SMX use did not result in colonization or infection with TMP-SMX-resistant Gram-negative bacilli, and patients were less likely to be colonized with *Candida*, possibly due to less antibiotic treatment for infection; however, their infections were more likely to be caused by resistant bacteria than the placebo group. TMP-SMX prophylaxis was found to be cost-beneficial and to have minimal effect on the hosts' microflora [275]. Another randomized, controlled trial using various doses of TMP-SMX found that prophylaxis with high dose (320/1600 mg daily) reduced UTI in the first month after transplant as compared with patients given low or moderate dose prophylaxis [276]. For patients intolerant of TMP-SMX, ciprofloxacin has been studied as an alternative for UTI prophylaxis. Low-dose ciprofloxacin (250 mg daily) as compared to single strength (80/400 mg daily) TMP-SMX daily for 6 months showed ciprofloxacin to be at least as effective as TMP-SMX in preventing urinary tract infection and had better tolerability [277]. Pneumocystis pneumonia occurred in 14% of the ciprofloxacin group; no cases were observed in the TMP-SXM group; however, a follow-up uncontrolled study found ciprofloxacin prophylaxis combined with monthly aerosolized pentamidine was effective in preventing both UTI and pneumocystis pneumonia.

The use of routine perioperative surgical prophylaxis, typically directed at preventing wound infections, will vary by center protocol. Among a retrospective study of 349 renal transplant recipients who received TMP-SMX but not additional perioperative antibiotic prophylaxis, wound infections developed in only 7 patients (2%) and were more common in obese and older patients [122]. All wound infections in the study period were superficial and responded well to wound drainage and outpatient antibiotic therapy. Without additional perioperative antibiotic prophylaxis, the incidence of UTI in the first postoperative month was still low, occurring in 1.7% of patients overall, although this was notably higher in patients who had ureteral stents (11.4% vs 0.3%, $P < 0.001$). The authors suggest that, given the rarity of perioperative bacterial infection in the renal transplant population on TMP-SMX prophylaxis, routine perioperative antibiotic prophylaxis be restricted to patients older than 60, with a body mass index greater than 35, or complicated transplants requiring ureteral stents in order to reduce emergence of drug resistance, costs, and adverse events. However, most centers still opt to give at least short-term prophylaxis with cefazolin or similar agents, and this remains an area for ongoing study.

Oral and esophageal *Candida* prophylaxis with clotrimazole lozenges, nystatin, or fluconazole is recommended for 1–3 months after transplantation and for 1 month after treatment with antilymphocyte antibody [242]. This is also effective against contamination of perfusion fluid with *Candida* species. Use of fluconazole requires concurrent adjustment and monitoring of immunosuppressant levels.

Prophylaxis for tuberculosis should be given for renal transplant recipients diagnosed with latent TB infection or those meeting criteria for non-transplant patients such as a known active TB exposure. Screening and diagnosis of latent TB in the renal transplant recipient is discussed further in the Pretransplantation Screening for Potential Recipients section. In the case of renal or pancreas-renal transplant recipients where bridging therapy with dialysis is an option, there is generally sufficient time in the pretransplant evaluation for patients to undergo TB screening, have imaging done to rule out active disease, discuss prophylaxis options, and begin – or possibly even complete – treatment prior to transplantation. However, latent TB should never be a barrier to proceeding to urgent or life-saving transplantation, but treatment should be started as soon as possible after transplant, ideally within 1 month. A notable exception is patients undergoing simultaneous liver -kidney transplant who may not tolerate the hepatotoxic side effects of TB prophylaxis until after transplant. The most frequently used prophylactic regimens include daily INH for 9 months or rifampin daily for 4 months, although use of rifampin in the posttransplant period has greater potential

Table 4.14 Antimicrobial prophylaxis in the kidney and kidney-pancreas transplant recipient

Agent	Indication	Duration posttransplantation
Acyclovir	Prevention of recurrent HSV outbreaks	Varies
	Prevention of herpes viruses infection in CMV D−/R− patients (vs. a preemptive monitoring strategy which may be used in some centers)	At least 3 months
		Extend or reinstitute for 6 weeks after treatment with a T-cell depleting antibody
	Postexposure prophylaxis in a susceptible patient after varicella exposure if varicella Ig and IVIG are not available or if greater than 96 h have elapsed between exposure and initiation of care	7 days
Antifungal (clotrimazole, nystatin, fluconazole)	Prevention of oral or esophageal candidiasis, prevention of Candida UTI/pyelonephritis in the setting of perfusion fluid contamination	1–3 months after transplant
		Extend or reinstitute for 1 month after treatment with antilymphocyte antibody
Entecavir	Treatment of patients with positive HBsAg or detectable serum HBV DNA	Lifelong
	Prevention of reactivation of latent HBV in a core-Ab positive recipient	Low risk for reactivation Consider prophylaxis or preemptive monitoring strategy with ALT and HBV DNA NAT
	Prevention of transmission from a core-Ab positive donor	
Ganciclovir/ valganciclovir	Prevention of CMV viremia/infection in D+/R−, D−/R+, and D+/R+ patients	3–6 months
		Extend for 1–3 months after treatment for acute rejection
Isoniazid (INH) Co-administered with vitamin B6	Latent tuberculosis	9 months
		If started prior to transplantation, no need for extension as long as there are no significant interruptions in therapy
Trimethoprim-sulfamethoxazole (TMP-SMX)	Prevention of urinary tract infection and pneumocystis	At least 6 months
		Extend or reinstitute for at least 6 weeks after treatment for acute rejection
Varicella Ig	Postexposure prophylaxis in a susceptible patient after varicella exposure if presenting within the first 96 h after exposure	Single dose, may be repeated

for interaction with a number of commonly used antirejection medications. Substitution of rifabutin may have less profound drug-drug interactions [242] but is not recommended among the first-line latent TB regimens by the CDC [278]. Use of either isoniazid or rifampin should prompt a discussion with the patient regarding hepatotoxicity side effects and symptoms of acute liver failure; regular liver function testing is advised. Patients with diabetes, renal failure, HIV, alcoholism, and malnutrition are at increased risk of developing neuropathy from INH use and should take concurrent pyridoxine for prevention of drug-induced neurotoxicity [279]; in most clinical practices, all patients on INH will receive pyridoxine as it has little adverse effect.

CMV prophylaxis with oral ganciclovir or valganciclovir should be administered to all kidney transplant recipients who do not fall into the donor-negative/recipient-negative CMV serostatus group for at least 3 months after transplantation and for 6 weeks after treatment with a T-cell depleting antibody [242]. For the highest risk serogroup (D+/R−), prophylaxis should be extended to 6 months [228]. CMV prophylaxis also confers a protective effect against other herpes viruses, including HSV, VZV, and EBV.

For kidney transplant recipients who experience frequent HSV outbreaks, prophylactic antiviral medication may be considered [242]. If a known varicella exposure occurs in a susceptible recipient, varicella zoster immunoglobulin or intravenous immunoglobulin (IVIG) can be administered within 96 hours of exposure; if neither varicella Ig or IVIG is available or greater than 96 hours have elapsed since exposure, a 7-day course of oral acyclovir can be started within 7–10 days following exposure [242].

A general summary of antimicrobial prophylaxis use is outlined in Table 4.14.

Infections in Intestinal and Multivisceral Transplantation

5

Raffaele Girlanda, Joseph G. Timpone Jr,
Kevin M. Soriano, and Thomas M. Fishbein

Introduction

Intestinal and multivisceral transplantation (IMVTx) has evolved from being an experimental procedure to become an effective treatment for patients with irreversible intestinal failure (IF) and life-threatening complications from parenteral nutrition (PN) [1]. The availability of more potent immunosuppression compared to the early era, especially the use of tacrolimus and of induction therapy, resulted in decreased incidence of acute rejection and improved patient survival up to 90% at 1-year post-transplant in experienced centers, comparable to the survival of patients on home PN. However, IMVTx poses a greater immunological and infectious challenge compared to other solid organs. Unlike the liver or kidney transplant, the intestinal and multivisceral grafts contain a large number of immune cells, and their lumen is heavily colonized by microbes that are transferred to the recipient. As a consequence, on the one hand, the intestine is a highly immunogenic graft being so heavily populated by immune cells; on the other hand, it carries a high risk of infections given the rich composition of microbes. In fact, severe acute rejection remains the main cause of graft loss and death, and infectious complications cause major morbidity pre- and post-transplant. Furthermore, sepsis with multi-organ failure is a major cause of death after treatment of severe rejection. Therefore, the balance between effective immunosuppression and prophylaxis of infections is a major challenge in the management of IMVTx recipients. In addition, IF in itself presents a combination of risk factors for severe infections in the IMVTx candidate, including short gut, bacterial overgrowth, prolonged central venous access for PN, and others. Furthermore, the transplant candidate often carries the sequelae of prior complex abdominal surgery, resulting in defects of the abdominal wall, enterocutaneous fistulae, chronic obstruction, and abscesses. The complexity of scenarios presented by patients with IF and by IMVTx recipients makes them among the highest risk among transplant recipients. Over the last decade there has been significant progress in the management of IMVTx patients including a better understanding of the immunologic mechanisms at play in the gut and improved treatment of infections. At the same time, increasing interest has been focused on the role of the gut microbiome (see below) in the pathogenesis of intestinal and extraintestinal disease. These recent discoveries are likely to translate in improved outcomes of IMVTx recipients. In this chapter, after a brief presentation of current indications and outcomes of IMVTx, we outline recent advances in intestinal immunology and describe specific risk factors for infections associated with IF and IMVTx. We also discuss the current management of common infections after IMVTx.

Indications for Intestinal and Multivisceral Transplantation and Types of Graft

According to the 2009 Intestinal Transplant Registry report, more than 2200 IMVTx have been performed worldwide since 1985 [2]. However, the number of transplants performed so far has only recently increased, reaching 200 transplants/year only in the last 4 years. Therefore, IMVTx represents the most recent development in abdominal organ transplantation. In addition, unlike liver or kidney transplants that are performed in virtually every transplant program, IMVTx is performed in very few specialized centers: as of 2009, only 8 centers worldwide have performed 100 IMVTx or more; therefore current experience remains concentrated in very few transplant programs.

The indication for IMVTx as recognized by the Centers for Medicare and Medicaid Services [3] is irreversible IF defined as the loss of nutritional autonomy of the gut associated with life-threatening complications of PN including liver failure, loss of central venous access secondary to thrombosis,

systemic sepsis from line infection requiring hospitalization, and frequent episodes of dehydration [4–6]. The most common cause of IF is short bowel syndrome secondary to a number of different etiologies in adults and children (Table 5.1).

Table 5.1 Causes of short bowel syndrome in adults and children

Adult	Pediatric (congenital)
Mesenteric vein thrombosis and/or bowel ischemia	Gastroschisis
Crohn's disease requiring multiple small bowel resections	Intestinal atresia
Abdominal trauma due to gunshot wounds	Intestinal volvulus
Radiation enteritis	Congenital short small bowel
Recurrent small bowel obstruction	Necrotizing enterocolitis
Motility disorders	
Neoplasm's of the mesentery (e.g., GIST[a])	
Iatrogenic complications of multiple abdominal surgeries	

[a]Gastrointestinal stromal tumor

Other causes of IF include motility disorders, malabsorption (mucosal defects), and neoplasms of the mesentery.

The intestine is transplanted either as isolated small intestine or combined with the liver in patients with parenteral nutrition-associated liver failure (PNALD). Alternatively, patients with disease involving the foregut and/or the entire colon receive a multivisceral graft that, in addition to the small intestine, includes the stomach and/or the colon (Fig. 5.1).

The donor colon (usually the cecum, right and transverse colon) is included in the graft in selected recipients with absent native colon in order to improve water reabsorption and prevent severe dehydration episodes and renal failure. Since the colon carries a higher microbial load than the small intestine, in the initial experiences of IMVTx, the colon was excluded from the graft to reduce the risk of sepsis post-transplant [7]. However, more recent reports demonstrated that the infection risk and graft survival associated with inclusion of the colon are comparable to non-colon grafts [8, 9].

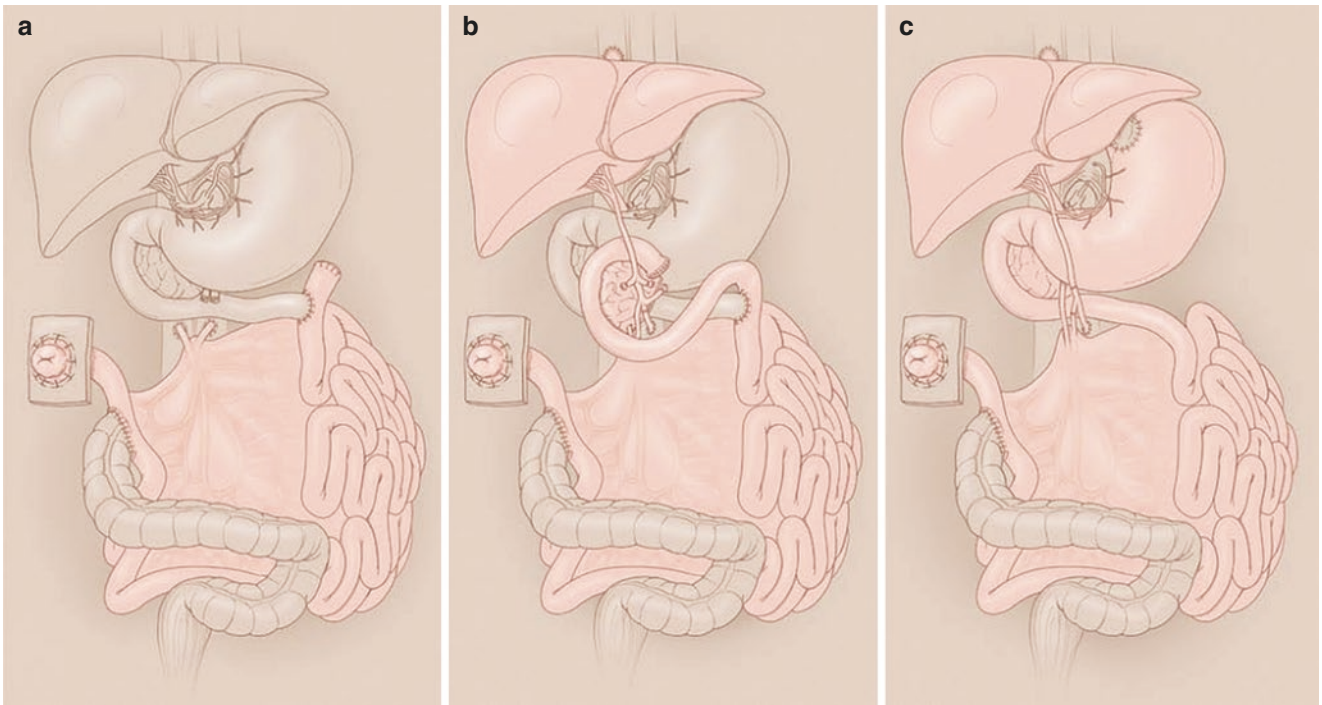

Fig. 5.1 Three types of transplants in intestinal failure. When the small intestine (jejunoileum) is transplanted alone, it is referred to as an isolated intestinal transplant (Panel a), with systemic drainage to the vena cava. A composite liver and intestinal transplant usually includes the duodenum and an intact biliary system and portal circulation, with the native foregut preserved (Panel b). In a multivisceral transplant, which involves the liver, stomach, duodenum, pancreas, and small intestine, the foregut is removed, and a new stomach is transplanted (Panel c). This type of transplant sometimes includes the colon, kidney, or both. The transplanted organs are shown in pink, and the native organs or structures are shown in light brown. Immunosuppression

Given the higher immunogenicity of the intestinal graft and higher incidence of acute rejection compared to other solid organ transplants, IMVTx recipients receive heavier immunosuppression compared to other organ recipients. Although protocols vary between centers, generally immunosuppression regimens for IMVTx include induction with T cell-depleting agents such as thymoglobulin or alemtuzumab or the non-T cell-depleting anti-CD25 interleukin-2 receptor blockers (basiliximab, daclizumab). Alemtuzumab (Campath) is a monoclonal antibody targeting CD52 used in some conditioning regimens for bone marrow transplantation, kidney transplantation, and islet cell transplantation. Maintenance immunosuppressive treatment is usually with a combination of tacrolimus, sirolimus, mycophenolate mofetil, and corticosteroids. The introduction of the calcineurin inhibitor tacrolimus in 1990 made a significant impact in reducing the incidence of rejection and improving survival compared to the cyclosporine era [10]. Recently, with the use of the newer induction regimens, acute cellular rejection rates within the first 90 days have been reported to decrease to 30–50% [1]. Target tacrolimus trough levels are typically higher than levels maintained in other abdominal organ transplants: 20–25 ng/ml for the first month with gradual de crease to the 12–20 range for the first 6 months and then 5–8 indefinitely. Monitoring for rejection includes frequent surveillance endoscopy and biopsy. Episodes of rejection are graded as mild, moderate, or severe according to established parameters based on crypt apoptosis and distortion of the epithelial architecture [11, 12]. Treatment of rejection mandates increased immunosuppression based on the severity of the rejection episode: mild and moderate rejection is generally treated with pulse corticosteroids and increased tacrolimus levels, whereas severe rejection is usually treated with T cell-depleting antibodies (thymoglobulin or alemtuzumab). Traditionally the target of immune therapy against rejection has focused on T cell-mediated mechanisms. Recently, antibody-mediated mechanisms responsible for acute and chronic allograft damage are being investigated and targeted by novel therapies, especially in kidney and heart transplantation. Although donor-specific antibodies have been implicated in worsening episodes of IMVTx rejection [13], a definite entity of antibody-mediated rejection has not been established in IMVTx [14].

Antibacterial agents against intraluminal-colonizing organisms such as aerobic Gram-negative bacilli and anaerobes (e.g., ciprofloxacin and metronidazole) are often added to the treatment of severe rejection given the high risk of bacterial translocation and sepsis associated with exfoliation of the intestinal mucosa. Prophylaxis of opportunistic infections post-transplant generally follows established guidelines adopted for other solid organ transplants. However, due to the high rates of rejection, prophylaxis is often intensified or extended beyond the standard duration and is usually resumed during treatment of rejection episodes and will be described in more detail below.

Immunology of the Intestine

The gut has the largest mucosal surface in the body, estimated to extend up to 200 m^2, making it a very efficient absorptive surface for nutrients. At the same time, the intestinal mucosa is a protective barrier against invasion of pathogens. The barrier is constituted of a single layer of columnar epithelial cells (enterocytes) linked at the apico-lateral membranes by intercellular tight junctions to prevent the paracellular diffusion of luminal contents. As discovered in recent studies, the intestinal epithelium functions not only as a mechanical barrier but also as an immune barrier. In case of B cell deficiency, for example, the enterocyte takes on immune functions at the expenses of metabolic function by upregulating INF pathways and reducing the expression of genes of fat uptake and metabolism, as evidenced by the occurrence of lipid malabsorption in HIV [15]. In addition, enterocytes actively participate to defense mechanisms by interacting with immune cells: goblet cells, for example, which are typically producing mucous for the mucosal barrier, are also able to deliver luminal antigens to dendritic cells of the *lamina propria*, and goblet cell deficiency or dysfunction in mice and humans has been linked to the development of intestinal inflammation [16]. The impact of immune functions of the intestinal epithelium on the barrier function of the graft during posttransplant immune depletion is still incompletely understood and may have implications on the risk of rejection post-transplant.

In addition to the intestinal epithelium, other barrier structures limit the invasion of pathogens: a layer of mucins (membrane-bound glycoproteins or glycocalyx) produced by the goblet cells, secretory IgA, and antimicrobial peptides (defensins) secreted by Paneth cells. Within the epithelium and underneath it, a large number of immune cells (lymphocytes, macrophages, and dendritic cells) populate the intestinal mucosa and the mesenteric lymph nodes. These immune cells are constantly exposed to foreign antigens and to resident bacterial flora. In normal conditions, a delicate balance is maintained between immune protection from infection

and tolerance to harmless antigens of commensal microbes and nutrients. Special mechanisms regulate this balance in the intestinal wall, and the interplay between different cell populations of the intestinal wall is only beginning to being discovered. Alterations of the immune homeostasis of the gut are increasingly being recognized and implicated in the pathogenesis of inflammatory bowel disease and of extraintestinal autoimmune disorders [17]. Also, breach to the intestinal barrier predisposes to bacterial translocation (see below) and sepsis. The complex equilibrium between tolerance to nutrients and rejection of potential pathogens is maintained by special characteristics of the immune cells of the intestine, different from immune cells of the rest of the body. Intestinal macrophages, for example, unlike macrophages present in other organs, have the ability to clear antigens from the *lamina propria* without mounting an inflammatory response. Indeed, intestinal macrophages do not express the LPS coreceptor (CD14), the Fc receptors (CD89, CD16, CD32, and CD64), or receptors for IL-2 (CD25) and IL-3 (CD123). In addition, intestinal macrophages do not produce pro-inflammatory cytokines IL-1 and TNF after stimulation with LPS [18]. This role of intestinal macrophages is critically important to maintain a noninflammatory state within the *lamina propria* of the gastrointestinal tract. In fact, despite close proximity with immunostimulatory bacteria, intestinal macrophages acquire profound "inflammatory anergy" while retaining avid scavenger and host defense functions. A second important component of mononuclear phagocytes of the intestinal mucosa is constituted by dendritic cells (DC). Several subsets of DC have been characterized at multiple levels: in the *lamina propria*, in isolated lymph follicles, in Peyer's patches, and in mesenteric lymph nodes. DC are characterized by very high plasticity, their phenotype and function being driven by local tissue factors. DC in the intestine can both drive or suppress effector responses: in the *lamina propria*, DC extend dendrites between enterocytes, penetrate epithelial tight junctions, and sample luminal contents and microbiota [19, 20], thus priming naïve T cells for an immune response. Other sub-types of DC (CD103+ DC) promote the conversion of naïve T cells into regulatory T cell via TGF-β and retinoic acid [21]. Therefore, under normal circumstances the aggregate function of DC of the intestine contributes to maintain intestinal immune homeostasis. Mutations in genes coding for bacterial sensing receptors such as NOD2 in DC have recently been described [22] and are likely to impact on the risk of infections and/or rejection after IMVTx. Finally, several studies have recently highlighted the features of multiple subsets of T cells in the gut (T-helper 17 cells, γδ T cells, natural killer (NK) cells, and NK T cells). These cells contribute to the mucosal response to pathogens by secreting cytokines which in turn induce the secretion of chemokines and antimicrobial peptides, thereby orchestrating the response of the mucosal barrier against pathogens. In particular, Th17 cells [23], a subset of T-helper cell distinct from Th1 and Th2, have recently been shown to play multiple roles in the gut defense including recruitment of neutrophils to areas of bacterial infection, induction of proliferation of enterocytes, and production of defensins [24–26].

Microbes

Unlike other transplants that are sterile, the intestine is transplanted with a large content of intraluminal commensal microbes. In the past, the intestinal graft used to be "decontaminated" at the time of procurement by flushing the lumen with antimicrobial decontamination solution. The chemical damage of such solutions to the graft mucosa and the recognition of the important role of the intraluminal flora have made this decontamination now obsolete.

The intestinal lumen is populated by a tremendous number of commensal microorganisms, estimated to reach 10^{14} bacteria belonging to over 1000 species, predominantly comprised of the heterogeneous, Gram-positive phylum *Firmicutes* (which includes organisms such as *Bacillus sp.*, *Lactobacillus*, *and Clostridia sp.*) and the Gram-negative anaerobic bacilli, *Bacteroides*. Importantly, the cumulative genetic material carried by intestinal microbes (microbiome) is 100× the size of the human genome. Microbes play multiple roles in host metabolism, including energy recovery from nutrients, generation of digestible carbohydrates and short-chain fatty acids from otherwise nondigestible fibers, and synthesis of amino acids and vitamins. In addition, intraluminal microbes exert immune functions advantageous to the host including competition with pathogens and maintenance of the trophism of the colonic epithelium by synthesis of short-chain fatty acids, like butyrate, an essential growth factor for colonic enterocytes [27]. An increasing interest has recently focused on the role of gut microbiota in health and disease and on the mechanisms regulating this symbiotic relationship between microbes and human intestine [28, 29]. Both beneficial and deleterious effects are being discovered as a consequence of alterations or manipulations of this equilibrium (i.e., alteration of the gastrointestinal microbiome also known as dysbiosis). In fact, germ-free animals are more susceptible to infections; on the other hand, colonization of germ-free mice with a single bacterial species is sufficient to enhance the mucosal immune system, including increased numbers of intraepithelial lymphocytes and increased activity of local antigen-presenting cells (APCs) [30]. Intestinal bacterial commensals communicate via innate detection systems (nucleotide oligomerization domain [NOD] and other Toll-like receptors [TLRs]) to generate adaptive lymphoid tissue and maintain intestinal homeostasis: the peptidoglycan of Gram-negative bacteria induces the generation of isolated lymphoid follicles in the intestinal wall which later

mature into large B cell clusters [31]. In IMVTx intraluminal pathogens can be the source of sepsis following damage to the mucosal barrier secondary to rejection or preservation injury (translocation; see below). Finally, although the exact cause-effect relationship remains to be clarified, alterations of the intraluminal flora of the graft have been recently associated with increased risk of rejection [32].

Bacterial Translocation

Damage to protective barriers of the intestinal mucosa results in bacterial translocation, the passage of viable bacteria or their products, such as lipopolysaccharide and bacterial DNA, from the gut lumen to extraintestinal sites [27]. Under normal circumstances, a low-grade portal vein endotoxemia of gut origin is rapidly cleared by the reticuloendothelial system of the liver. The diseased gut, however, can translocate endotoxin in large amounts such that systemic endotoxemia can be present in patients with acute inflammatory bowel disease [33] and in children with necrotizing enterocolitis, even in absence of bacteremia [34]. A recent study documented increased bacterial DNA in the intestinal wall of children with NEC [35]. The systemic consequences of bacterial translocation (endotoxemia) include damage to the vascular endothelium with induction of intravascular coagulation, increased muscle protein degradation, suppression of cellular immunity, cholestasis, and septic shock. The mechanisms leading to translocation include direct transmucosal migration across the bowel wall toward the mesenteric lymph nodes or migration into the peritoneal cavity. Pretransplant intestinal stasis and bacterial overgrowth increase the risk of translocation. Posttransplant immunosuppression and damage to the bowel wall secondary to ischemia-reperfusion, infection, (especially viral) or rejection result in altered permeability of the graft mucosa and increased risk of bacterial translocation. Episodes of graft dysfunction requiring resumption of parenteral nutrition result in protein depletion and increased mucosa permeability [36]. Cicalese et al. [37] found 44% incidence of bacterial translocation in human IMVTx with an average of 1.9 episodes per patient (defined as simultaneous positivity of stool and blood culture); a third of all episodes of bacterial translocation occurred within the first month post-transplant, and risk factors included prolonged cold ischemia time (>9 hours), inclusion of the colon in the graft, and rejection.

High Infection Risk in Intestinal Transplantation

As compared to other types of solid organ transplantation, IMVTx recipients present a unique clinical situation that predisposes them to an exceedingly high risk for infectious complications. Rates of infection have been reported to be as high as 90% [38] and are likely related to the high density of microbes within the donor intestinal allograft and the potential for bacterial translocation associated with damaged intestinal mucosa in the setting of acute rejection. This coupled with the need for higher levels of immunosuppression necessary to treat and prevent rejection can result in a "perfect storm" for the development of infection. This high risk of infection begins during the pretransplant period and persists throughout the perioperative and postoperative periods and remains an important threat in the years of follow-up in patients who have undergone successful IMVTx. Table 5.2 demonstrates the major risk factors for infection in persons with intestinal failure and small intestinal transplantation.

Table 5.2 Risk factors for infection in patients with intestinal failure and small intestinal transplantation

Pre-transplant risk factors	Post-transplant risk factors
Intra-abdominal anatomic abnormalities resulting in:	Technically complicated surgery
Recurrent enterocutaneous fistulas	Intestinal allograft with dense microbial burden
Recurrent intra-abdominal abscesses/peritonitis	Intensive immunosuppression
Bacterial translocation	Rejection
Total parenteral nutrition	High rates of acute rejection
Recurrent CLABSIs[a]	Mucosal injury with rejection
Fungemia	
Immunosuppression secondary to malnutrition	Bacterial translocation
Frequent hospitalizations	Bloodstream infections/sepsis
Increased risk for HCAIs[b]	Possible decreased absorption of anti-infective prophylactic medication
Colonization/infection with MDROs[c]	Recurrent hospitalizations
	Increased risk for HCAIs[b]
	Colonization/infection MDROs[c]

[a]Central line-associated bloodstream infections
[b]Healthcare-associated infections
[c]Multidrug-resistant organisms

Risk of Infection in the Pretransplantation Period in Patients with Short Bowel Syndrome

Intestinal failure in both adult and pediatric patient populations is associated with multiple medical comorbidities that can result in multiple hospital admissions and prolonged lengths of stay which increases the exposure to and infection with healthcare-associated pathogens. Patients with IF and short gut syndrome are at particular risk for infection due to (1) anatomical alterations as a result of their underlying disease and/or surgical interventions, (2) the relative immunosuppression associated with protein-calorie malnutrition, and (3) the presence of intravascular catheters and gastrojejunostomy tubes for nutritional support.

The underlying diseases experienced by patients with IF often result in multiple surgical procedures such as the resection of ischemic bowel (as in the setting of mesenteric thrombosis) or the resection and repair of multiple intra-abdominal fistulae (as experienced in Crohn's disease). Additionally, these patients also develop spontaneous intra-abdominal abscesses from perforations associated with diseased bowel. Enterocutaneous fistula formation is another common complication in this patient group and may serve as a source of abdominal sepsis and colonization with enteric bacteria as well as streptococcal and staphylococcal species. It is estimated that 80% of deaths associated with enterocutaneous fistulas are due to abdominal sepsis [39–41]. Enterocutaneous fistulas can be associated with peritonitis and discrete intra-abdominal abscesses. Approximately 50% of patients with enterocutaneous fistulas will have an intra-abdominal abscess present on abdominal imaging [42]. Therefore it is important for clinicians caring for patients with IF and enterocutaneous fistulas to have a high index of suspicion for intra-abdominal infections. Although the indications for a surgical approach in this setting is beyond the scope of this chapter, successful management of intra-abdominal abscesses associated with enterocutaneous fistulas using computed tomographic percutaneous drainage has been successful at our center, as well as being reported by others [43]. Patients with enterocutaneous fistulas complicated by intra-abdominal infection also require appropriate antibiotic therapy – which often times is of an extended duration, due to either recurrences or failure to adequately drain the abscess cavity. The need for prolonged antibiotic treatment in this patient population as well as a prolonged hospital length of stay can place them at risk for colonization and infection with multidrug-resistant organisms [44–46].

Intestinal failure is associated with malnutrition. Protein-calorie malnutrition can contribute to a patient's net state of immunosuppression and results in an increased risk of infection. Malnutrition is associated with T lymphocyte depletion and their response to mitogens, failure of B cells to respond appropriately to antigen presentation, and decreased function of neutrophils [47]. Savendahl and colleagues demonstrated that in the setting of a 7-day fast, there can be a decrease in circulating CD3 lymphocytes, as well as CD4 T-helper lymphocytes. In that same study, there was an attenuated IL-2 response to mitogen stimulation [48]. Neonates with necrotizing enterocolitis and congenital abnormalities resulting in short gut syndrome may be in a more precarious situation than adults with short bowel syndrome as a result of their immunologic immaturity. Therefore it is imperative that patients with short bowel syndrome are cared for by physicians with expertise in hyperalimentation and nutritional supplementation. Unfortunately, the chronic use of PN places patients at risk for catheter-related bloodstream infections and liver disease. It is estimated that 50% of patients on chronic PN will develop liver disease within 5–7 years [49]. Chronic liver disease can also contribute to the level of immunosuppression in this patient population, being associated with defects in humoral immunity and neutrophil dysfunction. These patients often have decreased capacity for the opsonization of foreign antigens due to hypocomplementemia [50]. Neutrophil chemotaxis and adherence is also depressed in patients with liver disease [51]. Finally, it has been noted that in cirrhotic patients, the sinusoidal macrophages (Kupffer cells), which play an important role in the clearance of bacteria and foreign antigens, may be bypassed due to portosystemic shunting [52]. Overall, patients with short bowel syndrome who are being considered for small intestinal transplantation may experience secondary immunodeficiency either due to their nutritional state or PN-induced chronic liver disease.

Parenteral nutrition is an important treatment for patients with short bowel syndrome but carries with it a risk for central line-associated bloodstream infections (CLABSIs). In a prospective study evaluating home infusion therapy in 827 outpatients, the rate of infection was 0.99 infections/1000 days. The use of PN was an independent risk factor for the development of infection [53]. Other risk factors are micronutrient deficiency and immune dysfunction. Central line-associated bloodstream infections are important causes of hospitalization and may contribute to both morbidity and mortality in this patient group during the pretransplant period. In one study, PN was identified as the most important risk factor for the development of CLABSI [54]. In addition to isolated bacteremia, chronic central vascular catheter use is associated with endovascular infections such as endocarditis and suppurative thrombophlebitis.

In the neonatal population with short bowel syndrome, CLABSIs are quite common and in one study occurred in 66% of children on home PN within the first 6 months of hospital discharge [55]. In that same study, the highest incidence occurred within the first month, and the most common infections were due to polymicrobial causes followed by Gram-positive, Gram-negative, and fungal causes, respectively [55]. Moreover, the use of PN in the neonatal patient population with short bowel syndrome has been associated with the relatively rapid development of cholestasis, and this has been observed as a complication of infection and sepsis [56, 57].

In one observational study, the risk of CLABSIs in patients receiving chronic PN (mean duration of follow-up was 4.5 years) was noted to be 80.9% [58]. Additionally, 78.9% of these patients had more than one CLABSI, and 23.8% of these episodes were polymicrobial [58]. Although the majority of patients with CLABSIs present with either fevers or a clinical syndrome consistent with sepsis, in one study, 33% of patients with SBS and liver disease on PN had occult bacteremia just prior to their intestinal transplantation.

This patient group had more postoperative days of mechanical ventilation and a more prolonged length of stay as compared to patients who did not have occult bacteremia at the time of transplantation [59].

Microbiology of CLABSIs

Although patients with SBS are a clinically unique population, it is reasonable to assume that the microbiology of CLABSIs is similar to other patient populations. There are no large studies on the causes of CLABSIs in persons on chronic PN who are awaiting IMVTx. It has been our experience that these patients have CLABSIs due to similar pathogens such as staphylococci, enterococci, *Candida* species, and Gram-negative bacilli. The SCOPE (Surveillance and Control OF Pathogens of Epidemiological Importance) study reported on a total of 24,179 cases of CLABSIs in hospitalized patients over a 7-year period and noted a rate of 60 cases/10,000 patient admissions. In this study, Gram-positive organisms accounted for 65%, Gram-negative bacilli accounted for 25%, and fungi accounted for 9.5% of CLABSIs. The most common isolates were coagulase-negative staphylococci (31%), *Staphylococcus aureus* (22%), *Enterococcus* (9%), *Candida* species (9%), *Escherichia coli* (6%), *Klebsiella* species (5%), *Pseudomonas* species (4%), *Enterobacter* species (4%), *Serratia* species (2%), and *Acinetobacter baumannii* (1%) [60].

In general, patients with SBS often require frequent hospitalizations and are likely to have similar microbiological causes of CLABSIs. However, there are several factors that distinguish this patient group and warrant further consideration when assessing these patients for a presumed CLABSI. Although colonization by skin flora (staphylococci and streptococci) is the most likely source of CLABSIs, due to alterations in the integrity of the gastrointestinal tract, they may be at increased risk for enteric pathogens such as Gram-negative bacilli, enterococci and vancomycin-resistant enterococci. As these patients are on PN, the role of contaminated infusates as a source needs to also be considered. Gram-negative organisms such as *Serratia* and *Pseudomonas* species have been associated with infusate contamination [61, 62]. *Candida parapsilosis* fungemia has been associated with contaminated TPN infusate [63–65].

In addition to the risk of contaminated infusate, patients with SBS have numerous risk factors that are associated with invasive candidiasis and candidemia. Specifically, these include the chronic use of central vascular catheters, the use of broad-spectrum antibiotics, the use of PN, and multiple intra-abdominal surgical procedures [66–68]. Candidemia has been associated with mortality rates as high as 47% in adults and 29% in children [67]. While *C. albicans* remains the most common isolate, non-*albicans* species such as *C. glabrata* have been reported more recently [68, 69]. Furthermore, PN appears to place these patients at increased risk for fungemia due to all *Candida* species and has also been associated with *Candida* chorioretinitis and endophthalmitis in other patient populations receiving PN [70–72].

Practice guidelines for the treatment and management of CLABSIs have been established [73]. In addition to appropriately targeted antibiotic therapy, catheter removal is warranted for CLABSIs due to *Staphylococcus aureus*, *Candida* species, and multidrug-resistant Gram-negative bacilli. Catheter removal is also warranted in the setting of sepsis and the presence of or evidence of metastatic foci of infection [73]. Unfortunately, this patient population is also at risk for catheter-associated thrombosis which may often limit vascular access options and in select situations may result in the need for line salvage in the setting of a bloodstream infection. Antibiotic lock therapy and ethanol lock therapy have been employed to supplement systemic antibiotic therapy when considering line salvage [73–75].

Additionally, in a small study of pediatric patients with either small intestinal transplantation or SBS on PN who had frequent CLABSIs, the use of tobramycin lock therapy was effective in reducing CLABSIs and decreasing the number of hospital admissions due to CLABSIs [76]. Practice guidelines for the treatment of catheter-related bloodstream infections have been published and report additional information on this important management issue [73]. In summary, patients with SBS, who are being considered for IMVTx, have both anatomical and immunological alterations that predispose them to bacterial and fungal infections. Bloodstream infections and intra-abdominal infections are the most common infectious complications that these patients experience prior to transplantation. The routine use of PN, as well as the frequent need for hospitalization, places them at increased risk for healthcare-associated infections due to multidrug-resistant pathogens and *Candida* species prior to the time of their transplantation. Therefore this unique patient group carries a risk of antimicrobial selection pressure that may need to be considered when choosing for a surgical antibiotic prophylactic regimen at the time of transplantation.

Pretransplant Evaluation

The pretransplant evaluation includes not only a comprehensive assessment of the patient's clinical status to rule out contraindications for transplant but also optimization of the nutritional status, patient's compliance, and adequate support system post-transplant. This is essential for IMVTx patients because the hospital stay is often more prolonged than other transplants and the posttransplant recovery period may be slow and complicated by infections or need for repeat

surgery. Since virtually every IMVTx candidate presents with a significant infection history (catheter-related bacteremia, previous multiple operations), the optimization of nutrition and compliance and support system are important to reduce the infection risk post-transplant. The panel of pretransplant laboratory tests in the evaluation of the IMVTx candidate is comparable to the panel of other organ recipients and includes viral serology (*hepatitis A, hepatitis B, hepatitis C, herpes simplex virus, CMV, EBV, human immunodeficiency virus, varicella-zoster virus, measles, rubella*) and toxoplasmosis. Patients with a positive tuberculin skin test (PPD) pre-transplant or a history of prior tuberculosis undergo additional screening to rule out active disease. The use of interferon-gamma release assays has not yet been studied in this patient population but may offer some benefit in screening patients for latent tuberculous infection, based on some data from its use in liver transplant candidates [77, 78]. Imaging studies (Doppler survey of central veins, echocardiogram, and computed tomography imaging of the thorax, abdomen, and pelvis) assess the patency of central vessels and rule out occult or known foci of untreated/unresolved infections such as bacterial endocarditis due to frequent episodes of pretransplant bacteremia or fungemia or intra-abdominal abscess as a complication of an enterocutaneous fistula. Aggressive management of pretransplant infections in order to reduce the infection risk post-transplant includes repair of enterocutaneous fistulae and of abdominal wall defects when feasible, drainage of abscesses, and management of bacterial overgrowth. The identification of pretransplant colonizing flora may assist in decisions regarding an individualized peri-transplant prophylactic antimicrobial regimen, although in one study, pretransplant stool surveillance cultures were not predictive of the types of bacteria that were isolated in the setting of a documented infection in the post-transplant setting [79]. Pretransplant vaccination is recommended as for other solid organ transplant recipients (see guidelines of AST Infectious Disease Community of Practice, AJT) [80]. Inactivated vaccines are recommended for post-transplant immunization. Although theoretically the administration of foreign antigen for the purpose of vaccination can cross-reactivate clones of immune cells, there has been no definite documentation of increased risk of rejection related to vaccination.

Approach to Common Post-intestinal Transplant Infections

Timeline of Infections

The timeline of post-transplant infections in solid organ transplant recipients has traditionally been classified into (1) perioperative (first 4 weeks) post-transplantation often due to healthcare-associated infections and due to underlying disease/chronic condition; (2) early post-transplantation (1–6 months), often due to opportunistic pathogens due to higher levels of immunosuppression; and (3) late post-transplantation (>6 months) often due to community-acquired pathogens, molds, as well as manifestations of later viral infections and infection-related neoplasms such as post-transplant lymphoproliferative disorders [PTLD] associated with prolonged enhanced immune suppression [81]. In IMVTx recipients this timeline is not well delineated and is often altered by several factors which include (1) prolonged hospital stay in the post-transplantation period as a result of the complications, (2) the relatively higher rates of repeat surgery, (3) the need for recurrent hospitalizations due to other complications, (4) a more intensive immunosuppressive regimen and maintaining tacrolimus at higher levels for more prolonged durations as compared to other types of solid organ transplant recipients, (5) higher rates and often numerous rejection episodes, and (6) the risk of bacterial translocation that can be associated with mucosal damage that is seen with rejection. As a result, these patients appear to always be at risk for the bacterial and fungal infections that are typically seen within the first month post-transplantation and are often encountered months and even years after transplantation – depending upon the number of readmissions that a patient experiences. Additionally, there is a persistence of the risk of hospital-acquired infections well beyond the first month as these patients often have prolonged initial lengths of stay post-transplantation. Therefore healthcare-associated bacterial infections and fungal infections (due primarily to *Candida* species and *Aspergillus*) remain a persistent or reemergent threat throughout the lifetime of IMVTx recipient. While it is expected that the risk of opportunistic pathogens is highest from 1 month through 6 months post-transplantation, given the relatively high rates of rejection, the clinician caring for these patients needs to "reset" this timeline after each rejection episode, and appropriate prophylaxis should be continued or resumed. These rejection episodes can theoretically contribute to the risk of bacterial or fungal infections as the damaged mucosa allows a portal of entry for colonizing intestinal bacteria and *Candida* species. Finally, the bioavailability and drug exposure of prophylactic agents such as trimethoprim-sulfamethoxazole, valganciclovir, and the azole antifungal agents may demonstrate wide variability in the setting of acute and chronic intestinal allograft rejection; therefore, opportunistic infections could potentially occur despite the use of these prophylactic agents.

There is only one published prospective study that defines a timeline for the development of various types of infections. In a small cohort of IMVTx recipients, it was noted that the median time from the day of transplant to the development of bacterial infections was 11 days, viral infections (CMV and EBV) was 91 days, and fungal infections was 181 days [38].

Based on our own clinical experience and the limited reports in the medical literature, IMVTx recipients may always be at risk for bacterial and fungal infections – especially if they have been recently hospitalized. Although viral infections can typically occur within 1–6 months from transplantation, the numerous rejection episodes may extend this risk to the late post-transplantation period (i.e., >6 months). Therefore we will divide our discussion of infections in IMVTx recipients as follows: (1) the "immediate" post-transplant period (<6 weeks) and (2) the "later" post-transplant period (>6 weeks). Bacterial infections will be addressed in the "immediate" posttransplantation period section, whereas viral, fungal, and parasitic infections will be presented in the "later" posttransplantation section. A proposed timeline and the most common infections in IMVTx are depicted in Table 5.3.

Perioperative Infections

Overview, Incidence, and Risk Factors

Infection continues to be an important cause of morbidity and mortality in patients receiving IMVTx [1, 82, 83]. In one series, infection was the attributable cause of mortality in 17.8% of intestinal transplant recipients and was present in 76.2% of the patients who had died [83]. Furthermore, in one large retrospective series, infection was the second most common cause associated with allograft loss after rejection [82]. It is estimated that nearly 90% of patients who have undergone IMVTx develop a bacterial infection by their follow-up at 6 months [83], and approximately 61% develop a bloodstream infection during their first 6 months post shown to occur in 58–80% of patients who have undergone IMVTx [38, 83, 84]. As most of the studies are small and there is no uniformity in the type of induction and maintenance immunosuppressive regimens, it is difficult to establish clear risk factors that predispose this patient group to such high rates of infection. For example, in one study, there were similar rates of bacterial infections within the first month of transplantation (approximately 60%) when induction therapy with daclizumab (humanized monoclonal antibody to the alpha subunit of the IL-2 T cell receptor) was compared to alemtuzumab [85]. It has been postulated that these high rates of infection are related to bacterial translocation of intraluminal enteric gut flora from the intestinal allograft to sterile sites such as the peritoneum and the bloodstream. It is conceivable that the presence of bacterial flora within the small bowel allograft could gain access to the lymphatics and bloodstream in the immediate postoperative setting as a result of microscopic gastrointestinal mucosal trauma which could occur during

[a]Intestinal transplant

cold ischemia time. Additionally, there are animal models that have demonstrated that bacterial translocation has been associated with antibiotic use, bacterial overgrowth and gastrointestinal dysmotility, malnutrition, use of TPN, and ischemic injury and subsequent bowel reperfusion [37, 86, 87]. All of the above factors are seen in this patient group and can be further compounded by the high level of immunosuppression that is necessary to prevent rejection of this allograft which is rich in lymphoid tissue. In the setting of small bowel allograft rejection, the mucosal injury could facilitate bacterial translocation, and this has been reported in approximately 10% of patients who had undergone IMVTx [37]. In that same study, by obtaining simultaneous stool samples, it was estimated that 44% of the patients who had developed infections (approximately 2.0 episodes/patient) had experienced bacterial translocation that resulted in a documented infection. Bacterial translocation was most commonly documented during the first postoperative month at an incidence of 31%. The organisms that were most commonly associated with bacterial translocation were coagulase-negative staphylococci, *Klebsiella pneumoniae, Enterococcus faecalis, Enterococcus faecium, and Enterobacter cloacae* [37]. A prolonged ischemic time (>9 hours) and the inclusion of a colon as part of the allograft were associated with bacterial translocation [37]. More recently, it has been noted that colonic inclusion was not associated with an increased risk of bacteremia [88], and colonic inclusion as part of the small bowel allograft is considered to be an appropriate option in the management of IF in patients with SBS [8]. The role of bacterial translocation as a contributory cause may be further supported by the predominance of enteric pathogens that are noted as a cause of infection in this patient population [84]. It has also been reported that the microbial environment of the small intestinal allograft shifts from a population of predominantly anaerobic bacteria to a population of *Enterobacteriaceae* and lactobacilli [89].

The role of donor-derived and recipient-derived infections has contributed to the infectious disease-associated morbidity in solid organ transplant recipients during the immediate postoperative period [90]. The role of donor-derived infections may be increasingly important in the setting of small intestinal transplantation as the small bowel allograft (with or without the colon) has a high density of bacterial flora [37]. It is also possible that these donors, while hospitalized, can develop intestinal colonization by drug-resistant enteric bacteria. Concern over the risk of transmission of bacterial and fungal infections from the donor allograft has resulted in the use of gut decontamination protocols at many centers [39, 82, 83]. In a rat model of orthotopic small intestinal transplantation, rats were given polymyxin E and tobramycin by orogastric gavage postoperatively. There was a significant reduction in the amount of enteric bacteria in the ileum and cecum and marked reduction in bacterial translocation to the mesenteric lymph nodes of the group that received the postoperative gut decontamination as compared to the group that did not receive gut decontamination [91]. Selective gut decontamination protocols are employed postoperatively and given as an oral suspension via a gastrostomy or jejunostomy tube into the intestinal allograft. These gut decontamination suspensions target predominantly enteric Gram-negative organisms and fungi and have included various combinations of polymyxin, tobramycin, gentamicin, clindamycin, nystatin, and amphotericin B [38, 83, 84]. The routine use of selective gut decontamination in the intestinal allograft is no longer being employed at our center due to concerns that this practice may result in a "less favorable" intraluminal microbial environment.

Recipient-derived infections have also contributed to the postoperative infectious complications in solid organ transplant recipients, including the transmission of resistant organisms [90, 92]. One study has demonstrated the high prevalence of extended-spectrum B-lactamase (ESBL)-producing *Klebsiella pneumoniae* in stool surveillance cultures of pediatric patients who were undergoing or have received liver or small intestinal transplantation [92]. Bacteremia due to ESBL-producing *Klebsiella pneumoniae* was also noted in this patient population, which supports the hypothesis that colonization of the recipient with multidrug-resistant organisms can result in infections post-transplantation [92]. It is interesting to note that in another study, there was no concordance between the types of organisms isolated from stool surveillance cultures preoperatively and the types of organisms associated with documented infections in the post-intestinal transplant period [79]. Although there is no definitive data, donor-derived and recipient-derived infections likely play an important contributory role in the immediate posttransplantation period, and clinicians may consider altering the perioperative antimicrobial regimen based on prior microbiological history.

Infections in the "Immediate" Posttransplantation Period (<6 Weeks)

The complicated nature of the surgical procedures used in small intestinal and multivisceral transplantation places this patient population at increased risk for healthcare-associated infections in the immediate postoperative period. These patients tend to have prolonged postoperative lengths of stay which expose them to the microbial environment of the hospital. Therefore the predominant initial infectious diseases threat to these patients is bacterial and fungal infections which are characteristic of the types of infections that accompany any critically ill patient who has undergone extensive intra-abdominal surgery. Based on our observations and previous discussion, the "immediate" posttransplantation period

will be defined as <6 weeks from the time of transplantation. This is a somewhat arbitrary cutoff, as these patients can experience these types of infections any time post transplantation, given their need for hospital readmission due to various complications such as rejection, surgical complications, acute kidney injury, etc.

Sites of Infections in the "Immediate" Posttransplantation Period

As in other critically ill postoperative patients, healthcare-associated infections predominate at this time and most commonly involve the bloodstream, surgical site, abdomen, respiratory tract, and urinary tract. It has been our experience that the mean length of stay for adult patients who have undergone IMVTx is 24 days; this increases to 42 days in patients who develop one or more infections. In patients who develop multiple infections (>2), the length of stay increases to 71 days [84]. Based on our observations and those of others, bacterial infections occur in at least 58% of patients within the first 4 weeks post-transplantation and then increase to approximately 80% by 8 weeks post transplantation [83, 84]. The incidence of bacterial infections decreases to 3% per month after 6 months from the time of transplantation [83]. Initial bacterial infections occur very early in the postoperative period with a mean or median time to first infection of 9–11 days [38, 83, 84].

Bloodstream infections and sepsis are an important cause of bacterial infection and represent 26–59% of all bacterial sites of infection during the early postoperative period [38, 83, 84]. In one study, 1.6 episodes of bacteremia occurred per patient, with 2.1 episodes occurring in patients with this type of infection [83]. The 6-month cumulative incidence in adults and pediatric patients who had undergone IMVTx at our center was noted to be 61% and was more common in patients who had also received a liver as part of their transplantation [88]. Pediatric transplant recipients were also more likely to develop a bloodstream infection than the adult patients. This same study did not find an association between the inclusion of a colon or acute rejection with regard to the development of a bloodstream infection, which may call into question the role of bacterial translocation in the setting of rejection [88]. Interestingly, we have observed that bacterial infections preceded episodes of rejection by 15 days in the majority of patients who developed allograft rejection within the first month [84].

The predominant causative organisms associated with bloodstream infections were Gram-positive cocci – accounting for 59–66% of the isolates – followed by Gram-negative enterics accounting for 34–41% of the isolates, and *Candida* species accounting for approximately 3% of the isolates [83, 88]. Of note, *Enterococcus* species (including vancomycin-resistant *Enterococcus faecium)* were noted to be the most common Gram-positive isolate identified which supports the intestinal tract as a source [88].

The management of bloodstream infections is beyond the scope of this chapter but clearly includes source control (i.e., central vascular catheter removal or drainage of an intra-abdominal abscess), along with appropriate targeted antimicrobial treatment.

Intra-abdominal infections including intra-abdominal abscesses, infected intra-abdominal fluid collections, and peritonitis are quite common and account for approximately 13–37% of bacterial infections within the immediate postoperative period (Fig. 5.2) [38, 83, 84].

It was noted in one study that the presence of an intra-abdominal abscess and a positive peritoneal culture was associated with a high mortality within the first month of

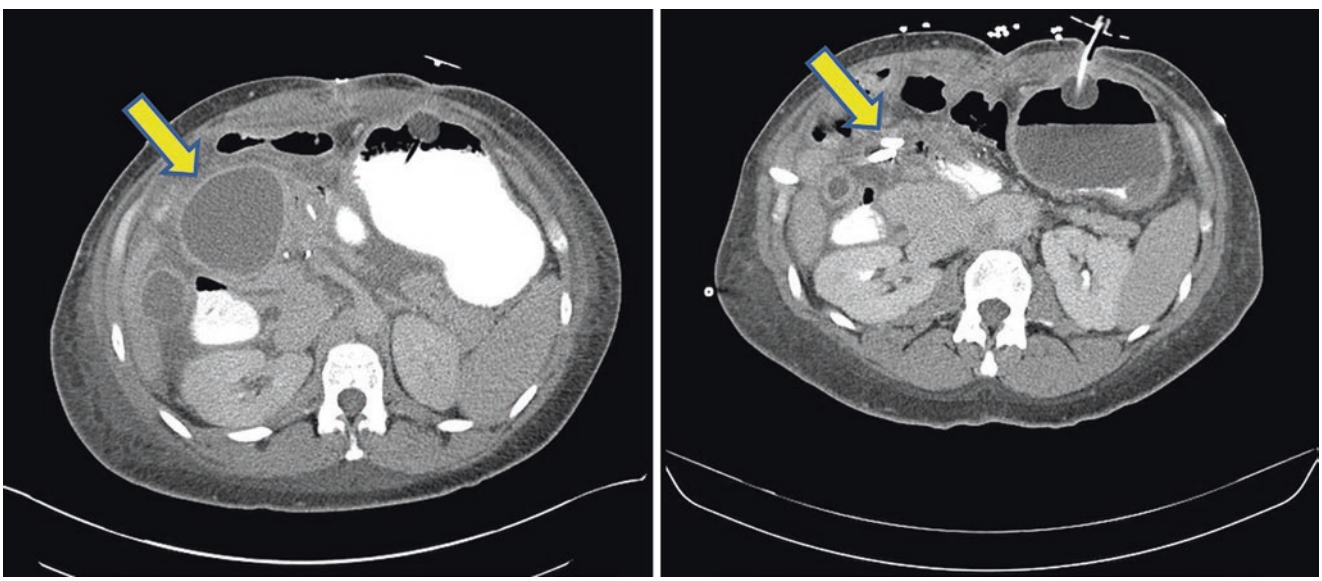

Fig. 5.2 CT scan of abdominal fluid collection post-Tx pre- and post-percutaneous drainage. (Fluid culture: *E. faecium*)

diagnosis (approximately 30%) in small intestinal transplant recipients [83]. Collectively, enteric pathogens including *pseudomonas aeruginosa*, *Enterococcus* species (including vancomycin-resistant *Enterococcus*), *Enterobacter cloacae*, *E. coli*, and *Candida* species have been most commonly reported [83, 84]. Given the reportedly high mortality rate, it is imperative to establish a diagnosis in an effort to improve patient outcomes. The use of computed tomography (CT) to identify intra-abdominal fluid collections and/or abscesses should be employed if there is a high index of clinical suspicion. Management options can include CT-guided percutaneous drainage of intra-abdominal fluid collections as well as exploratory laparotomy and intra-abdominal washout along with appropriate targeted antimicrobial agents.

Respiratory tract infections including healthcare-associated pneumonia (HCAP) account for 14–17% of bacterial infections in small intestinal recipients [38, 83, 84]. It has been reported that 39.5% of HCAPs occur within the first 2 months post-transplantation, with a median onset of 36.5 days. The microbiology of HCAPs in this patient population does not differ from other patient populations and includes *Pseudomonas aeruginosa, Klebsiella pneumoniae, Escherichia coli, Acinetobacter baumannii,* and *Staphylococcus aureus* [83, 84],. The clinician caring for these patients should refer to the practice guidelines for the diagnostic and management of HCAP (Practice Guidelines for HCAP, IDSA). Other atypical bacterial respiratory pathogens have not been reported in this patient population. Although tuberculous and non-tuberculous *Mycobacteria* can cause disease in solid organ transplant recipients (often between months 1–6 post-transplantation), to date, no cases have been reported in IMVTx recipients. We have seen a case of pulmonary infection with *Nocardia* asteroids that disseminated to the central nervous system in a multivisceral transplant recipient – occurring many months after transplantation.

Surgical site infections account for 9–17% of bacterial infections in small intestinal transplant recipients, with a higher percentage due to Gram-negative enterics as the causative pathogens [83, 84]. Urinary tract infections accounted for 15–17% of the bacterial infections in small intestinal or multivisceral transplant recipients [38, 84]. There have also been other types of bacterial infections reported at other miscellaneous sites which include empyema, cholangitis, sinusitis, otitis media, and septic arthritis [83].

As discussed previously, multidrug-resistant organisms may be a common occurrence in small intestinal and multivisceral transplant recipients. It has been our experience that drug-resistant organisms account for 47% of all bacterial infections within the immediate postoperative period, with 71% of Gram-positive cocci demonstrating significant resistance and 39% of Gram-negative enterics exhibiting significant resistance. Vancomycin-resistant *Enterococci* accounted for 75% of all enterococcal isolates, and 100% of *Staphylococcus aureus* isolates were methicillin resistant. Thirty-one percent of *Klebsiella* and *E. coli* isolates were ESBL-producing, and 39% of *Pseudomonas aeruginosa* isolates were multidrug-resistant [84]. The predominance of these multidrug-resistant organisms in the immediate postoperative period raises the possibility to consider empiric coverage for multidrug-resistant organisms based on local antimicrobial resistance patterns when an infection is suspected.

Antimicrobial Prophylaxis in the Peri- and Postoperative Transplant Periods

Although protocols are often center-specific, antimicrobial prophylaxis against bacterial, fungal, viral, and protozoal pathogens follows many of the same principles as in other solid organ transplantations. Perioperative prophylaxis for bacterial infections includes agents such as ampicillin/sulbactam, as well as piperacillin/tazobactam. The duration of surgical prophylaxis varies from 3 days to approximately 7 days and is often center-specific. At our center, ampicillin/sulbactam has been the preferred agent of choice and is maintained for at least 3 days postoperatively or until biopsy confirms mucosal integrity of the allograft. Some centers also employ the use of selective gut decontamination in the donor allograft and recipient (see above).

Antifungal prophylaxis with azole therapy such as fluconazole, as well as a lipid preparation of amphotericin B, has been used by most centers. It has been our practice to discontinue fluconazole once the first allograft biopsy was noted to be normal. Some centers maintain antifungal prophylaxis until the time of hospital discharge [38]. Significant drug interactions exist between the azole antifungals, fluconazole, and voriconazole, with tacrolimus due to inhibition of cytochrome P450 isoenzymes [93]. Therefore, the initiation or discontinuation of azole antifungal agents needs to be coordinated with the close monitoring of tacrolimus levels.

All IMVTx recipients receive intravenous ganciclovir at a dosage of 5 mg/kg every 12 hours to prevent infection with cytomegalovirus (CMV) and other herpes viruses. At our center, patients are usually maintained at this induction dose for at least 2 weeks and then are switched to maintenance dosing with oral valganciclovir. Most centers also employ the use of CMV hyperimmune globulin for CMV prophylaxis. We routinely use CMV hyperimmune globulin at a dosage of 150 mg/kg weekly until postoperative day 30.

Prophylaxis for *Pneumocystis jiroveci* with trimethoprim-sulfamethoxazole is also initiated postoperatively and maintained for at least 6 months after transplantation. It is not unreasonable to consider lifelong prophylaxis due to the high level of immunosuppression that these patients undergo. Trimethoprim-sulfamethoxazole may also provide prophylaxis against *Toxoplasma gondii*, *Listeria monocytogenes*, and some *Nocardia* species.

Infections in the "Late" Post-transplant Period (>6 Weeks)

Viral Infections

Cytomegalovirus (CMV)

CMV, a double-stranded DNA herpesvirus, is among the most common viral infections post-transplantation and causes significant morbidity. Here we discuss aspects of CMV infection pertinent to IMVTx and refer to published guidelines for issues related to aspects common to other solid organ transplantations [94–96].

Historically, CMV has been a major cause of morbidity since the early era of intestinal transplantation. In the first report on 38 patients, an incidence of 39% of CMV disease was found, most commonly during the second month post-transplantation and affecting the intestinal graft in 81%. Factors associated with disease were donor +/recipient serostatus, isolated intestinal transplantation, and the amount of immunosuppression (tacrolimus levels and cumulative corticosteroid dose) [97]. In early reports there was no significant impact on survival at 1 and 2 years [97, 98]. Importantly, undetectable CMV plasma viremia by PCR was reported in 48% of patients with clinical and histopathological invasive CMV disease [97, 99]. In pediatric recipients CMV disease was reported with a lower incidence than in adult recipients (24%), at a median of 53 days post-transplantation, and affecting the intestinal allograft in 90%. Importantly, no CMV disease occurred in the subgroup of D−/R− patients [98]. Resolution of CMV occurred in >90% cases after 2–4 weeks of antiviral therapy, but recurrence rates as high as 50% were documented, similar to adult intestinal allograft recipients and to other solid organ transplant recipients [94]. The cumulative doses of corticosteroid boluses and steroid recycles were associated with a higher incidence of CMV in children [98]. More recent experience in pediatric intestinal transplant recipients reported an 18% incidence of CMV infection post-transplantation and a decreased incidence of invasive CMV disease (7%) [100] compared to earlier experience. At our center, we observed an 18.2% incidence of CMV infection/disease among 88 adult and pediatric IMVTx recipients over a 5-year period [101]. The majority of invasive CMV disease involves the intestinal allograft, and recurrences are reported between 50% and 86% [98, 100]. Furthermore, CMV disease significantly shortened survival with an 11-fold increase in mortality risk when not only the direct cytopathic effects of CMV were considered but also the indirect immunomodulatory effects and the associated increase risk of other infections including EBV and subsequent PTLD [100].

The donor and recipient CMV serologic status is an important predictor of post-transplant CMV infection [5, 99]. The highest risk for development of invasive CMV, recurrent CMV, and ganciclovir-resistant CMV is in CMV-seronegative recipients of a CMV-seropositive donor (D+/R–). While not an absolute contraindication to transplantation, D+/R– status is an indication for more intensive monitoring and more stringent preventive strategies post-transplantation than in donor/recipient pairs with a lower risk of CMV. However, the seropositive recipient, regardless of donor status, is at risk for CMV reactivation and usually receives either prophylaxis or preemptive monitoring and therapy. Irrespective of donor/recipient serostatus, intestinal transplant recipients are at high risk for CMV disease, given the heavy immunosuppressive regimens (including high tacrolimus levels) used in these patients. Although practices remain center-specific, some programs (including ours) now exclude CMV-seropositive donor intestinal allografts for CMV-seronegative recipients who are awaiting isolated small intestinal transplantation. In fact, CMV disease in D+/R– takes much longer to resolve histologically (up to 7 months) and, in addition to involving the graft, also more frequently involves the native gastrointestinal tract [98]. It is also an established practice that seronegative recipients receive CMV-negative blood products during the transplant and postoperatively.

Manifestations of CMV infection and disease post-intestinal transplantation include asymptomatic detectable CMV DNA, a viral syndrome (fever, myalgia, leukopenia, elevated transaminases), and end-organ involvement. CMV enteritis post-transplantation, in addition to systemic symptoms, manifests with increased ileostomy output or diarrhea and gastrointestinal bleeding and affects the intestinal allograft more than the native gastrointestinal tract [98, 100]. Endoscopic findings of CMV allograft enteritis vary between mild (superficial ulceration) (Fig. 5.3) and severe mucosal

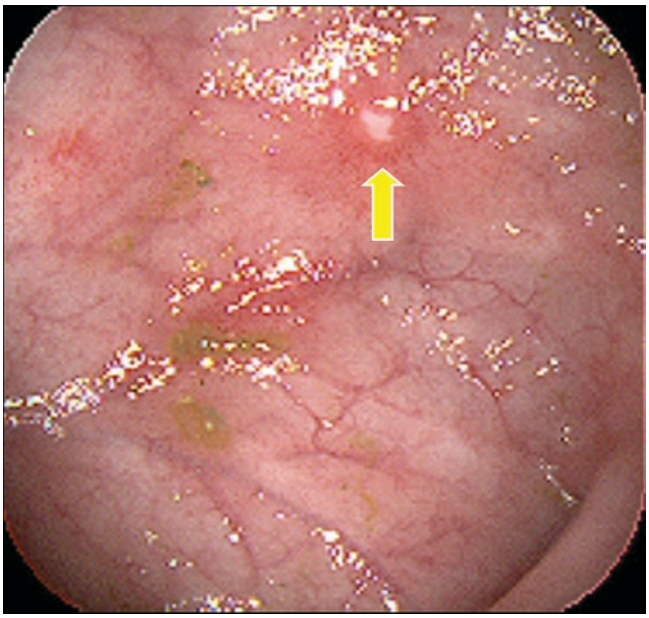

Fig. 5.3 Mild CMV allograft enteritis. (Courtesy of Dr. Stuart Kaufman)

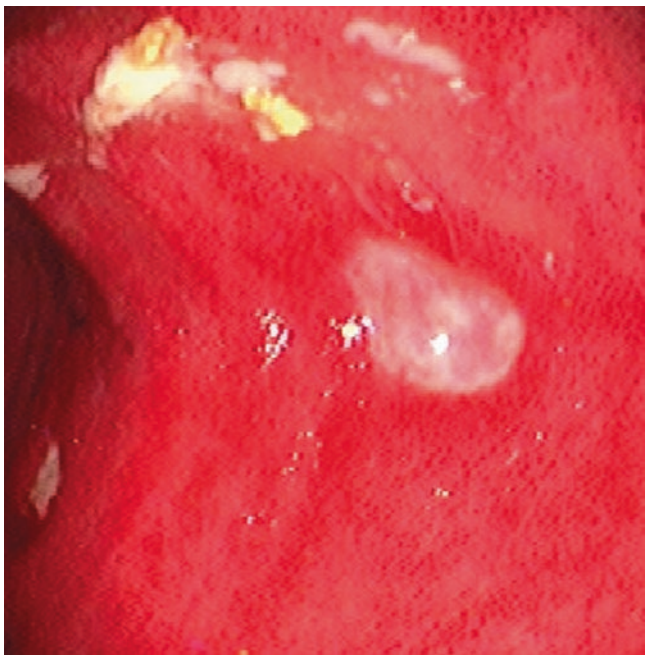

Fig. 5.4 Severe CMV allograft enteritis. (Courtesy of Dr. Stuart Kaufman)

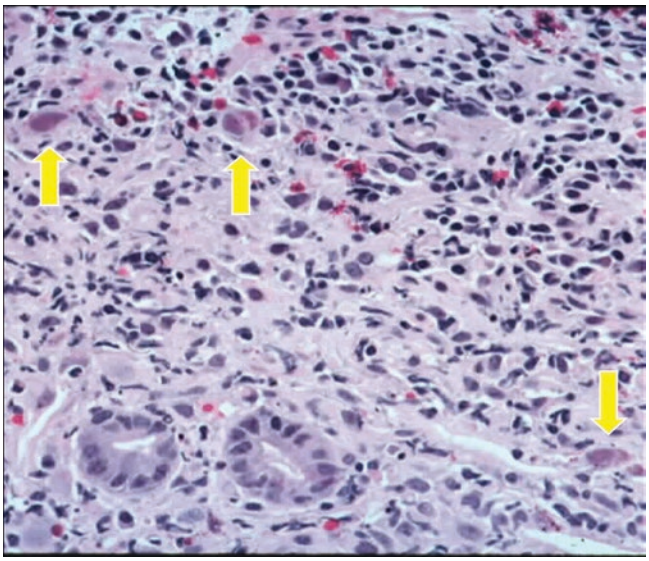

Fig. 5.5 CMV enteritis with inclusion bodies and inflammatory infiltrate

damage (Fig. 5.4) with the potential for bowel perforation, especially following T cell depletion therapy (e.g., thymoglobulin) for acute rejection.

Histologic features suggestive of CMV allograft enteritis include mucosal damage (crypt and villous loss), plasma cell and lymphocyte infiltrate with few eosinophils, and CMV inclusion bodies (Fig. 5.5) with positive CMV immunostaining [102].

In IMVTx recipients, other organs are less frequently involved and include the lungs [98], liver, and kidneys. One patient at our center developed a CMV polyradiculitis that resulted in a severe sensory-motor deficit of the lower extremities.

Generally early prophylaxis is recommended for all intestinal transplant recipients with intravenous ganciclovir for 14–100 days post-transplant in association with CMV immune globulin followed by oral valganciclovir. The optimal duration of antiviral prophylaxis is not uniformly established, and options vary between 3 and 6 months to indefinitely. After completion of prophylaxis, CMV DNA PCR is monitored indefinitely for preemptive resumption of therapy, and intravenous ganciclovir is usually resumed during treatment of acute rejection episodes. Prophylaxis in the form of valganciclovir and CMV immunoglobulin is costly, but it lowers the risk in such a high-risk population like intestinal transplant recipients. As in other solid organ transplants, late-onset CMV disease is a potential problem with prophylaxis, occurring in 15–30% of cases after discontinuation of prophylaxis, whereas CMV resistance has been observed with both prophylaxis and preemptive therapy [94]. The efficacy of prophylaxis with either CMV immune globulin (CMVIG) or intravenous immune globulin (IVIG) in combination with ganciclovir/valganciclovir in high-risk transplant recipients has been investigated in few studies [103, 104], but in intestinal transplantation, practices remain center-based.

The treatment of CMV disease follows guidelines established for other solid organ transplant recipients and usually includes intravenous ganciclovir at a dose of 5 mg/kg every 12 hours for 2–4 weeks or until negative viral replication [105, 106]. Oral valganciclovir 900 mg twice daily may be considered as long as the intestinal allograft is functioning. In most other patient populations, oral valganciclovir may achieve similar drug exposure as intravenous ganciclovir given its good bioavailability (approximately 60%). The pharmacokinetics of valganciclovir in small intestinal transplant recipients has not been extensively studied, although one case report noted a bioavailability of 64.7% when used for CMV prophylaxis in a small intestinal recipient [107]. However in the setting of the small intestinal transplant recipient, intravenous ganciclovir may be preferred over valganciclovir, as valganciclovir may provide sub-optimal drug exposure when allograft function is questionable (as in the setting of acute or chronic rejection). In the setting of CMV allograft enteritis, it is our preference to treat with intravenous ganciclovir to ensure adequate drug exposure. Many centers including ours employ the use of CMV hyperimmune globulin in addition to intravenous ganciclovir for the treatment of invasive CMV disease.

Ganciclovir-resistant CMV has been reported in 1–2% of solid organ transplant recipients, and risk factors include

prolonged oral prophylaxis, D+/R– serostatus, and heavy immunosuppression [94, 96]. At our center we noted a rate of nearly 6% for ganciclovir-resistant CMV among all of our IMVTx recipients. However, in those patients with either CMV viremia or invasive disease, we documented a rate of 31% of ganciclovir resistance, which appears to be the highest rate among all types of solid organ transplantations [101]. In our series, all patients with ganciclovir resistance were D+/R– serostatus, and 80% (4/5) of these patients had invasive CMV allograft enteritis. Two of the 5 patients with ganciclovir resistance had both the UL 97 and UL 54 mutation [101]. The diagnosis of CMV resistance is confirmed by genotypic testing, and treatment options include lowering baseline immunosuppression level, intravenous foscarnet adjusted for renal function, cidofovir, or leflunomide. Recently a case has been reported of multidrug-resistant cytomegalovirus in a modified multivisceral transplant recipient [108].

Although it is established that intensified immunosuppression to treat rejection increases the risk of subsequent CMV infection, it is also commonly recognized that CMV increases the risk of rejection at least in kidney transplant recipients. The mechanism is attributed to an immunostimulatory effect of both CMV infection and CMV disease [98, 109], but to date a definite link between CMV and rejection has yet to be established in IMVTx [98].

Epstein-Barr Virus (EBV)

Epstein-Barr Virus (EBV) is another double-stranded herpesvirus. EBV-related posttransplant lymphoproliferative disorders (PTLD) are feared complications among all solid organ transplants. EBV infects, transforms, and immortalizes B lymphocytes and in transplant recipients may progress to PTLD due to inadequate anti-EBV cytotoxic T cells. It can also progress from EBV-driven proliferation to EBV-independent lymphoma. Guidelines have been published on the diagnosis and management of EBV-related disease in solid organ transplant [110]. Among organ transplant recipients, IMVTx are at the highest risk for development of PTLD (up to 32%) compared to other solid organ transplant recipients (1–12%) [110]. However, the incidence of PTLD in IMVTx recipients has recently decreased to 5–10% compared to the early era (30%) secondary to routine quantitative EBV DNA PCR monitoring [111]. In fact, patients with undetectable or low viral loads for the first 6 months after IMVTx are unlikely to develop PTLD regardless of their pretransplant EBV serological status [112]. The decreased incidence of acute rejection after IMVTx (and its treatment) has also contributed to reduce the incidence of EBV-related disease [111].

EBV-seronegative recipients of a graft from an EBV-seropositive donor are at greatest risk of post-transplant infection, although EBV-seropositive recipients remain at significant risk [111]. Usually PTLD follows primary EBV infection in seronegative recipient (most commonly pediatric recipients) of an EBV-seropositive graft, although PTLD can also develop in the seropositive recipient secondary to EBV reactivation under the influence of augmented immunosuppression. Protocols for the surveillance of EBV, diagnosis, and management of PTLD in solid organ transplant patients have been published elsewhere [110, 113].

The timing of development of PTLD is most commonly within the first year post-transplant, but cases have been described as late as 10 years post-transplant, especially EBV-negative PTLD or the rare T cell PTLD [114].

Main risk factors for PTLD are primary EBV infection post-transplantation and the net state of immunosuppression, especially the use of high dose or repeated courses of antilymphocyte globulins which impact on the cytotoxic activity of EBV-specific T cells [110, 115]. Cytomegalovirus infection may also contribute to the net state of immunosuppression and is known to be a risk factor for PTLD [110].

Clinical manifestations of EBV infection post-transplantation include infectious mononucleosis (fever, malaise, exudative pharyngitis, lymphadenopathy, hepatosplenomegaly, and atypical lymphocytosis), specific organ diseases such as hepatitis, pneumonitis, gastrointestinal symptoms, and hematological manifestations such as leucopenia, thrombocytopenia, hemolytic anemia, and hemophagocytosis. Manifestations of PTLD are multiple and include subcutaneous hard and immobile nodules, generalized lymphadenopathy, snoring in children due to adenoidal hypertrophy, mouth breathing with ulcerating palatine tonsils, pneumonia with lung and/or mediastinal masses, diarrhea secondary to diffuse small bowel mucosal infiltration, gastrointestinal bleeding in case of multiple ulcerating lesions, and abdominal pain with or without bowel obstruction [111, 116]. PTLD of the intestinal graft can be discovered incidentally during routine surveillance endoscopy for rejection or following symptoms of mass, abdominal pain, partial obstruction, feeding intolerance in children, fever, and gastrointestinal bleeding [111].

Endoscopically PTLD of the graft may present as a protruding intramural mass with central umbilication (Fig. 5.6) which histologically appears as a lymphocytic mass without follicular organization (Fig. 5.7) and positive on CD20 immunostaining (Fig. 5.8).

Histological diagnosis of PTLD is confirmed by in situ hybridization of EBV DNA and the more sensitive RNA in situ hybridization targeting EBV-encoded small nuclear RNA (EBER) [117].

Prophylaxis with antivirals (ganciclovir) does not impact on EBV-driven B cell proliferation but may reduce the number of EBV-infected cells, thus reducing the risk of PTLD especially in EBV D+/R– mismatch [114].

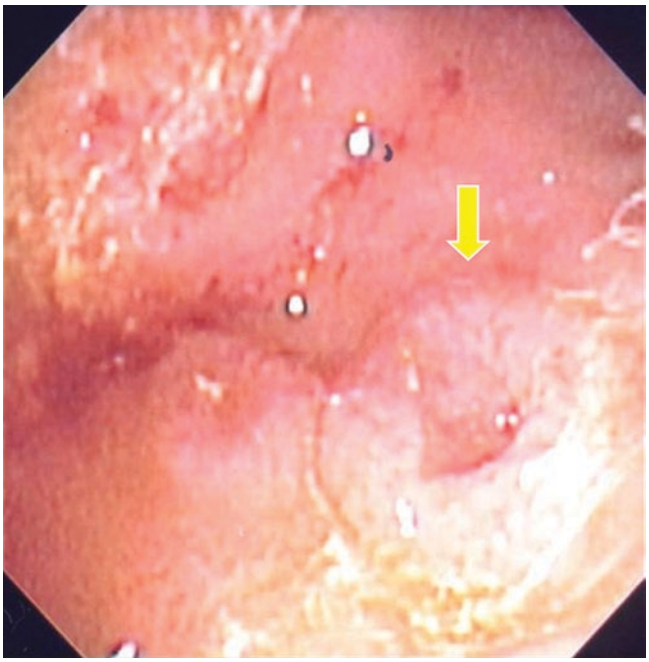

Fig. 5.6 PTLD: endoscopically protruding intramural mass with central umbilication. (Courtesy of Dr. Stuart Kaufman)

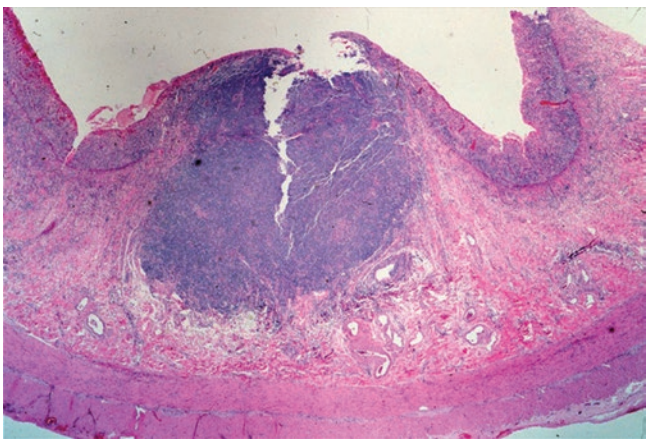

Fig. 5.7 PTLD: intramural lymphoid mass with absent follicular organization

The treatment of PTLD includes reduction of immunosuppression in combination with intravenous ganciclovir, CMV immune globulin, and rituximab (anti-CD20 monoclonal antibody) [118]. The response to reduction of immunosuppression is variable (between 20% and 80%) based on different weaning protocols and on the heterogeneity of disease (localized/diffuse, monomorphic/polymorphic). Aggressive reduction of immunosuppression requires frequent endoscopy and biopsy to monitor the graft for rejection.

Although used off-label, the anti B cell antibody (rituximab) has been used with success in the treatment of PTLD,

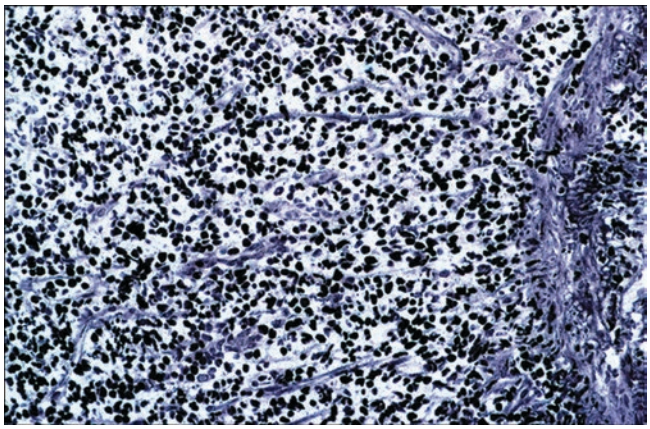

Fig. 5.8 PTLD: CD-20 [B-cell marker] stain

with response rates reported between 50% and 60%, and a low incidence of relapses are also reported [119–121].

Localized PTLD involvement of the graft represents the only situation potentially cured with limited resection and preservation of the graft, whereas diffuse involvement of the graft and/or poor response to therapy often mandates allograft enterectomy.

Most resistant cases of PTLD are considered for chemotherapy (based on cyclophosphamide and corticosteroids), with remission rates of 60% but with significant 2-year mortality of 30–50% often related to toxicity of chemotherapy [122, 123].

Intestinal Allograft Viral Enteritis

Overall, bacterial and viral infections target the intestinal graft with an incidence up to 39% after IMVTx [124], especially in infants and children. Two thirds of allograft infections are secondary to viral enteritis which, in addition to systemic DNA viruses CMV, EBV, and adenovirus, include enterotropic RNA viruses norovirus and rotavirus. The morbidity and mortality associated with systemic DNA viruses are significant, whereas infections with enterotropic viruses are usually associated with a lower mortality risk. Viral enteritis may be clinically indistinguishable from rejection, but it is critical to differentiate between these entities because treatment of rejection could result in viral dissemination. Conversely, decreasing immunosuppressive therapy for presumed viral enteritis may promote graft rejection. Furthermore, it is important to identify the correct pathogen because antiviral treatment may improve CMV infection, whereas no standard treatment is established for adenoviral or other viral infections.

Adenovirus

Adenovirus is a systemic DNA virus with tropism for multiple cell lines, including enterocytes. Like EBV, adenovirus may remain latent in lymphoid tissue thus exposing the

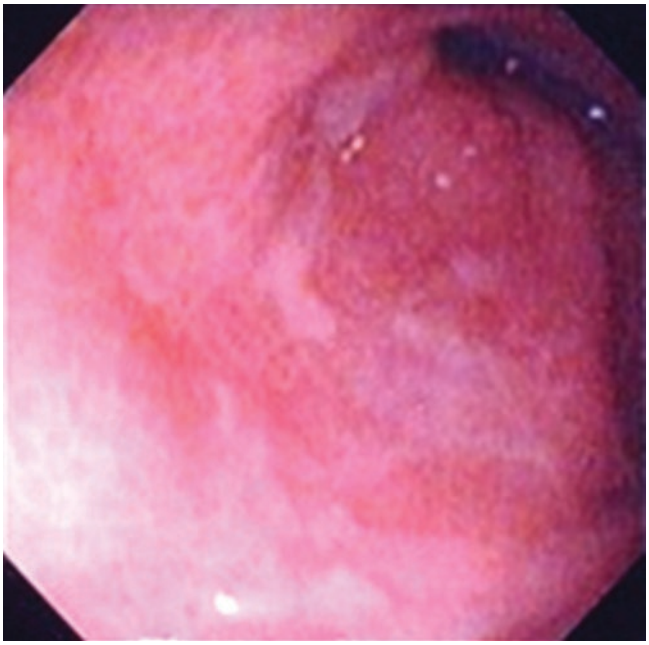

Fig. 5.9 Adenovirus allograft enteritis. (Courtesy of Dr. Stuart Kaufman)

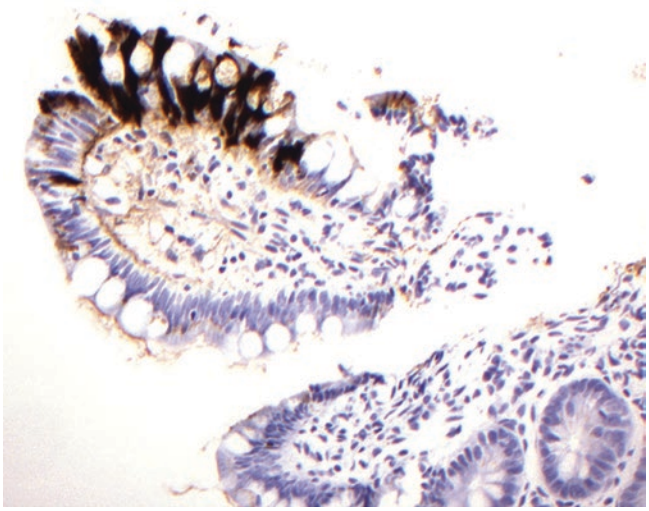

Fig. 5.10 Adenovirus allograft enteritis: enlarged and atypical nuclei with positive immunohistochemical stain for antibody to adenovirus (H&E-stained and immunohistochemical-stained sections, 200×)

recipient to the risk of reactivation post-transplantation. Adenovirus infection is more common in infants than in young children and adults with an incidence reported between 20 and 50% in pediatric intestinal transplant series [125–127], and in 80% of the cases, it occurs within the first 6 months post-transplantation. In a recent study, 36% of the cases were diagnosed in the first month, 32% in the following 5 months, 16% of the cases between 6 and 12 months after transplantation, and 16% after 1 year [100].

The intestinal allograft is more susceptible to adenoviral infection than other target organs, with an incidence of up to 80% of infections involving the intestinal graft [128]. The spectrum of manifestations of adenoviral infection varies between early asymptomatic viral replication, usually of donor origin, to adenoviral enteritis which is usually related to level of immunosuppression within the first 6–12 months post-transplant (Fig. 5.9).

Cases of late infection are sporadic. The main manifestation of adenoviral enteritis is usually osmotic diarrhea, infrequently accompanied by fever and rarely by gastrointestinal bleeding. Endoscopic appearances also vary and include erythema, edema, and increased mucous production, often not limited to the transplanted intestine but also involving the native bowel. Histologically the main features of adenoviral enteritis are apoptosis (like in rejection), villous injury (usually more prominent than in rejection), and cytopathic nuclear inclusions, the latter being a key component to differentiate adenoviral infection from rejection [129, 130].

The diagnosis is confirmed by serum and tissue DNA PCR and by immunohistochemistry (Fig. 5.10).

Usually mild adenoviral infection is limited to the graft in the setting of low immunosuppression, involves more the ileum than the jejunum, (unlike norovirus and rotavirus that affect more the jejunum than the ileum; see below), persists usually for 1–2 weeks, and only rarely produces extra GI manifestations. On the contrary, a more severe disease is usually associated with heavy immunosuppression like after treatment for rejection and causes multi-system involvement (the lungs, liver, pancreas) with significant mortality up to 20% [126]. Routine monitoring in the peripheral blood is not recommended in solid organ transplant recipients [131]. We monitor adenovirus DNA PCR in small children with suspicious viral illness or episodes of graft dysfunction. The management of adenoviral infection includes supportive treatment, reduction of immunosuppression levels, and cidofovir [131]. Although there is no established antiviral treatment for adenovirus infection, cidofovir is considered the standard of care. However, data are lacking to evaluate the efficacy and the response rate of adenovirus enteritis to cidofovir in IMVTx.

Rotavirus

Rotavirus enteritis presents with sudden watery osmotic diarrhea causing significant dehydration requiring intravenous fluid resuscitation and often temporary parenteral nutrition. Like other causes of viral enteritis, it usually affects the pediatric population, although adult recipients are not excluded from infection [132]. The severity and duration of infection are related to the intensity of immunosuppression and are typically worse during the first months after transplant. Endoscopically the infection appears with mild erythema, villous atrophy, and edema (Fig. 5.11) or normal mucosa.

Fig. 5.11 Rotavirus allograft enteritis. (Courtesy of Dr. Stuart Kaufman)

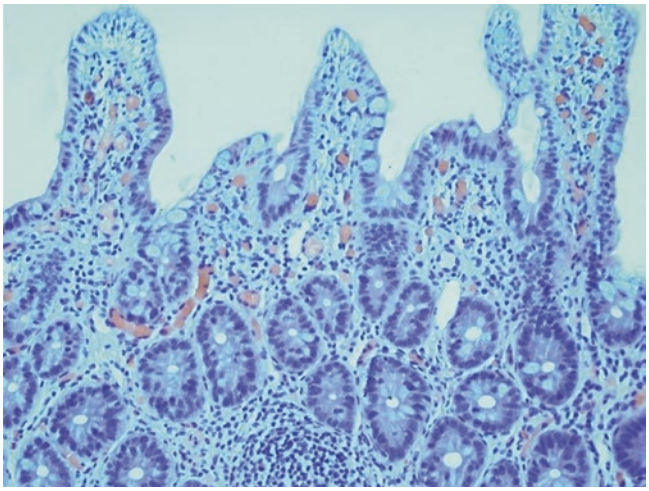

Fig. 5.12 Rotavirus allograft enteritis

The endoscopic jejunal changes are often more visible than the ileal. The differentiation between viral enteritis and acute rejection is not endoscopically or histologically immediate: key endoscopic features of rejection include a coarse mucosal surface with focal erosions. On biopsy, rejection is characterized by single/multiple crypt apoptosis with nuclear fragmentation, but usually, unlike in viral infections, the surface epithelium is preserved.

Other histological characteristics of rotavirus enteritis are villus blunting, mixed inflammatory infiltrate, superficial epithelial disarray, and goblet cell depletion (Fig. 5.12).

The diagnosis is confirmed by culture and immunostaining. The treatment for patients with rotaviral infection includes supportive care and endoscopic surveillance of the graft with biopsy while the patient is recovering. Although most cases are self-limited, rejection can be associated with or follow rotavirus infection in up to 69% of patients with rotaviral enteritis [132] and requires prompt diagnosis and treatment. Mechanisms implicated in rejection during or after infection include diarrhea-related poor drug absorption resulting in sub-therapeutic tacrolimus levels and immune activation secondary to viral infection.

Norovirus

Norovirus, a single-stranded RNA virus, is a common cause of acute self-limited enteritis in healthy persons but can cause protracted diarrhea and severe dehydration especially in pediatric IMVTx recipients [133, 134]. In the immunocompetent host, epidemics caused by this virus are particularly common among persons confined to institutions and other enclosed areas and often spread by contaminated foods. In the immunosuppressed population and after IMVTx, the incidence of norovirus infection is not known given the absence of established monitoring strategies. The timing of infection varies between 17 days and 1 year post-transplant in the limited published series [134].

Typically norovirus enteritis is characterized by protracted excretion of viruses (up to 80 days) [134] and by persistent osmotic diarrhea worsened by enteral feeding. Prolonged excretion of norovirus into ileostomy fluid from immunosuppressed infants may be a risk factor for nosocomial spread. Although antibodies produced in response to acute infection may be long-lasting, there is the potential for recurrent disease with the same or heterotypic strain. Histologically norovirus enteritis shows apoptosis involving both villous enterocytes and crypts, making it more challenging to differentiate from rejection based solely on biopsy. The diagnosis is confirmed by RT-PCR of biopsy material and of intestinal fluid [133]. Management of norovirus enteritis includes supportive care with intravenous fluids, nutritional supplementation, and reduction of maintenance immunosuppression levels (target trough tacrolimus levels <10 ng/ml, discontinuation of sirolimus, and reduction of steroid dose). Although often protracted, the infection is usually self-limited with restoration of normal graft function and limited morbidity unless superimposed to other infections (adenovirus, CMV).

Fungal Infections

The increased availability of diverse and potent immunosuppressive drugs has improved the outcomes of IMVTx but at the same time has increased the risk of opportunistic infections, including fungal infections. As in other solid organ transplant recipients, fungal infections pose major challenges in the management of small intestinal transplant recipients.

Usually fungal infections are healthcare-acquired infections due predominantly to *Candida* species and *Aspergillus*. Risk factors for fungal infections in the IMVTx recipients include the use of central venous catheters, PN, broad-spectrum antibiotics, intra-abdominal surgery requiring reoperation, and intensive immunosuppressive regimens. *Candida* and *Aspergillosis* are the two major fungal pathogens in small intestinal transplant recipients, with a reported incidence of approximately 25% [128, 135] and will be discussed here. While a number of other fungal infections have been reported in other types of solid organ transplant recipients [136], the endemic mycoses, as well as emerging molds, have rarely been reported in the small intestinal and multivisceral transplant recipient and are covered in the section entitled "Miscellaneous Infections" [137].

Candida

Candida spp. are the most common invasive fungal infections after solid organ transplantation, and this trend is also seen in IMVTx recipients [66, 138]. While *Candida* is usually a healthcare-associated infection occurring during the first 3 months post-transplantation in other solid organ recipients, in intestinal transplantation it can also occur later as it may be associated with intensification of immunosuppression (i.e., corticosteroids) for the treatment of rejection episodes. In a study of pediatric small bowel recipients, it was noted that nearly 80% of candidemia episodes occurred greater than 6 months from the time of transplantation, with a median time of 163 days post-transplantation [128]. At that same center, it was noted that approximately 70% of pediatric small intestinal transplant recipients developed fungemia within 1 year of transplantation and was associated with TPN and antibiotic use [100]. The incidence of invasive candidiasis is reported to be up to 28% of intestinal transplant recipients [38, 139].

The main risk factors for *Candida* infection in small intestinal transplant recipients are the presence of central vascular catheters, use of PN, exposure to broad-spectrum antibiotics, use of immunosuppression for induction and rejection episodes, anastomotic leaks or intra-abdominal collections, the need for multiple abdominal surgical procedures, and the presence of a multivisceral graft. Additional risk factors common to other transplants are renal failure and recent CMV infection.

The clinical manifestations of *Candida* infection in this patient population post-transplantation predominantly involve the bloodstream and the abdominal cavity. In one series, candidemia accounted for 66%, and *Candida* intra-abdominal infections accounted for 29% of all yeast infections [128]. Other sites of infection include the urinary tract and respiratory tract. We have observed an endovascular infection at a mesenteric anastomotic site due to *Candida albicans* in a small intestinal transplant recipient.

In general, *C. albicans* accounts for approximately 50% of all infections, and non-*albicans Candida* species collectively account for the other 50%. However in the small intestinal transplant recipient, 63% of *Candida* infections are due to non-*albicans Candida*, and *C. albicans* account for only 37% [128]. The diagnosis of invasive candidiasis depends on the demonstration of candida in sterile body sites, although culture methods, especially blood cultures, often have limited sensitivity (70%) [66].

Many centers employ the use of antifungal prophylaxis (usually with fluconazole) in the immediate postoperative period. The duration of fluconazole prophylaxis for *Candida* infection is variable and may be up to 4 weeks post-transplantation, but it is prolonged further in the presence of ongoing intestinal mucosal injury or in the setting of rejection episodes.

Candidemia has been associated with a mortality risk up to 40% [140] especially if empiric antifungal treatment is delayed until positive blood cultures are documented [141]. The management of candidemia follows the same guidelines as used for other patient populations [66]. Empiric treatment of candidemia may include the triazole agents such as fluconazole and voriconazole, the echinocandins such as caspofungin and micafungin, and the lipid preparations of amphotericin B. Based on limited data from one series [128], as well as our own observations [84], empiric antifungal therapy targeted at non-*albicans Candida* species such as *Candida glabrata* should be considered in the setting of fungemia. As fluconazole prophylaxis is used at our center, echinocandins are used initially for the management of candidemia until final species identification is available. In addition, it is recommended to remove infected central venous catheters, to obtain ophthalmologic exam to rule out candida chorioretinitis/endophthalmitis and maintain intravenous antifungal treatment for at least 2 weeks after there is documented clearance of blood cultures [66]. As stated previously, there are significant drug interactions between the azole antifungal agents and tacrolimus; therefore, close monitoring of tacrolimus levels should be performed when these agents are used and then discontinued [93].

Aspergillosis

Aspergillus spp. is a common filamentous mold in the environment that usually does not cause significant disease in the immunocompetent population. In the immunosuppressed patient, it may invade the lungs (invasive aspergillosis; see Fig. 5.13) and spread to other organs, including the sinuses, brain (Fig. 5.14), gastrointestinal tract, skin, and very rarely the bones.

Invasive aspergillosis represents only 1–3% of invasive fungal infections in small intestinal transplant recipients but is associated with significant morbidity and mortality up to 60–90% [142–144]. The most important risk factor for the

development of aspergillosis in solid organ transplant recipients is the net state of immunosuppression associated with the intensity of the immunosuppressive therapies, as well as coinfection with immunomodulatory viruses such as CMV. As there are no case-controlled studies in the IMVTx population that determine risk factors for invasive aspergillosis, probably the most appropriate comparison can be made with liver transplant recipients (as many small intestinal transplant recipients include a liver). Factors that are associated with an increased risk of invasive aspergillosis in liver transplant recipients include re-transplantation, kidney injury requiring renal replacement therapy, CMV infection, and prolonged stay in an ICU [145–150].

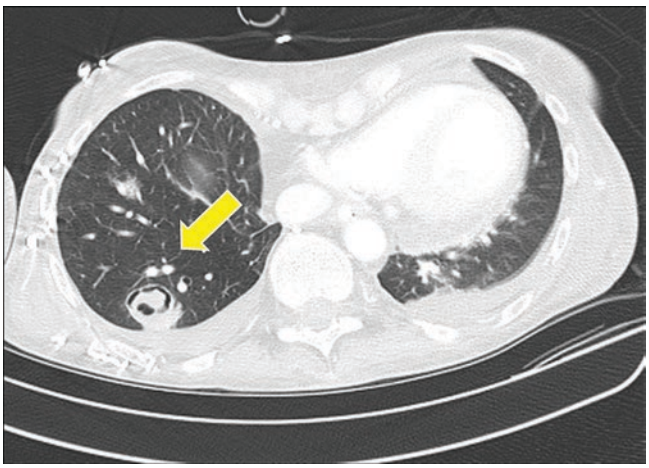

Fig. 5.13 Invasive lung aspergilloma

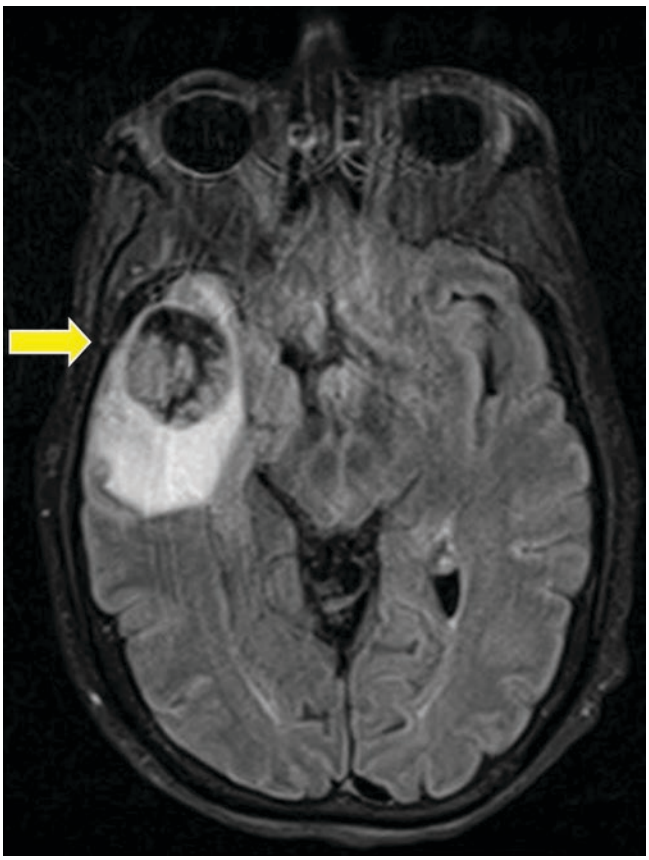

Fig. 5.14 Intracranial post-transplant aspergilloma

Notably, acute kidney injury, CMV infection, and prolonged ICU stays are important postoperative complications in the small intestinal transplant recipient and potentially could increase the risk of aspergillosis in this patient population as well.

The most common site of infection due to *Aspergillus* are the lungs, and patients may present with fever, cough, chest pain, and shortness of breath. Angioinvasion results in necrosis of tissue, which may ultimately lead to cavitation (Fig. 5.13) and/or hemoptysis. In the few cases reported in the literature, as well as our own observations, dissemination to the central nervous system appears to be common [143]. A definitive diagnosis of invasive aspergillosis can be difficult to make without confirmed histopathology demonstrating tissue invasion of the mold. As there are no large case series in the small intestinal transplant patient population, clinicians should use guidelines that are established for other solid organ transplant recipients [142].

There are no established guidelines for the prophylaxis of invasive aspergillosis in IMVTx recipients. The treatment of invasive aspergillosis includes voriconazole as the first-line agent. Alternatives may include liposomal amphotericin B, caspofungin, micafungin, and posaconazole. The surgical excision or debridement of single lung lesions may be indicated for persistent or life-threatening hemoptysis or for lesions invading the pericardium or lesions not responding to maximal antifungal therapy. Depending on location, access, and potential neurological sequelae, surgical resection is also considered in selected cases of intracranial aspergillosis (Fig. 5.14). Due to the lack of data in the small intestinal transplant patient population, optimal management should be based on established guidelines [142].

Miscellaneous Infections

Although bacteria, fungi, and viruses are the predominant causes of infection in the IMVTx recipient, this section will address the isolated and unusual case reports that have been reported in the literature in this specific patient population.

Pneumocystis jiroveci is an important cause of pneumonia in solid organ transplant recipients as well as other immunocompromised hosts but has only rarely been seen in IMVTx recipients. We have seen one case in an adult with an isolated small intestinal transplant recipient. There are two case reports of *Pneumocystis* pneumonia in pediatric patients. One case occurred in an 8-month-old who had intestinal failure and a congenital immunodeficiency with abnormal lymphocyte function who underwent a small intes-

tinal and liver transplantation. The postoperative course was complicated by *Pneumocystis* pneumonia and graft versus host disease, and the child expired on the 23rd postoperative day [151]. The other case of *Pneumocystis* pneumonia occurred in a 2.5-year-old who underwent a living-related small intestinal transplantation that was complicated by four episodes of rejection and CMV infection and ultimately succumbed to *Pneumocystis* pneumonia 16 months after transplantation [152]. Donor-derived disseminated toxoplasmosis has been reported in a pediatric patient who had received a small intestinal transplantation [153].

Several intestinal parasites have been identified as causes of infection in small intestinal transplant recipients. In one case series of cryptosporidioses among pediatric solid organ transplant recipients, one case of cryptosporidioses was diagnosed in a small intestinal transplant recipient which did resolve with treatment [154]. There is also a single case report of *Isospora belli* infection that was diagnosed 3 months after a successful small intestinal transplantation which resolved with treatment with trimethoprim-sulfamethoxazole [155]. There have been two case reports of infection due to *Strongyloides stercoralis* in isolated intestinal transplant recipients, one of which was complicated by *Strongyloides* hyperinfection syndrome and associated with polymicrobial bacteremia and meningitis [156, 157]. We have also recently observed a case of *Strongyloides* infection in a multivisceral transplant recipient (personal communication, J. Timpone). What is interesting to note about all three of these patients is that the source of the *Strongyloides* was donor derived [156, 157]. All three cases were treated with (and responded to) ivermectin, although one case also received thiabendazole [156, 157].

Isolated cases of endemic mycoses have not been reported in the small intestinal and multivisceral transplant population; however, cryptococcosis has been identified. In one retrospective review of solid organ transplant recipients at a single center, one case of cryptococcal meningitis was reported in a small intestinal transplant recipient [158]. Molds other than aspergillus have been rarely reported in small intestinal and multivisceral transplant recipients. There is an isolated case report of an invasive sinusitis due to *Trichoderma longibrachiatum* in an adult patient on tacrolimus and prednisone who had received a combined small intestinal and liver transplantation. The patient was treated with surgical debridement, amphotericin B, and itraconazole with resolution of the infection [159]. There was also a case report of an invasive esophagitis due to the dematiaceous fungus *Cladophialophora bantiana* in a small intestinal transplant recipient [160].

There have been two cases of mucormycosis reported: one case of *Cunninghamella bertholletiae* cutaneous infection which occurred in the setting of treatment of acute rejection 1 year after multivisceral transplantation [161] and one case of *Lichtheimia ramosa* (formerly *Absidia* species) infection presenting as gastrointestinal hemorrhage occurring 5 days postoperatively in the stomach allograft of a modified multivisceral transplant recipient [162]. Given the intensity of immunosuppression seen in this patient population, infections due to unusual molds should be anticipated by the clinicians caring for these patients.

Infections due to *Mycobacterium tuberculosis* have not been reported in small intestinal and multivisceral transplant recipients, although this population may be at increased risk. There has only been one case report of nontuberculous mycobacteria, and this was a surgical site infection due to *Mycobacterium abscessus*, occurring 8 months post-transplantation [163]. Disseminated infections due to *Nocardia* species have been reported. In an adult patient with an isolated small intestinal transplant, prostatitis and bacteremia due to *Nocardia asteroides* complex were reported [164]. The patient was successfully treated with ceftriaxone and trimethoprim-sulfamethoxazole [164]. We have observed another patient at our center who had undergone a multivisceral transplantation and then developed disseminated infection due to *Nocardia asteroides* involving the lungs and the central nervous system. This patient was successfully treated with a prolonged course of meropenem and trimethoprim-sulfamethoxazole.

The most common viral infections have already been discussed previously. Notably, in one small case series (n = 11), infections due to human herpesvirus 6 have not been reported in a patient population that was not receiving valganciclovir prophylaxis [165]. However in another case series (n = 27), two cases of HHV-6 have been reported in two pediatric small intestinal transplant recipients presenting with pancytopenia and encephalitis which responded to ganciclovir [163]. In that same case series, there was one case of BK polyoma virus infection that presented with hemorrhagic cystitis and viremia occurring 5 months after small intestinal transplantation [163].

Conclusion

Intestinal and multivisceral transplantation have become effective treatment options for patients with irreversible intestinal failure although the immunological and infectious challenges remain significant. Effective antiviral, antibacterial, and antifungal agents are now available and significantly reduce the morbidity risk in intestinal transplant recipients. Advances in understanding the immunological homeostasis of the gut will likely result in improved immunosuppressive regimens to manage intestinal allograft rejection and ultimately decrease the rates of infection in this population.

Infections in Limbs, Integuments, and Face Transplantation

6

Justin M. Broyles and Chad R. Gordon

Introduction

Solid organ transplantation poses a unique problem in the prophylaxis, treatment, and prevention of microbial colonization and infection. Early infection remains one of the most important causes of morbidity and mortality in patients undergoing solid organ transplantation. By nature of the immunosuppressive regimen, the patient is continually at risk for developing infections which threaten the survivability of the transplanted allograft. A myriad of factors dictates the solid organ transplant recipient's risk of infection, including time from transplant procedure, antimicrobial prophylaxis, environmental exposure, and immunosuppressive regimen given to prevent and treat graft rejection. The net sum of all of these factors dictates that patient's overall risk for developing infectious complications would provide direction in how to develop and implement strategies for prevention and effective management of such complications.

Infections in solid organ transplant recipients can be classified into three broad categories based upon the length of time from transplantation [1, 2]. In the 1st month after surgery, infections that occur are similar to those of other solid organ transplants or surgeries involving that region of the body. These include superficial and deep surgical site infections, catheter-related infections, ventilator-associated pneumonia, and urinary tract infections [1]. The risk factors which appear to contribute to these infections include (1) prolonged mechanical ventilation, (2) prolonged indwelling intravascular catheter placement, (3) prolonged ICU stay, and (4) the development of hematomas or seromas at the surgical site [3–6]. Upon recognition of these problems, immediate action should be taken to remove the suspected potential source for infection. Additionally, judicious culture-directed antibiotics should be initiated in an effort to eradicate the suspected organism(s). Some of the more virulent organisms that can be associated within this 1st month following transplant surgery include methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE), and Gram-negative organisms including *Klebsiella* and *Pseudomonas* spp. Rarely, the allograft may be contaminated or procured from a donor with active systemic infection, which virtually ensures the recipient will become colonized or infected due to graft-transmitted pathogen.

The second category in the posttransplant infection timetable ranges from the 2nd to 6th month after initial transplantation. This period is dominated by opportunistic infections that result from the immunosuppressive actions of the various posttransplant medications given to the patient. These infectious can be either derived from the environment, recrudescence of remotely acquired latent infections, or worsening of subclinical infections acquired from the donor allograft [2]. Common infections which occur during this initial phase are oral candidiasis and the reactivation of herpes simplex virus (HSV), type I or II. Common guidelines dictate prophylaxis against these pathogens with either nystatin or clotrimazole for thrush prevention or acyclovir or valacyclovir for HSV suppression [7–10]. Other more serious viral infections that occur during this timeframe include cytomegalovirus (CMV), Epstein-Barr virus (EBV), parvovirus, polyomaviruses, hepatitis B virus (HBV), and hepatitis C virus (HCV). Fungal colonization and subsequent invasive disease can also occur during this window, and common culprits are *Aspergillus* spp., *Pneumocystis jirovecii*, and *Cryptococcus* spp. Six months after the transplant, the patient enter the third and final timeframe for infection risk [11, 12]. From this point on the patient will fall into one of three distinct populations. The first group is comprised of patients who have done well up to this point and are candidates to have their immunosuppression gradually reduced. These patients will slowly approach the infection risk of the general population that resides in patients proximity, albeit, these individuals will

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_6

harbor some degree of increased susceptibility for the community-acquired infections. Therefore, annual influenza vaccinations and updated new-generation pneumococcal vaccinations are especially important in transplant recipients [13, 14]. The second group of patients is characterized by patients who have had difficulties with rejection and have to have their immunosuppressive regimen intensified. Because of this, these patients will maintain an infection risk identical to those seen in the patients during the second period following transplantation. Finally, a third group of patients is comprised of patients who have done well but will develop effects of long-term viral infections such as BK polyomavirus, CMV, HBV, HCV, and human papillomavirus infection (HPV) [2] (Table 6.1).

Comprehension of this timetable is essential and provides guidance to healthcare providers in effective prevention, anticipating, and treating infections that may be encountered in individuals undergoing composite tissue allotransplantation. While this may not be an absolute timetable, it should however serve as a guide in evaluation of each individual patient to better refine protocols and treatment interventions.

Treatment Modalities in Solid Organ Transplantation

There are three ways to prevent and treat infections in solid organ transplant patients. The most obvious way to eradicate an active infection is with the most effective antimicrobial regimen. Prophylaxis is the administration of antimicrobial agents to a susceptible population of patients in order to prevent expected or anticipated infections during various posttransplant periods. Preemptive therapy is the administration of antimicrobial agents to a subgroup of patients defined by certain clinical characteristics that predicts a heightened risk for a specific infectious disease.

Table 6.1 Timing of infectious complications in solid organ transplants

<1 month	1–6 months	>6 months
Aspergillus	*Aspergillus*	*Aspergillus*, atypical molds
Candida	Adenovirus	Community-acquired pneumonia
Aspiration	CMV	CMV
Catheter-related infectious	*Cryptococcus neoformans*	EBV
Clostridium difficile colitis	EBV	HSV
HSV	HSV	HSV encephalitis
Wound infectious	*Pneumocystis carinii*	JC polyomavirus infection
(*Staphylococcus aureus*)	VZV	

Unique Considerations in Composite Tissue Allotransplantation

Each solid organ transplant hosts its own unique properties which make perioperative care unique. Facial and hand composite tissue allotransplants can consist of many different types of tissue such as skin, fat, muscle, bone, nerves, lymphatics, and mucosal services, all of which have a variety of antigenic properties [15, 16]. Therefore, such patients demand a higher degree of drug-induced immune suppression comparable to recipients of other interval visceral transplants. Anatomic and physiologic features of a particular transplant can dictate unique treatment considerations. For example, the alveolar lining in a lung transplant recipient is exposed to the outside environment leading to infections resulting from environmental colonization of the mucosal surfaces due to specific community- and hospital-acquired pathogens. Composite tissue transplant recipients, such as face and limb allografts, also share direct contact with the external environment. Therefore, these transplants can be prone to unique infections not routinely seen in patients undergoing other internal visceral transplantations.

Composite facial transplantation, depending upon the extent of the anatomy of the transplanted graft, may contain many unique mucosal surfaces. These include oral mucosa, nasal mucosa, sinus mucosa, and the mucosa of the upper airways. The oral mucosa can be a source of many pathogenic microorganisms including *Streptococcus* spp., *Capnocytophaga* spp., *Candida* spp., and various microaerophilic and facultative anaerobic bacteria. The sinuses, nasal mucosa, and upper airways can harbor fungal spores including *Aspergillus* and *Rhizopus*, among other rare filamentous molds that can result in serious invasive disease during the posttransplant periods of iatrogenic drug-induced immune suppression [17–19]. Additionally, the patients, both donor and recipient, may become colonized by any variety of drug-resistant potential pathogens prior to undergoing transplantation procedure. These organisms may become clinically relevant after transplantation resulting in soft tissue infections, pneumonia, and various other difficult-to-treat systemic infections [20–24].

Both facial and hand allotransplantation grafts contain large amounts of donor-derived external skin. While native skin is normally colonized by a host of innocuous microorganisms, it is possible that allograft skin may be colonized with certain pathogens such as *Staphylococcus aureus*, *Propionibacterium* spp., diphtheroids, *Corynebacterium*, and other various Gram-negative organisms. This should be kept in mind when devising strategies for prevention and treatment protocols for possible surgical site infections in these high-risk patients. Additionally, these risks can be potentiated by an extended stay in intensive care units or prolonged hospitalization [25–28].

Bacterial Infections

The exposed oral surfaces of a composite facial allotransplant expose the recipient to donor-derived pathogens as well as continuous exposure of the environmental microflora. Immediate oral antimicrobial prophylaxis should concentrate on organisms such as Streptococci, *Capnocytophaga* spp., anaerobic bacteria, and *Candida* spp. Ampicillin-sulbactam provides adequate bacterial prophylaxis for these patients and should be implemented immediately [29]. Nystatin or clotrimazole can provide treatment as well as prophylaxis for *Candida* spp. during this period. If the patient develops an oral infection despite prophylactic measures, the source should be immediately assessed, and culture-directed antibiotic therapy should be promptly given. If there is any concern for methicillin-resistant *Staphylococcus aureus* (MRSA) or Gram-negative bacterial infection, empiric therapy with vancomycin and piperacillin-tazobactam should be started. The duration of prophylaxis is dependent upon a myriad of factors including physician judgment, duration of ICU stay(s), healing of intraoral suture lines, and intensity of antirejection drug-induced immune suppression.

The face transplant recipient is at a heightened risk for bacterial infection involving the paranasal sinuses. Close attention must be directed toward fevers or leukocytosis in the absence of any obvious clinical sign of infection. Serial imaging of the sinuses can be performed, and endoscopic cultures may be obtained if sinusitis is suspected [30]. The common bacterial pathogens include *Streptococcus pneumoniae*, *Moraxella catarrhalis*, *Staphylococcus aureus*, and other streptococci species. However, care must be taken to exclude fungal etiology.

Patients who receive hand or face transplants have similar risks of acquiring pneumonia as recipients of other solid organ transplants. Risk factors for the development of pneumonia in transplant patients include mechanical ventilation, prolonged ICU stay, sedation, history of smoking cigarettes, and patients with underlying asthma or COPD [31, 32]. Face or hand transplant patients who develop pneumonia within the 1st month following transplantation are often susceptible to pathogens associated during ICU stay such as *Pseudomonas aeruginosa*, *Klebsiella pneumonia*, *Acinetobacter* spp., and MRSA. These infections can be either healthcare-associated pneumonia (HAP), ventilator-associated pneumonia (VAP), or community-acquired pneumonia (CAP).

Antimicrobial prevention of pneumonia in the immunosuppressed solid organ transplant recipients has been advocated by many. One of the more effective prophylactic therapies in solid organ transplant recipients is the use of trimethoprim-sulfamethoxazole for the first 6 months following transplantation [33–36]. At many transplant centers, the incidence of *Pneumocystis jirovecii* pneumonia in patients who do not receive prophylaxis is greater than 10%. Prophylaxis with trimethoprim-sulfamethoxazole may also reduce the risk of other important opportunistic pathogens such as *Listeria monocytogenes*, *Toxoplasma gondii*, and *Nocardia asteroides*.

Patient undergoing composite tissue allotransplants are also at higher risk for catheter-related infections. The use of indwelling intravascular devices is nearly universal in this population due to the need for accessible vascular access for medications, transfusion of blood and blood products, monitoring of physiologic parameters, blood draws, and parenteral nutritional supplementation. Bloodstream infection due to microorganisms other than coagulase-negative staphylococcus thought to be related to an infected intravascular devise; it is prudent to remove such infected devices, especially in the severely immunocompromised transplant recipients. Finally, all lines should be discontinued when no longer needed.

Diarrhea is a common problem in solid organ transplant recipients [37–39]. *Clostridium difficile* is the most common cause of healthcare-associated diarrhea. In the hospitalized population, *Clostridium difficile* is responsible for 10–25% of cases of antibiotic-associated diarrhea [40–42]. The risk of becoming colonized with toxigenic *Clostridium difficile* in hospitalized patients is proportional to the length of stay, and most colonization occur within 3 weeks after hospitalization [43, 44]. The incidence of *Clostridium difficile* infection (CDI) in solid organ transplant recipients is highest within the first 3 months due to the immunosuppressive regimen and frequent antimicrobial exposures [45]. Face and hand transplant patients are likely to receive multiple antimicrobial agents for prevention and treatment of bacterial infection and are at an elevated risk for *Clostridium difficile* infection. Diagnosis is confirmed by stool assay identifying the virulent *Clostridium difficile* or one or more if its toxins. Patients with CDI commonly present with copious, malodorous diarrhea, elevated white blood cell count, persistent fever, and abdominal pain. This may progress to abdominal distention, ileus, toxic megacolon, bowel perforation, complicated peritonitis, and sepsis requiring emergent colectomy. Treatment options include cessation of the offending antibiotic drug when possible, treatment with oral vancomycin, and intravenous metronidazole in combination with oral vancomycin for patients with serious illness [46].

CMV Infection and End-Organ Disease

CMV infection has traditionally been one of the more devastating infectious complications following solid organ transplantation. Seroprevalence of CMV in the general population approaches 60–80% depending upon the region. Therefore, most organ donors and recipients have prior exposure to CMV infection [47, 48]. Accordingly, CMV infection occurs

in 50% of solid organ transplant recipients within the first 3 months if no antiviral prophylaxis is given.

CMV is a beta herpesvirus that retains a lifelong latency following the primary exposure/infection. It is an immunomodulatory virus that can cause many secondary immunologic phenomenon in addition to the primary infection [49, 50]. Posttransplant infection occurs either as a reactivation of latent remotely acquired infection or via acquisition of the virus from the donor tissue or unscreened blood or blood products. Individuals who are CMV seronegative prior to transplantation and acquire the virus from the donor tissue are at the highest risk for invasive CMV disease, which in most cases result in a devastating complication due to the immunologic novelty of the newly acquired viral infection compounded by the severity of drug-induced immune suppression given in the early posttransplant period.

CMV infection can manifest itself in one of three clinical scenarios. Asymptomatic viremia refers to detectable levels of CMV in a peripheral blood assay in the absence of clinical symptoms. CMV syndrome describes the signs and symptoms of acute CMV infection. This includes fevers, chills, myalgias, leukopenia, thrombocytopenia, and elevation of liver function tests. Finally, end-organ CMV disease refers to specific tissue damage caused by mostly uninterrupted intracellular CMV replication. Histopathology of the affected tissue demonstrates CMV inclusion bodies. Various forms of CMV tissue invasive disease include CMV pneumonitis, hepatitis, esophagitis, gastritis, enteritis, retinitis, colitis, and encephalitis [51].

The two major prevention strategies against CMV infections in face and hand transplantation are prophylaxis and preemptive therapy. Prophylaxis refers to providing antiviral drug for infection prevention given to at risk patients who undergo transplantation. Preemptive therapy refers to providing antiviral therapy to individuals with evidence of high risk for CMV end-organ disease such as those with asymptomatic CMV viremia. When universal prophylaxis was compared with preemptive therapy, results indicated that both strategies were comparable in preventing CMV disease and reducing the incidence allograft rejection in solid organ transplantation [52–54]. Although the strategies appeared to equally prevent CMV disease, patients who received universal anti-CMV prophylaxis were less likely to experience potentially life-threatening bacterial and fungal infections due to probably immune-modulating effect of CMV reactivation or acute infection, especially in the severely immunocompromised transplant recipients [55]. Both preemptive and universal prophylactic strategies have reduced the rate of symptomatic CMV infection to <10%. The most commonly used drug for CMV prophylaxis is valganciclovir, and at most transplant center, it is continued for 3 months following transplantation. In the face transplant performed at the Cleveland Clinic, intravenous ganciclovir followed by oral valganciclovir is given for 5 months.

Prophylaxis and preemptive CMV treatment is not without consequence. Both ganciclovir and valganciclovir have the potential for causing drug-induced multi-lineage myelosuppression resulting in profound neutropenia, anemia, and severe thrombocytopenia. Additionally, these drugs can produce renal dysfunction, gastrointestinal toxicities, and mental status changes. Ganciclovir and valganciclovir are both potentially teratogenic, and this should be kept in mind if the patient undergoing transplantation is of childbearing age. Due to their potential for promoting adverse reactions, ganciclovir and valganciclovir should not be administered together.

The effects of acute CMV infection can be devastating in the presence of a face or hand transplant. This has been illustrated most notably in the second French face transplant that was performed in 2007. This patient developed ganciclovir-resistant CMV infection with an episode of acute rejection. This episode required 8 weeks of therapy with foscarnet to prevent continuing rejection and declining CMV viremia [56]. Foscarnet therapy can result in renal failure requiring renal replacement therapy. Therefore, great care must be practiced when starting the patients on high-dose foscarnet induction therapy.

The impact of CMV infection in the setting of composite tissue allotransplantation has been clearly illustrated in its brief history [57, 58]. In a cohort of hand transplants form Pittsburg, PA, five of nine patients had clinically relevant CMV infection. Two of these patients had high viral loads; several had relapsing or remitting courses of treatment with combination of foscarnet and cidofovir. The face transplant patient from the Cleveland Clinic developed refractory CMV viremia. Her treatment was further complicated by recurrent neutropenia associated with ganciclovir and valganciclovir usage despite supportive care with recombinant myeloid growth factor use such as granulocyte colony-stimulating factor. Other antiviral medications have been considered; however, the risk posed by these medications was deemed too high in an already tenuous situation. Foscarnet is nephrotoxic and in the absence of adequate precautions can lead to urogenital contact ulceration. Cidofovir can lead to nephrotoxicity, cytopenias, and ocular problems. After consultation with multiple specialty services, she received the investigational drug CMX001 (combines Chimerix's Lipid-Antiviral-Conjugate Technology with cidofovir) under emergency IND from the FDA. The implementation of this regimen resulted in reduced CMV viral load, which after 6 weeks of therapy became undetectable in the peripheral blood [59].

CMV infection remains an important pathogen in solid organ transplantation; it appears as if this association may be particularly strong in patients undergoing composite tissue

allotransplantation [56–58]. Indeed, CMV infection has been a major complication in two of the first four face transplants as well as five of nine hand transplant recipients. While most would advocate not performing seropositive transplants to a seronegative recipient, however, the high CMV seroprevalence in the general population makes this approach impractical by severely limiting the donor graft pool. Future research in safe and effective new antiviral drugs, standardizing CMV prevention and preemptive treatment strategies, will ensure the greatest benefit for patients undergoing composite tissue allotransplantation.

Other Viral Infections

Viruses other than CMV can contribute to morbidity and mortality after solid organ transplantation. These agents commonly display temporal patterns of infection, with the 1st month displaying HSV seropositive recipients at heightened risk of HSV-1 and HSV-2 infection [60]. The 2nd to 6th months following transplantation are characterized by lowered cell-mediated immunity due to the intensifying effects of immunosuppression. CMV is the most serious infection during this period. Six months after transplantation, varicella-zoster virus (VZV) reactivation resulting single or multiple dermatomal herpes zoster or disseminated disease may occur. Human papillomavirus (HPV), adenoviruses, respiratory syncytial virus (RSV), influenza, and parainfluenza can occur at any time, although severe disease is witnessed in the first 3 months following transplantation [61, 62] (Figs. 6.1 and 6.2). A thorough understanding of the various infectious presentations and their treatments will prepare the team to deal with these problems as they arise.

Fig. 6.1 Hand transplant displaying papillomavirus-associated warts at the back of both hands at 9 months after double forearm transplantation [63]. (Reprinted from Schneeberger et al. [63], with permission from Springer)

HSV1 is a ubiquitous virus and reaches a prevalence of 80% among people over the age of 60. This virus may reactivate as cutaneous and mucosal eruptions presenting as painful vesicular lesions. HSV2 is less common with a prevalence of 30% among adults in the general population. The clinical presentation can be genital, perianal, or generalized mucocutaneous vesicular lesions. Additionally, there is a potential for disseminated visceral disease involving the lungs, gastrointestinal tract, and central nervous system. Because the incidence of clinically significant disease in HSV seropositive recipients' approaches 70%, antiviral prophylaxis with acyclovir is recommended during the first 4 weeks after transplantation [64]. The first face transplant recipient in France received HSV prophylaxis; however, she developed orolabial HSV on day 185 posttransplant, which responded to a combination of oral valacyclovir and topical acyclovir cream [26].

The VZV is a highly transmissible virus that causes chickenpox and varicella zoster. After primary infection, the virus remains dormant in the dorsal root ganglia. Approximately 90% of adults are either varicella-seropositive or have immunity from prior immunization. Majority of VZV infections in transplant recipients are as a result of reactivation of dormant remotely acquired virus. In seronegative patients, vaccination should be given at least 4 weeks prior to the anticipated transplantation procedure. Additionally, the live-attenuated virus should be avoided after the patient has undergone transplantation.

Epstein-Barr virus may cause clinically symptomatic disease any period after organ transplantation. Posttransplant lymphoproliferative disorder (PTLD) is a life-threatening complication due to EBV reactivation and may present with a variety of features ranging from reactive lymphadenopathy to malignant treatment-refractory lymphoma. Risk factors include (1) recent EBV infection, (2) coinfection with CMV, and (3) profound drug-induced immune suppression [65, 66]. Prescreening of transplant recipients may identify a patient who is seropositive and help guide therapy. However, there is no clear established role for antiviral prophylaxis. If patients are found to have PTLD, the mainstay of treatment is reduction in immunosuppression. However, new strategies in treating PTLD in solid organ transplants include anti-CD20 monoclonal antibodies given in an effort to limit the proliferation of EBV-infected immortalized cells.

Various other herpesviruses such as herpesvirus 6 (HHV-6) can cause infection in transplant patients. Seropositivity in the general population is high, and reactivation following transplantation may occur resulting in pancytopenia, pneumonitis, hepatitis, and meningoencephalitis. To date, there has been no clear antiviral prophylaxis established. Herpesvirus 8 (HHV-8) is the primary agent of Kaposi sarcoma, Castleman's disease, and body cavity or primary effusion lymphoma. There is no clear role for antiviral

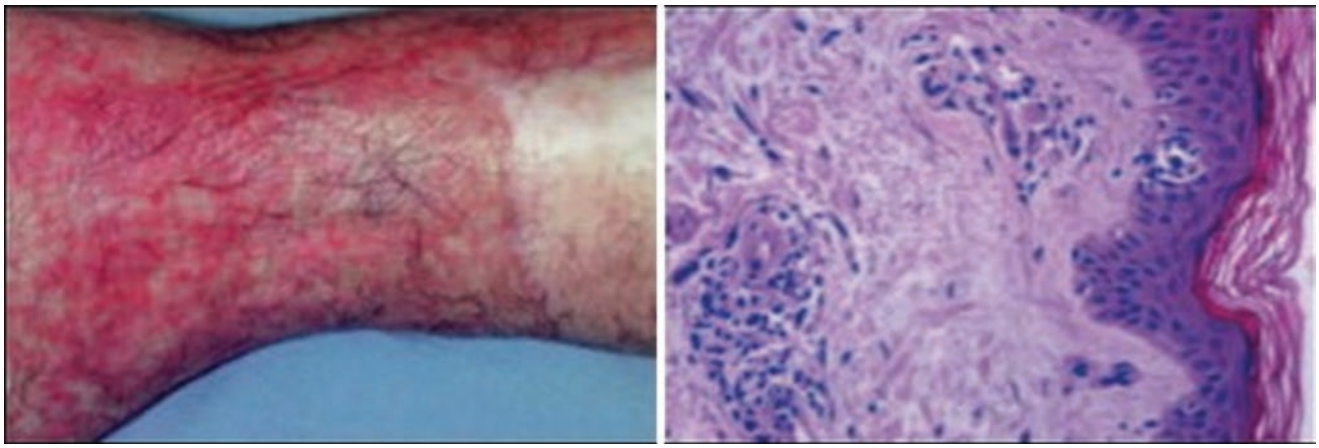

Fig. 6.2 Hand transplant displaying disseminated erythema and papulous lesions as signs of rejection at 55 days after hand transplantation. Histology demonstrated perivascular and interstitial mononuclear cell infiltrates [63]. (Reprinted from Schneeberger et al. [63], with permission from Springer)

prophylaxis for this pathogen, and reduction in drug-induced immune suppression remains the cornerstone for treating patients with HHV 8-related disease.

Both HBV and HCV have been exhaustively studied within the solid organ transplant population. Many studies have been performed identifying the virus' role in predicting, performing, and recovering from liver failure and liver transplantation. To date, there have been no hand or face transplant donors or recipients who have been seropositive for HBV or HCV. However, vaccination against HBV is universally recommended in the preoperative setting.

The clinical manifestations of respiratory viral diseases are often typical, and solid organ transplant recipients are at risk to develop more severe and prolonged illness. Symptoms include congestion and rhinorrhea to an increasingly severe lower respiratory tract infection. Because there is no pathognomonic symptom for a specific virus, judicious culturing or preferably nested PCR respiratory pathogen panels should be performed for any transplant patient suspected respiratory viral disease. Influenza, parainfluenza, RSV, and adenoviruses may result in severe lower respiratory tract infections, and every effort must be made to deter progression to lower respiratory disease. Prevention is the most important strategy for respiratory viruses. Infection control measures are critical and should be strictly implemented in the transplant units. Accordingly, patients with suspected influenza or other respiratory viruses should be isolated using standard and droplet precautions. Additionally, the patients and healthcare workers should receive mandatory annual influenza vaccination. If the patient is found to have influenza, treatment should be implemented according to seasonal viral drug-resistance profile; common agents used in prevention and treatment of influenza viral infections include M2 inhibitors and neuraminidase inhibitor. By implementing policies such as strict adherence to handwashing, contact and droplet precautions as part of hospital infection control strategies, and unwavering compliance with annual influenza vaccination recommendations, infection rates can be reduced in these highly susceptible patients with the potential for devastating respiratory viral disease.

Fungal Infections

Universal antifungal prophylaxis in solid organ transplantation is not accepted based on available data. However, targeted prophylaxis according to risk criteria is generally more evidence based. Additionally, one can start antifungal therapy based upon a positive diagnostic test prior to clinically evident disease. This allows for appropriate dosing of antifungal agents at an early stage of infection and the reduction of unnecessary treatment and toxicity. *Candida*, *Aspergillus*, and *Cryptococcus* species are the most frequent causes of infection in patients undergoing solid organ transplantation. *Histoplasma capsulatum* and *Coccidioides immitis* can cause serious disease, albeit, such infections are only prevalent in certain geographic regions and are less common.

Invasive fungal infections can be broadly categorized into one of two groups, geographically endemic fungi and opportunistic fungal infections. Geographically endemic fungi are endemic to a particular region and present as reactivation of a remotely acquired latent infection or a newly acquired primary infection in a person visiting these specific regions. Opportunistic infections rarely cause clinically relevant invasive disease in immunocompetent patients and have no geographical restriction. Examples of opportunistic fungi include *Candida*, *Aspergillus*, and *Cryptococcus neoformans*.

Candida yeast is the most common opportunistic fungal infection in organ allograft recipients. *Candida* is part of the

normal microflora of skin and orointestinal tract; it also frequently colonizes lower genitourinary mucosa in women. Oral candidiasis is common in the early posttransplant period. Other forms of infection include catheter-related candidemia and deep surgical site infections. The treatment for topical and mucosal candidiasis is nystatin or clotrimazole and frequently suggested for oral prophylaxis. The first full-face transplant recipient in France developed oral candidiasis on postoperative day 18. The initial presentation of "diffuse erythema and edema" appeared indistinguishable from acute graft rejection and illustrated the importance of recognizing and treating these infections when they occur. The patient's symptoms resolved with systemic antifungal therapy.

Cryptococcus is an encapsulated yeast found in the soil and has the potential for severe invasive systemic disease in the immunocompromised patients. Most cases of cryptococcal disease occur during 1st year after transplantation [67]. Fungal meningitis, cellulitis, and pneumonia are common diseases. An increased intracranial pressure in patients with cryptococcal meningitis mandate neurosurgical decompression along with combination antifungal drugs and other aspects of medical management.

Coccidioidomycosis and histoplasmosis are both endemic to certain geographic regions in the United States. Coccidioidomycosis is found predominantly in the southwestern United States. Fungal spores are acquired through inhalation. Infections are mostly seen within the 1st year following transplantation and often present as reactivation of remotely acquired infection [68, 69]. The infection presents clinically with acute respiratory infection. Generally, the disease will resolve rapidly, but a small percentage of patients may go on to develop chronic pulmonary disease. A smaller number of patients will progress to develop disseminated disease involving skin, joints, and central nervous system. Histoplasmosis is the most prevalent fungus in the Americas. It is geographically centered in the Midwest region of the United States. Most infections are asymptomatic; however, disseminated pulmonary disease can occur in the immunocompromised individuals.

Aspergillus is ubiquitous filamentous mold commonly isolated from soil and water. Transmission of the fungus is via inhalation of infectious germinating microconidia. Infection in immunocompetent patients is rare, and this fungus typically only becomes invasive in individuals who are severely immunocompromised. The principal manifestation of invasive fungal disease involves the lower respiratory tract resulting in bronchitis, fungal lung nodules that may progress to necrotizing pneumonia and systemic dissemination. Lung transplant recipients are at a higher risk than other solid organ recipients, in part, due to the exposure of allograft to the external environment and prolonged respiratory tract fungal colonization prior to undergoing transplantation procedure.

Risk factors for the development of invasive fungal infections include prolonged ICU stay, extensive exposure to broad-spectrum antibiotics, diabetes mellitus, exposure to agricultural or horticultural products, and marijuana smoking [70]. Preventative strategies include avoidance of exposures in the hospital and limitation of environmental exposure once discharged from the hospital. The face transplant patient at Cleveland Clinic received prophylaxis with voriconazole, which had to be discontinued due to an elevation in liver enzymes and derangement of tacrolimus serum levels. This difficulty is seen with several commonly used triazole antifungal drugs. Additionally, the patient was monitored for histoplasmosis with the urinary *Histoplasma* antigen for approximately 4 months due to exposure to chickens early in life. Fortunately, this patient never developed invasive fungal disease and did well without antifungal prophylaxis.

Other Infections in Face and Hand Transplantation

Because of the intense immunosuppression required in composite tissue allotransplantation, the patients are at risks for a myriad of infectious agents. In addition to traditional bacterial and viral pathogens, these patients are at risk for mycobacterial and parasitic infections. Because these pathogens can be difficult to detect and devastating if they become disseminated, a thorough preoperative screening for *Mycobacterium tuberculous*, *Strongyloides stercoralis*, *Leishmania* spp., and *Trypanosoma cruzi* should be performed. Patients with a history of exposure to *Mycobacterium* should be screened using new-generation gamma interferon release assays and offered isoniazid prophylaxis for untreated latent tuberculosis infection. Positive *Strongyloides* serology should prompt the consideration of preoperative ivermectin therapy.

Immunization Strategies in Composite Tissue Allotransplantation

Face and hand transplants are entirely elective operations; therefore, care must be taken to ensure that the patients have exhaustive evaluation for prevention and prophylaxis prior to becoming a candidate for transplantation. Several infections are associated with an increased risk of solid organ graft rejection and dysfunction. Infections are a major determinant of the patient's overall prognosis. Interventions to prevent infection include vaccination, antimicrobial prophylaxis, and preemptive therapy. A thorough evaluation of vaccination and immunization status prior to transplantation includes a thorough history and physical

examination, a complete vaccination history, and standard measurement of titers for HBV, HCV, VZV, varicella, measles, mumps, and rubella.

To further optimize the patient's status prior transplantation, they should undergo further serologic evaluation for CMV, HSV I and II, VZV, EBV, human immunodeficiency virus, HBV, HCV, *Treponema pallidum*, *C. neoformans*, and *Toxoplasma gondii*. Additionally, if the patient lives in an endemic area or there is suspicion for infection, additional serologic titers should be sent for *S. stercoralis*, *Leishmania* spp., *T. cruzi*, *Histoplasma capsulatum*, and *Coccidioides immitis*. One should keep in mind that the patient risks losing immunity with higher degree of immunosuppression; there needs to be a well thought-out delicate balance between risk assessment for certain infections and prevention and treatment for such infections.

The patient should receive appropriate vaccinations prior to transplantation and initiation of immunosuppressive therapy. Pneumococcal vaccine should be administered if not given in the prior 5 years [71]. Tetanus-diphtheria-acellular pertussis (Tdap) should be given if the last tetanus immunization was greater than 10 years before transplantation [72]. HBA and HBV vaccines should be given to seronegative or patients with low titers. Seasonal influenza vaccination, including H1N1 when recommended by the Centers for Disease Control and Prevention, should be administered according to existing guidelines. Poliovirus and *Haemophilus influenza* vaccines should also be given if the vaccination status is questionable [71]. Finally, women aged 9–26 years of age should receive the HPV vaccination. The indications for recombinant HPV vaccination may possibly extend in the future. To these authors' knowledge, there have been no studies to assess long-term efficacy of pretransplant vaccination in this patient population. Due to an increased risk of infection, patients who have started immunotherapy should not receive live-attenuated vaccines.

Lifestyle Adaptations in Composite Tissue Allotransplantation

Once the patient's immediate surgical needs have been met, the face or hand transplant patient enters the recovery period. Here, the patient has been discharge from the inpatient hospital setting, and they begin intensive physical and occupational therapy as well as psychosocial rehabilitation. In this period, it is imperative that the patient is educated for potential environmental exposure risks and how to avoid them. Recipients of face and hand transplants can enjoy many of the activities of everyday life; however, there are certain precautions regarding water, food, animals, and travel-related exposure that should be addressed and periodically reinforced. For instance, the face transplant patient at Cleveland Clinic suffered from transient diarrheal illness. Further investigation revealed *Aeromonas* in her stool and drew attention to the issues surrounding well water as a potential source for the infection.

Patient should try and consciously limit their exposure to pets and other animals, including farm animals. Face and hand transplant patients can be owners of dogs, cats, and other pets, and their emotional attachment to these animals is often strong due to the fact that many of the patients have had difficulty integrating into the society prior to transplantation. The patient should be screened and educated that further exposure to the animals is not without significant risk. For example, exposure to cat feces can lead to *T. gondii* infection. Birds and parrots can transmit fungal infections as well as *Chlamydia psittaci*. Finally, reptiles and amphibians can transmit *Salmonella typhi*. With meticulous education, screening, and prevention, these patients can minimize their infectious risk.

Concomitant Facial and Upper Extremity Transplantation

The combination of facial and upper extremity transplantation appears to provide a solution to one of the most challenging problems in reconstructive surgery. This large surgical undertaking puts an increased stress on the already strained immune system. Undoubtedly, the most puzzling aspect of this proposed solution is unquestionably how the immunosuppressive regimen will change.

It is evident that larger composite tissue allografts contain more donor-derived epidermis. The skin, the largest organ in the human body, contains a variety of immune cells including Langerhans cells and keratinocytes making it the most antigenic tissue component in the allograft. It is not clear as to whether this type of increased antigenic load directly equates to the need for increased levels of immunosuppression and whether this would equate with negative outcomes. To date, there has been no difference in rejection between wrist-level hand versus more extensive higher levels transplantation with more allograft donor skin involved although there are several conflicting studies indicating amplified immunologic responses with an increased antigenic quantity of donor skin transplanted [73, 74].

Additionally, it is unclear if a larger transplant will increase the infection risk. Although intuitive, it is unclear if any additional precautions should be taken and if perioperative topical skin care has any role in preventing these infections. What is clear is that as composite tissue allotransplantation becomes more commonplace and these operations become more aggressive, our understanding in the spectrum of infectious complications will improve.

Conclusions

All patients undergoing long-term immunosuppression for solid organ transplantation are at risk for the development of infectious complications that could not only threaten the viability of the transplanted graft, but this may also threaten their life. As we enter the era of reconstructive transplantation, these risks cannot be understated. It is important that the medical and surgical teams, the patient, and the patient's family are aware of the risk and benefits of this life improving intervention as well as the signs and symptoms of secondary complication such as infections, graft rejection, and drug toxicities. While face and extremity transplants appear to have much in common with solid organ transplants, it is clear that certain subtleties do exist. Namely, the apparent unique microflora in facial transplant and the seemingly increased risk of CMV infection and rejection appear to provide new avenues for investigation. Future work should provide greater insight into the novel strategies for safe effective CMV prevention and treatment of end-organ disease.

Principles of Hematopoietic Stem Cell Transplantation

7

Michelle Limei Poon, Richard E. Champlin, and Partow Kebriaei

Introduction

Hematopoietic stem cell transplantation (HSCT) refers to the process of intravenous infusion of self-renewing hematopoietic stem and progenitor cells to restore normal hematopoiesis and/or treat malignancy. The term "hematopoietic stem cell transplantation" has replaced the term bone marrow transplantation because the current advances in the field of transplantation have allowed these self-renewing progenitor and stem cells to be derived not just from bone marrow but also from peripheral blood and umbilical cord blood. In addition, HSCT can be further characterized according to whether they are obtained from the patients themselves (referred to as autologous transplantation), a genetically identical twin (referred to as syngeneic transplantation), or from another individual (referred to as allogeneic transplantation). After decades of refinement, transplantation of both autologous and allogeneic hematopoietic stem cells has become increasingly safe and effective. HSCT now forms an integral part of the curative treatment of hematological malignancies, metabolic disorders, and benign hematological disorders including hemoglobinopathies, immune deficiency syndromes, as well as inherited and acquired marrow failure syndromes. Thus, not surprisingly, the NMDP reports more than 50,000 autologous and allogeneic transplants being done worldwide annually for the treatment of various disorders [1].

The initial concept of the curative potential of HSCT was through allowing increased, myeloablative doses of chemotherapy to be given while avoiding the risk of permanent marrow aplasia. While this may be true for autologous HSCT, the basis for allogeneic HSCT is engraftment of donor-derived hematopoietic stem cells into the recipient. These cells reconstitute hematopoiesis and immunity. Following successful transplantation, recipients are considered chimeras with hematopoietic and immune cells derived from the donor, while mesenchymal and epithelial tissues remain predominantly host derived. Importantly, there is an additional component of an immunotherapeutic graft-versus-leukemia effect, mediated by immunologically competent lymphocytes within the donor graft, which helps improve chances for a cure. The evidence for this graft-versus-tumor effect (GVT) has been clearly demonstrated by studies which show (1) an inverse correlation between relapse and severity of graft-versus-host disease (GVHD) and a comparatively higher rate of relapse following syngeneic or autologous HSCT using the same myeloablative conditioning regimen [2], (2) a higher incidence of relapse rates in T-cell-depleted grafts, and, most significantly, (3) the observations that donor lymphocyte infusions (DLIs) given at a time distant from the original conditioning regimen can treat leukemia relapse successfully. In addition, the potency of the GVT effect varies among the various diseases [3–6]. Indolent lymphoid and myeloid malignancies are most responsive to GVT effects, with durable remissions noted after modulation of immunosuppression or DLI in patients with chronic myeloid leukemia, chronic lymphoid leukemia, and follicular lymphoma [7]. In contrast, diseases such as high-grade lymphoma and acute lymphoblastic leukemia appear less susceptible to the GVT effect, although patients with GVHD do have a reduced risk for relapse [8]. The rapid rate of proliferation of these malignancies may also outpace a developing immune response leading to a generally poor response to DLI. Reduced-intensity conditioning (RIC) regimens were developed based on the potency of the GVT effect rather than the intensity of the conditioning regimen. The advent of RIC regimens has made HSCT accessible to older and more medically infirm patients.

Other progresses in the field of HSCT have included the increasing use of alternative donor sources such as umbilical cord blood transplants and haploidentical transplantations

again allowing HSCT to be made accessible to patients who have no matched donors and who previously would have been precluded from a HSCT. These transplantations however are associated with higher risks of morbidity and mortality, including higher risks of infective complications, due to delayed immune reconstitution.

In this chapter, we aim to look at some important principles of HSCT including the immunobiology of stem cell transplantation, as well as the impact of HSCT on the host immune system, and discuss the principles of immune reconstitution following HSCT. In addition, we will also discuss the choice of preparative regimens, stem cell sources, the importance of post-transplant immunosuppressive therapy, as well as the indications for HSCT. The complications related to HSCT will be briefly touched upon, but these will be covered in greater detail in the relevant chapters.

Historical Perspectives of HSCT

There has been increased interest in the use of marrow cells to facilitate hematopoietic reconstitution since the late nineteenth and early twentieth century, with reports of the use of oral, intramuscular, and intramedullary injections of marrow infusions to facilitate hematopoietic recovery in patients with leukemia or marrow aplasia. In 1939, Osgood et al. reported the first unsuccessful attempt to treat a patient with aplastic anemia using intravenous infusion of viable marrow cells [9]. These early attempts, however, were carried out in isolation, and it was not until the clinical observations of the severe myelosuppressive effects of radiation among nuclear bomb survivors at Hiroshima and Nagasaki that concerted research efforts were started to develop methods to reverse the myelosuppressive effects of radiation, including the use of marrow infusion. Early pivotal work by Jacobson et al. in 1948 demonstrated that mice who had splenic shielding could survive otherwise lethal doses of irradiation with marrow recovery [10]. He further showed that bone marrow failure following otherwise lethal doses of irradiation could also be prevented by infusing either spleen cells or bone marrow cells from a litter mate into the animal [11]. The mechanisms of these findings were initially poorly understood and attributed to either a hormone or growth factor contained in the infusion. Further studies however in the 1950s and 1960s debunked the "hormonal theory" and confirmed that it was the living cells within the marrow infusion that were responsible for hematopoietic recovery. These studies formed the initial basis for the development of stem cell infusion as a treatment for leukemia and bone marrow failure. Further advances in the field of HSCT came with the understanding of the concept of histocompatibility, as a result of the canine studies done by E. Donnall Thomas and colleagues in Seattle in the 1960s. They noted that in lethally irradiated dogs, marrow grafts from mismatched littermates always failed, while grafts between dog lymphocyte antigen (DLA)-matched donors and recipients showed improved survival. They also demonstrated that the administration of a short course of MTX for immunosuppression after grafting improved the long-term survival of matched recipients [12–14]. This understanding of the major histocompatibility complex (MHC) and human leucocyte antigens (HLA) as the major determinants of graft rejection further advanced laboratory studies and clinical applications of allogeneic HSCT. This led to the first successful reports of clinical HSCT for patients with immunodeficiency disorders, aplastic anemias, and advanced leukemias in the late 1960s and early 1970s [7, 15–17].

The initial transplants were associated with significant morbidity and mortality as a result of complications from infections and graft-versus-host disease (GVHD). In the last 10–20 years, however, the outcomes of HSCT have improved dramatically due to refinements in the transplant approach, as well as better supportive care/infectious disease management. Better tissue typing of donors and recipients using molecular methods and improved understanding of the pathogenesis of GVHD and improved GVHD prophylactic measures have led to reduced rates of both acute and chronic GVHD. Improved and novel, reduced-intensity conditioning regimens, together with the increased numbers of matched unrelated donor (MUD) registries and development of alternative stem cell sources including cord blood and haploidentical sources, have made HSCT more accessible to a larger patient population, who would have been ineligible for transplant previously. In addition, improvements in supportive care, and especially in the field of infectious diseases, have further reduced infection-related morbidity and mortality. The summation of these exciting developments has led to HSCT being a standard treatment option not just for many hematological malignancies but also for benign disorders including immunodeficiency syndromes, metabolic disorders, and defective hematopoietic states. Rarely, allogeneic HSCT may also have a role in situations of nuclear accidents, where it may be used to treat victims who receive exposure to marrow-ablative doses of radiation, such as following the Chernobyl nuclear disaster in 1986 [18]. While such situations are rare, this concept has been brought to the forefront again with the recent Japanese Fukushima nuclear disaster, and with the increasing use of nuclear resources as a source of energy, as well as the constant threat of nuclear warfare worldwide.

Basic Principles of HSCT

Immunobiology of HSCT

The fundamental principles underlying the development of stem cell transplantation are the use of a combination of

drugs and/or radiotherapy (conditioning regimen) to eradicate the underlying disease process and to create space within the bone marrow niches for the incoming marrow cells. The conditioning regimen also has the role of immunosuppressing the host in order to prevent a host-versus-graft reaction. Hematopoietic stem cells (HSCs) with the capacity for self-renewal and differentiation into the various lineages are collected either from the patient (autologous transplants) or from the donor (allogeneic transplant). Following the conditioning regimen, HSC are then introduced. These cells then migrate through the blood and across endothelial vasculature to various organs, and eventually to the marrow niches, a process termed homing. Homing is a coordinated multistep process, which usually occurs rapidly within 24 h, and is the first and most essential step in clinical stem cell transplantation. The understanding of the details of this complex process remains the work of much ongoing research.

Durable engraftment of allogeneic HSC is subsequently dependent on the donor CD8+ T cells which are needed to overcome any residual host-versus-graft response created by the donor-specific host T cells (that remain following the conditioning). Donor CD8 and CD4 T cells interact with peptide antigens complexed with MHC class I and II molecules, respectively, on antigen-presenting cells (APCs) of the recipient. This leads to subsequent donor T-cell proliferation and a successful allo-response against residual recipient T cells, causing the elimination of the recipient immune system. Donor T-cell engraftment is important in establishing long-term hematopoiesis. CD34 stem cells and their progeny within the graft also help in engraftment by blocking residual host T-cell function through a "veto" effect, as well as by further differentiating into natural killer (NK) cells which favor engraftment through their recognition and killing of residual recipient lymphocytes. Once engrafted, donor HSCs continue to maintain hematopoiesis as well as aid in immune reconstitution within the host.

Reconstitution of Immunity Following Allogeneic HSCT

Reconstitution of immunity post HSCT involves the reconstitution of different immune cell subsets, including NK cells, the T and B cells, APCs, and the production of antibodies.

Recovery of Innate Immunity

NK cells, derived from the infused CD34 progenitor cells, and driven by lymphocyte growth factors and cytokines, are the first immune cells to reach normal levels and are crucial components of the innate immune system. Donor-derived antigen-presenting cells (APC) including monocyte-macrophages, dendritic cells (myeloid and plasmacytoid), and Langerhans cells also develop from CD34 cells within weeks after the transplant and return to normal levels within 6 weeks following the transplant.

Recovery of Adaptive Immunity

The initial T-cell recovery in the first 3 months following HSCT is dependent on peripheral expansion of post-thymic donor T lymphocytes that were transfused within the graft. These T cells consist predominantly of central and effector memory cells with a smaller population of naive T cells and end-stage effector cells. These memory T cells are driven by cytokines and the presence of alloreactive antigens, as well as reactivating viruses, and expand and mature into an expanded memory pool but with decreased diversity in both naive and memory lymphocytes. The TCR repertoire resulting from these early expansions is typically skewed and oligoclonal. These post-thymic cells are largely responsible for the success or failure of the transplant through their impact on engraftment, GVHD, GVT, and reactivating viruses.

While early post-transplant T-cell reconstitution is dependent upon peripheral T-cell expansion, an optimal cellular immunity, with a diverse T-cell receptor (TCR) repertoire, is only achieved following thymopoiesis, which normally starts about 120 days post-transplant. CD4-positive T cells rely more on thymic production of naive T cells after HSCT and hence reconstitute later than CD8 + T cells, leading to an inversion of the CD4/CD8 ratio prior to thymopoiesis. Naive T cells are formed by the CD34 precursors within the marrow and processed by the recipient thymus to form a new immune repertoire. In children and young adults where the thymus function is normal, a new T-cell repertoire develops within 1–2 years. In contrast, in older patients with limited thymic activity, naive T cells and total CD4+ T-cell reconstitution may be impaired indefinitely leading to higher risks of opportunistic infections, leukemia relapse, and chronic GVHD.

B-cell reconstitution post HSCT recapitulates the normal B-cell development. However, this process is commonly impaired due to prolonged low levels of circulating B cells, a relative deficit of mature B cells due to impaired immunoglobulin class switching, and a diminished ability to undergo somatic hypermutation. The reconstitution of the B-cell compartment representing humoral immunity may take up to 2 years after HSCT and may result in patients being at high risks of infection by encapsulated organisms and may also result in diminished vaccine responses to infectious antigens even after normal B-cell numbers have been achieved.

1. The pattern of reconstitution of immunity explains the pattern of infective complications seen post-transplantation. Re-engraftment (D1-30): Bacterial infections are commonest during this period followed by fungal infections especially candidemia and invasive aspergillosis, due to the significant neutropenia while awaiting engraftment of HSCs.
2. Post-engraftment (D30-100): Viral and fungal infections (especially mold infections) may develop as a result of the defective cellular and humoral immunity, as well as defective phagocytic function.
3. Late post-engraftment (days >100): Risks for viral and fungal infections persist until eventual recovery of cellular and humoral immunity.

Importantly, there are a number of factors that affect immune reconstitution post-transplant. These include the age of the patient, the transplant preparative regimen, and whether anti-T-cell therapy such as antithymocyte globulin (ATG) or alemtuzumab was included, the graft source, and the development of GVHD. These will be discussed in the subsequent relevant sections below.

Technical Aspects of HSCT

Tissue Typing and Donor Selection

The major histocompatibility complex (MHC) is the term given to genes clustered on the short arm of chromosome six that form the human leukocyte antigen (HLA) system. The most important HLAs include HLA A, B, and C (found on the class 1 loci) and HLA DR, DQ (found on the class 2 loci). A single set of MHC alleles described as a haplotype are inherited from each parent, resulting in HLA pairs. As a result of this inheritance, parents are half matched with their children, while the probability that two siblings would share the same haplotypes would be one in four. In allogeneic HSCT, donor and recipient are matched for HLA in order to reduce GVHD (where immunologically active cells from the graft attack body tissues in the transplant recipient/host) or, less commonly, graft rejection (where immunologically active cells from the recipient/host reject the donor cells). While histocompatibility was previously defined by serologic assays (also called low-resolution HLA typing), the development of molecular assays has resulted in the serologic groups being further subdivided into specific alleles (high-resolution typing). Studies have shown that HLA matching of donors and recipients at a high-resolution level (using molecular methods of typing) especially for unrelated transplants have been associated with reduced GVHD rates and improved overall survival. Currently, a "matched" donor is defined on the basis of HLA high-resolution matching at four loci, HLA A, B, C, and DRB1, ("8/8" match) or five loci, HLA A, B, C, DRB1, and DQB1 ("10/10" match).

Sibling donors are the preferred donor source, because of the least risks of GVHD and graft rejection. For patients without a fully HLA-matched sibling donor, alternatives include an unrelated HLA fully matched donor or partially matched cord blood units or a partially HLA-matched family member [19–21].

MUD Donors

Depending on the ethnic background of the patient, the possibility of identifying a HLA-matched unrelated (MUD) donor is between 50% and 80%. As a result of better HLA matching with improved molecular typing techniques, the current results of matched unrelated donor transplants for malignancy are not significantly different compared with HSCT from matched sibling donor transplants [22, 23]. This has led to the use of MUD HSCTs for patients at an earlier stage in their disease, and these transplants now account for almost 15% of all allogeneic transplants performed worldwide. Problems with using MUD donors however include the longer time (up to 2–3 months or longer) needed to identify and procure cells from an unrelated donor, which may not be fast enough for patients with rapidly progressive malignancies.

Umbilical Cord Blood Donors

Umbilical cord blood transplantation was first performed successfully by Gluckman et al. in a patient with Fanconi's anemia in 1988 [24]. Since then, the field has expanded rapidly, with over 25,000 cord blood transplants performed worldwide and over 500,000 cord bloods being collected for public use. The umbilical cord contains fetal blood collected following the delivery of the placenta and separation from the fetus and is rich in hematopoietic and progenitor cells [25]. Normally up to 50–100 cc of cord blood can be collected from each delivery. The small volumes of cord blood available usually results in much lower stem cell dose as compared to that collected from peripheral blood or bone marrow, for the adult patient. The advantages of umbilical cord blood transplant over an unrelated donor include the rapidity at which the product can be obtained (usually less than 4 weeks). In addition, because of the high percentage of naive T cells present within the cord blood, HLA mismatches in up to two of six HLAs are acceptable in cord blood transplant, allowing for a higher likelihood of finding a donor for a patient with rarer HLA genotypes. The rates of aGVHD with UCBTs also appear lower compared with normal unrelated BM transplants, and this is again attributed to the high naive T-cell population present within the cord blood graft [26]. The low stem cell dose and possibly the smaller number of lineage committed late progenitor cells within cord blood grafts however, especially for adult patients, lead

to higher risks of graft rejection, slower engraftment and immune reconstitution, and higher infective complications and treatment-related mortality (TRM) compared with unrelated HSCTs. In addition, no remaining product is left after infusion in the event of disease relapse or graft rejection. While there has been no randomized controlled trials comparing the outcomes of UCBT to other graft sources, there have been a number of retrospective studies in the literature which has explored this issue. In one of the largest studies, a review of registry data from the CIBMTR, comparing the outcomes of 165 myeloablative single UCBT with 888 MUD peripheral blood stem cell (PBSC) recipients and 472 MUD bone marrow (BM) recipients, it was found that UCBT was associated with higher TRM, but overall DFS and OS were similar among all three groups [27]. In an attempt to overcome the poor outcomes associated with the low cell doses in the cord blood grafts, there has been a shift toward using double rather than single cord blood units [28], as well as studies looking at ex vivo expansion of one of the cord blood units [29, 30] or the use of CD34 cells from haploidentical donors for temporary support while awaiting cord blood engraftment [31]. Brunstein et al. reported data from Seattle and Minnesota, comparing double UCBT with related, matched, or 1-antigen-mismatched MUD and found TRM was higher [dUCB (34%, 95% CI, 25%–42%), MRD (24%, 95% CI, 17%–39%), and MUD (14%, 95% CI, 9%–20%), but relapse rates were lower in the UCBT group (15%, 95% CI, 9%–22%) compared with MRD (43%, 95% CI, 35%–52%) or MUD (37%, 95% CI, 29%–46%), leading to comparable overall survival among the different groups [32].

Haploidentical Donors

Haploidentical transplantation is another alternative for patients with no unrelated donors. It involves alloHSCT using a partially HLA-matched family member among first-degree relatives, who share at least one haplotype with the potential recipient. The advantage of haploidentical transplantation includes donor availability, since virtually all patients should have a haploidentical donor. The initial experiences with haploidentical HSCT using unmanipulated bone marrow grafts with standard immunosuppressive therapy post-transplant were associated with dismal outcomes with high rates of graft rejection, GVHD and TRM, especially in the setting of two or more HLA mismatches [33–35]. This led to work by several groups to overcome the immunological barrier through novel graft manipulation techniques, improved GVHD prophylaxis, and the development of new conditioning regimens. Most strategies have involved T-cell depletion pre-transplant, using either in vivo techniques (using monoclonal antibodies or antithymocyte globulin) or ex vivo techniques using T-cell depletion with agglutination and E-rosetting methods and CD34+-selected cells, a technique pioneered by the Perugia group in Italy [19, 36, 37]. While these techniques have been associated with marked reduction in graft failure and GVHD rates, delayed immune reconstitution and high TRM due to infections remain a significant deterrence. In addition long-term disease control with haploidentical HSCT is limited in patients with active disease at time of transplant. Another novel approach in the field of haploidentical transplant has been the use of post-transplantation cyclophosphamide to overcome the HLA barrier [38–40]. It has been shown in animal models that both graft rejection and GVHD after histoincompatible BMT can be mitigated by the post-transplant administration of high-dose cyclophosphamide, which is known to be highly toxic to proliferating alloreactive lymphocytes, though high relapse rates remain an issue.

Given the differences between the various stem cell sources, generally sibling donors are preferred, followed by MUD donors. For patients with no MUD donors, the selection of cord blood versus haploidentical family member donor remains largely dependent on institutional expertise, in the absence of comparative studies.

HSC Acquisition

Following identification of a donor, procurement of hematopoietic progenitor cells is necessary before proceeding with a HSCT. Collection of sufficient numbers of hematopoietic stem cells is required for reconstitution of hematopoiesis and immunity post-transplantation. These stem cells primarily reside in the bone marrow, and in the past, all hematopoietic transplantation utilized unfractionated bone marrow cells harvested via repeated aspirations from the posterior iliac crest. However, HSCs also circulate in low frequency in the peripheral blood, and since the 1980s, hematopoietic growth factors, primarily granulocyte colony-stimulating factor (GCSF), have been used to mobilize higher numbers of HSC into the peripheral blood pool, and HSCs are then collected via an aphaeresis procedure from the donor [41, 42]. Importantly, there are many significant differences in the composition of peripheral blood HSC as compared with marrow grafts. GCSF-stimulated peripheral blood grafts have an approximately two to five times higher HSC concentration than in bone marrow, as well as one log more T cells than marrow grafts [43]. In contrast, bone marrow grafts contain mesenchymal stromal cells, as well as reticular endothelial cells, macrophages, fibroblasts, endothelial progenitor cells, adipocytes, and osteogenic progenitor cells, which provide various cell-to-cell interactions essential for hematopoiesis and progenitor cell differentiation. Some consistent differences in outcomes identified from comparative studies include faster engraftment of all cell lineages, faster immune recovery (see section on Immune reconstitution post-transplant), and a trend toward more overall and exten-

sive chronic GVHD rates in PB transplants [44–51]. In addition, an individual patient meta-analysis using data from the nine randomized trials also found an improved overall survival and disease-free survival in patients with late-stage hematologic malignancies disease who received a PBHC transplant compared to a bone marrow transplant [52]. The results of these studies, as well as the ease of PBHC collection as compared to BM harvests, have led to increased use of PBHC grafts, and currently, about 70% of all allogeneic transplants in Europe and worldwide are performed with PBHC instead of BM grafts. What is important to realize however is that these prospective randomized studies comparing PBHC vs. BM transplants have been done in matched sibling transplants and mainly included patients with leukemias and other hematologic malignancies. For other patients with benign disorders such as aplastic anemia, where a graft-versus-tumor effect is not needed, retrospective registry data has suggested that BM grafts are the preferred option over PBHC grafts because of their lower risks for chronic GVHD [53]. In the matched unrelated setting, a large Phase III, randomized, multicenter, trial looking at the issue of PBHC versus BM graft has been recently reported in abstract form [54]. In this large study involving 278 subjects from 50 centers in the United States and Canada, PBHC grafts appear to be associated with higher rates of chronic GVHD and BM associated with increased rate of graft failure, with similar rates of acute GVHD, relapse, non-relapse mortality and overall survival.

Currently, selection of the optimal source of stem cells depends on the underlying disease subtype, as well as the donor and transplant type. In patients undergoing autologous transplantation, PBHCs are now almost universally used in preference to BM grafts since chronic GVHD is not an issue of concern. For allogeneic matched-related donor transplants, the use of PBHCs will be preferable in patients being allografted for advanced leukemias, whereas for transplants done for benign disorders such as aplastic anemia, BM grafts are preferable. In the unrelated donor setting, the optimal graft choice remains unclear, though given the recent intriguing data from the BMT-CTN studies; the choice for BM versus PB HSC depends on individuals' concerns for chronic GVHD versus graft failure.

Preparative Regimens

Myeloablative Versus Reduced-Intensity Conditioning

Following the selection of the appropriate donor and stem cell source, patients are then put on conditioning regimens prior to the infusion of the hematopoietic stem cells. For autologous transplant, where the hematopoietic cells come from the patient themselves, the only role of the conditioning regimen is tumor eradication. In contrast, in myeloablative allogeneic transplant, the conditioning regimens have three main roles:

1. First, reduction of the disease burden to a minimal level
2. Second, creation of "space" within the marrow microenvironment to allow engraftment of HSC
3. Third, to provide sufficient host immunosuppression to prevent graft rejection and allow donor cells engraftment

Until recently, all patients received myeloablative conditioning regimens, defined as a regimen which contained a combination of agents expected to produce profound and irreversible pancytopenia and myeloablation within 1–3 weeks from administration and which needed hematopoietic stem cell infusion to restore hematopoiesis. When given with stem cell rescue, the ability to escalate doses of agents used in myeloablative regimens is limited by their toxicity to organs and tissues other than the bone marrow.

The discovery of the curative potential of the immune-mediated GVT effect has led to increasing use of reduced-intensity conditioning (RIC) regimens [55, 56]. These reduced-intensity conditioning regimens have been designed not to eradicate malignancy but rather to provide sufficient immunosuppression and immunoablation to achieve engraftment and allow induction of a GVT effect. They are associated with lower toxicities and hence can be safely performed in many patients in whom HSCT would have been previously contraindicated. Although all these low-dose nonablative preparative conditioning regimens devised are broadly classified as "reduced-intensity" transplants, there are significant differences in the relative degree of immunosuppression and myelosuppression involved, and they can be further divided into the truly nonmyeloablative regimens (NMA) and RIC regimens [57]. Nonmyeloablative regimens are defined as regimens associated with minimal cytopenia that do not require stem cell support. In nonmyeloablative regimens, the conditioning regimen is mainly for immunosuppression to allow stem cell engraftment and depends mainly on the GVT effect for disease control. The lack of neutropenia with such regimens reduces risks of bacterial sepsis, and hence such treatments are very tolerable and may even be performed in the outpatient setting. In contrast, RIC regimens are a category of regimens which are intermediate in intensity between myeloablative and NMA regimens. These regimens have an element of antitumor effect in addition to their immunosuppressive effect. They are associated with observable aplasia and have greater toxicities compared to NMA regimens but have the advantage of greater debulking of residual disease. With RIC regimens, cytopenias may be prolonged, and stem cell support required, and although unlike myeloablative regimens, autologous recovery would

eventually occur, the pancytopenia would be of such duration to cause significant morbidity and mortality.

GVHD and Its Prophylaxis

GVHD is a major cause of morbidity and mortality in allogeneic HSCT patients. Acute GVHD typically occurs within the first 100 days post-transplant and is due to the reactivity of the mature donor T lymphocytes present in the graft directed against disparate major or minor histocompatibility of the host. In contrast, chronic GVHD is a syndrome of disordered immune dysregulation with features similar to that of a number of autoimmune disorders and generally develop between 100 days and 2 years post-transplant. These cutoffs however are not absolute, and patients can present with symptoms typical of chronic GVHD in the early weeks after transplant and with symptoms typical of acute GVHD at times beyond day 100.

The pathophysiology of acute GVHD involves three phases [58]. The first phase involves conditioning regimen-related tissue injury, which results in cytokine release, upregulation of HLA molecules as well as activation of macrophages, and generation of a pro-inflammatory state. In the second phase, alloreactive T cells recognize allogeneic antigens presented on host dendritic cells and become activated and expand. In the third phase, there is generation of effector cells and cytokines that are responsible for tissue injury. The skin, GI tract, and liver are the primary target tissues of acute GVHD. In contrast, chronic GVHD is a syndrome of immune dysregulation with generation of autoreactive T cells directed against shared MHC determinants and production of autoantibodies. Chronic GVHD is related to thymic dysfunction and failure of the thymus to delete autoreactive cells and induce tolerance, and may be associated with significant immunosuppression, and a higher risk for opportunistic infections.

Pharmacological immunosuppression is generally administered for the first 6 months post-transplant to reduce the incidence and severity of GVHD, and the current standard of care combines either cyclosporine or tacrolimus with a short course of methotrexate [59, 60]. Cyclosporine and tacrolimus prevent activation of T cells, whereas methotrexate targets proliferating T cells that were activated in the early post-transplant phase by host antigens. Addition of corticosteroids is the first line of therapy in patients who develop acute GVHD [61], and approximately half of patients have a sustained response with steroid dose being able to be tapered off. Steroid-resistant GVHD has an unfavorable prognosis. With current immunosuppressive prophylaxis, the incidence of acute GVHD is about 25–50% of patients after transplants from an HLA identical sibling, and up to 60–90% has been reported following transplants from mismatched and unrelated donors, while chronic GVHD affects 25–60% of recipients of allogeneic transplantation who survive more than 6 months after transplant.

Table 7.1 Complications after hematopoietic transplantation

Immune complications
Graft rejection
Acute graft-vs-host disease
Chronic graft-vs-host disease
Regimen-related toxicity of the preparative regimen
Mucositis
Hemorrhagic cystitis
Veno-occlusive disease of the liver
Diffuse alveolar hemorrhage and interstitial pneumonitis
Hematologic complications
Cytopenias
Hemolytic anemia
Thrombotic thrombocytopenic purpura and hemolytic disorders
Infections and immunodeficiency
EBV-associated lymphoproliferative disease
Late complications:
Growth disturbances
Endocrine-related issues: e.g., hypothyroidism, hypogonadism, and sterility
Cataracts
Avascular necrosis
Secondary malignancies
Cognitive deficits (with TBI-based regimens)

Treatment-Related Complications

Hematopoietic transplantation has been associated with a number of serious complications including immune-mediated processes such as graft failure and graft-versus-host disease, toxicities from the pre-transplant conditioning regimen, as well as infections related to neutropenia and post-transplant immune deficiency. Supportive care post-transplantation including hydration, close monitoring, appropriate use of growth factors to hasten WBC recovery, appropriate use of antimicrobial prophylaxis, and good nutritional support are important in preventing these complications. Table 7.1 summarizes the complications associated with HSCT.

Indications for HSCT

Malignant Disorders

Both autologous and allogeneic HSCT are now well established as important treatments for hematological malignancies. Selection of the type of transplantation (autologous or allogeneic) depends on the type of malignancy, age, availability of a suitable donor, the ability to collect a tumor free graft, the stage of disease, as well as disease susceptibility to the GVT effect.

Autologous transplants do not require HLA-matched donors, as the stem cells come from the patients themselves, hence making this process readily available.

Autologous transplants are also associated with lower TRM than allogeneic transplants, because of various factors, including faster immune reconstitution and lower opportunistic infections, lower risk of life-threatening complications, and no GVHD issues and only rare graft failure issues. The process is hence well tolerated and can be offered to older patients.

However, autologous transplants have several drawbacks including potential contamination of the autograft by clonogenic tumor cells that can contribute to relapse, as well as the lack of an immune-mediated graft-versus-malignancy effect, hence leading to higher relapse rates as compared to allogeneic transplants. In addition, the use of high-dose chemotherapy, especially in patients with extensive prior therapy, may be associated with risks of developing therapy-related myelodysplastic syndrome and secondary leukemias.

Benign Disorders

In addition to their benefits in patients with hematological malignancies, allogeneic transplantation is also indicated in nonmalignant disorders including immunodeficiency disease, metabolic diseases, hemoglobinopathies, and aplastic anemia as well as other marrow failure syndromes.

Table 7.2 provides recommendations on the appropriate timing for transplantation consultation, based on the 2012 guidelines were developed jointly by the National Marrow Donor Program® (NMDP) and the American Society for Blood and Marrow Transplantation (ASBMT) [1].

Table 7.2 Indications for stem cell transplantation

Hematologic malignancies
(i) Acute myeloid leukemia (AML)
High-risk AML including antecedent hematological disease (e.g., myelodysplasia (MDS)), therapy-related AML, or induction failure
CR1 with intermediate- or poor-risk cytogenetics or molecular markers
Relapsed AML
(ii) Acute lymphoblastic leukemia (ALL)
CR1 standard risk or
CR1 high risk including persistent minimal residual disease, poor-risk cytogenetics (e.g., Philadelphia chromosome (t(9;22)) or 11q23 rearrangements), high WBC (>30,000–50,000) at diagnosis, no CR within 4 weeks of initial treatment, and induction failure, persistent minimal residual disease
ALL after relapse
(iii) Myelodysplastic syndromes (MDS)
Intermediate-1 or -2(INT-1 or INT-2) or high IPSS score
Any MDS with poor prognostic features, including older age, refractory cytopenias, adverse cytogenetics, transfusion dependent
(iv) Chronic myeloid leukemia
No hematologic response post-tyrosine kinase inhibitor (TKI) initiation
No complete cytogenetic response post-TKI initiation
Disease progression
Intolerance to TKI
Accelerated phase or blast crisis (myeloid or lymphoid)
(v) Chronic lymphocytic leukemia (CLL)
High-risk cytogenetics or molecular features (e.g., 11q or 17p deletions, unmutated Ig V_H mutational status)
Short initial remission
Poor initial response
Fludarabine-resistant
(vi) Non-Hodgkin lymphoma
Follicular
Poor response to initial treatment
Initial remission duration <12 months
Second relapse
Transformation to diffuse large B-cell lymphoma
Diffuse large B-cell or high-grade lymphoma
At first or subsequent relapse
CR1 for patients with high or high-intermediate IPI risk
No CR with initial treatment
(vii) Hodgkin lymphoma
No initial CR
First or subsequent relapse
(viii) Multiple myeloma
After initiation of therapy
At first progression
Other malignant diseases
(i) Germ cell tumors if
Short initial remission
Poor initial response
(ii) Neuroblastoma if
Short initial remission
Poor initial response or at progression
Nonmalignant disorders
(i) Immune deficiency disease (including severe combined immunodeficiency syndromes, Wiskott-Aldrich syndrome, Omenn syndrome, X-linked lymphoproliferative syndrome, Kostmann syndrome): at the time of diagnosis
(ii) Inherited metabolic disorders (including Hurler's syndrome, adrenoleukodystrophy, and others): at diagnosis
(iii) Hemoglobinopathies
Thalassemia major: at the time of diagnosis
Sickle cell disease with aggressive course (CNS or lung complications, frequent pain crises)
(iv) Hemophagocytic lymphohistiocytosis (HLH): at diagnosis
(v) Severe aplastic anemia and other marrow failure syndromes (including Fanconi anemia, Diamond-Blackfan anemia, and others): at diagnosis

Adapted from the 2012 guidelines developed by the National Donor Marrow Program and the American Society for Blood And Marrow Transplantation [1]

Future Directions

Over the last two decades, the increased understanding of the various aspects of HSCT has led to significant improved safety of this procedure and increased applicability of this treatment to a larger patient population and provided a means

of delivering potentially curative treatment in many situations where it was not previously possible. Areas under current development include the improvement preparative regimens through the use of molecularly targeted anticancer therapies, the broadened use of alternative donors, and continuous improvement in supportive care for patients. In addition, promising work has been done with the use of adoptive cellular therapy such as the use of T cells with chimeric receptor antigens, tumor vaccines, as well as the use of expanded NK cells to augment the GVT effects. Major challenges ahead remain the development of strategies to enhance the immune antitumor effect with both autologous and allogeneic transplants, as well as strategies to separate the GVT effect from the GVHD effect so as to improve upon TRM. Carefully planned prospective clinical trials and collaborative efforts from the various research groups will be necessary to attain these goals.

Infections in Pediatric Transplant Recipients

8

Aspasia Katragkou, Lucy O'Connor, Emmanuel Roilides, and Thomas J. Walsh

Introduction

Infections are major causes of morbidity and mortality in pediatric patients undergoing hematopoietic stem cell and solid organ transplantation (HSCT, SOT, respectively). They also represent the most significant barrier to short- and long-term survival of the implant allograft. Advances in pediatric infectious diseases supportive care have resulted in the ability of patients to undergo intensive immunosuppression and aggressive invasive procedures. The achievements during the past 30 years have resulted in remarkably improved outcome for pediatric transplant recipients. These advances of pediatric infectious disease supportive care have contributed substantially to the improved survival, outcome, and reduction of suffering and pain due to infectious complications.

This chapter reviews the epidemiology, clinical manifestations, and strategies for managing infectious diseases in pediatric transplant recipients. Because the immune defects and the possible etiologic agents for infection vary with the time elapsed since transplantation, the chapter is organized in such a manner. Timetables of infection after hematopoietic stem and solid organ transplantation are useful as they help differential diagnosis, infection control, and, eventually, treatment (Figs. 8.1 and 8.2).

Pediatric Versus Adult Patients

Pediatric transplant patients are different from their adult counterparts in several ways. These include the spectrum of underlying diseases requiring transplantation, the intensity of chemotherapeutic regimens, and the incidence and severity of comorbid medical conditions preceding the transplantation. Additionally, the percentage of patients with indwelling central venous catheters, the community exposures to infectious pathogens, and maturation of the immune system may be different in different ages. Therapeutic and diagnostic issues are also different between adults and children. Many antimicrobial agents lack pediatric approval or rigorous pediatric dose identifying, while important surrogate markers for infection have not been validated in chil-

dren. Notably, a risk stratification system widely evaluated or clinically adopted in pediatrics is missing. Lastly, a number of psychosocial issues including family dynamics are remarkably different between adults and children [3, 4].

These differences between adult and pediatric patients affect the frequency and nature of episodes of fever and neutropenia. A review of results from four EORTC studies highlighted some of these differences [5]. They reported that the sites of infection and spectrum of infecting organisms are different in children and adults. Children more often do not have a clinically apparent site of infection and consequently have a higher rate of fever without a source. When a defined site is present, children were more likely than their adult counterparts to have upper respiratory tract findings. The overall incidence of bacteremia is similar; however, the rate of death during fever and neutropenia was 1% in children compared to 4% in adults [5].

Infections in Pediatric Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation involves the intravenous infusion of syngeneic, autologous, or allogeneic stem cells obtained from bone marrow, umbilical cord blood, and peripheral blood. HSCT has become standard of therapy for patients with malignant and nonmalignant hematologic diseases, neuroblastoma, and a variety of genetic conditions. Infections occurring after HSCT are dependent on the underlying primary disease and the suppression of host defenses that occur after transplantation. The severity and type of infections that develop during HSCT depend on a number of factors including the type of transplant, intensity of the preparative regimen, the presence of donor T cells, histocompatibility mismatch, preventive therapy against graft-versus-host disease (GVHD), serologic status

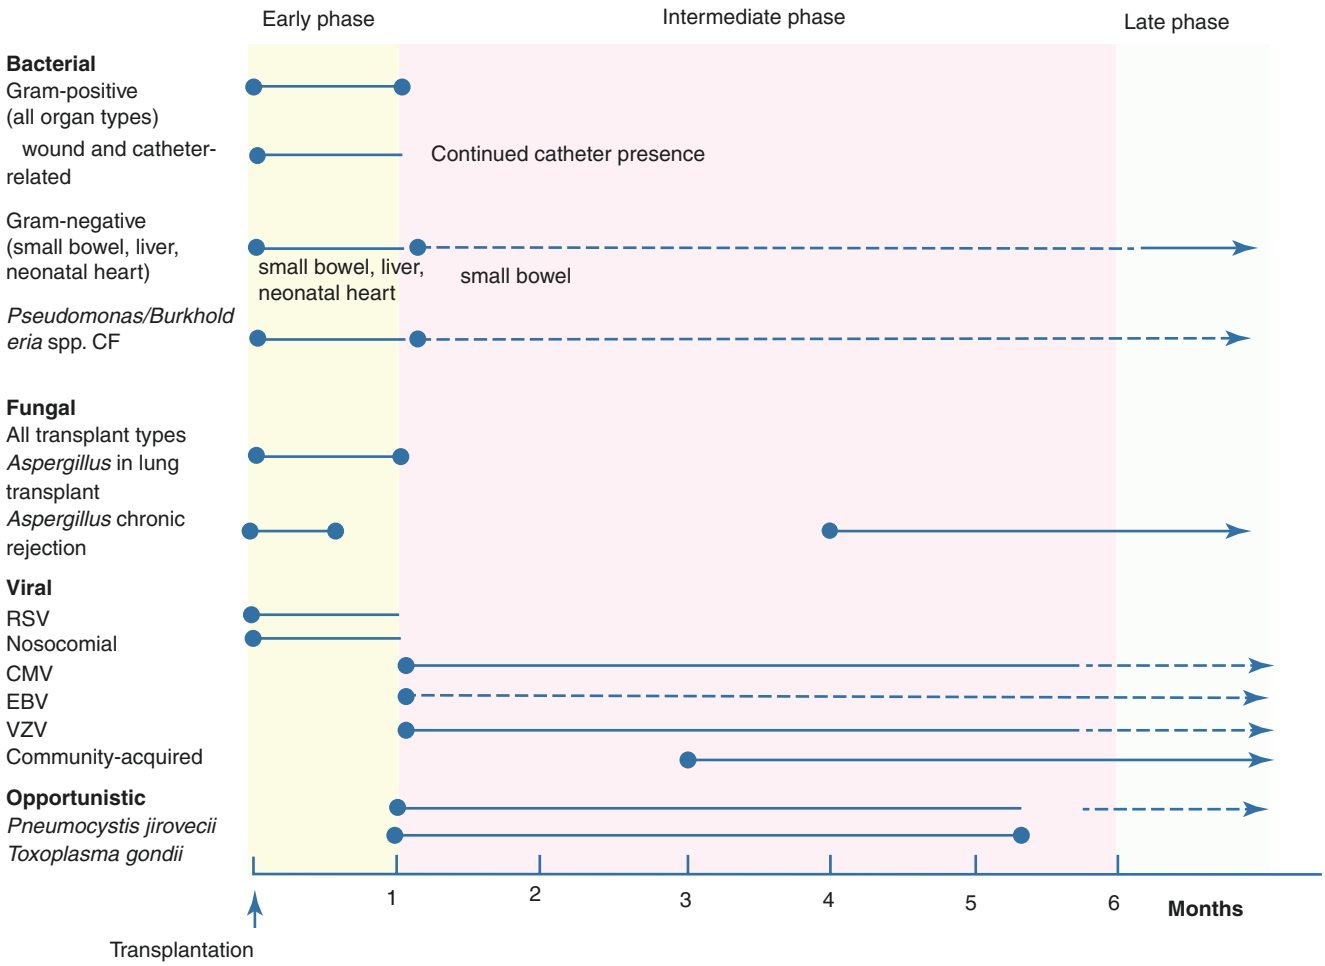

Fig. 8.2 Timing of infections after solid organ transplantation [2]. (Adapted from Fishman [2])

of the donor and recipient, previous antibiotic exposure, and the presence of indwelling medical devices.

Infections During the Pre-engraftment Phase (Phase I)

The pre-engraftment phase begins with the time of the conditioning regimen, usually 5–10 days before stem cell infusion, and continues until engraftment, about 30 days after transplantation. The major host defense defects in this period are aplasia with severe neutropenia and disruptions of the mucocutaneous integrity caused primarily by the myeloablative effects of the conditioning regimens and the use of vascular catheters. Pre-engraftment period is similar to that of patients with hematologic malignancies with neutropenia after chemotherapy. The most common causes of infection in this period are bacteria, fungi, and viruses [6, 7].

Bacterial Infections

Primary bacteremia accounts for approximately one-third of all infections in the pre-engraftment period. The spectrum of etiologic agents is similar to that in other chemotherapy-induced neutropenic patients. Epidemiologic data show a predominance of infections caused by Gram-positive cocci, especially coagulase-negative staphylococci, while, more recently, other organisms like viridans streptococci, *Enterococcus* spp., and *Streptococcus pneumoniae* have become important causes of bacteremia. The rise in staphylococcal and streptococcal infections was related to the use of indwelling intravascular catheters and antibiotic prophylaxis with fluoroquinolones. Gram-negative organisms, such as *Escherichia coli*, *Klebsiella* spp., and *Enterobacter* spp., are isolated in 30–40% of bloodstream infections following transplantation procedure. Methicillin-resistant *S. aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE), and extended-spectrum beta-lactamase (ESBL)-producing *Enterobacteriaceae*

reflect some of the ongoing challenges being particularly worrisome as they display high rates of resistance to many frontline antibiotics [6].

The frequency of catheter-associated bacteremia may vary depending on the institution. The spectrum of etiologic agents includes most frequently staphylococcal and streptococcal spp., while other organisms like *Corynebacterium* spp. and *Stomatococcus* spp. have been implicated.

Pulmonary infections may occur during prolonged neutropenia or later in the course of HSCT with reduced intensity preparatory regimens. During this phase of transplantation, most commonly a number of noninfectious pulmonary complications may also occur (Table 8.1). A less common but potentially lethal infection reported in this period is neutropenic enterocolitis or typhlitis. This is a fulminant necrotizing process of the gastrointestinal tract defined by neutropenia, abdominal pain, and fever. Clinical and imaging findings are non-specific. The etiologic agents responsible for typhlitis include anaerobes and Gram-negative bacilli, especially *P. aeruginosa*. *Clostridium difficile* is recognized increasingly as an important cause of typhlitis. Most patients respond to conservative management without surgical resection of the involved segment of colon [6].

Table 8.1 Differential diagnosis of pneumonia in pediatric transplant recipients [8]

Localized infiltrates	Diffuse infiltrates
Non-neutropenic patients	
Bacteria: *Streptococcus pneumoniae*, *Moraxella* spp., *Legionella* spp., mycobacteria, *Nocardia* spp.	**Fungi**: *Pneumocystis jirovecii*, *Cryptococcus neoformans*, *Histoplasma capsulatum*
Fungi: *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Coccidioides immitis*, *Aspergillus* spp. (the latter especially in HSCT recipients post-engraftment)	**Bacteria**: mycobacteria, *Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*, less commonly *Legionella* spp. and *Nocardia* spp.
Viruses: RSV, adenovirus, influenza, CMV	**Viruses**: RSV, adenovirus, HSV, VZV, CMV, influenza
	Protozoa: *Toxoplasma gondii*
	Drugs: bleomycin, busulfan, cyclophosphamide, methotrexate, cytosine arabinoside
	Radiation
Neutropenic patients	
Bacteria: any Gram-positive or Gram-negative; mycobacteria, *Legionella* spp., *Nocardia* spp.	**Bacteria**: any Gram-positive or Gram-negative; mycobacteria, *Mycoplasma pneumoniae*, *Chlamydophila pneumonia*, less commonly *Legionella* spp. and *Nocardia* spp.
Fungi: *Aspergillus* spp., Zygomycetes, *Fusarium* spp., *Scedosporium* spp., other filamentous fungi (see text)	**Fungi**: *Pneumocystis jirovecii*, *Cryptococcus neoformans*, *Histoplasma capsulatum*
Viruses: RSV, adenovirus, influenza	**Viruses**: RSV, adenovirus, HSV, VZV, CMV, influenza
	Protozoa: *T. gondii*

Fungal Infections

Candida infections typically occur during the second or following weeks of neutropenia, and *Aspergillus* infections typically occur later during the third and subsequent weeks of neutropenia. A number of clinical and imaging findings may differentiate these common fungal infections [9]. Prolonged severe neutropenia, heavy colonization with *Candida* spp., severe acute and extensive chronic GVHD, and high-dose systemic corticosteroid therapy are factors associated with invasive fungal infections in pediatric HSCT patients [10–12].

The last few decades have witnessed an epidemiologic shift in invasive fungal infections toward a higher prevalence of non-*albicans Candida* spp. and non-*fumigatus Aspergillus* species. Infections due to *Candida tropicalis*, *Candida krusei* or *Aspergillus terreus*, and other molds such as Zygomycetes, *Fusarium*, and *Scedosporium* are on the rise. Most of the filamentous fungi use the respiratory tract as their portal of entry and cause sinopulmonary disease. They have the capacity for hematogenous dissemination to other remote body sites, and due to neurotropism, fungal brain involvement is a dreaded complication for such infections [13–15].

Viral Infections

The most common viral infection is usually due to herpes simplex virus (HSV). It usually occurs within the first 4 weeks after transplantation coinciding with the maximum suppression of the lymphocyte response. Reactivation of latent virus is the primary mechanism of infection, while donor immunity does not prevent reactivation of disease. HSV-seropositive patients before transplantation have 70–80% risk of developing clinical disease regardless of the autologous or allogeneic source of stem cells. Among the common disease manifestations are stomatitis, esophagitis, pneumonitis, and bacterial or fungal superinfection of the skin lesions. HSV-1 accounts for 85% of all HSV-related infections, while HSV-2 is relatively unusual. HSV-2 infection presents with genital ulcers or extragenital vesicles [6, 16].

Enteric viruses such as rotavirus, coxsackie, adenovirus, and respiratory viruses like RSV, influenza, and parainfluenza are usually seasonal or may also occur in epidemics [17]. Among the viruses causing significant morbidity and mortality in this population are adenoviruses, which may lead to disseminated disease with multiple manifestations including hemorrhagic cystitis, pneumonia, nephritis, hepatitis, colitis, and pancreatitis [18–20].

Infections During Early Post-Engraftment Phase (Phase II)

The post-engraftment phase begins with resolution of the neutropenia heralding engraftment, about 30 days after transplantation, and continues approximately 100 days after transplantation. During this period the risk of infection is decreased as major immune defects have resolved. However, there are still abnormalities as recovery of the immune function is asynchronous with different components normalizing at varying times and rates. Infections in this period occur predominantly due to defects in cell-mediated immunity. Other factors that influence the immune response are the presence of acute GVHD and deficits in cellular, humoral, and reticuloendothelial functions [7, 21].

Bacterial Infections

Typically, the bacterial infections in this phase are less common. Gram-positive cocci and less often Gram-negative bacteria are the usual bacterial pathogens associated with the presence of indwelling vascular catheters and complications and consequences from GVHD and anti-GVHD therapy, respectively.

Fungal Infections

Candida spp. and *Aspergillus* spp. are the predominant fungal pathogens during this phase with *Candida* preceding invasive aspergillosis chronologically. Hepatosplenic candidiasis or chronic disseminated candidiasis usually appears during this phase. It is manifested as fever with abdominal symptoms and rising alkaline phosphatase in a patient who has recently recovered from, often prolonged period of, severe neutropenia. Imaging reveals multiple lesions called "bull's eye" in the liver and spleen, blood cultures are usually negative, and definitive diagnosis requires liver biopsy. Brain abscesses are a common manifestation of fungal infections during the period.

Pneumonia due to *Pneumocystis jirovecii* commonly presents with hypoxemia and dyspnea on minor exertion, cough, fever, and bilateral interstitial lung infiltrates. After the introduction of trimethoprim-sulfamethoxazole prophylaxis, the incidence of pneumocystis pneumonia has been decreased to less than 5%.

Protozoan Infections

Toxoplasmosis following HSCT is an infrequent infection usually occurring 2–6 months after transplantation as reactivation of latent disease. Cerebral toxoplasmosis is the usual manifestation associated with high mortality [22–25].

Viral Infections

Prior to routine prophylaxis, CMV pneumonitis was a common cause of viral pneumonia in this phase after HSCT [26]. The most frequent causes of CMV infection and subsequent disease are reactivation of latent virus in seropositive patients and acquisition of CMV from donor marrow in seronegative patients [27]. Among CMV-seronegative recipients of HSCT from seropositive donors, there is a high risk of death due to bacterial infections and invasive mycoses likely due to the indirect immunosuppressive effects of CMV infection on host innate and adaptive immune function [28]. CMV pneumonitis most often occurs between 30 and 100 days after allogeneic bone marrow transplantation, coinciding with the period of highest risk for the development of acute GVHD [29]. CMV pneumonitis is characterized radiographically by diffuse bilateral linear or nodular infiltrates. However, CMV pneumonitis occasionally may present as a lobar or segmental consolidation or as a solitary nodule. The diagnosis of CMV pneumonia can be made by isolation of CMV from BAL fluid, demonstration of either CMV antigen or nucleic acid in pulmonary alveolar macrophages, or characteristic histopathology. Until recently, CMV pneumonitis was associated with an extremely high mortality of greater than 85% despite the use of a variety of antiviral and immunotherapeutic agents. Combined therapy with ganciclovir and intravenous immune globulin either pooled or enriched anti-CMV immunoglobulins has improved survival to more than 50% in allogeneic HSCT recipients with CMV pneumonitis [30, 31]. Despite the limited enrollment and uncontrolled nature of these trials, the dramatic results have led to an acceptance of ganciclovir and immune globulin combination therapy as a standard of care for transplant recipients with CMV pneumonitis.

Although CMV infections predominate in the early post-engraftment period, other viral infections may occur. Among these adenovirus is increasingly recognized as a significant pathogen [32]. The timing of adenovirus infection following HSCT is highly variable, and the median time to onset is 54 days after HSCT [18]. The most severe manifestations of adenovirus disease are due to respiratory and hepatic involvement [33]; however adenovirus may cause disease in other sites such as the urinary and gastrointestinal tract or occasionally in the central nervous system [32]. Reported mortality is as high as 60% in patients with disseminated disease since there are few proven therapeutic options [18, 33, 34]. None of the approved antiviral agents has proven efficacy for the treatment of severe adenovirus infection [32]. Cidofovir is the most widely used antiviral therapy against adenovirus; however, no controlled clinical trials have been performed. When used preemptively, cidofovir can reduce adenovirus viral load. Adenovirus-specific T-cell therapy is in development [35].

Infections During Late Post-Engraftment Phase (Phase III)

The late phase of HSCT occurs around 100 days after transplantation and is characterized by a declining risk of infec-

tion. The defects in immune function usually resolve by 1 year after transplantation; however, they are persistent in the presence of chronic GVHD or inadequate stem cell engraftment. Further, up to 90% of patients with extensive GVHD may demonstrate functional asplenia. At the beginning of this stage, the immune defects concern the cellular and humoral arms, which have not fully recovered [21].

Bacterial and Fungal Infections

At this stage encapsulated bacteria such as *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae* are the predominant causes of bacterial infections. Usually the infections are localized to the skin, upper respiratory tract, and lungs. Invasive fungal infections are rare in this phase, and oropharyngeal candidiasis most frequently occurs [6].

Viral Infections

The usual viral infections in this period are due to VZV, which occur up to 60% of pediatric HSCT recipients. Most infections represent reactivation of VZV. Predisposing factors to VZV infection are acute and chronic GVHD, allogeneic transplant, and lymphoma as underlying disease [6, 36, 37].

Infections in Solid Organ Transplantation

Solid organ transplantation is a major therapeutic option for many children with end-stage organ failure. For a successful SOT, a careful balance between prevention of allograft rejection and immunosuppression-associated infection plays a central role. The risk of infection in the recipients of SOT is determined by the interaction of multitude of factors related to the recipient, the transplantation procedure, and the net state of immunosuppression occurring from the pretransplantation until posttransplantation period (Table 8.2) [3, 38].

Infections in SOT recipients follow a temporal trend and tend to be predictable. While it would be oversimplistic to suggest that specific infections occur only at specific time points, it is, nevertheless, helpful to divide the period following transplantation into specific phases. In each phase specific organisms predominate; however, infectious disease syndromes such as pneumonia can occur at any time during the posttransplant period; however, the etiology changes at different points in time. The timing of infections can be divided into three intervals: early, 0–30 days after transplantation; intermediate, 30–180 days after transplantation; and late, >180 days after transplantation (Fig. 8.2) [39]. However, polymicrobial infections are not uncommon and may occur simultaneously or sequentially. The prototype of this interaction is the immunomodulatory effect of CMV infection, which results in immunosuppression and, thereby, promotes hosts' susceptibility for other opportunistic viral, bacterial, and invasive fungal disease(s) [40, 41].

Table 8.2 Risk factors determining the risk of infections in solid organ transplant recipients [3]

Pretransplantation factors	Peri-transplantation factors	Posttransplantation factors
Young age	Type of organ transplanted	Net state of immunosuppression
Underlying disease	Transplant procedure (injury, prolonged time, technical problems)	Dose, duration, and temporal sequence of immunosuppressive agents (steroids, calcineurin inhibitors, sirolimus)
Duration and frequency of hospitalizations	Indwelling medical devices	Rejection and its treatment (antithymocyte globulin, alemtuzumab, palivizumab)
Palliative surgery before transplantation		
Complications of end-stage organ disease		Host defense defects due to underlying disease
Malnutrition		
Environmental exposures (community, hospitals)		Technical/anatomic abnormalities that compromise the integrity of mucocutaneous barriers
Travel		Neutropenia
		Metabolic abnormalities (protein-calorie malnutrition, uremia, hyperglycemia)
		Viral infections with immunomodulating effect (CMV, EBV, HBV, HCV, HIV)
		Environmental exposure (community, hospital)
		Indwelling medical devices

Adapted from Fonseca-Aten and Michaels [3]

Early Phase Infections During 0–30 Days After Transplantation

The net state of immunosuppression at this phase is not great despite the high doses of immunosuppressive therapy. Therefore, opportunistic infections that are caused by pathogens such as *Aspergillus*, *Listeria*, and *Nocardia* are rare. There are three main types of infections during this period: (1) infections present in the recipient before undergoing transplantation, which are exacerbated after the transplantation due to transplant surgery and immunosuppressive drug

therapy; (2) donor-derived infections which are usually due to critical or terminal illness, organ harvesting procedure and transport, and donor's undiagnosed infections such as West Nile virus, HIV, rabies, and among others [42–44] as well as undiagnosed critical care-related bacterial infections such as pneumonia including HAP/VAP, bacteremia, and endovascular infections; and finally (3) infections transmitted perioperatively that could also occur in an immunocompetent patient. The majority of the infections during the early phase after transplantation is of this last variety and determined by the technical integrity of the operation and the post-surgery use of indwelling medical devices. Early graft injuries resulting from tissue ischemia (bile ducts) or reperfusion injury (lungs) may later become foci of liver or lung abscesses [45].

Intermediate Phase Infections (30–180 Days After Transplantation)

The infections occurring in this phase are the result of immunosuppression and the immunomodulatory effects of coinfecting viruses. There are three types of infections during this period: (1) continuation of infections acquired during the previous phase; (2) opportunistic viral infections such as CMV, Epstein-Barr virus (EBV), herpesvirus-6, and other pathogenic viruses like hepatitis B virus and hepatitis C virus and HIV. However, other rare viral pathogens such as polyomavirus BK and adenovirus have also emerged and (3) opportunistic fungal infections due to *Pneumocystis jirovecii* and *Aspergillus fumigatus* which usually suggest an environmental source. Additionally, infections due to non-endemic and endemic dimorphic fungi like *Cryptococcus* spp., *Histoplasma*, *Coccidioides*, and *Blastomyces* are noted during this period. *Trypanosoma cruzi* and *Strongyloides stercoralis* may cause potentially devastating disease in SOT recipients during this period; a thorough travel and potential exposure history is crucial for evaluating patients being considered for organ transplantation [3, 46].

Late-Phase Infections After 6 Months Following Transplantation

There are three types of infections during this period: (1) patients with good transplantation outcome requiring minimal immune suppression and good allograft function, in which no opportunistic viral infections are at risk from community-acquired respiratory viruses such as influenza, parainfluenza, and respiratory syncytial virus; (2) patients with chronic viral infections that may cause allograft injury such as recipients HCV infection of hepatic allograft, bronchiolitis obliterans in lung transplant recipients, accelerated vasculopathy in heart transplant recipients with CMV infection, or a malignant condition such as posttransplantation lymphoproliferative disorder (PTLD) or skin or anogenital cancer; and (3) patients with poor result from transplantation like repeated episodes of acute and chronic allograft injury, excessive immunosuppression, and chronic viral infections. These patients are at risk for opportunistic infections with *Listeria monocytogenes* or *Nocardia* species, invasive fungal infections such as zygomycetes and dematiaceous molds, and unusual organisms like *Rhodococcus* species [3, 45–47].

Diagnosis and Laboratory Findings

A careful history and physical examination directed toward identifying possible foci of infection is important as a guide to further management. As surrogate markers able to accurately evaluate the relative risk for each patient for infection do not exist, it is essential that these patients be monitored carefully and receive early intervention for signs or symptoms of an infectious disease.

Fever in immunocompromised patients may be the first and only sign of infection [5, 48]. However, one should keep in mind that noninfectious causes such as pyrogenic medications, transfusions of blood products, and drug reactions may also be responsible for a febrile episode. The absence of fever in immunocompromised patients with localizing signs does not exclude the possibility of an ongoing infection. Further, clinical signs and symptoms frequently indicative of an infectious process such as pain, warmth, erythema, and tissue swelling may be blunted or lacking. Patients should be questioned about the presence of any localizing pain or discomfort. Attention on history and physical examination should be focused on areas such as the oropharynx, respiratory tract**,** perianal area, central venous catheter sites, and any site of recent invasive procedures, as well as the skin and soft tissues.

According to the specific phase after transplantation, the diagnostic approach should be guided toward the most frequent pathogens (Figs. 8.1 and 8.2). Blood cultures should be obtained from all lumens of central venous catheters, when present. Volume of blood cultures is the most important factor for detection of circulating bacteria and fungi. Urine cultures should be routinely submitted where feasible. Other cultures should be obtained based on clinical suspicion including stool, cerebrospinal fluid, central line site, or surgical wound. A routine complete blood count and serum chemistry profile could provide evidence of disease from an infectious agent or indicate noninfectious causes of hepatic or renal disease such as GVHD.

The diagnosis of a catheter-related versus non-catheter-related bacteremia is difficult. Evidence of catheter-related infection as opposed to bacteremia from other sources includes a greater number of colony-forming units per mil-

liliter of blood from cultures of the central line compared with simultaneous peripheral cultures and positive catheter tip cultures. Another approach is to use differential time to positive blood culture. However, as peripheral blood cultures in pediatric patients are inconvenient and contribute little to increasing the diagnostic yield of bacteremia, their utility is questionable. The volume of blood drawn is the critical determinant for recovery of bacteria during bloodstream infections. Thus, two or three blood cultures through the central venous catheter, one set per each lumen will provide a yield similar to that of central cultures plus peripheral cultures but without the patients' discomfort and the potential for contamination from cutaneous flora.

Nasopharyngeal washes for viral pathogens, including respiratory RSV, parainfluenza, influenza, and adenovirus, are important in patients with concomitant upper respiratory tract infection-like symptoms. Nucleic acid detection assays, such as PCR, are useful for detecting and follow-up of the response to therapy of certain pathogens like herpesviruses and parvovirus B19. The impact of PCR on diagnosis of HSV encephalitis is especially apparent [49–53]. Recent advances in PCR may assist in noninvasive diagnosis of CNS toxoplasmosis and detect *Mycoplasma* and *Chlamydia* DNA in BAL samples [54, 55].

Serologic testing is useful for diagnosing toxoplasmosis, bartonellosis, histoplasmosis, and blastomycosis. However, serology tests in transplant recipients are of limited value as these patients are immunosuppressed and a good number of them may have received pooled immunoglobulin therapy. Nevertheless, when PCR is not available, acute and convalescent serum antibody titers against herpesviruses, echoviruses, and the less common arboviruses should be measured. Specific cerebrospinal fluid antibody may be detected in cases of mumps, HSV, or VZV.

A chest radiograph should be obtained in all patients with fever and neutropenia. Routine chest radiographs in asymptomatic neutropenic patients may provide an important baseline for future reference. The presence of a pulmonary infiltrate should also prompt consideration for subsequent evaluation by bronchoscopy for a more definitive microbiological diagnosis. Computed tomography scans of the brain, paranasal sinuses, chest, and the abdomen are useful when evaluating patients with invasive fungal disease. Radiologic examination of the sinuses is useful for diagnosis of sinusitis in children older than 1 year of age. Radiographic evaluation with a CT scan is more sensitive than conventional chest radiography and may provide more information regarding the pattern and extent of disease [56]. Specific findings of a "halo" sign, crescent sign, nodular infiltrate, peripheral pleural-based lung lesions, or wedge-shaped infiltrate are indicative of a possible angioinvasive filamentous fungal disease, including, but not limited to, *Aspergillus* spp. [57–59]. Flexible fiber-optic bronchoscopy can provide evidence for a specific diagnosis in immunocompromised patients with pneumonia. The yield of bronchoscopy depends on the clinical situation and the extent of prior therapy [60]. Bronchoalveolar lavage (BAL) can yield a specific diagnosis in approximately 80% on cases of PCP, whereas it is significantly less sensitive for detection of invasive fungal infections or bacterial infections in patients who have received prior antibiotic therapy. Ultrasound can be used to diagnose abdominal problems such as typhlitis.

The double sandwich ELISA system for detection of galactomannan antigenemia is an important advance in the non-culture diagnosis of invasive aspergillosis among HSCT recipients. Depending upon the patient population, several studies have demonstrated a sensitivity ranging from 50% to 95% and specificity ranging from 87% to 99% for diagnosis of invasive aspergillosis. Additional studies indicate that serial serum galactomannan antigen levels permit therapeutic monitoring and have prognostic implications [61–64]. Coupled with a CT scan that is radiographically compatible with invasive pulmonary aspergillosis in the appropriate host population, a positive serum galactomannan assay establishes a reasonable diagnosis of probable invasive aspergillosis HSCT recipients [65].

Management and Therapy

The initial management of patients with fever and neutropenia after transplantation is similar to that of cancer patients with chemotherapy-induced fever and neutropenia. It is well recognized that bacteremia in the neutropenic host can progress rapidly to septic shock and death making, thus, empirical therapy a therapeutic consensus [66, 67]. Empiric antibiotic therapy should be started after obtaining appropriate samples for culture [68]. When considering a particular empiric antibacterial regimen, the choice should be dictated by the local epidemiology of bacterial infections, antibiotic susceptibility profiles, cost, toxicity, as well as the patient's surveillance isolates. Hence, an empiric antibiotic regimen must cover a broad-spectrum of bacteria, provide high serum bactericidal drug levels, be stable against the emergence of resistant bacteria, and be nontoxic and simple to administer. Several regimens, usually consisting of a cephalosporin, an aminoglycoside, and extended-spectrum penicillin, have been employed [69–71]. A combination that provides broad coverage to Gram-negative bacteria and Gram-positive cocci would be ceftazidime or cefepime with or without vancomycin. If *Pseudomonas aeruginosa* is suspected, an aminoglycoside should be added. Once antibiotics have been initiated empirically, a meticulous investigation of the cause of fever is warranted.

Other clinical findings indicating the addition of other agents as empirical therapy are described in Table 8.3.

Table 8.3 Indications for the addition of specific agents in the empirical therapy of the febrile neutropenic child with transplantation [8]

Head, eyes, ears, nose, throat	
Necrotizing or marginal gingivitis	Add specific anti-anaerobic agent (clindamycin or metronidazole) to empirical therapy
Vesicular or ulcerative lesions	Suspect HSV infection. Culture and begin acyclovir therapy
Sinus congestion, tenderness or nasal ulcerative lesions	Suspect invasive fungal infection with Aspergillus or Zygomycete; obtain imaging studies and ENT consultation. Adjust antifungal therapy according to organism recovered
Gastrointestinal tract	
Retrosternal burning pain	Suspect candida or herpetic esophagitis, or both. Add antifungal therapy and, if no response, acyclovir. Bacterial esophagitis also is a possibility. For patients not responding within 48 h, endoscopy should be considered
Acute abdominal pain	Suspect typhlitis, as well as appendicitis, if pain in right lower quadrant, even in the absence of fever. Add specific anti-anaerobic coverage (e.g., metronidazole to ceftazidime; or substitution of imipenem for ceftazidime) to empirical regimen and monitor closely for need for surgical intervention
Perianal tenderness	Evaluate for anal fissures, perianal cellulitis, perianal fistulas, or perirectal abscesses. Add specific anti-anaerobic drug to empirical regimen, as indicated, and monitor need for surgical intervention, especially when patient is recovering from neutropenia
Respiratory tract	
New focal lesion(s) in patient recovering from neutropenia	Observe carefully, as such lesions may be a consequence of inflammatory response to previously occult pneumonic process detected in concert with neutrophil recovery
New focal lesion(s) in patient with continuing neutropenia	Invasive pulmonary aspergillosis is the chief concern. Rule out other causes of fungal pneumonia. Perform BAL or transthoracic needle aspirate with appropriate direct exams and cultures. Add voriconazole or lipid formulation of amphotericin B, depending upon findings (do not administer voriconazole and amphotericin B simultaneously)
New interstitial pneumonitis	Attempt diagnosis by examination of induced sputum or BAL. If patient is symptomatic, begin empirical treatment with trimethoprim-sulfamethoxazole, pending procedure. Consider noninfectious causes and need for open-lung biopsy if diagnosis is not established

Adapted from Pizzo and Poplack [8]

Guidelines for the management of fever and neutropenia specifically for children with HSCT have recently been published by the International Pediatric Fever and Neutropenia Guideline Panel [68].

Empiric antifungal therapy is recommended for patients who remain persistently granulocytopenic and febrile after 5–7 days of antibiotic therapy without identification of a bacterial cause. Conventional amphotericin B, liposomal amphotericin B, voriconazole, caspofungin, and itraconazole have been well characterized for empirical antifungal therapy for persistent fever in high-risk neutropenic patients. Selection of an agent for empirical antifungal therapy will depend upon the patterns of infection in one's institution, cost, and the risk for end-organ toxicity (e.g., renal or hepatic dysfunction) [72–76].

For patients who remain neutropenic, antifungal therapy should be continued until the resolution of neutropenia. Persistence or recrudescence of fever should prompt a meticulous investigation for non-fungal infections such as bacterial or viral superinfections or for a fungus that is resistant to initial empirical antifungal coverage like *Aspergillus* spp., *Trichosporon*, *Fusarium* spp., *Pseudallescheria boydii*, *Scedosporium* spp., and agents of mucormycosis. Patients who develop a documented fungal infection should be treated with the appropriate antifungal agent (Table 8.4). The indications, dosages, and activity spectrum of the most commonly used antibacterial, antifungal, antiviral, and anti-pneumocystis agents in pediatric patients are shown in Tables 8.4, 8.5, and 8.6.

Catheter-Associated Bacteremia

Removal of chronic indwelling central venous catheters is best determined by the type of organism recovered, the hemodynamic stability of the patient, and the presence of persistent bacteremia, rather than by differences in colony counts suggesting evidence of direct involvement of the catheter (Table 8.7). Removal and replacement of chronic indwelling catheters carry the risk of general anesthesia, pneumothorax, and hemorrhage, particularly in thrombocytopenic patients.

Prevention of Infections

The most efficacious and practical intervention to prevent or reduce infections in the immunocompromised host is adherence to strict handwashing practices [77].

Another measure to decrease the acquisition of new organisms is to maintain a cooked diet during periods of granulocytopenia, with avoidance of fresh fruits and vegetables and non-processed dairy products, because these foods are naturally contaminated with Gram-negative bacteria, especially *E. coli*, *K. pneumoniae*, and *P. aeruginosa* [78, 79].

Environmental sources can contribute to fungal especially *Aspergillus* spp., *Fusarium* spp., and *Zygomycetes* and bacterial such as *Legionella* spp., *Pseudomonas* spp., and *Acinetobacter* spp. colonization and infection. In medical cen-

Table 8.4 Antifungal agents used in children for infections after transplantation

Class	Agent	Route	Spectrum	Daily dose (maximum)			Comments
				Neonates (0–30 days)	Infants (31 days–1 year)	Children (>1–17 years)	
Polyenes	Deoxycholate amphotericin B	IV	Very broad antifungal activity including *Candida* spp., *Aspergillus* spp., Zygomycetes, *Cryptococcus neoformans*, *Histoplasma capsulatum*	Empirical therapy: 0.5–1.5 mg/kg Q24h	Empirical therapy: 0.5–1.5 mg/kg Q24h		Children can generally tolerate higher doses than adults
				Documented fungal infections: 1.0–1.5 mg/kg	Documented fungal infections: 1.0–1.5 mg/kg Q24h		
	Lipid formulations (amphotericin B lipid complex, amphotericin B colloidal dispersion, and liposomal amphotericin B)	IV	Same spectrum as deoxycholate formulation	5 mg/kg Q24h	Empirical therapy: 3 mg/kg Q24h		Significantly less nephrotoxicity with efficacy at least equal to that of deoxycholate amphotericin B
					Documented fungal infections: 5 mg/kg Q24h (max. dose 10 mg/kg, but no evidence for improved efficacy)		
Triazoles	Fluconazole	PO, IV	*Candida* spp., (not *C. krusei* and not some strains of *C. glabrata); C. neoformans*, *Trichosporon* spp. and *Coccidioides immitis*	Treatment: 12 mg/kg Q24h	12 mg/kg Q24h	3–12 mg/kg Q24h	Excellent bioavailability, independent of gastric acidity. Higher dose required in children and infants due to shorter half-life
				Prophylaxis: 3 mg/kg twice weekly		Life threatening infections: 12 mg/kg/day Q12h (max 600 mg/day)	
	Itraconazole	PO, IV	*Aspergillus* spp., *Candida* spp., *H. capsulatum*, *Blastomyces dermatitidis,* and *C. immitis*	Unknown	Unknown	Load with 6 mg/kg/day Q12h × 1 day; maintain with 2.5–5 mg/kg/day Q12h[a] (max 10 mg/kg/day)	Absorption erratic but increased with taking drug with meals or by using cyclodextrin formulation. Dosing Q12h preferred in children. TDM recommended
	Voriconazole	PO, IV	*Candida* spp., *Aspergillus* spp., *Trichosporon* spp. and some strains of *Scedosporium* spp., and *Fusarium* spp.	8–16 mg/kg/day Q12h (IV, PO)		Loading dose 6 mg/kg Q12h day 1, then 4 mg/kg Q12h IV for invasive aspergillus and serious mold infections; 3 mg/kg Q12h for serious candida infections	Linear pharmacokinetics in children. Higher dosages may be necessary in pediatric patients to achieve comparable adult drug exposures. Pediatric suspension is available; bioavailability is reliable and is enhanced with empty stomach. TDM recommended
						PO, <40 Kg: 200 mg Q12h then 100 mg Q12h	
						40 Kg: 400 mg Q12h then 200 mg Q12h	
	Posaconazole	PO	Zygomycetes, *Candida* spp., and *Aspergillus* spp.	Unknown	Unknown	Prophylaxis: 600 mg/day Q8h	TDM recommended
						For oropharyngeal candidiasis (OPC): Load with 100 mg Q12h × 1 day, maintain with 100 mg/day Q24h	
						For refractory OPC: 800 mg/day Q6-12h	

Table 8.4 (continued)

Class	Agent	Route	Spectrum	Daily dose (maximum)			Comments
				Neonates (0–30 days)	Infants (31 days–1 year)	Children (>1–17 years)	
Echinocandins	Caspofungin	IV	*Candida* spp. and *Aspergillus* spp.	25 mg/m^2 Q24h	50 mg/m^2 Q24h	Load with 70 mg/m^2/day for 1 day; maintain with 50 mg/m^2/day Q24h (max 70 mg)	Dosing should be adjusted for hepatic insufficiency to 35 mg/m^2 Q24h

[a]IV formulation for itraconazole is available, but dosage and pharmacokinetics have not been defined in pediatric patients

Table 8.5 Antibacterial agents used in children for infections after transplantation

Class	Generic agent name (trade names)	Route	Spectrum[a]	Daily dose (maximum)			Comments
				Neonates (0–30 days)	Infants (31 days–1 years)	Children (>1–17 years)	
Third-generation cephalosporin	Ceftazidime	IV, IM	Enteric bacteria, some Gram-positive aerobes, no anaerobic coverage	0–7 days: 50 mg/kg Q12h	Inappropriate for mild infections		Only ceftazidime covers *Pseudomonas aeruginosa*: 200–300 mg/kg/day recommended for serious pseudomonas infection
				8–30 days: 50 mg/kg Q8h	Moderate infections: 90–150 mg/kg/day Q8h (max 6 g/day)		
Fourth generation cephalosporin	Cefepime	IV, IM	Enteric bacteria, Gram-positive aerobes	0–7 days: 50 mg/kg Q12h	Inappropriate for mild infections		Active against some *P. aeruginosa*, *Enterobacter* spp., and *Serratia* spp. resistant to ceftazidime; broader Gram-positive spectrum
				8–30 days: 50 mg/kg Q8h	Moderate infections: 100–150 mg/kg/day Q8h or Q12h (max 6 g/day)		
Carbapenems	Imipenem-cilastatin	IV, IM	Most Gram-negative including those producing beta-lactamases and *P. aeruginosa*; Gram-positive aerobes, including enterococci; excellent anaerobic coverage	Inappropriate	Inappropriate for mild infections		*Stenotrophomonas maltophilia* and *Burkholderia cepacia* not covered. IM form not approved for <12 years of age
					Moderate infections: 60–100 mg/kg/day Q6h (max 4 g/day)		
	Meropenem	IV	Similar to imipenem	Sepsis: 60 mg/kg/day Q8h	Inappropriate for mild infections		Less likely than imipenem to cause seizures
				Meningitis: 120 mg/kg/day Q8h	Moderate infections: 60–120 mg/kg/day Q8h (max 3 g/day)		
Extended-spectrum penicillins	Piperacillin, azlocillin, mezlocillin	IV	Enteric aerobes, including some *P. aeruginosa*, *Enterobacter* spp., *Serratia* spp.; anaerobes	Unknown	Inappropriate for mild infections		Must be paired with an aminoglycoside for coverage of *P. aeruginosa*
					Moderate infections: 200–300 mg/kg/day Q6h or Q8h (max 21 g/day)		
	Piperacillin-tazobactam	IV	Similar to piperacillin, increased activity versus some beta-lactamase-producing Gram-positive cocci, Gram-negative bacilli, and anaerobes	0–7 days: 100 mg/kg Q12h	Inappropriate for mild infections		Not adequate as monotherapy for *P. aeruginosa*; aminoglycoside should be added
				8–30 days: 100 mg/kg Q8h	Moderate infections: 240–300 mg/kg/day of piperacillin Q6h or Q8h (max 12 g/day)		

(continued)

Table 8.5 (continued)

Class	Generic agent name (trade names)	Route	Spectrum[a]	Daily dose (maximum)			Comments
				Neonates (0–30 days)	Infants (31 days–1 years)	Children (>1–17 years)	
Monobactams	Aztreonam	IV	Exclusively aerobic Gram-negative aerobes including *P. aeruginosa*	0–7 days: 30 mg/kg Q12h	Mild infections: 90 mg/kg/day Q8h (max 4 g/day)		Limited spectrum requires pairing with Gram-positive agent, not cross-reactive with beta lactams so can be used in penicillin or cephalosporin allergic patients
				8–30 days: 30 mg/kg Q8h	Moderate infections: 120 mg/kg/day Q6h (max 4 g/day)		
Glycopeptide	Vancomycin	PO, IV	Exclusively Gram-positive	Inappropriate	Inappropriate for mild infections		No need to add vancomycin routinely for empirical coverage for fever and neutropenia
					Moderate infections: 40–60 mg/kg Q6h or Q12h (max 3 g/day)		
Lipopeptide	Daptomycin	IV	Exclusively Gram-positive, including ORSA and susceptible strains of VRE	6 mg/kg Q12h	2–5 years 10 mg/kg/day Q24h	4 mg/kg/day Q24h (based on total body weight)	Data in pediatrics are limited at this time
					6–11 years 7 mg/kg/day Q24h		
Oxazolidinone	Linezolid	PO, IV	Exclusively Gram-positive, including MRSA, susceptible strains of VRE, and penicillin and cephalosporin resistant *S. pneumoniae*	0–7 days (unless TBW >2 kg): 10 mg/kg Q12h	30 mg/kg/day Q8h	30 mg/kg/day Q8h	Excellent oral bioavailability
				8–30 days or TBW >2 kg: 10 mg/kg Q8h		>12 years, 1200 mg/day Q12h	
Streptogramin	Quinupristin/dalfopristin	IV	Exclusively Gram-positive, similar to linezolid but spectrum does not include *E. faecalis*	Inappropriate	22.5 mg/kg/day Q8h		Venous irritation should be given via central venous catheter

Adapted from Michelow and McCracken [106]

ters where *Aspergillus* spp. and *Fusarium* spp. are a significant problem, special air filtration systems, such as high-efficiency particulate air filters (HEPA filters) and close attention cleaning bathroom facilities, may be helpful [80, 81].

Total protective isolation is a comprehensive regimen designed to reduce patients' endogenous microbial burden while preventing the acquisition of new organisms. A sterile environment is created in a clean-air room with constant positive-pressure airflow. It is maintained by an aggressive program of surface decontamination and sterilization of all objects that enter the room and by an intensive regimen to disinfect the patient, including oral nonabsorbable antibiotics, skin antiseptics, antibiotic sprays and ointments, and a low-microbial diet. The total protective environment reduces the number of infections in profoundly granulocytopenic patients. However, a total protective environment is expensive, and because of the improvement in treating established infections, it does not offer a survival advantage to patients. Total protective isolation is not necessary for the routine care of immunosuppressed patients. Modifications of the approach are used, on occasion, for patients undergoing allogeneic bone marrow transplantation and for patients who are likely to experience periods of 30 or more days of profound neutropenia [82].

In recipients of SOT, the organ donor is frequently the source of various pathogens. To prevent transmissible pathogens from the solid organ donor, the current requirements for donor and recipient screening are provided in Table 8.8 [46, 83].

Antibacterial Prophylaxis

The fluoroquinolone antibiotics are attractive for oral prophylaxis because of their bioavailability, tolerability, and broad-spectrum. These agents have been widely used in

Table 8.6 Antiviral and anti-pneumocystis agents used in children for infections after transplantation

Class	Agent	Route	Spectrum[a]	Daily dose (maximum)			Comments
				Neonates (0–30 days)	Infants (31 days–1 years)	Children (>1–17 years)	
Anti-herpetic agents	Acyclovir	PO, IV	HSV, VZV	0–7 days (unless TBW >2 kg): 40 mg/kg/day Q12h 8–30 days or TBW >2 kg: 60 mg/kg/day Q8h	Empirical therapy: 15–60 mg/kg/day Q8h (IV) 60–80 mg/kg/day Q6-8 h (PO) HSV: 750 mg/m²/day Q8h or 5 mg/kg Q8h VZV: 1500 mg/m²/day Q8h or 10 mg/kg Q8h		IV dose for VZV is twice that for HSV Hydration should be ensured when administering high doses
	Ganciclovir	PO, IV	CMV, HSV, VZV, EBV, HHV-6	CMV: 12 mg/kg/day Q12h	CMV: 10–15 mg/kg/day Q12h for 14 days induction, then 5 mg/kg/day for maintenance/suppression (IV) VZV, HSV: 10 mg/kg/day Q8h (IV) 90 mg/kg/day (PO)		Neutropenia is the major dose-limiting toxicity; not routinely used for HSV, VZV but dose used for CMV is effective for the other herpesviruses
	Foscarnet	PO, IV	HSV, VZV, CMV (including most acyclovir and ganciclovir resistant strains)	Inappropriate	CMV treatment: 180 mg/kg/day Q8h for 14 days then 90–120 mg/kg/day for maintenance/suppression VZV, HSV: 120 mg/kg/day Q8h		Nephrotoxicity is dose-limiting effect; renal function and electrolytes require close monitoring
Anti-pneumocystis agents	Trimethoprim-sulfamethoxazole	PO, IV	*Pneumocystis jirovecii* (formerly, *P. carinii*) also is active against many Gram-positive and Gram-negative bacteria, including *S. maltophilia* and *B. cepacia*	Inappropriate	Empirical therapy: 8–10 mg of TMP/kg/day UTI prophylaxis: 2 mg of TMP/kg/day PCP treatment: 15–20 mg of TMP/kg/day Q12h (IV) PCP prophylaxis: 150 mg of TMP/m²/day Q12h 3×/week		May cause bone marrow suppression in high doses
	Pentamidine	IV, IM	*P. jirovecii*	Inappropriate	4 mg/kg/day Q24h (IV) for treatment		Adverse effects include pancreatitis, hypoglycemia, hypocalcemia, infusional hypotension
	Dapsone	PO	*P. jirovecii*		Prophylaxis: 2 mg/kg/day Q24h (max. 100 mg/day)		High incidence of hemolytic reactions can also cause methemoglobinemia
	Atovaquone	PO	*P. jirovecii*	30 mg/kg/day	45 mg/kg/day	30 mg/kg/day Q12h for treatment, Q24h for prophylaxis (max. 1500 mg/day)	Suspension formulation has better bioavailability

Adapted from Michelow and McCracken [106]

adult oncology patients but are not generally used for prophylaxis in children because of concern of cartilage toxicity with long-term exposure. In adults, comparative studies have shown no advantage of the oral quinolones over more traditional regimens of infection prophylaxis, such as trimethoprim-sulfamethoxazole, for prevention of infection. Moreover, none of the studies of antibacterial prophylaxis has demonstrated a reduction in mortality caused by infection [84, 85].

Antifungal Prophylaxis

Fluconazole is FDA-approved for prevention of deeply invasive fungal infections in neutropenic patients and HSCT recipients when the risk of aspergillosis is not high. Randomized, placebo-controlled studies demonstrated that the prophylactic administration of fluconazole to allogeneic HSCT recipients reduced the incidence of both disseminated and mucosal candidiasis [86, 87]. However the shift in the

Table 8.7 Management of central venous catheters in patients with bacteremia [8]

Criteria for central venous line removal
1. Evidence of a local tunnel infection
2. Persistently positive blood cultures
3. Recurrently positive blood cultures with the same pathogen
4. Positive blood cultures for:
Staphylococcus aureus
Candida spp.
Polymicrobial infections
Atypical mycobacteria (e.g., *M. fortuitum*, *M. chelonae*, *M. abscessus*)
Bacillus spp.

Table 8.8 Screening requirements for solid organ donors and recipients [46, 83]

Pathogen	Donor	Recipient	Action required
HIV-1 and 2	+	–	Reject donor
	–	+	Accept donor if HIV well controlled
HTLV-1 and 2	+		Exclude donor (may be used in life-threatening conditions)
Hepatitis B virus	HBsAb+	+ or –	Accept donor
	HBsAg+	HBsAb – or +	Reject donor
	HBcAb IgM+	HBsAb – or +	Reject donor
Hepatitis C virus	+	+	Accept (by some centers)
	+	–	Decision depends on urgency
CMV	+ or –	+	Accept
	+	–	Accept (high risk for CMV infection)
EBV	+ or –	+	Accept
	+	–	Accept (higher risk for primary EBV infection and PTLD)
Toxoplasma gondii	+ or –	+	Accept
	+	–	Accept
Treponema pallidum	+	+ or –	Accept
CNS viral pathogens (LCMV, rabies, WNV)	Clinical suspicion of infection		Reject

colonization pattern toward more resistant species, including *C. glabrata*, *Candida krusei*, *Candida parapsilosis*, *Aspergillus*, and other filamentous spp. fungi, is of concern [88]. More recent studies involving pediatric patients demonstrated that micafungin is superior to fluconazole in prevention of proven and suspected invasive fungal infections in neutropenic HSCT patients [89].

Antiviral Prophylaxis

Acyclovir, given orally or intravenously, is effective prophylaxis against reactivation of HSV in seropositive HSCT recipients [90–92]. Intravenous doses ranging from 250 mg/m^2 every 8 h to 5 mg/kg every 12 h, and oral doses of 400 mg given three times daily, are effective in preventing reactivation of HSV in seropositive individuals. Although acyclovir is therapeutically less active against VZV or CMV, prophylactic acyclovir given to HSCT recipients may nonetheless decrease the occurrence of zoster and invasive CMV disease during the posttransplant period [93, 94]. Refractory lesions may respond to foscarnet [95].

Ganciclovir prophylaxis can reduce the frequency of invasive CMV disease in HSCT recipients. However, myelosuppressive effects of ganciclovir are problematic for most patients, making it undesirable for routine anti-CMV prophylaxis. Targeting transplant recipients at highest risk for severe CMV disease has yielded the practice of "preemptive" ganciclovir therapy, that is, treatment of patients who have evidence of CMV reactivation in surveillance assays such as CMV antigenemia, or quantitative CMV PCR. This approach has been shown to effectively suppress CMV viremia, when present and, accordingly, appropriate selection of patients reduces universal need for prophylaxis and dramatically reduces the risk for end-organ CMV disease [96, 97].

Pneumocystis Prophylaxis

There are several effective regimens for *Pneumocystis jirovecii* pneumonia prophylaxis. The choice among them often depends on the patient's tolerance of their various side effects. TMP-SMX, given twice a day for 3 days a week, is considered the first-line regimen [98]. For patients who can tolerate this regimen, protection against PCP is virtually complete [99]. In a number of individuals, presence of skin rash, neutropenia, and gastrointestinal symptoms may limit the routine use of TMP-SMX. Alternative compounds for prevention of PCP in patients who are intolerant of or refractory to TMP/SMX include dapsone, atovaquone, and aerosolized pentamidine.

Immunization

There are no universally accepted recommendations for immunizing children undergoing transplantation. The American Academy of Pediatrics and the CDC regularly publish updated guidelines regarding immunization practices in healthy and transplant pediatric recipients [100, 101] (Table 8.9).

Table 8.9 Immunizations in patients after hematopoietic stem cell transplantation (HSCT) [102]

Vaccine	Recommended time after HSCT
Pneumococcal[a]	12 and 24 months
Haemophilus influenzae type b	12, 14, and 24 months
Tetanus-diphtheria toxoid[a]	12, 14, and 24 months
Inactivated polio	12, 14, and 24 months
Hepatitis B	12, 14, and 24 months
Hepatitis A	Routine administration not recommended
Measles, mumps, rubella (MMR)[a]	24 months
Meningococcal	Routine administration not recommended
Varicella zoster virus[a]	Contraindicated
Influenza	6 months (yearly lifelong)

Modified from Centers for Disease Control and Prevention, Infectious Disease Society of America, American Society of Blood and Marrow Transplantation [102]
[a]See text

Children and adolescents before undergoing HSCT or SOT should receive immunizations recommended for their age at least 4 or 2 weeks before the transplantation, respectively.

Immunizations can be started 6–12 months after HSCT as long as the patient has no persistent complications (GVHD) and is not receiving immunosuppressive therapy.

If the patient is <7 years old, three doses of diphtheria, tetanus toxoids, and acellular pertussis (DTaP) vaccine should be administered starting 6 months after HSCT. If the patient is >7 years old, three doses of tetanus and diphtheria toxoid-containing vaccine [including two doses of tetanus and diphtheria (TD) and one dose of adolescent tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap)] should be used [100].

For HSCT recipients who are seronegative to measles and without GVHD or immunosuppression, one dose of MMR vaccine should be given to adolescents and adults and two doses to children at least 24 months after transplantation [100].

Varicella vaccine is contraindicated for HSCT recipients less than 24 months after transplantation. Given the lack of access of immunocompromised patients to the live attenuated varicella vaccine, passive immunoprophylaxis either with varicella zoster immune globulin (VZIG) within 96 h of exposure or regular infusions of gamma globulin is indicated in the high-risk children with no reliable history of varicella. If inadvertent contact occurs between an immunocompromised child and a recent varicella vaccine recipient, administration of VZIG is not recommended as the transmission rate is low and varicella from the Oka strain, albeit unlikely, would be mild and self-limiting. Finally, one should be aware that the varicella vaccine may not be fully protective against varicella, particularly in an outbreak setting.

The 13-valent pneumococcal conjugate vaccine (PCV13) shows good immunogenicity after three doses starting 3–6 months after HSCT. At 12 months after HSCT in children ≥2 years is recommended a dose of pneumococcal polysaccharide vaccine to broaden the serotype coverage given that the patient does not have chronic GVHD. For patients with chronic GVHD, a fourth dose of PCV13 can be given at 12 months after HSCT [100].

After SOT, DTaP, HIB, hepatitis A, hepatitis B, inactivated influenza and pneumococcal and meningococcal conjugate and polysaccharide vaccines can be administered if indicated. Immunization schedules vary between centers, but most experts recommend waiting at least 6 months after transplantation. Administration of live-virus vaccines such as MMR and varicella is advised in patients who are stable at least 6 months after SOT, who are receiving minimal immunosuppressive agents, and who have not had recent episodes of organ rejection.

Household and health-care contacts of HSCT and solid organ transplant recipients should have immunity or be immunized against poliovirus, measles, mumps, varicella, influenza, and hepatitis A [100, 101].

Use of CSFs in Stem Cell Transplantation

Recombinant human cytokines and colony-stimulating factors (CSFs) for adjunctive therapy in immunocompromised patients have been an important assistance in attenuating the myelotoxic effects of HSCT. Granulocyte-CSF (G-CSF; filgrastim) and granulocyte-macrophage-CSF (GM-CSF; sargramostim) have undergone extensive evaluation for their potential role in reducing infectious morbidity during periods of severe immunosuppression. However, they should be used judiciously in order to maximize medical benefit, limit potential toxicity, and be cost-effective. The effects of G-CSF and GM-CSF in prevention of infections in neutropenic patients are perhaps best illustrated in the impact of these agents on stem cell mobilization in HSCT donors. Transfusion of peripheral mobilized stem cells has led to a substantial reduction in depth and duration of neutropenia [103–106]. G-CSF and GM-CSF also are used in HSCT recipients as part of most immediate posttransplant regimens for their impact on shortening the duration of neutropenia. The effects on the incidence of fever or documented infections, antibiotic usage, or duration of hospitalization have been more variable and dependent on clinical trial design. Notably, as these cytokines do not augment platelet recovery, thrombocytopenia remains a challenging problem for HSCT recipients.

Part II

Clinical Disorders in Transplant Recipients

Febrile Neutropenia in Transplant Recipients

9

Lior Nesher and Kenneth V. I. Rolston

Introduction

Hematopoietic transplantation has been used to treat many disorders including neoplastic, hematologic, immunologic, and metabolic diseases. Currently, most hematopoietic transplants are performed for the treatment of hematologic malignancies [1]. Hematopoietic cells for transplantation can be collected from various sources including bone marrow, peripheral blood, and umbilical cord blood. Autologous transplants utilize the patient's own cells, whereas allogeneic transplants utilize cells obtained from a different individual. Syngeneic transplants are between genetically identical twins. Conditioning therapy given prior to hematopoietic transplantation can be myeloablative or non-myeloablative (i.e., reduced intensity) and produces significant neutropenia (absolute neutrophil count [ANC] $\leq$500 cells/mm^3), which is the most common predisposing factor for the development of bacterial and fungal infections during the pre-engraftment phase. Neutropenia is more prolonged in recipients of myeloablative allogeneic transplants than in recipients of non-myeloablative or autologous transplants. Thus, the frequency and severity of infection in allogeneic transplant recipients are greater than in other transplant subgroups [2–6]. Some patients with hematologic malignancies may have normal or even elevated ANCs but may be at increased risk for infection due to defects in neutrophil function (qualitative neutropenia). These defects include significant reduction in phagocytosis, decreased bactericidal and fungicidal activity, decreased production of superoxide anions, and defects in granulocyte locomotion. Myeloablative conditioning regimens also inflict substantial damage to mucosal barriers causing mucositis of the mouth and gastrointestinal tract, resulting in increased risk of infections arising from these sites [7, 8]. Early recognition and aggressive management of infection is critical for the overall survival of hematopoietic transplant recipients, and delays in the administration of appropriate anti-infective therapy are associated with poorer outcomes [9]. Unfortunately, signs and symptoms commonly associated with infection may be blunted in these highly immunosuppressed patients. Often the only manifestation of infection during an episode of neutropenia is fever. This condition is commonly referred to as "febrile neutropenia." The widely accepted definition of febrile neutropenia is an oral temperature of $\geq$38.3 °C, or two consecutive readings of >38 °C during a 2 h period, and an absolute neutrophil count of <500/mm^3 [10]. It has been estimated that approximately 80% of allogeneic transplant recipients and a smaller but substantial proportion of allogeneic transplant recipients will develop febrile neutropenia. It is important to keep in mind that some neutropenic patients, especially those receiving corticosteroids, may not mount an adequate inflammatory response and may be afebrile or even hypothermic while developing or harboring a significant infection. A high index of suspicion and close monitoring during periods of increased risk is essential in such patients.

The administration of prompt, broad-spectrum, empiric, antimicrobial therapy has become the standard of care for most febrile neutropenic patients including transplant recipients [10]. The general principles of such therapy for both adult and pediatric patients have been published in guidelines issued by various learned societies [10–13]. Specific treatment regimens for individual patients generally take into consideration local epidemiologic trends and local susceptibility/resistance patterns since geographic and institutional differences do occur. Periodic surveillance studied to monitor changes in the epidemiology of infections and in susceptibility and resistance patterns are important especially in

institutions that perform large numbers of hematopoietic transplants.

Types of Febrile Episodes

Although fever is the most frequent and occasionally the only manifestation of infection in neutropenic patients, a substantial number of patients remain febrile without a specific infection being documented. A specific causative pathogen, most often bacterial or fungal, is identified in only 20–25% of febrile neutropenic episodes, referred to as episodes of microbiologically documented infection [14]. An additional 20–25% of patients will have an identifiable site of infection (e.g., pneumonia, cellulitis, enterocolitis) but will have negative cultures (Fig. 9.1). This may be due to various reasons such as the use of antimicrobial prophylaxis which may render cultures negative or substantially delay the time to positivity or a blunted inflammatory response which can result in paucity of specimens (e.g., sputum) to culture. These episodes are referred to as clinically documented infections. Approximately 40–50% of febrile neutropenic patients have neither clinical evidence of infection nor positive microbiological documentation of one, which are referred to as episodes of unexplained fever. The majority of these episode are probably caused by undetected infections as most of them respond to empiric antimicrobial therapy. A small proportion of patients with fever and neutropenia have noninfectious causes of fever such as drug fever or tumor fever. This is not surprising since fever is induced by cytokine release which is not limited to infections. All febrile neutropenic patients should undergo a thorough evaluation to detect infection before the possibility of a noninfectious etiology is entertained. Most microbiologically documented infections are monomicrobial (i.e., caused by one organism) with Gram-positive bacteria being predominant [10, 15]. However, polymicrobial infections are being documented with increasing frequency at many transplant centers and may account for up to 25% of bacterial infections [16]. Recent data show that ~10–15% of bacteremias in neutropenic patients are polymicrobial [17]. Infections involving deep tissue sites such as pneumonia, enterocolitis, and perirectal infections are often polymicrobial [16, 18]. Most polymicrobial infections are caused by multiple bacterial species although bacterial and fungal, bacterial and viral, or fungal and viral infections may be present at the same time. These infections are generally associated with greater morbidity and mortality than monomicrobial infections.

Sites of Infection

The most common sites of infection documented in neutropenic hematopoietic transplant recipients are listed in Table 9.1. Infections of the respiratory tract occur most often followed by bloodstream infections (including central line-associated bloodstream infection, CLABSI), urinary tract infections, skin and skin structure infections (SSSIs), and infections originating from the oropharynx, the gastrointestinal tract, and the biliary tract [14]. Less frequent but clinically important sites include the central nervous system, the musculoskeletal system, and the end organs such as the spleen and liver. The frequency of bloodstream infection (BSI) varies from center to center and also on the type of transplant, generally being more frequent in allogeneic transplant recipients [19, 20]. Recent data indicate that the incidence of at least one episode of BSI is around 21% with an attributable mortality of ~3% [21]. Approximately 25% of patients with profound neutropenia lasting >10–12 days will develop lung infiltrates. These often do not respond to broad-spectrum antimicrobial therapy and establishing a specific diagnosis in such patients remains a significant challenge [22]. Data regarding other sites of infection are not as robust as those describing BSIs.

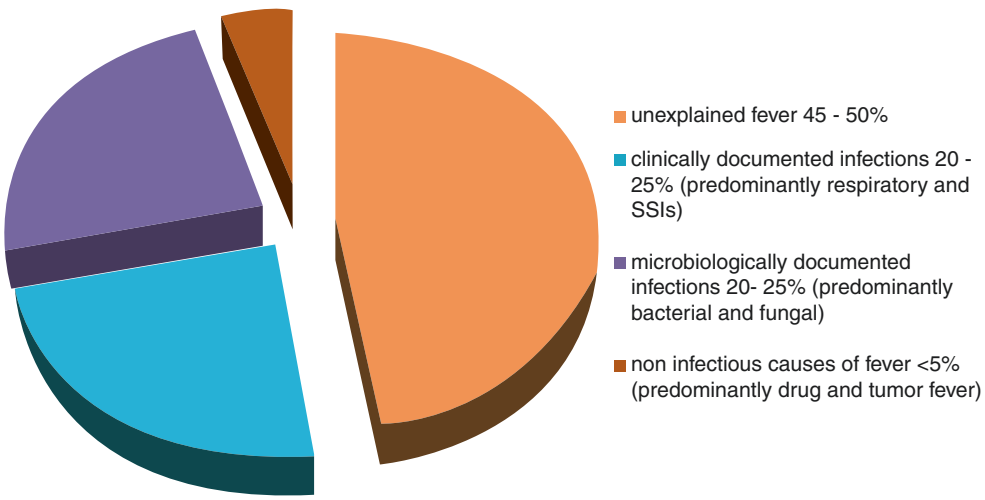

Fig. 9.1 Types and distribution of febrile episodes in neutropenic patients

Table 9.1 Common sites of infection in febrile neutropenic patients

Site of infection[a]	Frequency range
Respiratory tract[b]	35–40%
Bloodstream[c]	15–35%
Urinary tract	5–15%
Skin and skin structure[d]	5–10%
Gastrointestinal tract[e]	5–10%
Other sites[f]	5–10%

These data were extracted from various epidemiologic surveys conducted at the University of Texas MD Anderson Cancer Center between 2004 and 2014

[a]Approximately 15–20 % of patients will have multiple sites of infection (i.e., bacteremia + pneumonia). These are not always caused by the same organisms

[b]Includes the para nasal sinuses, the upper respiratory tract, the lungs, and infections such as empyema

[c]Includes primary and catheter-related bacteremia

[d]Includes infections at surgical sites, bone marrow biopsy sites, and radiation fields

[e]Includes infections arising from the oral cavity, esophagitis, appendicitis, neutropenic enterocolitis, cholangitis, and perirectal infections

[f]Central nervous system, bone, joint, etc.

Most microbiologically documented infections arise from the patient's endogenous microflora, with only a small proportion being acquired from exogenous sources and/or environmental exposure. It is therefore often possible to anticipate the potential etiology of an infection and provide appropriate empiric coverage based on the site where the infection originated. For example, most infections with a cutaneous origin are caused by *Staphylococcus* species and other organisms that colonize the skin (*Bacillus* spp., *Corynebacterium* spp., *Candida* spp.) [23]. Patients with severe oral mucositis and/or poor periodontal status are more likely to have infections caused by viridans group streptococci (VGS) and *Stomatococcus mucilaginosus* [24–26]. In patients with significant lower intestinal mucositis, enterococcal and Gram-negative bacillary infections occur more often. Bacterial infections generally occur during the initial stages of a neutropenic episode, while fungal infections arise more frequently in patients with prolonged (≥7 days) neutropenia. The widespread use of long-term central venous catheters in transplant recipients has had an impact on the frequency and spectrum of infection. The ability of certain organisms (notably coagulase-negative staphylococci (CoNS), *Staphylococcus aureus*, and *Candida* spp.) to produce and get embedded in biofilm, and the poor penetration of many antimicrobial agents into biofilm, makes catheter-related infections difficult to eradicate without removal of the offending catheter [27]. Consequently many transplant centers perform routine weekly blood cultures from central venous catheters in an attempt to detect colonization/infection early [28, 29]. This practice, however, has not been shown to accurately predict the development of CLABSI and may lead to unnecessary interventions [30]. The most common organisms isolated from CLABSI are CoNS. Other organisms include S. *aureus*, *Bacillus* spp., *Corynebacterium* spp., *Pseudomonas aeruginosa*, *Enterobacteriaceae*, *Enterococcus* spp., *Acinetobacter* spp., *Stenotrophomonas maltophilia*, and *Candida* spp. Despite the widespread use of catheters, the infection rate seldom exceeds 15% or more than two episodes per 1000 catheter days [31].

Bacterial Infections

Several recent epidemiologic surveys conducted in pediatric and adult hematopoietic transplant recipients have documented the predominance of Gram-positive organisms over Gram-negative bacilli [32–34]. Some of the reasons for this predominance include (1) the widespread use of central venous catheters, (2) the frequent use of intensive chemotherapeutic regimens that produce significant oral mucositis, and (3) the use of antibacterial prophylaxis (generally with a fluoroquinolone) directed primarily against enteric Gram-negative bacilli. Fluoroquinolone prophylaxis has in fact been show to increase the frequency of Gram-positive infections especially with organisms such as VGS that are often resistant to them [35]. The proportion of Gram-positive infections has been reported to be as high as 70–80% at some centers. Many reports, however, include data only on BSI caused by single organisms (monomicrobial BSI) and either exclude or provide very little details regarding infections at other sites and on polymicrobial infections [36]. These reports provide an overestimate of Gram-positive infections since the majority of bacteremias, particularly CLABSI, are indeed caused by Gram-positive organisms that inhabit the skin. As mentioned previously, BSIs account for only 20–25% of microbiologically documented infections. Infections at most other sites such as lungs, intestinal tract, urinary tract, and biliary tract have a predominance of Gram-negative pathogens. Additionally, ~60–80% of polymicrobial infections have a Gram-negative component, and ~30–35% are caused exclusively by multiple Gram-negative species [16, 18]. Therefore, when all sites of infection, not just BSI and monomicrobial as well as polymicrobial infections are pooled together, the apparent predominance of Gram-positive organisms seems less striking, with Gram-negative organisms being isolated almost as frequently [37]. Indeed, some institutions are beginning to report a resurgence in the frequency of Gram-negative pathogens even in patients with BSI [32]. The main reason for this appears to be the discontinuation of fluoroquinolone prophylaxis at some institutions since this practice has resulted in the emergence of fluoroquinolone-resistant and even multidrug-resistant organisms [32]. For reasons that remain unclear anaerobes are seldom isolated from neutropenic patients, although it is customary to provide anaerobic coverage especially for infections arising from or involving the intestinal tract. Real-time knowledge of local epidemio-

logical patterns is critical, and empiric regimens need to be based on such information. Consequently, transplant centers are encouraged to perform periodic surveillance studies in order to keep abreast of epidemiologic changes. The organisms causing the majority if bacterial infections in neutropenic hematopoietic transplant recipients are listed in Tables 9.2 and 9.3.

Table 9.2 The spectrum of Gram-positive organisms isolated from febrile neutropenic patients

Organism	% Frequency
CoNS[a]	20–50
Staphylococcus aureus[a]	10–30
Enterococcus species[b]	10–20
VGS[c]	5–25
Micrococcus species	2–8
Corynebacterium species	2–5
β hemolytic streptococci[d]	4–6
Bacillus species	4–6
Aerococcus species	<3, respectively
Streptococcus pneumoniae	
Stomatococcus mucilaginosus	
Lactobacillus species	
Leuconostoc species	
Pediococcus species	

These data were extracted from various epidemiologic surveys conducted at the University of Texas MD Anderson Cancer Center between 2004 and 2014

[a]CoNS – coagulase-negative staphylococci – approximately 7% of CoNS were *S. lugdunensis*. >95% of CoNS and >65% of *S. aureus* isolates were methicillin-resistant

[b]Approximately 18% of *Enterococcus species* were vancomycin-resistant enterococci (VRE)

[c]VGS – viridans group streptococci – the most common species were *S. mitis*, *S. sanguis*, and *S. salivarius*

[d]Included groups A, B, C, G, and F

Table 9.3 Spectrum of Gram-negative organisms isolated from febrile neutropenic patients

Organism	% Frequency
Escherichia coli[a]	20–45
Klebsiella species[b]	10–20
Other *Enterobacteriaceae*[c]	15–20
Pseudomonas aeruginosa[d]	18–24
Stenotrophomonas maltophilia[d]	2–5
Acinetobacter species[d]	<3
Other NFGNB[e]	<3

These data were extracted from various epidemiologic surveys conducted at the University of Texas MD Anderson Cancer Center between 2004 and 2014

[a]Approximately 40% of isolates were fluoroquinolone-resistant, approximately 9% produced ESBLS and 4% were multidrug resistant

[b]*K. pneumoniae* 78% and *K. oxytoca* 22%. Increasing rates of ESBL and carbapenemase-producing organisms are being reported

[c]Primarily *Enterobacter* species, *Serratia* species, and *Citrobacter* species

[d]Increasing frequency of multidrug resistant (MDR) isolates (i.e., resistant to at least three classes of antimicrobial agents)

[e]NFGNB – non-fermentative Gram-negative bacilli

Gram-Positive Organisms

Coagulase-negative staphylococci are isolated most often with the most common species being *Staphylococcus epidermidis*, *S. hominis*, and *S. haemolyticus*. These organisms are of low virulence and seldom cause life-threatening infections even in severely neutropenic patients. CLABSI are the most common infections caused by CoNS. These can often be treated with antimicrobial agents alone, although catheter removal may be required if the infection recurs [38]. The one exception is *S. lugdunensis*, which more closely resembles *S. aureus* in virulence [39–41]. Many experts recommend that these organisms should not be considered to be harmless commensals and infections caused by them should be managed like those caused by *S. aureus*. Other Gram-positive organisms that colonize the human skin and cause infections in neutropenic patients include *Bacillus* spp., *Corynebacterium* spp., and *Micrococcus* spp. Like CoNS, these organisms cause CLABSI most often, although serious infections such as endophthalmitis, endocarditis, septic arthritis, and pneumonia develop occasionally. As mentioned, *S. aureus* are more virulent than other staphylococci and are associated with substantial morbidity and mortality. Patients with *S. aureus* bacteremia should be evaluated with infections such as endocarditis and deep-seated abscesses [42]. Unlike CoNS catheter removal is almost always necessary in *S. aureus* CLABSI [43]. Of concern are the increasing rates of methicillin resistance among *S. aureus* (MRSA) isolates worldwide. Although MRSA rates as low as 10% are still reported occasionally, many institutions are reporting MRSA rates in the range of 55–60%, making them more common than methicillin-susceptible isolates. Some MRSA isolates have developed tolerance (MBC ≥32 times the MIC) or reduced susceptibility to vancomycin (referred to as the MIC creep), thereby reducing the therapeutic impact of this agent, which until recently has been considered to be the agent of choice for the treatment of Gram-positive infections in neutropenic patients [44, 45]. Alternative agents are being recommended for infections caused by such organisms [46].

Alpha-hemolytic streptococci or VGS are major components of the human oral microflora. Patients particularly prone to VGS infections are recipients of high-intensity chemotherapy with agents such as cytosine arabinoside which induces severe mucosal damage and facilitates translocation of these organisms into the bloodstream. Other predisposing factors include the use of fluoroquinolone prophylaxis and the use of antacids and histamine type-2 (H2) antagonists. Although not recommended by most authorities, vancomycin-based prophylaxis in the peri-transplant period has been used by some, in order to reduce the frequency of VGS bacteremia [47]. This practice

requires close monitoring of patients for the development of resistant organisms such as VRE and/or staphylococcal isolates with reduced susceptibility or resistance to vancomycin. It should only be considered in institutions where the frequency of infections caused by VGS is very high. Also of concern is the possibility that this practice might lead to the development of reduced susceptibility to other agents (daptomycin, dalbavancin). Some investigators believe that mucositis, which generally occurs at the nadir of neutropenia, is the primary predisposing factor for the development of infection in this setting, and have coined the phrase "febrile mucositis." Additionally, periodontal inflammation including gingivitis, periodontitis increases the possibility of VGS bacteremia [24, 48]. The most common manifestation of VGS infection is bacteremia. Approximately 5–10% of patients may develop disseminated infection, the so-called streptococcal toxic shock syndrome in which the mortality rate is in the range of 40–50% despite appropriate therapy [49]. *Streptococcus mitis*, *S. sanguis*, and *S. salivarius* are the species isolated most often from patients with VGS bacteremia. Of increasing concern are reports that up to 20–60% of VGS isolates are non-susceptible or overtly resistant to penicillin [50]. All isolates are currently susceptible to vancomycin, although occasional tolerance to this agent has been described [45]. They are also susceptible to newer-generation quinolones such as moxifloxacin and agents such as linezolid, daptomycin, telavancin, and dalbavancin, although clinical experience with these agents is limited [51–53]. The use of antibiotic combinations may be warranted, especially against organisms with high MICs or tolerance to vancomycin.

The enterococci reside mainly in the lower intestinal tract. They are seldom primary pathogens but are isolated most often following prolonged therapy with broad-spectrum agents such as the carbapenems. The most common manifestations include BSI and urinary tract infections. Enterococci are also often isolated from polymicrobial infections such as neutropenic enterocolitis and perirectal infections. The increased and prolonged use of vancomycin in neutropenic patients was in part responsible for the emergence of vancomycin-resistant enterococci (VRE) globally, and currently, 15–20% of all enterococcal isolates in the United States are VRE. Fecal colonization with VRE in hematopoietic transplant recipients is not uncommon, and approximately 15–40% of colonized patients will develop BSI or other serious infections [54–58]. Consequently, some experts recommend the preemptive use of agents with activity against VRE when patients with fecal colonization develop febrile neutropenia. Fecal decolonization has been attempted, but most attempts have been unsuccessful. Therefore, antimicrobial stewardship and infection control measures to limit the emergence and spread of VRE are extremely important.

Gram-Negative Organisms

The gastrointestinal tract serves as an important source of infection in neutropenic patients, with the predominant pathogens being enteric Gram-negative bacilli. The use of antimicrobial prophylaxis in high-risk neutropenic patients including hematopoietic transplant recipients led to a decline in the frequency and, to some extent, the morbidity and mortality associated with documented Gram-negative infections. This practice also led to the emergence of resistance among *Escherichia coli* and other Gram-negative species [59–61]. Therefore, many institutions are re-evaluating this practice, and some institutions have even discontinued fluoroquinolone prophylaxis in neutropenic patients [32]. Many institutions conduct surveillance studies in high-risk patients looking for fecal colonization with VRE, *Pseudomonas aeruginosa*, and other resistant organisms such as extended-spectrum beta-lactamase (ESBL) producers and carbapenem-resistant *Enterobacteriaceae* (CRE), since positive surveillance cultures often predict the development of infections during subsequent episodes of neutropenia [55, 62, 63]. This information is useful in picking appropriate empiric regimens when colonized patients develop febrile neutropenia, as well as in antimicrobial stewardship efforts if surveillance cultures are negative. ESBL-producing organisms are being reported with increasing frequency [64]. Carbapenemase-producing Gram-negative bacteria (*Klebsiella pneumonia* carbapenemase, KPC; New Delhi metallo-beta-lactamase 1, NDM-1; non-metallo-beta-lactamase producers) have emerged over the past few years and are spreading across the globe [65, 66]. Gram-negative infections are usually associated with greater morbidity and mortality than Gram-positive infections. Many epidemiological studies have shown that *E. coli*, *Klebsiella* species (*K. pneumoniae* and *K. oxytoca*), and *P. aeruginosa* remain the three primary Gram-negative pathogens in neutropenic patients causing 45–60% of such infections [36, 37]. Other *Enterobacteriaceae* (*Citrobacter* spp., *Enterobacter* spp., *Proteus* spp., *Serratia* spp.) are less common, although institutional differences do exist [67, 68]. Nationwide outbreaks of *Serratia marcescens* bacteremia due to contaminated prefilled heparin and saline syringes have been reported [69, 70]. Despite the overall decline in the frequency of Gram-negative infections, the proportion of infections caused by non-fermentative Gram-negative bacilli (NFGNB) such as *P. aeruginosa*, non-aeruginosa pseudomonads, *Stenotrophomonas maltophilia*, and *Acinetobacter* species has increased [67, 71]. Collectively, NFGNB now cause ~40% of all Gram-negative infections, a proportion that has steadily increased over the past two decades. *P. aeruginosa* is the most important and most frequently isolated NFGNB and causes between 15% and 20% of Gram-negative infections [72]. Bacteremia and pneumonia are the two most common manifestations, although infections at various other

sites are not uncommon. It is also the most common Gram-negative organism isolated from polymicrobial infections [16]. These organisms develop resistance to antimicrobial agents using multiple mechanisms and often acquire resistance to several classes of agents (multidrug resistance, MDR) and are difficult to treat and eradicate. Combination therapy is often necessary. Prolonged use of fluoroquinolones and carbapenems has been identified as risk factor for the development of resistance [73–75]. Consequently, many antimicrobial stewardship efforts focus on curtailing or minimizing the use of these agents. Colonization/infection with *S. maltophilia* is also being reported more often especially in patients with hematologic malignancies and hematopoietic transplant recipients [76, 77]. The shift from trimethoprim/sulfamethoxazole (which has potent activity against *S. maltophilia*) to fluoroquinolones (which do not) as the preferred agents for antimicrobial prophylaxis in neutropenic patients may account for this increase. These organisms are almost always multidrug resistant, and as is the case with *P. aeruginosa*, combination therapy (trimethoprim/sulfamethoxazole + minocycline or tigecycline) is frequently necessary [77, 78]. Other infrequent but important NFGNB include *Acinetobacter* spp., *Achromobacter* and *Alcaligenes* spp., and non-aeruginosa *Pseudomonas* species such as *P. putida* and *P. fluorescens*. Many outbreaks caused by these organisms have been traced to contaminated dialysis fluid, de-ionized water, mechanical ventilators, and chlorhexidine solution. Many of these organisms are also multidrug resistant.

Anaerobic Infections

Anaerobic infections are seldom documented in febrile neutropenic patients, with the overall range of positive blood cultures being 0–5% [79]. The most common sites of infection are the intestinal tract (neutropenic enterocolitis, perirectal infections, abdominal/pelvic abscesses), complicated skin and skin structure infections, biliary tract infections, and respiratory infections [14, 80]. It is customary to provide anaerobic coverage to treat these infections even if anaerobes have not been isolated. The presence of significant oral or intestinal mucositis increases the risk of anaerobic infections. Purulence, which is the hallmark of anaerobic infections in immunocompetent patients, is often absent in patients with neutropenia. The organisms isolated most often include *Peptostreptococcus* spp., *Fusobacterium nucleatum*, *Bacteroides* spp., *Prevotella* spp., and *Clostridium* spp. Due to the frequent and prolonged use of broad-spectrum antimicrobial agents, *Clostridium difficile*-associated diarrhea is not infrequent in patients with neutropenia [81]. Approximately 13% of hematopoietic transplant recipients develop *C. difficile* infection mainly in the 1st month post-transplantation [82]. Colonization with toxigenic strains of *C. difficile* has been shown to be predictive for the development of *C. difficile*-associated diarrhea in hematopoietic transplant recipients [83, 84]. Response to treatment may be lower and relapses or recurrent infections may be higher in this setting.

The spectrum of bacterial infection in neutropenic patients continues to change with significant geographic and institutional differences being commonplace. In institutions wherein fluoroquinolone prophylaxis is still in use, Gram-positive pathogens predominate, whereas in institutions that have suspended or discontinued the use of fluoroquinolone prophylaxis, Gram-negative pathogens are more common. Resistance patterns also vary from region to region and, indeed, sometimes within the same region or institution. Resistant organisms are uncommon in Scandinavian countries. VRE appears to be more common in the United States than in Europe. The frequency of ESBL-producing, carbapenemase-producing, and MDR Gram-negative organisms appears to be increasing worldwide. Consequently, generating real-time local epidemiologic and susceptibility/resistance data is important.

Fungal Infections

Bacterial infections predominate during the initial 7–10 days of neutropenia. With more prolonged neutropenia, fungal infections begin to develop. Infections caused by *Candida* spp. and *Aspergillus* spp. are documented most often although many opportunistic fungi are pathogenic in this setting (Table 9.4). Invasive candidiasis was the most common fungal infection in neutropenic patients prior to the development of agents such as fluconazole, with *C. albicans* being the predominant species. With the routine usage of antifungal prophylaxis in high-risk patients including hematopoietic transplant recipients, the frequency of invasive candidiasis has been substantially reduced with manifestations like esophagitis and chronic systemic or hepatosplenic candidiasis becoming almost of historic interest. Currently candidemia, most often catheter-related, is the most common manifestation of invasive candidiasis. There has also been a shift in the epidemiology of candidiasis, in part related to the usage of agents such as fluconazole, with the emergence of *Candida* species other than *C. albicans such as C. glabrata*, *C. tropicalis*, *C. parapsilosis*, *C. krusei*, *C. auris* as frequent pathogens in this setting [85, 86]. Regional differences have been documented with a preponderance of different species in different institutions. These differences may be due to divergent use of antifungal prophylaxis and/or geographic diversity. As with bacterial infections, local epidemiologic and susceptibility/resistance data should be used to guide empiric

Table 9.4 The spectrum of fungal and viral infections in neutropenic patients

Fungal pathogens (yeast) – 8–24% of blood stream infections in patients with hematological malignancy
Candida albicans
Other candida species[a]
Trichosporon beigelii
Geotrichum capitatum
Malassezia furfur
Hansenula anomala
Streptomyces cerevisiae
Fungal pathogens (molds) – 2–28% of patients with hematological malignancy
Aspergillus fumigatus
Other Aspergillus species[b]
The Zygomycetes[c]
Fusarium species
Scedosporium species
Viral pathogens
Herpes simplex viruses (reactivation)
Community respiratory viruses[d]

These data were extracted from various epidemiologic surveys conducted at the University of Texas MD Anderson Cancer Center between 2004 and 2014

[a]Includes *C. glabrata*, *C. tropicalis*, *C. krusei*, *C. auris*, and *C. parapsilosis*

[b]Includes *A. flavus*, *A. niger*, *A. terreus*, *and A. oryzae*

[c]*Rhizopus*, *Mucor*, *Rhizomucor*, *Absidia*, *and Cunninghamella* are the most common human pathogens

[d]Includes influenza A and B, parainfluenza viruses, respiratory syncytial virus (RSV), human metapneumovirus, corona viruses, rhinoviruses, and bocavirus. Infection may not necessarily be more common in neutropenic patients but tends to be more severe

and targeted antifungal therapy. Other yeasts occasionally encountered in this setting include *Trichosporon beigelii*, *Hansenula anomala*, Geotrichum capitatum, *Malassezia furfur*, *and Streptomyces cerevisiae*.

Invasive mold infections are the most common life-threatening infections in patients with neutropenia that last longer than 2 weeks [87]. The vast majority of these infections are caused by *Aspergillus* species with *A. fumigatus* being the predominant species. Other species of Aspergillus have emerged as significant pathogens as well, including *A. flavus*, *A. terreus*, *A. niger*, and *A. oryzae* (Table 9.4). The most common site of involvement is the lung, resulting in invasive pulmonary aspergillosis (IPA). Other frequent sites of involvement include the paranasal sinuses and the central nervous system. Fungemia is rarely documented. Although still relatively uncommon, mucormycosis has emerged as an increasingly important infection in neutropenic patients in the last 15–20 years [88]. The most common organisms causing this infection are *Mucor* spp., *Rhizopus* spp., *Rhizomucor* spp., *Cunninghamella* spp., and *Absidia* spp. The increasing frequency of mucormycosis has in part been attributed to the use of voriconazole, due to its lack of activity against these organisms [89–91]. Like aspergillosis, common sites of infection include the paranasal sinuses, the rhino-orbital area, the lungs, and the central nervous system [92]. Other uncommon but important molds that cause infection in this setting include *Fusarium* spp. and *Scedosporium* spp. Unlike most other molds, fungemia is a common manifestation of fusariosis and may occur in up to 50% of patients [93]. Necrotic cutaneous lesions are also relatively common. The incidence of *Scedosporium* infection appears to be increasing in recent years. This increase may also be related to the fact that these organisms are resistant to many commonly used antifungal agents [94].

Viral Infections

Viral infections, especially those caused by human herpes viruses, are common in high-risk patients with neutropenia including hematopoietic cell transplant recipients. Most are effectively prevented with antiviral prophylaxis and/or preemptive therapy. Most herpes simplex virus (HSV 1 and HSV 2) infections in adults are due to reactivation of latent infections in seropositive patients. The likelihood of viral reactivation depends on the intensity of the chemotherapeutic/conditioning regimen. Reactivation occurs in two-thirds of patients undergoing induction chemotherapy for acute myelogenous leukemia and in recipients of hematopoietic transplants in the absence of antiviral prophylaxis [95, 96]. Ulcerations of the oral and esophageal mucosa, ulcers, or vesicles on the lips, genitalia, skin, or perianal areas are the most common manifestations. The HSVs can cause numerous syndromes including encephalitis, meningitis, myelitis, esophagitis, hepatitis, ocular disease, pneumonia, and erythema multiforme. Reactivation, or less commonly, primary acquisition of other human herpes viruses such as Cytomegalovirus, Epstein-Barr virus, and human herpes virus 6 can also occur, albeit, seen mostly during late transplant period [97–100].

Infections caused by respiratory viruses may not necessarily occur more frequently in neutropenic patients, but their manifestations tend to be more severe in this setting [101]. This may even impact the decision to proceed with hematopoietic cell transplantation, and several guidelines recommend delaying transplantation in patients with pre-transplant upper respiratory tract infections [101–103]. These pathogens include the influenza viruses (influenza A and B), respiratory syncytial virus (RSV), parainfluenza viruses, adenovirus, and metapneumovirus [104]. The risk for infection by these organisms tends to coincide with respiratory virus outbreaks in the general population. The severity of infection and specifically the rate of progression from upper respiratory tract disease to lower respiratory tract disease such as pneumonia depend on the level, duration, and type of immunosuppression [104–107].

Polymicrobial Infections

As previously mentioned, approximately 25–30% of microbiologically documented infections are polymicrobial. In the past polymicrobial infections have been ignored or underappreciated and underreported [16]. Of late, greater attention is being paid to such infections. In general, they are associated with greater morbidity and mortality than monomicrobial infections. This may be because polymicrobial infections frequently involve deep tissues (pneumonia, empyema, neutropenic enterocolitis, perirectal infections) where penetration of antimicrobial agents might be subtherapeutic and large areas of under perfused or necrotic tissue may be present. Recent studies also show that ~15% of bacteremic infections including CLABSI are polymicrobial [17]. Gram-positive organisms, predominantly staphylococci and enterococci, are isolated from up to 40% to 50% of polymicrobial infections, whereas Gram-negative organisms are isolated from ~80% of polymicrobial infections with *P. aeruginosa* and *E. coli* being isolated most often. Approximately one-third are caused by multiple Gram-negative species e.g., *E. coli & P. aeruginosa* [18]. Occasionally bacterial and fungal, bacterial and viral, fungal and viral, or multiple fungal infections may coexist.

It is important to remember that neutropenia is often superimposed on other immunological defects such as impaired cellular or humoral immunity both as a result of the underlying malignancy and/or its treatment prior to transplantation. If such deficits are present in addition to neutropenia, the spectrum of infection widens considerably as these deficits are associated with their own unique set of pathogens.

Management of Febrile Neutropenia

The principles of managing episodes of febrile neutropenia have been developed and refined over several decades [10, 108–110]. Many societies including the Infectious Diseases Society of America (IDSA), the National Comprehensive Cancer Network (NCCN), the American Society of Clinical Oncology (ASCO), and the European Society of Medical Oncology (ESMO) have published evidence-based guidelines that provide current information regarding the management (including prevention) of these episodes [10, 11, 13, 111, 112]. All febrile neutropenic patients should undergo a quick but thorough initial evaluation and should receive prompt, broad-spectrum, empiric, antibiotic therapy based on current local epidemiologic and susceptibility/resistance patterns. Several options are available for initial empiric therapy including (1) monotherapy with a broad-spectrum antipseudomonal agent or (2) various combination regimens. Depending on the patients' risk group, such therapy may be administered in the hospital or in an outpatient setting and may be parenteral or oral. Close monitoring for response or progression of infection, the development of complications or drug-related adverse effects, and the development of superinfections is critical. Modification of the initial regimen may be required in up to 30% of patients depending on the risk group, nature and site of infection, and the development of a superinfection (including a suspected or documented fungal infection). Removal of infected catheters and other medical hardware may be necessary. Surgical intervention may be indicated in specific settings (e.g., perirectal infection/abscess). The overall duration of therapy depends on several factors such as the patients risk group, nature and site of infection, and resolution or persistence of neutropenia. These principles are discussed below.

Initial Evaluation

A detailed history should be taken including the nature and intensity of chemotherapy, prior antibiotic usage (prophylactic and therapeutic), use of corticosteroids or other immunosuppressive agents, recent surgical procedures including placement of medical hardware, allergies, and recent travel or potential exposure to sick contacts. A history of past infection and/or colonization with resistant organisms will also have an impact on the selection of an appropriate empiric antimicrobial regimen. A thorough physical examination is mandatory and often reveals important sites of infection including cutaneous lesions such as ecthyma gangrenosum, cellulitis, and perirectal infection/abscesses. The examination of catheter insertion sites, external auditory meatus, nares and nasal septum, and the oropharynx may also often reveal foci of infection. Additionally, it is important to remember that some neutropenic patients, especially those receiving corticosteroids, may be afebrile. Others may just feel unwell and may even hypothermic. Such patients may harbor serious infections such as Gram-negative septicemia.

Laboratory evaluation should include a complete blood count (CBC) with differential leucocyte count and platelet count, measurement of serum creatinine blood urea nitrogen (BUN) to assess renal function, and measurement of serum electrolytes, total bilirubin, and hepatic transaminase enzymes. At least two sets of blood cultures should be obtained (one from a peripheral vein and the other from a central venous catheter, if present). Each lumen of multilumen catheters should be cultured separately [113]. Culture specimens from other sites (urine, wounds, sputum if available) should be obtained as indicated. Chest radiographs are not recommended routinely but should be obtained in patients with respiratory symptoms or signs [114].

The initial evaluation of a febrile neutropenic patient should also include risk assessment as this guides the choice

of the empiric antibiotic regimen (combination vs monotherapy), the route of administration (parenteral vs oral), the setting in which therapy is administered (hospital vs outpatient), and the duration of therapy. The most commonly used risk assessment system in adults is the MASCC risk index [115]. High-risk patients have a MASCC risk score of <21 and should be admitted to the hospital for empiric therapy and close monitoring. Low-risk patients have a MASCC risk score of ≥21 and may be candidates for outpatient (oral or parenteral) therapy. Separate risk assessment tools are available for pediatric febrile neutropenic patients [116, 117].

Empiric Therapy

An algorithm for the management of febrile neutropenic patients is provided in Fig. 9.2. Once the initial evaluation and risk assessment have been completed, empiric antibiotic therapy should be administered without undue delay [10]. Low-risk patients can be treated with oral or parenteral regimens (Table 9.5). These can be administered during a short period of hospitalization followed by outpatient therapy or treatment of the entire episode in the outpatient setting. Most oral regimens are fluoroquinolone-based combinations although fluoroquinolone monotherapy has also been shown to be safe and effective [118, 119]. It is important to point out that hematopoietic cell transplant recipients (even those receiving non-myeloablative and/or autologous transplants) seldom fall into the low-risk category. Most hematopoietic transplant recipients with febrile neutropenia will either already be in the hospital or will require hospitalization for the administration of parenteral antibiotic therapy. Monotherapy with an antipseudomonal beta-lactam agent such as cefepime, a carbapenem such as meropenem or imipenem-cilastatin (but not ertapenem, as it is not active against *P. aeruginosa*), or piperacillin-tazobactam is recommended (Table 9.5). Other agents (aminoglycosides, fluoroquinolones, tigecycline, polymyxin-colistin, metronidazole) may be needed if antimicrobial resistance is suspected or documented or a specific pathogen such as an ESBL-producing or carbapenemase-producing Gram-negative bacillus or an anaerobe is isolated. The initial use of agents such as vancomycin, daptomycin, or linezolid is discouraged except when prior colonization or infection with a resistant Gram-positive organism (MRSA, VRE) has been documented or a catheter-related infection is strongly suspected [10, 120]. The empiric use of vancomycin has not been shown to reduce the overall mortality in patients with Gram-positive infections with the possible exception of infections caused by VGS. Additionally, one recent study has demonstrated that the empiric use of linezolid in febrile neu-

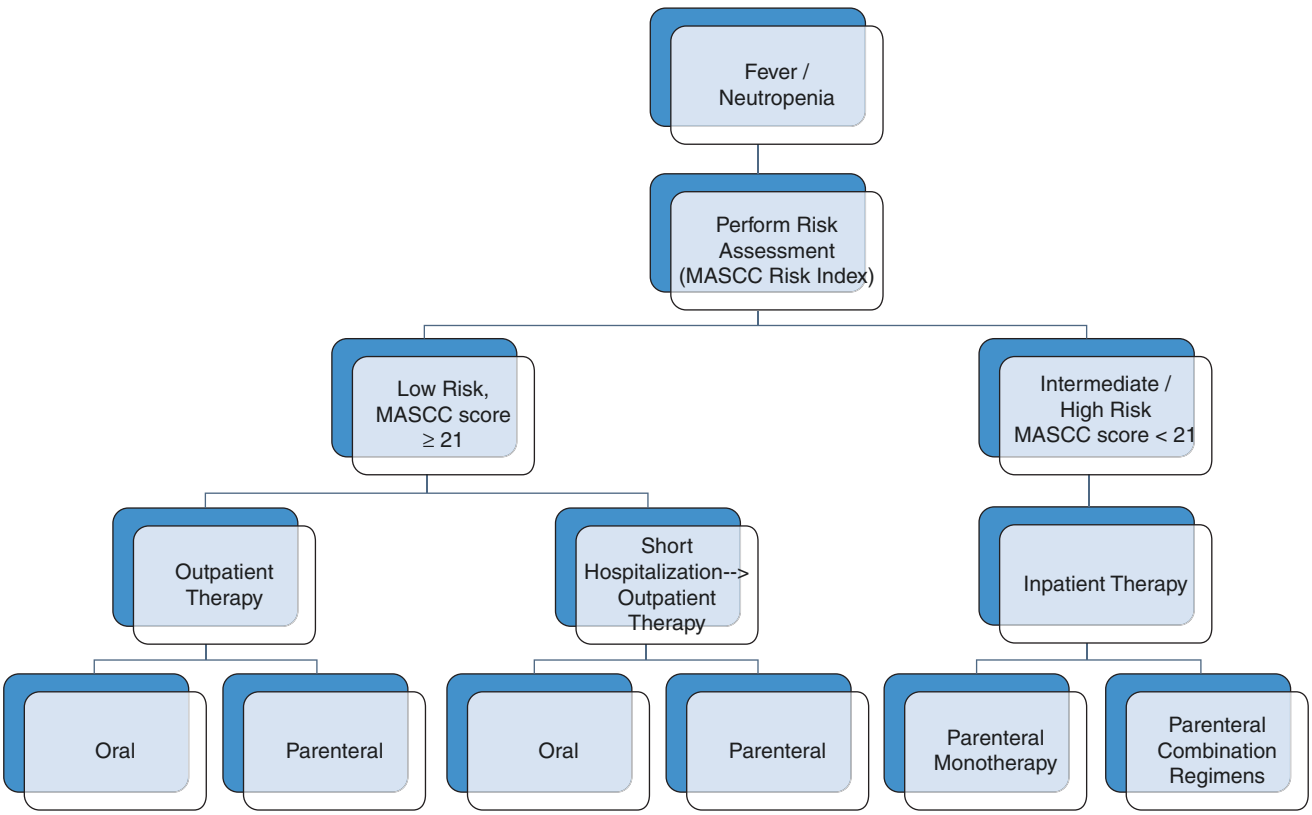

Fig. 9.2 Treatment algorithm for febrile neutropenic patients. Specific agents/regimens are listed in Table 9.5

Table 9.5 Common antibiotic regimens used in febrile neutropenic patients

Regimens in low-risk patients
Parenteral regimens
Ceftriaxone or Ertapenem +/− an aminoglycoside
Aztreonam plus clindamycin or azithromycin
Quinolone plus clindamycin or azithromycin
Cefepime
Oral regimens
Quinolone plus amoxicillin/clavulanate
Quinolone plus clindamycin or azithromycin
Quinolone monotherapy
Regimens in intermediate to high-risk patients
Monotherapy
Cefepime
Piperacillin/tazobactam
Carbapenem (meropenem or imipenem/cilastatin)
Combination therapy
Agents used for monotherapy + an aminoglycoside
Agents used for monotherapy + vancomycin[a]

[a]Alternative agents such as daptomycin and linezolid are being used with increasing frequency although clinical data are limited

Table 9.6 Strategies for Antimicrobial stewardship program

General strategies
Determine and monitor local epidemiology and resistance patterns
Develop multidisciplinary antimicrobial stewardship team (MAST)
Antimicrobial usage strategies
Limit antibacterial prophylaxis
Encourage targeted/specific therapy
Consider formulary restriction and/or pre-authorization
Create local guidelines and clinical pathways
Consider antimicrobial heterogeneity
Consider de-escalation (streamlining) of empiric regimen
Dose optimization
Parenteral to oral transition
Optimize duration of therapy
Other strategies
Prospective audits of antimicrobial usage with feedback to prescribers
Educational activities (grand rounds, in-services)
Strict adherence to infection control policies

Adapted from [123, 125–127]

tropenic patients colonized with VRE had no impact on mortality as well [121]. Concern has also been raised about the development of linezolid resistance, which has already been reported with increased usage of this agent [122]. Empiric antifungal coverage should be instituted if patients remain febrile after 4–7 days.

Duration of Therapy

The duration of therapy continues to be vigorously debated. In patients with episodes of unexplained fever, therapy is generally continued until marrow recovery (ANC >500 cells/mm^3 for 2 consecutive days). Some experts recommend discontinuation of therapy if the patient has defervesced, even though marrow recovery as defined above has not yet occurred. It is recommended to place these patients on their initial prophylactic regimen until neutropenia resolves. In patients with microbiologically or clinically documented infections, the duration of therapy usually depends on the site of infection (cellulitis or UTI requiring a shorter duration than bacteremia or pneumonia) and the organism isolated. In patients with CLABSI caused by *S. aureus*, *P. aeruginosa*, *Candida* spp. or other fungi, or mycobacteria, catheter removal in addition to appropriate antimicrobial therapy is recommended [43].

Therapy is generally continued until marrow recovery or longer if clinically indicated. The ultimate decision as to when to stop therapy often needs to be individualized and may depend on numerous factors such as the patient's risk group, the presence of a documented infection, and/or the persistence of neutropenia.

Infection Control and Antimicrobial Stewardship

Hand hygiene, cutaneous antisepsis, and maximum sterile barrier precautions are recommended for all procedures such as CVC insertions and bone marrow biopsies. Strict adherence to infection control practices and policies is essential in minimizing the spread of infections and controlling outbreaks, especially those caused by resistant organisms in the hospital and in other healthcare settings. Antimicrobial stewardship is essential especially since the frequent use of antimicrobial therapy in these high-risk patients creates selection pressures leading to the development of resistance. The various strategies for antimicrobial stewardship are listed in Table 9.6 and include a multidisciplinary antibiotic stewardship team (MAST), institutional pathways/guidelines, formulary restrictions or pre-approval requirements for certain agents, and de-escalation or streamlining of therapy when appropriate and feasible [123, 124]. Antimicrobial stewardship programs have been successfully instituted at several institutions [125–127]. Although currently the primary focus of these programs has been stewardship of antibacterial agents, it is anticipated that these programs will soon expand to include antifungal and antiviral agents as well.

Cytopenias in Transplant Patients

10

Maura Barry, Sunandana Chandra, and Kenneth B. Hymes

Anemia in Solid Organ Transplants

Anemia is commonly seen after solid organ transplant (SOT). It can result from a number of different etiologies including bleeding or hemorrhage, iron deficiency, hemolysis, drug related, lack of erythropoietin, marrow suppression, and congenital etiologies. The frequency and severity of anemia is dependent on the type of solid organ transplant and the duration of time that has passed since the transplant. Much of the data for the causes of anemia following SOT is from renal transplant and cardiac transplant populations. In these renal transplant patients, the prevalence of anemia is about 40% 1-year posttransplant. Severe anemia, defined as Hb <11 g/dL in males and 10 g/dL in females, is seen in 8.5% of patients 6–60 months post-kidney transplant [1]. Anemia to a hematocrit of less than 33% can persist for greater than 5 years in 25% patients and can result in worsened renal graft function and graft loss [2, 3]. Pre-transplant anemia often seen in dialysis can often improve posttransplant, but then may recur if there is graft failure. About 40% of cardiac transplant patients also experience posttransplant anemia [4]. Pre-transplant anemia that is seen in 25% of this population negatively affects 1-year survival posttransplant [5].

Hemolysis

Mismatched ABO solid organ transplantation is often employed due to the shortage of transplantable organs. Three different groups of ABO incompatibility can be found in transplantation: minor, major, and bidirectional. Complications arising from minor ABO-mismatched solid organ transplants include the passenger lymphocyte syndrome (PLS) [6]. Recipients of minor ABO-incompatible transplantation express ABO antigens that are not expressed in the donor and may result in a graft-versus-host (GvH) reaction, including delayed hemolysis of recipient red blood cells [7]. Passenger lymphocyte syndrome occurs when antibodies that are produced by the donor B-lymphocytes result in a primary or secondary immune response against the recipient's ABO and Rh antigens. The severity of hemolysis depends on the level of red cell isoagglutinins in the donor tissue that are passively transferred with the organ and the subsequent rise in antibodies in the transplant recipient that occurs 1–3 weeks posttransplant and usually resolves within 3 months posttransplant [7]. In rare instances, PLS can occur due to non-ABO/Rh antibodies if the organ had been previously sensitized to other red cell antigens in the setting of pregnancy or transfusion [8–11]. PLS occurs more frequently in the heart and lung transplants and less frequently in liver and kidney transplants [7].

Drugs

There are numerous drugs that are often used in the solid organ transplant setting that can cause myelosuppression, including anemia, through a variety of pathophysiologic mechanisms. A number of immunosuppressants with various pharmacologic mechanisms of action are used to prolong graft and recipient survival. The immunosuppressants mycophenolate mofetil and tacrolimus have been shown to cause anemia in renal transplant recipients [12]. One-year posttransplant, renal transplant patients with anemia who are on

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_10

mycophenolate mofetil have a lower rates of survival and higher rates of cardiovascular death [13]. Sirolimus, another immunosuppressant, may result in greater myelosuppression compared to mycophenolate mofetil [14]. Sirolimus and calcineurin inhibitors such as tacrolimus and cyclosporine have been shown in renal and lung transplant recipients to cause hemolytic anemia, thrombotic thrombocytopenic purpura, and atypical hemolytic uremic syndrome [15–17]. The calcineurin inhibitors have been shown to cause anemia ranging from 1% to 5% in European trials to 38–47% in US trial [18]. The antimetabolite azathioprine, a purine-analog drug, can also cause cytopenias. Mycophenolate mofetil, tacrolimus, azathioprine, and anti-thymocyte globulin have all shown to cause pure red cell aplasia [19, 20].

Primaquine and dapsone are used for PCP treatment, and both can result in hemolysis in glucose-6-phosphate-dehydrogenase-deficient patients, which is not restricted to solid organ transplant settings. In patients with low body weight or renal failure, dapsone may induce a hemolytic anemia and produce methemoglobinemia even if the G6PD levels are normal [21–23].

Ribavirin and interferon can cause bone marrow suppression in liver transplant recipients who are being treated with recurrent hepatitis C virus [24]. Ribavirin is used in treating respiratory syncytial virus after transplant in both the oral and inhaled formulations, both of which can cause bone marrow suppression [25]. In patients who are co-infected with human deficiency virus (HIV) and hepatitis C virus, myelosuppression can be seen with the anti-retroviral medication, AZT, and the anemia can be exacerbated with the co-administration of ribavirin. The antibiotic trimethoprim-sulfamethoxazole can also cause myelosuppression including anemia. Valganciclovir has been reported to cause bone marrow failure in renal transplant patients who received this antiviral as prophylaxis [26].

Newer immunosuppressants have been developed which allow for the sparing of steroids and calcineurin inhibitors, the latter of which can cause chronic nephropathy. These newer agents include alemtuzumab, a human anti-CD52 antibody that depletes T- and B-cells, daclizumab, a human anti-CD25 antibody that targets the IL-2 alpha subunit, and anti-thymocyte globulin (ATG). Alemtuzumab has been reported to be associated with red cell aplasia, autoimmune hemolytic anemia, and idiopathic thrombocytopenia purpura in pancreas transplant patients [27].

Iron Deficiency

Iron deficiency is often overlooked in transplant patients. In renal transplant patients, those with a hematocrit of less than 30% have iron studies checked only 40% of the time [28]. Perioperative bleeding and frequent phlebotomies for laboratory studies can contribute to iron deficiency anemia. Anemia of chronic disease is also frequently seen in the transplant population due to chronic inflammation, abnormal erythropoietin production due to allograft nephropathy after renal transplant. Drugs such as ACE inhibitors that are often used in chronic kidney disease are also associated post-kidney transplant anemia [1].

Infections

Numerous infectious etiologies that can occur during the posttransplant immunosuppressed period have been shown to cause myelosuppression including anemia. Parvovirus B19, a single-stranded DNA virus, has been known to cause red cell aplasia with anemia, reticulocytopenia, and erythroid maturation arrest [29]. Elevated parvoviral B19 titers have been found by PCR in lung transplant recipients who had anemia with other etiologies that were ruled out [30–32]. Cytomegalovirus (CMV) infection as well as its first-line therapies, ganciclovir and valganciclovir, can be associated with bone marrow suppression. Also tuberculosis, histoplasmosis, Epstein-Barr virus (EBV), human herpes virus-6, and human herpes virus-8 infections can be associated with bone marrow suppression and pancytopenia [33]. Posttransplant lymphoproliferative disorder that can be seen with immunosuppressive therapy can also be associated with pancytopenia.

Posttransplant Lymphoproliferative Disorder

Posttransplant lymphoproliferative disorder (PTLD) which includes the spectrum of infectious mononucleosis, EBV-driven polyclonal lymphocyte proliferation, and non-Hodgkin's lymphoma can be seen with solid organ transplantation [29]. PTLD is due to the impaired EBV-specific cytotoxic T-cell activity that allows for recipient B cells that have latent EBV infection to expand. PTLD can result in bone marrow infiltration and pancytopenia, as well as cause autoimmune hemolytic anemia. The severity of PTLD depends on the level of immunosuppression and usually occurs within the 1st year after transplant.

Graft-Versus-Host Disease

Graft-versus-host disease (GVHD) is rarely seen after SOT and is due to the engraftment and proliferation of allograft-associated lymphocytes in the immunosuppressed transplant recipient causing an immune-mediated response toward HLA-unmatched host tissue. Risk factors for the development of GVHD includes the volume of lymphoid

tissue that is transplanted and therefore is seen more with small bowel and liver transplants, in those over 65 years of age and with HLA mismatch between donor and recipient [34, 35]. GVHD, in contrast to the development of PTLD, occurs early after SOT, on the order of weeks to months depending on the type of solid organ transplant. The clinical presentation usually includes fever, rash, diarrhea, and cytopenias, and diagnosis is made by histologic confirmation of affected tissue.

Hemophagocytic Syndrome

Hemophagocytic syndrome is a systemic inflammatory disease that can include the symptoms of fever, hepatosplenomegaly, lymphadenopathy, pancytopenia, rash, jaundice, cough, dyspnea, cachexia, and neurologic dysfunction and can often occur in response to a precipitant, such as infection [29]. This syndrome is a result of aberrant immune response of abnormal T-cell activation leading to hemophagocytosis by activated, nonmalignant macrophages that secrete numerous cytokines including interleukin (IL)-1, IL-6, IL-12, and tumor necrosis factor-alpha in the bone marrow, liver, lymph nodes, and spleen, resulting in a "cytokine storm" [29]. Acquired hemophagocytic syndrome has been documented in the renal, liver, heart, and pancreas-kidney solid organ transplants. There have been cases of hemophagocytic syndrome due to disseminated histoplasmosis in renal transplant recipients which were diagnosed by bone marrow biopsy [36].

Leukopenia in Solid Organ Transplants

Leukopenia can be defined as having a white blood cell (WBC) count of less than 3000–4000 cells/μL, with neutropenia defined as an absolute neutrophil count (ANC) <500/mm^3 by the Infectious Diseases Society of America [37]. Leukopenia is commonly seen after solid organ transplantation and can be caused by noninfectious and infectious etiologies. It can signal an underlying infection or disease process, such as posttransplant lymphoproliferative disorder (PTLD). It also increases the risk of developing further complications such as opportunistic infection and can require reduction of immunosuppression, increasing the risk of graft rejection. While there is no data to suggest a clear independent relationship between leukopenia and graft rejection, the complications of leukopenia mentioned above provide ample reason to investigate the etiology of the decreased white cell count. Solid organ transplant recipients are at risk for developing infections due to their medically induced immunodeficiency following transplant, required to prevent rejection of the transplanted organ.

Noninfectious Etiologies

Noninfectious causes of leukopenia include drugs that are often used in transplant settings. Numerous immunosuppressants can cause leukopenia, but given their use in combination, it is difficult to elucidate each agent's individual role in incidence and management. In one retrospective study of adult kidney and pancreas transplantations, the incidence of either leukopenia or neutropenia was 58%, with the first episode occurring at a mean of 91 days posttransplant [38].

One of the most common immunosuppressants, azathioprine, is a purine analog that causes an antimetabolite effect. Azathioprine may result in leukopenia in a dose-dependent manner, as well as based on the duration of treatment. The leukopenia that results from azathioprine is usually reversible upon dose-reduction or drug discontinuation. The leukopenia, often occurring late in the course of therapy, can be related to low or absent levels of S-methyl-transferase (TPMT) activity, which metabolizes 6-mercaptopurine, and can result in increased myelotoxicity [39].

Drugs that result in the depletion of T cells, such as thymoglobulin and alemtuzumab, can also lead to leukopenia in 10–14% of patients [40]. The immunosuppressant, mycophenolate mofetil (MMF), reversibly and noncompetitively inhibits the enzyme, inosine monophosphate dehydrogenase, the rate-limiting enzyme for de novo purine synthesis during lymphocyte proliferation [29]. MMF can result in leukopenia in 13–35% of patients. The myelosuppression of MMF is dose-dependent and is related to the trough level of the active metabolite, mycophenolic acid; however, brief discontinuations of the drug can lead to organ rejection, especially in the era of steroid-sparing regimens [41, 42]. The calcineurin inhibitors such as cyclosporine, tacrolimus, and sirolimus can also lead to cytopenias, including leukopenia.

Infections

Some of these agents can cause leukopenia as one of many symptoms of infection. For example, leukopenia (and often thrombocytopenia as well) have been observed as a sign/symptoms of infection with pathogens such as adenovirus, coronavirus, lymphocytic choriomeningitis virus (LCMV), parainfluenza, ehrlichiosis, and measles [43–45]. In areas endemic for the disease, dengue infection also causes both leukopenia and thrombocytopenia in patients after solid organ transplant [46]. Fungal infections such as histoplasmosis can cause disseminated organ infiltration, with the bone marrow being a common area of involvement, resulting in decreased hematopoiesis and cytopenias [33]. Parvovirus B19, much better known for its role in causing both acute and chronic anemia in solid organ transplants, is also reported to cause acute and chronic leukopenia in approximately 37.5% of solid

organ as well as hematopoietic stem cell transplant recipients who develop the infection [32, 47]. An acute infection with HHV-8 can present with fever, splenomegaly, and leukopenia (as part of a pancytopenia), with bone marrow biopsy revealing hypocellularity, plasma cell infiltration, and evidence of viral infection by immunohistochemical staining [33].

A retrospective analysis of liver and kidney transplant recipients was performed to assess the relationship between leukopenia and positive hepatitis B and C serologies. The investigators found that there was no significant correlation between leukopenia and hepatitis C infection, but that the incidence of leukopenia in those with active hepatitis B infection was 7.4%. They posited that, similar to other viruses, infection with hepatitis B virus could lead to "decreased or ineffective leukocyte production in the bone marrow…shifts of cells from the circulation to the marginal blood pools… [and] also produce peripheral destruction of white blood cells due to immune and nonimmune processes" [48].

Cytomegalovirus infection is the most well-known transplant-related infection to cause cytopenias, with leukopenia found in approximately 20% of infected transplant recipients and with most of the data and research conducted in kidney transplant populations [49]. Infection with CMV has direct effects on the bone marrow, inhibiting hematopoiesis by affecting both the bone marrow stroma and the stem cells and hematopoietic precursors [33, 50]. CMV disease (acute symptomatic infection) is most often seen in the first 6 months, particularly during the first 3 months posttransplant, and presents with constitutional complaints such as fever, abdominal pain, diarrhea, and respiratory symptoms along with cytopenias [33, 49, 51]. However, in heart transplant patients, a subclinical infection during the 1st year where infected individuals are asymptomatic has also been associated with leukopenia, with the most significant reductions occurring in the neutrophil and monocyte populations and preservation of the lymphocyte counts [52].

An added challenge when addressing CMV infection and leukopenia results from the frequent finding that the treatments for the disease can result in further leukopenia (discussed in "Noninfectious Etiologies of Leukopenia" section).

Additional diagnoses to consider when assessing the etiologies of leukopenia, as well as pancytopenia, with regard to infection are hemophagocytic syndrome (HPS) which is associated with CMV, EBV, HHV-6, HHV-8, and histoplasmosis, as well as EBV-associated PTLD [29, 33].

Thrombocytopenia and Solid Organ Transplant

As in all cases of thrombocytopenia, when evaluating a finding of low platelets in a patient after SOT, it must be determined whether the primary problem is one of impaired production in the bone marrow or if it is a matter of consumption or sequestration outside the marrow. Infections and drugs are known to suppress megakaryocyte production in the marrow, such as cytomegalovirus and trimethoprim-sulfamethoxazole (TMP-SMX). Additionally, both infections and medications as well as auto- and alloimmune processes can lead to destruction of platelets despite adequate production of megakaryocytes in the bone marrow.

Infectious Etiologies of Thrombocytopenia

Solid organ transplant recipients are at risk for developing infections due to their immunosuppression, and viral infections in particular are a potential contributor to the development of thrombocytopenia following solid organ transplant. Detailed discussions of these infections are found in other chapters of this book, but their involvement in thrombocytopenia is discussed below. In addition to the viral infections that contribute to thrombocytopenia, it is important to remember that thrombocytopenia can be a sign of bacterial infection and sepsis most often in the context of disseminated intravascular coagulation (DIC). Appropriate workup to rule out infection is among the first steps in examining thrombocytopenia in a solid organ recipient.

Cytomegalovirus

The virus of particular concern in regard to platelet count in transplant patients specifically is cytomegalovirus, though thrombocytopenia due to other viruses has also been described, often among a constellation of systemic symptoms.

Cytomegalovirus can cause thrombocytopenia both by decreasing production of and through destruction of platelets. Studies have shown that CMV can impair megakaryocyte production in its early stages by infection of stromal cells, which interferes with growth factor production, as well as by directly infecting myeloid cells [50], similar to CMV-related leukopenia.

The other reported etiology of thrombocytopenia from CMV is due to intravascular destruction of platelets by CMV-associated thrombotic microangiopathy (TMA), with a clinical picture resembling that of thrombotic thrombocytopenic purpura (TTP)/atypical hemolytic uremic syndrome (aHUS), consisting of varying degrees of Coombs-negative hemolytic anemia, thrombocytopenia, acute kidney injury, fever, and neurological findings. While this etiology is more often identified as a drug-related phenomenon, particularly due to the immunosuppressants required to prevent organ rejection (see next section), there have been multiple case reports associating CMV infection as a trigger of TMA in the posttransplant setting [53, 54]. This has been noted with particular frequency in the renal transplant literature, where

both de novo and recurrent forms of aHUS were associated with CMV infection in renal transplant recipients. However, particularly in the patients with "de novo" disease, it is possible that CMV may be directly driving the thrombotic microangiopathy, rather than solely by the complement-mediated events of aHUS. Mechanisms thought to be underlying CMV's endothelial effects include activation of CMV-specific cytotoxic immune responses and induction of primitive endothelial dysfunction as well as direct infection of endothelial cells by CMV [55, 56].

However, some investigators question how significant a contributor CMV actually is to thrombotic microangiopathy in transplant patients. In a review of TMA among lung transplant recipients by Hachem and colleagues, an analysis of 24 patients who were diagnosed with TMA following lung transplantation revealed that only 4 patients had evidence of CMV infection, and additionally that there were 229 incidences of CMV viremia among the 237 lung transplant patients who did not develop TMA. Additionally, in their univariate and multivariate analyses, neither CMV viremia nor serologic status was identified as a risk factor for TMA in the study population [57].

Epstein-Barr Virus

Infection with Epstein-Barr virus often results in conditions associated with pancytopenia, such as PTLD and hemophagocytic syndrome, both of which are described in greater detail in previous sections of this chapter (see "Leukopenia and Anemia" sections). EBV should be considered as a possible infectious etiology during the workup of thrombocytopenia, particularly if other systemic signs or symptoms are present.

Other Infectious Etiologies

Other infectious etiologies that have thrombocytopenia among the constellation of presenting symptoms that have been described in organ transplant recipients include coronavirus, particularly SARS, lymphocytic choriomeningitis virus (LCMV), and HHV-6, though the thrombocytopenia is unlikely to be the primary issue at presentation [58]. Parvovirus B-19 and polyoma BK virus infection have also been associated with development of aHUS [55, 59].

It is also important to note that chronic infection with hepatitis C can be an etiology for thrombocytopenia both in and outside the context of solid organ transplantation. The etiology of thrombocytopenia in the setting of hepatitis C infection can be due to hepatocellular damage including fibrosis and/or cirrhosis affecting thrombopoietin (TPO) production, hypersplenism due to portal hypertension, bone marrow suppression, immune dysfunction, and development of platelet autoantibodies [60]. Additionally, treatment for hepatitis C with interferon is known to cause thrombocytopenia.

Noninfectious Etiologies of Thrombocytopenia

There are numerous noninfectious etiologies of thrombocytopenia that have been identified in SOT patients. Many pharmacologic agents have been implicated in the development of thrombocytopenia following SOT through varying mechanisms, such as TMA, decreased megakaryocyte production, and auto- and allo-immune mechanisms of platelet destruction.

Pharmacologic Agents

Calcineurin Inhibitors

The drugs most strongly associated with decreased platelet counts due to thrombotic microangiopathy are the calcineurin inhibitors (CI) cyclosporine and tacrolimus. Calcineurin inhibitor induced TMA often occurs within weeks following SOT, and the CIs are thought to cause direct endothelial injury and platelet aggregation, although the specific mechanism has not been identified. When this is identified, numerous case studies in multiple different organ systems (lung, liver, kidney solid organ transplant) have reported that changing from one CI to another (tacrolimus to cyclosporine or vice versa) or to another class of medication such as sirolimus or mycophenolate mofetil can prevent further episodes of TMA from occurring [61–64]. However, the addition of the mTOR inhibitor sirolimus to a calcineurin inhibitor also increases the chance of developing TMA [57, 65].

Antivirals and Antibiotics

Ganciclovir and valganciclovir are used in prophylaxis and treatment of CMV. Both are known to have myelosuppressive effects, particularly on granulocytes and platelets, but generally there is rapid recovery of counts following withdrawal of the medication.

One of linezolid's most well-known adverse effects is thrombocytopenia, with the package insert reporting a rate of 3% in adults. Other studies have reported rates of grades III–IV thrombocytopenia of approximately 5.2% [66]. No mechanism has been identified for linezolid-related thrombocytopenia, though some evidence suggests that it is an immune-mediated phenomenon [67]. The medication is frequently used in the treatment of vancomycin-resistant enterococcus (VRE), which has been an infection seen in transplant patients, as well as non-transplant patients, with increasing frequency. A multicenter compassionate use trial published in 2003 showed that it was an effective drug in treating VRE, which was identified as having a mortality rate of up to 83%, with the authors reporting a 62% survival rate after treatment with linezolid. Thrombocytopenia was the main adverse effect of treatment, seen in 4.7%, but did not necessitate the cessation of therapy [68]. A second study in liver transplant patients treated with linezolid for VRE infec-

tion showed a similar treatment efficacy and again reported no cases (0/46 patients) requiring cessation of therapy due to severe thrombocytopenia, and furthermore found no correlation between treatment duration and platelet counts [69] though other articles advise caution when using linezolid for extended time periods [70]. Thus, while it may or may not require any intervention or change in treatment plan, it should be considered as part of the differential diagnosis when assessing thrombocytopenia.

Heparin

Heparin-induced thrombocytopenia is an additional drug-related event that can occur in the setting of solid organ transplant. Assessment of this as a possible etiology for thrombocytopenia follows the same algorithm as it would for any patient receiving heparin. The probability of the thrombocytopenia being related to heparin use would be based on the 4Ts whether the timing (>10 days following start of heparin use or sooner if heparin was used previously), degree of fall (>50% decrease from baseline), presence of thrombosis, and lack of alternate explanations for the thrombocytopenia suggest that heparin could be the causative agent [71]. Studies reveal that HIT is an uncommon occurrence in liver transplant recipients, and that thrombotic events and HIT antibody positivity were not well correlated [72, 73]. Case studies in renal transplant patients have reported some incidences of HIT posttransplant and graft-failure related to HIT, in part related to previous exposure to heparin in hemodialysis [74, 75].

HIT antibody immunoassays are often sent if a patient develops thrombocytopenia and has received heparin at any time during the hospitalization. However, the high sensitivity but low specificity of the test results in overdiagnosis of heparin-induced thrombocytopenia exposes patients to unnecessary risks associated with therapeutic anticoagulation. Chaturvedi and colleagues examined this phenomenon at Cleveland Clinic and found that utilizing the 4Ts algorithm to first rule out patients at low risk for HIT was a safe, reliable, and cost-effective [76]. Therefore, we recommend that immunoassays for HIT antibodies be utilized only in those patients whose 4T scores suggest intermediate or high probability of heparin-induced thrombocytopenia.

If a HIT antibody immunoassay is sent once a patient is determined to be of intermediate/high risk for HIT, it is important to understand how this test is interpreted. The immunoassay detects the presence of antiplatelet factor 4 (PF4) antibodies in patient serum and is interpreted by optical density (OD). A higher reported OD correlates to a higher titer of the antibody and is more strongly suggestive of a diagnosis of HIT. As mentioned previously, ELISAs for HIT have a high sensitivity (meaning a negative test can rule out the diagnosis) but a low specificity, underscoring the need to first confirm a high pretest probability.

Immune Etiologies

Immune Thrombocytopenic Purpura

Immune thrombocytopenic purpura (ITP) is characterized by very low platelet counts, petechiae and bruising, as well as mucosal bleeding, due to opsonization of platelets in the circulation. Occurrence of ITP following solid organ transplant has been documented particularly in the liver transplant literature, with the cases attributed to either autoimmune ITP, at times precipitated by an identified infectious etiology such as tuberculosis [77] or alloimmune etiologies. The literature reports that chronic renal disease and renal transplant in patients with ITP are noted to be very rare [78], and thus most of our knowledge of ITP as an etiology following transplant is from the liver transplant literature.

One study reported a case series of eight patients who developed ITP following orthotopic liver transplantation (OLT), with a mean time of presentation of ITP since OLT of 5.4 years [79]. These cases were all felt to be autoimmune cases, as there was no history of ITP in the donors. This case series also presented a review of the previous literature on ITP after OLT, and they noted two distinct time patterns of ITP presentation, early (within 3 months) or late (>3 months). The authors note that it has been proposed that the early-onset presentation may be due to passive transfer of antibodies from the donor to the recipient. Those that developed late-onset ITP were felt to have developed the antibodies independently of their donors [79].

Additionally, studies have reported on development of alloimmune thrombocytopenic purpura, with antibodies introduced from donors with a history of ITP [79, 80]. One case study described a case where a donor liver was obtained from a donor who had died after a cerebral hemorrhage secondary to ITP. The recipient developed ITP within 3 days of transplant and subsequently expired after developing portal vein thrombosis. The authors attributed the death to ITP in that they were unable to anticoagulate but were providing blood products that may have resulted in increased likelihood of thrombosis. It is also possible, however, that the donor was producing procoagulant antibodies, as approximately 20–25% of patients with ITP also have antiphospholipid antibodies [81, 82]. Based on this event, the authors recommended excluding cadaveric transplants from donors whose death is attributed to ITP [80].

Other Etiologies

Particularly in liver transplant patients, thrombocytopenia is often seen prior to transplant, and generally approximately 50% of transplant recipients develop worsening thrombocytopenia within 2 weeks following transplant. This acute decrease generally resolves within the 1st month after trans-

plant, and if thrombocytopenia persists, another etiology should be sought [79, 83, 84]. Thrombocytopenia following liver transplant can also be attributed to residual portal hypertension or hypersplenism, if either of these conditions persist following transplant. However, it is important to remain vigilant to other causes particularly drug-related and infectious etiologies that could cause a drop in the platelet count.

Additionally, while case reports exist of TMA with low ADAMTS13 levels attributed to inhibitors present in the blood [85], this is not a common phenomenon, and etiologies of TMA mentioned previously (infectious and drug-related) would be much more likely.

Treatment

In most cases, treatment of the underlying etiology of the thrombocytopenia will result in improvement in platelet counts. That may require antivirals, adjustment of the immunosuppressant regimen, withdrawal of other pharmacologic agents such as heparin, or supportive care. Platelet transfusions may be necessary if bleeding events occur or if additional procedures are necessary, but we do not recommend prophylactic transfusions for maintenance of the platelet count above a specific threshold.

TPO receptor agonists, romiplostim and eltrombopag, have been used in management of chronic thrombocytopenia due to ITP and liver disease and are being studied as a supportive medication in stem cell transplantation [86]. There is a case report in the pediatric transplant literature where romiplostim was used in the peri-transplant setting, which resulted in a platelet-transfusion-free liver transplant [87]. However at this time, there is no data to support use of TPO agonists outside of their approved indications following solid organ transplant.

Infections in Allogeneic Stem Cell Transplantation

11

Marcus R. Pereira, Stephanie M. Pouch, and Brian Scully

Introduction

Allogeneic hematopoietic stem cell transplantation (allo-HSCT) has become a widely used modality of therapy for a variety of malignant and nonmalignant diseases. While many advances have been made in the field, infection remains one of the most severe and frequently encountered complications of HSCT. In this chapter we review the defects in host defenses and important risk factors predisposing allo-HSCT recipients to infection, the major categories of infection and their time courses following transplantation, and preventive strategies.

Risk Factors for Infection Following Allo-HSCT

The severity of defects in host defenses and the subsequent risk of infection are influenced by a complex interaction between several factors. Particularly salient are (1) the underlying illness of the patient, (2) the conditioning regimen, (3) the graft and the closeness of the match, (4) the type of transplant, and (5) the presence of graft-versus-host disease (GVHD). Immediate local and remote epidemiological factors are also important. The timing of impaired host defenses and infectious risk in allo-HSCT recipients are outlined in Fig. 11.1.

Underlying Host Disease

Infection risk is very much impacted by the disease for which the patient is being transplanted and also by the presence of preceding infections. Acute leukemia, for example, predisposes to neutropenia and other defects of innate immunity. Profound neutropenia (<500 cells/mm^3) of greater than 10-day duration is considered a strong risk factor for bacterial and invasive fungal infection [1]. In addition to neutropenia, other factors that increase risk for invasive aspergillosis include advanced or refractory acute myelogenous leukemia, high-risk myelodysplastic syndrome, chronic neutropenia prior to chemotherapy, iron overload secondary to repeated peripheral blood transfusions, and prior fungal infection [2–6]. Further, antileukemic agents have been shown to diminish antibody response to primary antigens, thereby increasing susceptibility to bacterial pathogens even in the absence of neutropenia [7]. Other underlying diseases such as primary immunodeficiency, for example, may predispose to progression or reactivation of antecedent infections, and individuals with myelodysplastic syndrome who are neutropenic at the time of transplant are at an increased risk of infection and mortality. In addition to innate immune defects, increasing age, waning cellular immunity, organ dysfunction, fragile skin, and prior antibiotic exposure may all contribute to the progression of preexisting infection, including aspergillosis, as well as to the risk for new infections during the posttransplant period [8–11].

The presence of infection immediately preceding allo-HSCT also impacts infectious risk during the posttransplant period. In individuals scheduled to undergo allo-HSCT, active infections should be treated prior to transplantation whenever possible. The timing of allo-HSCT following the initiation of antibiotics for active infection should be made on a case by case basis by an experienced practitioner.

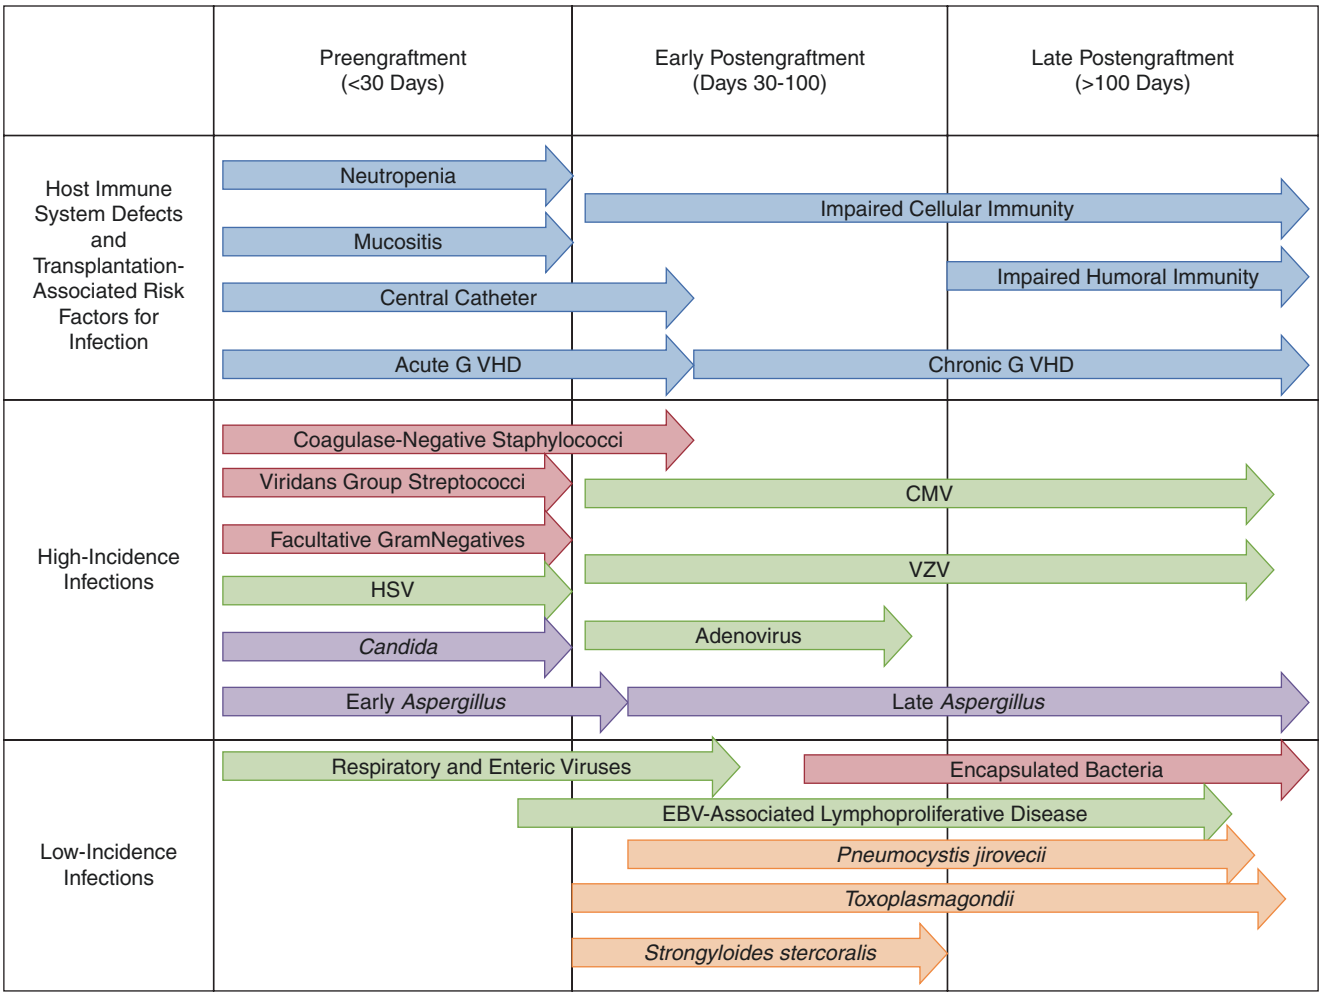

Fig. 11.1 Timeline of host immune defects and infections in Allo-HSCT recipients. Predictable opportunistic infections encountered following allo-HSCT. Immune defects and transplant-associated risk factors are shaded in blue, bacterial infections in pink, viral infections in green, fungal infections in purple, and parasitic infections in orange

The Conditioning Regimen

Prior to transplantation, the prospective recipient must be conditioned so as to allow engraftment of the transplant. The goals of conditioning are twofold: (1) to suppress the recipient's immune system, particularly the T-cell arm, in order to prevent rejection of the graft, and (2) to eliminate the tumor. Many regimens are myeloablative, employing total body irradiation and cytotoxic chemotherapy, with resultant profound and prolonged neutropenia, mucositis, and potential organ toxicities. Recipients of such conditioning are highly susceptible to early infection and sepsis. Less intense regimens increasingly used in some of the more vulnerable older patients may result in minimal neutropenia and mucositis and a correspondingly lower risk of infection [12]. However, recipients of reduced-intensity conditioning regimens may experience prolonged neutropenia should engraftment fail.

The Graft

The closeness of the human leukocyte antigen (HLA) match dictates the likelihood and severity of GVHD as well as the intensity of the immunosuppressive regimen. The various degrees of match include the following: the donor may be an HLA-matched sibling or twin, HLA-matched but unrelated, haploidentical such that donor and recipient share one complete haplotype, or partially matched. The latter two categories often necessitate more intense immunosuppressive regimens to prevent GVHD.

The source of the stem cells also impacts the risk of infection. Bone marrow transplant recipients have more prolonged periods of neutropenia and a higher risk for early infection, but lower risk of GVHD than peripheral stem cells mobilized by granulocyte colony-stimulating factor [13, 14]. Cord blood cells, in contrast, are typically obtained from unrelated donors and confer a much lower

stem cell dose than in the other transplants. Cord blood stem cell transplant recipients have delayed engraftment, such that neutropenia may extend for 6 weeks or longer and T-cell immune dysfunction may persist for months to years [15].

Graft-Versus-Host Disease

GVHD occurs when donor T-cells attack the recipient's tissues as a consequence of either T-cell ablation of the graft prior to transplant or by the administration of immunosuppressive drugs after transplantation. When unmanipulated bone marrow or peripheral stem cells are used, $24–300 \times 10^6$/kg CD3 cells are administered. Ex vivo pretreatment of the graft may produce up to a 3-log reduction in cells transplanted and decrease the potential risk and severity of GVHD. However, there is a resultant prolonged T-cell immunodeficiency, and the patient must then walk an immunological-infection tightrope for many months. If an untreated graft is transplanted, then any one of a variety of immunosuppressive regimens may be given. Examples are sirolimus and a calcineurin inhibitor, such as tacrolimus. It appears that these regimens pose a lower infection risk than pretransplant T-cell ablation [16]. Sirolimus therapy has also been associated with a reduced risk of cytomegalovirus (CMV) infection [17, 18].

GVHD is classified as acute when the onset is prior to posttransplant day 100 and chronic when the onset is after day 100. Acute disease may persist into the chronic period, in which case it is termed progressive. While GVHD may respond to treatment and go into remission, it may also reactivate at a later date.

Acute disease, characterized by secretory diarrhea, hepatitis, and skin rash, is categorized according to severity with grades 3 and 4 posing an increased risk of mortality. Corticosteroids are the mainstay of therapy. The intense immunosuppression associated with the condition itself and enhanced by its treatment, combined with disrupted barrier defenses, especially in the intestine, place patients at great risk of infection. CMV infection is common as are other viral, bacterial, and fungal infections such as aspergillosis [19].

In chronic GVHD, humoral defects and functional hyposplenism markedly suppress cellular immunity. Severe pneumococcal, disseminated fungal, and CMV infections are frequently seen in this context [20, 21]. Infections are even more problematic when steroid-refractory disease necessitates the use of potent immunosuppressive regimens such as cyclophosphamide, alemtuzumab, or anti-thymocyte globulin. In this situation, human herpesvirus-6 (HHV6), adenovirus, disseminated fungal and nocardial infections, as well as posttransplant lymphoproliferative disease (PTLD) may occur [22].

Timing of Opportunistic Infections in Allo-HSCT Recipients

Three periods of immunodeficiency occur following hematopoietic stem cell transplantation: pre-engraftment (days 0–30), early post-engraftment (days 30–100), and late post-engraftment (until day 100). The immune suppression that takes place during each of the periods conveys a particular risk for infection and drives the use of standard prophylaxis following transplantation (Figs. 11.1) [23, 24].

Pre-engraftment

The pre-engraftment period is associated with three major risk factors for infection: (1) prolonged neutropenia, (2) disruption of the mucosal barrier related to preparative chemotherapeutic regimens, and (3) the presence and frequent utilization of central venous access [24, 25]. The combined effect of neutropenia and mucositis contributes to high risk of reactivation of HSV in seropositive patients, prompting standard use of acyclovir during this period [26, 27]. These factors also predispose to candidemia and early-onset aspergillosis [24]. While prophylactic antifungals are used in the pre-engraftment period, fluconazole prophylaxis has been linked to an increased risk of non-albicans candidal infections, particularly due to *C. glabrata* and *C. krusei* [28–30]. Voriconazole prophylaxis has also been associated with an increased risk of zygomycosis in this setting [31–34]. Additionally, mechanical disruption of the skin and the use of prophylactic antibiotics targeted toward gut flora increase the risk for bloodstream infections with Gram-positive flora, particularly viridians group streptococci and coagulase-negative staphylococci [25, 35].

Early Post-engraftment

The early post-engraftment period extends from the time of neutrophil recovery (approximately day 30 posttransplantation) until day 100 and is notable for B- and T-lymphocyte dysfunction. In the setting of allo-HSCT recipients, the impact of this immunodeficiency is further mediated by GVHD and CMV infection, as well as their treatments. Such cell-mediated immune dysfunction contributes to increased risk for viral infections, including CMV, adenovirus, varicella zoster virus (VZV), and Epstein-Barr virus (EBV)-related PTLD, as well as late-onset aspergillosis and *Pneumocystis jirovecii* [24].

Late Post-engraftment

The late post-engraftment period extends from day 100 until normal immune function is regained. While immune func-

tion generally returns within 18–36 months of transplant, the duration of the late post-engraftment period may be extended in allo-HSCT recipients owing to chronic GVHD and its management. During this time, ongoing humeral and cell-mediated immune dysfunction contributes to the risk for infections with VZV, CMV, late-onset aspergillosis, and infections with encapsulated bacteria [24, 36, 37].

Bacterial Infections

The microbiology of bacterial infections in allo-HSCT patients has evolved over time. In the past decade or so, it has been greatly influenced by the widespread use of fluoroquinolone prophylaxis, the increased prevalence of *Clostridium difficile* infection, and the evolution of conditioning regimens. Once transplanted, patients are at increased risk for bacterial infections for the remainder of their lifetime.

Infection During the Pre-engraftment Period

During the pre-engraftment period, bacteremia occurs in up to 20% of patients [38]. Table 11.1 lists some common infecting pathogens, their particular risks, and their clinical manifestations. The main sources for bacteremia are the oral or gastrointestinal mucositis, the respiratory tract, and the presence of central venous catheters. Infecting organisms are commonly Gram-positive cocci such as *Streptococcus viridans* and enterococci or a variety of fermenting and non-fermenting Gram-negative rods. Enterococci are increasingly resistant to vancomycin, and these strains have been associated with a worse prognosis than vancomycin-sensitive strains [39]. Some recent studies also report an increase in infections due to multidrug resistant (MDR) Gram-negative rods such as *Pseudomonas aeruginosa and* carbapenemase-producing *Klebsiella pneumoniae* [40–43]. The isolation of such resistant bacteria has been associated with the use of fluoroquinolone prophylaxis and third-generation cephalosporins in several reports. These infections carry a high mortality and often relapse.

Gastrointestinal infections are prominent during this period. Necrotizing enterocolitis and typhlitis may occur in any severely neutropenic patient and can serve as a source of bacteremia and sepsis. *Clostridium difficile* colitis is very common, occurring in about 12% of allogeneic transplant patients versus 9% of autologous patients during the pre-engraftment period [44–46]. Extensive antibiotic exposures, mucosal damage from intense chemotherapy, and multiple prior hospitalizations are all contributory [47]. *Clostridium difficile* has been linked to levofloxacin, which is frequently given for bacterial prophylaxis in these patients [48]. Hypervirulent strains of *Clostridium difficile*, including the epidemic North American pulse-field gel electrophoresis type 1 (NAP1) and ribotype 027/toxinotype III strains, have specifically been associated with moxifloxacin and other members of the fluoroquinolone class [49, 50]. An association between *Clostridium difficile* colitis and subsequent GVHD has also been reported [46]. The colitis may be severe, often relapses, and may also serve as a source for secondary bloodstream infections.

The risk of infection and bacteremia during this neutropenic pre-engraftment period is reduced by the use of prophylactic antibiotics. In general fluoroquinolones, usually levofloxacin, are the preferred agents [51]. Prophylaxis should start with the stem cell infusion and should continue until the resolution of the neutropenia or the initiation of antibiotic therapy for neutropenic fever. Several meta-analyses have demonstrated decreased infection-associated morbidity, mortality, as well as cost benefit, with the use of

Table 11.1 Bacterial infections following allo-HSCT

Bacterial pathogens	Predisposing risks	Clinical manifestations
Streptococcus viridans	Neutropenia, oral mucositis	Bacteremia
Streptococcus pneumoniae	Graft-versus-host disease (GVHD), lack of immunization	Pneumonia, meningitis, sepsis
Enterococcus species	Cephalosporin use, *C. difficile* infection	Bacteremia
Staphylococcus aureus	Central venous lines (CVL), colonization	Bacteremia, pneumonia, soft tissue infection
Coagulase-negative staphylococcus	CVL	Bacteremia
Escherichia coli	Neutropenia, mucositis	Bacteremia, pneumonia
Klebsiella pneumoniae	Neutropenia, mucositis	Bacteremia, pneumonia
Pseudomonas aeruginosa	Neutropenia, mucositis	Bacteremia, pneumonia, ecthyma
Stenotrophomonas maltophilia	CVL, prior broad-spectrum antibiotic exposure	Bacteremia
Acinetobacter species	CVL, prior broad-spectrum antibiotic exposure	Bacteremia, pneumonia
Achromobacter species	CVL, prior broad-spectrum antibiotic exposure	Bacteremia
Anaerobic bacteria (e.g., *Clostridium septicum*, *Bacteroides* species)	Neutropenia, mucositis	Bacteremia, necrotizing enterocolitis, typhlitis
Clostridium difficile	Antibiotic exposure, GVHD, local epidemiology, previous *C. difficile* infection	Colitis, megacolon, secondary bacteremia

prophylactic antibacterials [52–54]. These agents do, however, increase the risk for selection of resistant bacteria and *Clostridium difficile*-associated disease [55].

Infection During the Early Post-engraftment Period

During the early period after engraftment, the risk of bacterial infections and bacteremia is reduced but ongoing. Risk is increased by general debility, by the presence of renal or hepatic dysfunction, and by the presence of GVHD. Central venous lines are often the source. Most of the patients by this time will have received antibiotic courses making them more likely to be infected with resistant pathogens. Staphylococci, enterococci (often vancomycin resistant), and non-fermenting Gram-negatives such as *Stenotrophomonas maltophilia* and *Acinetobacter* are frequent pathogens [38]. By virtue of their T-cell immunosuppression, these patients are also particularly susceptible to *Listeria* and *Legionella* if exposed [56, 57].

Infection During the Late Post-engraftment Period

During the late period following engraftment, the main predisposing factor for infection is the presence of GVHD. Many patients have B-cell dysfunction and are functionally asplenic [58, 59]. They are thus vulnerable to serious infections with encapsulated bacteria, most notably *Streptococcus pneumoniae,* with pneumonia as the usual source [36, 60, 61]. Some patients are hypogammaglobulinemic, further increasing their risk. Less common are infections due to mycobacteria and *Nocardia.* Case reports suggest a global incidence of nontuberculous mycobacterial infections in allo-HSCT recipients ranging from 0.4% to 4.9% [37, 62–66]. Tuberculosis in this patient population, however, ranges from 0.0014% to 3% in the United States to as high as 8.5% in Taiwan [67–70]. Systemic nocardiosis is rare, and one center reported a cumulative incidence of 1.75%; cases were all observed in patients with extensive chronic GVHD [71].

Preventive strategies include vaccination with the heptavalent conjugate pneumococcal vaccine at 3–6 months post-engraftment for all patients [51]. Immunogenicity of this vaccine, however, appears to be related to immune reconstitution, particularly in allo-HSCT recipients aged 50 and over. In this population, improved vaccine response has been associated with CD4 >200 cells/μL, IgG >500 mg/dL, and phytohemagglutinin within 60% of the lower limit of normal [72]. Patients with active GVHD should also receive antibiotic prophylaxis aimed at pneumococcus. Penicillin V usually suffices, but trimethoprim/sulfamethoxazole or doxycycline may also be considered depending on local resistance patterns. For patients who are severely hypogammaglobulinemic (<400 mg IgG), regular infusions of intravenous immunoglobulin (IVIG) can be considered. Meticulous care of central venous catheters is mandatory [51, 73].

Clostridium Difficile

Clostridium difficile can occur at any time, though the risk is greatest during periods of hospitalization. Risk is increased in proportion to antibiotic exposure, especially perhaps to fluoroquinolones, by the presence of GVHD and of course by nosocomial risks, e.g., during an outbreak. Relapses are common after treatment.

Viral Infections

Viral pathogens are a significant source of morbidity and mortality after allo-HSCT [74]. Allo-HSCT recipients are affected by a wide range of viruses, either through primary infection, donor-derived infection, or reactivation of latent virus.

Cytomegalovirus

CMV continues to be one of the most important pathogens in this group. It is estimated that about 50% of the population in the United States is latently infected with CMV [75]. In other places in the world, including developing nations, the prevalence is even higher [76, 77].

Prior to widespread use of anti-CMV prophylaxis, approximately 80% of seropositive allo-HSCT recipients developed CMV reactivation, usually in the first 3 months after transplantation [78]. Despite prophylaxis with either ganciclovir or valganciclovir, the incidence of CMV reactivation ranges between 20% and 50%, with episodes increasingly occurring after prophylaxis is finished (late CMV) [79–83]. Approximately 6–18% of allo-HSCT recipients with CMV reactivation develop disease [79, 80, 83]. Clinical manifestations of CMV disease are variable and include interstitial pneumonia, enteritis, hepatitis, retinitis, encephalitis, and a CMV syndrome that includes cytopenia and fevers. CMV-related mortality is on average 40–50%, but can be as high as 86% in cases of severe pneumonia [83]. In addition to its direct end-organ effects, CMV disease is also associated with increased bacterial, fungal, and other viral infections [84].

The classic and most important risk factor for CMV reactivation is the serostatus of the recipient and donor, with a CMV-infected (seropositive) patient receiving a graft from a CMV-naïve (seronegative) donor considered the highest risk.

Additional risk factors include total body radiation in the conditioning phase, development of acute and chronic GVHD, T-cell-depleting therapies, steroids at doses greater than 1 mg/kg per day, and the use of mismatched or unrelated donors [78, 79].

Diagnosis of CMV disease remains clinically challenging given the varied and nonspecific presentations. Although PCR analysis of CMV DNA in the serum has become the mainstay of diagnosis, no absolute cutoff in viremia exists for differentiation between infection and disease. The presence of viremia does not automatically indicate disease although studies have shown that the likelihood of disease is high when levels above 10,000 copies/mL are found [85]. Conversely, disease does not always correlate with viremia, especially in cases of gastrointestinal involvement. With the introduction of international units, better studies to correlate disease and viremia will be possible in the future.

Intravenous ganciclovir is first-line therapy for CMV disease in allo-HSCT recipients. In non-severe cases, including asymptomatic viremia, oral valganciclovir can be used. Due to toxicities, foscarnet and cidofovir are considered second-line drugs and reserved for treatment failure due to GCV resistance or in situations where GCV is not tolerated. It is recommended that continuing treatment for 14–21 days after CMV DNA is no longer detectable in serum, followed by 1–3 months of maintenance therapy [86]. CMV immunoglobulins have been studied and in general are reserved for severe cases, especially pneumonia, or lack of response to antiviral therapy [87]. Recent studies have suggested that CMV-specific T-cell administration can be effective in the prophylaxis and treatment of CMV [88].

Although risk-stratified prophylaxis with oral valganciclovir can be effective, problems with toxicity, especially bone marrow suppression, preclude it from being a standard approach. An alternative approach involves frequent serum CMV PCR monitoring and initiation of treatment if viremia is detected. This preemptive approach is usually more logistically difficult and leads to higher rates of CMV reactivation [51]. An elusive goal for many decades, the search for a vaccine has recently shown promising results around glycoprotein B and phosphoprotein 65 epitopes [89, 90].

Epstein-Barr Virus (EBV)

In the United States and worldwide, it is estimated that almost 95% of adults demonstrate past infection with EBV. The spectrum of EBV-related diseases includes asymptomatic viremia, a viral syndrome with fevers and neutropenia, oral hairy leukoplakia, and rarely meningoencephalitis. More importantly, EBV is also associated with 50–70% of cases of PTLD in allo-HSCT recipients [91].

PTLD usually occurs in the first year after transplant and arises when EBV-specific T-lymphocytes are depleted, allowing for unchecked proliferation of donor-derived monoclonal or polyclonal B cells [92]. The spectrum of PTLD includes extranodal lymphocyte infiltration to high-grade B-cell lymphoma and varies from an indolent to fulminant presentation. Although the overall incidence of EBV-related PTLD in this population is approximately 1% (up to 2.8% in children), mortality can be as high as 50–90% [93]. Risk factors include age >50; recipients of mismatched, matched unrelated, or T-cell-depleted transplants; acute and chronic GVHD; and use of T-cell-depleting agents such as thymoglobulin and alemtuzumab [92].

Treatment options range from reduced immunosuppression to chemotherapeutic agents such as rituximab or CHOP. Antiviral agents have a limited role in the treatment or prevention of EBV-PTLD. Given that persistent or increasing EBV viremia usually precedes PTLD, preemptive treatment with rituximab may reduce the risk of progression to PTLD [94, 95].

Herpes Simplex Virus (HSV)

More than 50% of US adults are latently infected with HSV-1 [96]. In allo-HSCT recipients who do not received antiviral prophylaxis, the rate of reactivation can be as high as 80% and often occurs earlier, 2–3 weeks post-engraftment, than other herpesviruses [97, 98]. Clinical manifestations most commonly include oral-labial lesions and esophagitis, but can be varied and cause bone marrow suppression, keratitis, pneumonia, hepatitis, as well as meningoencephalitis [99–104]. HSV-2, on the other hand, is less frequent and is usually involved with perineal lesions only. Recurrent episodes of either HSV-1 or 2 infections may warrant suppressive therapy [51].

Varicella Zoster Virus (VZV)

Similar to HSV, reactivation is the most common cause of VZV-related disease after allo-HSCT, occurring in about 16% of patients in the first year after transplant [105]. Since anti-HSV or CMV prophylaxis is effective against VZV, reactivation usually occurs after prophylaxis has stopped, although breakthrough can also occur [105, 106]. GVHD is a major risk factor for VZV reactivation [107]. Clinical manifestations include either classic or multi-dermatomal shingles with lesions usually taking longer to heal that in immunocompetent patients. Disseminated VZV is a rare but severe occurrence, which can involve the lungs, liver, and CNS [108].

Human Herpesvirus (HHV) 6, 7, and 8

HHV-6 reactivation is common early post allo-HSCT, ranging from 36% to 47% of patients in the first month [109, 110]. The vast majority of cases range from asymptomatic viremia to fevers and transient marrow suppression, but patients can infrequently develop severe disease, including encephalitis, hepatitis, and pneumonitis. Posttransplant acute

limbic encephalitis [111] is a form of CNS disease in allo-HSCT recipients that is related to HHV-6 reactivation [112]. In addition to its direct effects, HHV-6 viremia has been found to increase delayed engraftment and GVHD as well as predispose patients to CMV and EBV reactivation [109]. Risk factors for HHV-6 reactivation include cord blood transplantation as well HLA mismatch [113]. Ganciclovir has activity against HHV-6 and is used for treatment [114]. Screening and preventative measures have not been developed.

HHV-7 viremia is also a common occurrence, but its association with post-HSCT disease is not well documented at this time. Reports of CNS disease associated with this virus have been reported [115].

HHV-8 can be transmitted to seronegative recipients, but clinical manifestations of viremia are also not well documented at this time, although it may possibly be related to fever, rash, mild hepatitis, and bone marrow aplasia. Unlike solid organ transplantation, cases of Kaposi's sarcoma are very rare [116].

Adenovirus (ADV)

Besides reactivation of latent infection, allo-HSCT recipients are susceptible to transmission of ADV via the stem cell graft as well as primary acquisition of any of the other >50 serotypes. About 12% of allo-HSCT recipients are affected by ADV reactivation, most of which are children under 5 years of age [117]. Reactivation usually occurs between 30 and 90 days posttransplant. Besides young age, risk factors for reactivation include severe GVHD, high-dose steroids, as well as use of unrelated cord blood [74]. In recipients with ADV viremia, approximately 40–50% develop disease, which ranges from a viral syndrome (fever, elevated liver enzymes, and pancytopenia) to pneumonitis, nephropathy, hemorrhagic cystitis, colitis, myocarditis, and CNS disease. Mortality in the setting of ADV disease is estimated to be around 22% [117].

Diagnosis is usually a combination of high clinical suspicion, serum ADV quantitative PCR, and histology. Treatment is not well defined but usually consists of reduced immunosuppression and cidofovir, which has a high incidence of nephrotoxicity [118]. Preventative measures are also not well defined.

Respiratory Viruses

With continuously improving detection techniques, respiratory viral pathogens have been increasingly recognized as significant sources of morbidity and mortality among recipients of allo-HSCT. These include, among others, influenza [119], parainfluenza [120], RSV [121], human metapneumovirus [122], as well as multiple strains of rhinoviruses, coronaviruses, and bocaviruses [123, 124]. Both community and nosocomial outbreaks are responsible for majority of infections, and rates of respiratory viral infections among allo-HSCT recipients undergo seasonal variation, much like the general population [125]. Estimates vary, but studies have shown that influenza (both A and B), parainfluenza, and RSV are the most common causes of viral respiratory infections [125]. Risk factors include GVHD, lymphopenia, and the presence of children younger than 12 years of age at home. Diagnosis involves clinical suspicion and RT-PCR. Mortality is variable and is usually associated with complications such as respiratory failure and bacterial or fungal superinfection. Preventative measures include vaccination, hand washing, and isolation measures in the setting of outbreaks. Besides anti-influenza drugs, antiviral therapy for most other respiratory viruses remains largely unproven [119, 120].

Hepatitis B Virus

The main risk with hepatitis B virus is reactivation of previously resolved infection, which can occur in up to 20% of cases if prophylaxis is not instituted [126]. Among those who reactivate, liver failure can be a rare complication. It is recommended that both recipients and donors be checked for hepatitis B serologies prior to HSCT and appropriate therapeutic or prophylactic measures taken [127].

Polyoma Viruses (BK and JC)

Although more commonly affecting renal transplant recipients, BK virus reactivation has also been described to cause both hemorrhagic cystitis and nephropathy in allo-HSCT recipients [128–131]. JCV-related progressive multifocal leukoencephalopathy (PML) is a rare but well-described complication in allo-HSCT recipients with dismal prognosis [132].

Fungal Infections

Invasive fungal infections (IFIs) are a major cause of morbidity and mortality among HSCT recipients. Individuals undergoing allo-HSCT are at higher risk for developing IFIs compared to recipients of autologous grafts, largely owing to delayed engraftment and GVHD. The epidemiology of IFIs in HSCT recipients remains dynamic. Since the 1990s, there has been a decrease in the incidence of invasive candidiasis among HSCT recipients due to the more widespread use of fluconazole prophylaxis; however, IFIs due to *Aspergillus* and other filamentous molds remain a significant concern.

Candida

Candida species commonly inhabit the skin and mucosa of the gastrointestinal tract, and disruption of the integrity of either mucosal barrier can lead to invasive candidiasis. In the

setting of allo-HSCT, invasive candidiasis typically results from mucositis of the gastrointestinal tract incurred during conditioning. Additional risk factors for invasive candidiasis include HLA mismatch, recipient age, prolonged neutropenia, GVHD, gastrointestinal tract colonization, and CMV disease [133, 134].

In the early 1990s, two large trials demonstrated a significant decrease in candidiasis with the use of fluconazole prophylaxis, and its administration through 75 days posttransplant was later shown to significantly reduce mortality among allo-HSCT recipients [135–137]. This prompted the widespread use of fluconazole prophylaxis in the early posttransplant period. More recent data from the Prospective Antifungal Therapy (PATH) Alliance registry, however, reported a 28% and 23% incidence of invasive candidiasis in allo-HSCT recipients from matched-related and matched-unrelated donors, respectively [138]. While *Candida albicans* accounted for over half of all episodes of invasive candidiasis in HSCT recipients in the 1980s, invasive candidiasis caused by azole-resistant *Candida* species such as *C. glabrata* and *C. krusei* has increased since the 1990s, which may reflect the routine use of fluconazole prophylaxis [28–30, 137, 138].

Invasive candidiasis in allo-HSCT recipients most commonly presents as fungemia or hepatosplenic candidiasis. Candidemia occurs in approximately 3% of HSCT recipients and may be accompanied by sepsis, a discreet palpable vasculitic rash, and/or end-organ involvement including but not limited to meningitis, endophthalmitis, and endocarditis [139]. In contrast, hepatosplenic candidiasis, or chronic disseminated candidiasis, results from invasion of *Candida* species into the portal vasculature with subsequent seeding of the liver and/or spleen during periods of neutropenia. While the exact incidence of hepatosplenic candidiasis remains unknown, one autopsy study identified hepatic candidal infection in 9% of HSCT recipients [140]. Patients typically present with fever and an elevated alkaline phosphatase level following neutrophil recovery. Blood cultures tend to be negative in this setting, but computed tomography of the abdomen demonstrates multiple lesions in the liver and spleen; such lesions decrease in size with recurrent neutropenia, indicating that hepatosplenic candidiasis results from a systemic inflammatory response. Biopsy is required for definitive diagnosis, especially because other IFIs and malignancy can result in a similar clinical syndrome.

The diagnosis of invasive candidiasis remains challenging, particularly because conventional blood cultures may only have a sensitivity of 50% in those with deep fungal infection [141]. Newer diagnostic assays, including the beta-D-glucan test, which detects beta-glucans in the cell wall of molds and yeasts except zygomycetes and cryptococci, may be valuable in the diagnosis of invasive candidiasis. One recent study demonstrated a sensitivity and specificity of 87.5% and 85.5%, respectively, of this assay. The mannan antigen and antibody and the Cand-Tec *Candida* antigen assays have demonstrated lower sensitivities than the beta-D-glucan assay (58.9%, 62.5%, and 13%, respectively) [142].

Given the prevalence of azole-resistant *Candida* species in neutropenic patients, particularly *C. glabrata* and *C. krusei*, management of invasive candidiasis in allo-HSCT recipients should include amphotericin B or an echinocandin such as caspofungin, micafungin, or anidulafungin. Several studies have demonstrated comparable efficacy between both antifungal classes; however, echinocandins have been associated with a more favorable toxicity profile [143, 144]. Voriconazole may be used in situations where additional mold coverage is desired; however, since voriconazole resistance has been seen in 3% of Candida infections in solid organ and HSCT recipients, this agent should not be used unless susceptibility of the isolate is confirmed [145, 146]. As the majority of cases of hepatosplenic candidiasis are caused by *C. albicans*, clinically stable patients may receive fluconazole. Those who are acutely ill or who have relapsed disease should receive 1–2 weeks of induction with liposomal amphotericin B or an echinocandin followed by fluconazole. Duration of therapy for hepatosplenic candidiasis is dependent upon resolution of visceral lesions, typically 3–6 months. Chronic suppressive therapy may be used in individuals at high risk for recurrence, including those with GVHD [146].

Invasive Mold Infections

Aspergillus and other molds are ubiquitous environmental pathogens. HSCT recipients are at high risk of infection with these organisms, which are largely acquired via inhalation of conidia that are inadequately cleared in the setting of immunosuppression. Less common routes of infection include invasion of the gastrointestinal tract or cutaneous inoculation.

Aspergillus

Invasive aspergillosis is the most frequent IFI encountered among allo-HSCT recipients. Data from the PATH Alliance demonstrated an incidence of invasive aspergillosis of 53.5% and 59.8% in recipients of matched-related donor and matched-unrelated donor transplants, respectively [138]. While both autologous and allo-HSCT recipients are at risk for the development of invasive aspergillosis, prolonged neutropenia, as well as GVHD, and its treatment contribute to higher incidences of invasive aspergillosis among allo-HSCT recipients [147, 148].

The onset of invasive aspergillosis following HSCT occurs in a bimodal fashion, with the first peak noted within the first 40 days of transplantation [149] and corresponding to the period of neutropenia. The second peak occurs post-

engraftment ("late period"), typically defined as 41+ days following transplant, and tends to arise in the setting of acute or chronic GVHD [147, 148, 150]. Age >40 has been associated with the development of invasive aspergillosis at any time following transplantation, as have donor and recipient polymorphisms in various Toll-like receptors and genes regulating interleukin-1, interleukin-10 promoter, and plasminogen [147, 151–155]. Specifically, donor haplotype 1363T/1063G, which contains two cosegregated single nucleotide polymorphisms in the Toll-like receptor 4 gene, has been associated with the development of invasive aspergillosis [151]. Single nucleotide polymorphisms in the chemokine ligand 10 (CXCL-10) gene have also been demonstrated to reduce dendritic cell CXCL-10 expression when exposed to *Aspergillus* germlings; these polymorphisms have also been associated with invasive aspergillosis following allo-HSCT [154]. Hematologic malignancies other than chronic myelogenous leukemia in the chronic phase, as well as aplastic anemia, myelodysplastic syndrome, mismatched donor, the use of cord blood, summer season, lack of laminar air flow, and local building construction, have been identified as risk factors for invasive aspergillosis in the early posttransplant period. The risk of invasive aspergillosis in the late posttransplant period increases in the setting of underlying multiple myeloma, use of T-cell-depleted or CD34-selected stem cell products, neutropenia, lymphopenia, use of corticosteroids, CMV disease, respiratory virus infection, and GVHD [147, 148]. GVHD and CMV disease are the major risk factors for the development of invasive aspergillosis >6 months after transplantation [148]. The contribution of GVHD to the risk of invasive aspergillosis is highlighted by the fact that conditioning regimens do not appear to impact the incidence of this invasive fungal infection. While the period of neutropenia is shorter and the incidence of early invasive aspergillosis is less in non-myeloablative HSCT recipients, this group remains at highest risk in the late posttransplant period in conjunction with GVHD [12, 156–158].

Aspergillus fumigatus is the most commonly isolated species associated with invasive aspergillosis in allogeneic HSCT recipients; infections with *A. niger*, *A. flavus*, and *A. terreus* are less frequently encountered [147, 159]. The lungs represent the most commonly involved site of infection, though patients may develop sinusitis, CNS disease, and tracheobronchitis. Clinical presentation may be variable, but frequently includes fever, cough, chest pain, hemoptysis, and/or respiratory failure, and the presence of these symptoms should prompt CT of the chest. Lung lesions, with surrounding ground-glass halos, nodular infiltrates, and cavitations, are highly suggestive of pulmonary aspergillosis; however, radiographic findings can be variable in allo-HSCT recipients with concomitant GVHD and include focal infiltrates and/or bronchopneumonia [160]. Given the lack of specificity of symptoms and radiographic findings, prompt microbiologic diagnosis via bronchoscopy should be pursued. Diagnosis of invasive aspergillosis may also be facilitated with use of the *Aspergillus* galactomannan assay, which employs a double-sandwich enzyme immunoassay to detect the galactomannan component of the *Aspergillus* cell wall. While the sensitivity of the serum galactomannan assay has varied between studies, it has proven clinically useful for the diagnosis of invasive aspergillosis and monitoring of clinical response during therapy [161, 162]. The galactomannan assay on bronchoalveolar lavage fluid in patients with hematologic malignancies and HSCT recipients has demonstrated higher sensitivity than bronchoalveolar lavage culture, cytology, and the serum galactomannan assay [163]. Important caveats for the use of galactomannan testing include false negative results in individuals receiving concomitant antifungals, false positive results in children and patients receiving beta-lactams, particularly piperacillin-tazobactam, and cross-reactivity with plasmalyte [164–166]. The beta-D-glucan test, which detects beta-glucans in the cell wall of molds and yeasts except zygomycetes and cryptococci, may also be a valuable adjunctive screening test for invasive aspergillosis particularly in conjunction with the galactomannan assay, though the performance characteristics of the beta-D-glucan assay in the HSCT population have not yet been evaluated.

Empiric therapy for suspected invasive aspergillosis should include a mold-active azole or amphotericin B. The use of an echinocandin can also be entertained, though these agents are fungistatic, rather than fungicidal. Once the diagnosis of invasive aspergillosis has been confirmed, primary therapy should include voriconazole in most patients, as this agent has been associated with improved clinical outcomes and survival rates and less toxicity compared with amphotericin B [167, 168]. Voriconazole is also the preferred therapy for *Aspergillus* tracheobronchitis [168]. Combination therapy with an echinocandin and either amphotericin B or a mold-active azole may be more efficacious than voriconazole alone, however, particularly for salvage therapy [169, 170]. The duration of therapy in allogeneic HSCT recipients should be prolonged and continue at least until immunosuppressives, particularly corticosteroids, are completed.

Prevention of invasive aspergillosis in allogeneic HSCT recipients should include the use of high-efficiency particulate air (HEPA) filtration and/or laminar flow rooms during the pre-engraftment period. In addition, two recent studies have suggested that voriconazole may be appropriate secondary prophylaxis prior to HSCT in patients with previous IA [171, 172].

Other Molds

Mucor and *Rhizopus* species are the most commonly encountered zygomycetes in clinical practice, with an incidence of 8.5% and 5.9% in recipients of matched-related and matched-

unrelated allo-HSCT, respectively [138]. Infection with these organisms results in mucormycosis, which can occur in the late posttransplant period and causes devastating sino-orbital, CNS, and gastrointestinal disease, as well as cutaneous lesions and fasciitis. Among HSCT recipients, risk factors for zygomycosis include HLA mismatch, prolonged neutropenia, corticosteroid use, iron overload, and GVHD [173, 174]. Additionally, several studies have noted increasing numbers of zygomycosis cases among patients receiving voriconazole as either prophylaxis or treatment of invasive aspergillosis [32, 111, 175]. Whether this reflects azole-related selective pressure remains unknown.

Fusarium species are environmental organisms, which cause infrequent but severe invasive fungal infection in HSCT recipients. Cases of fusariosis among HSCT recipients have been linked to contamination of central venous catheters and hospital water supply [176, 177]. Risk factors for fusariosis include underlying multiple myeloma and HLA mismatch. As with invasive aspergillosis, the onset of fusariosis occurs in a bimodal fashion; infection in the early posttransplant period is associated with prolonged neutropenia, and late infection is associated with T-cell depletion, corticosteroid use, and GVHD. Infection with *Fusarium* species can mimic invasive aspergillosis; however, patients with fusariosis are more likely to have positive blood cultures and multiple papular or ulcerated skin lesions compared to patients with invasive aspergillosis [176, 178].

Scedosporium apiospermum and *Scedosporium prolificans* have also been isolated in HSCT recipients; their disease spectrum is similar to invasive aspergillosis. Risk factors for *Scedosporium* infection include prolonged neutropenia and GVHD [159, 179, 180].

Miscellaneous Infections

Pneumocystis Jirovecii (PJP)

Due to effective prophylaxis, PCP has become a rare event among allo-HSCT recipients with retrospective studies showing incidence rates from 1.3% to 2.5% [181, 182]. PCP is usually a late occurrence, and risk factors include treatment for GVHD or cessation of PCP prophylaxis [183]. Despite effective treatment, mortality can be high if infection occurs early after transplant [184].

Toxoplasmosis

The majority of cases of toxoplasmosis in allo-HSCT recipients are due to reactivation of latent infection. In the United States, the incidence of toxoplasmosis has been reported to be as low as 0.25% [185], reflecting a low seroprevalence in the population [186]. In regions of the world with a higher seroprevalence, incidence rates of toxoplasmosis are predictably higher [187]. Disease usually occurs in the first 6 months after transplantation [185, 186]. Besides seropositivity, the main risk factor for reactivation is intensification of immunosuppression due to GVHD [186]. The most common clinical presentation is encephalitis, which usually presents with focal neurological deficits. Extra-CNS forms of toxoplasmosis include pneumonitis, chorioretinitis, and myocarditis. Diagnosis of toxoplasmosis in any of the above manifestations requires a high clinical suspicion. A toxoplasma PCR can be obtained in serum and tissue such as CSF and vitreous fluid [188, 189]. First-line treatment includes extensive treatment with pyrimethamine and sulfadiazine. Despite best efforts mortality in allo-HSCT recipients remains high [185, 190]. Prophylaxis is usually accomplished with trimethoprim/sulfamethoxazole [191].

Strongyloides

Strongyloides stercoralis can latently infect auto-HSCT recipients who previously lived or visited endemic areas (tropical and subtropical region worldwide), even many decades earlier. In the setting of immunosuppression, the parasite's life cycle is accelerated and cause hyperinfection and disseminated disease [192]. Clinical manifestations include intestinal obstruction, respiratory failure including alveolar hemorrhage, bacterial sepsis, or meningitis [193]. Because of delays in diagnosis, infections can be devastating and carry high mortality. Patients from endemic areas should be serologically screened and treated with ivermectin prior transplant [193].

Preventative Strategies

Like solid organ transplant recipients, allo-HSCT recipients can benefit from measures aimed to prevent infectious complications in the posttransplant period. These can include infection control practices in hospitals and outpatient clinics as well as guidelines for the prevention of opportunistic infections.

The CDC/IDSA and ASBMT have published extensive evidence-based infection control guidelines that include specific practices regarding room ventilation, isolation and barrier precautions, cleaning, hand hygiene, equipment disinfection, plants, patient skin and oral care, prevention of intravascular catheter-related infections, construction and renovations, as well as healthcare workers [194].

In terms of specific infections, guidelines from the CDC were published in 2000. Because many of these organisms not only involve reactivation of latent infection in the recipient but can also be donor-derived, both donors and recipients should be universally tested for CMV, EBV, HIV I/II, HTLV I/II (although this is not done in all centers), hepatitis B and C, syphilis, and *M. tuberculosis* (in donor only if from endemic country). Additionally, all recipients should be tested for HSV I/II, VZV, and *Toxoplasma*. Potential donors and recipients

Table 11.2 Pretransplant screening in candidate allo-HSCT donors and recipients

Donor screening	Recipient screening
Standard	
CMV IgG	CMV IgG
EBV VCA IgG	EBV VCA IgG
VZV IgG	HSV I/II IgG
HIV Ab and NAT	VZV IgG
HTLV I//II Ab	HIV Ab and NAT
Hepatitis B surface Ag and core Ab	HTLV I/II Ab
Hepatitis C Ab, NAT	Hepatitis B surface Ag and core Ab
Syphilis screening (RPR)	Hepatitis C Ab, NAT
	Syphilis screening (RPR)
	Latent Tb screening (PPD or IGRA)
Optional (if risk factors are present)	
Hepatitis B NAT	Hepatitis B NAT
West Nile virus Ab	West Nile virus Ab
Toxoplasma Ab	*Toxoplasma* Ab
Strongyloides Ab	*Strongyloides* Ab
Trypanosoma cruzi	*Trypanosoma cruzi*
Leishmania Ab/PCR	*Coccidioides* Ab
Babesia Ab	*Histoplasma* Ab
Rickettsia Ab	*Brucella* Ab
Coxiella burnetii Ab	

Table 11.3 Recommended and optional vaccination of allo-HSCT recipients [195]

Vaccine	Comments on use after allo-HSCT	Time post-HSCT to initiate vaccine
Recommended		
Pneumococcal conjugate (PCV)	3–4 doses, a fourth dose with PPSV23[a] may be beneficial	3–6 months
Tetanus, diphtheria, acellular pertussis	3 doses, DTaP preferred over Tdap	6–12 months
Haemophilus influenzae conjugate	3 doses	6–12 months
Meningococcal conjugate	1 dose, follow country recommendations for general population	6–12 months
Inactivated polio	3 doses	6–12 months
Recombinant hepatitis B	3 doses, follow country recommendations for general population	6–12 months
Inactivated influenza	Yearly	4–6 months
Measles, mumps, rubella (live)	1–2 doses, all children and measles seronegative adults, not recommended if active GVHD or on immunosuppression	>24 months
Optional		
Hepatitis A	Follow country recommendations for general population	12 months
Varicella (Varivax, live)	Limited data regarding safety and efficacy. Not recommended if active GVHD or on immunosuppression	>24 months
Human papillomavirus	Follow country recommendations for general population	No data
Yellow fever (live)	Limited data regarding safety and efficacy. The risk-benefit balance may favor use of the vaccine in patients residing in or traveling to endemic areas	>24 months
Rabies	Appropriate for use in HCT recipients with potential occupational exposures to rabies. Postexposure administration of rabies vaccine with human rabies Ig can be administered any time after HCT, as indicated	12–24 months
Tick-borne encephalitis	According to local policy in endemic areas	No data
Japanese B encephalitis	According to local policy when residing in or travelling to endemic areas	No data

Contraindicated vaccines: BCG (live), oral polio (live), intranasal live influenza, cholera (live), typhoid (live and IM), *Rotavirus*, zoster vaccine (Zostavax, live)
[a]PPV23: 23-valent pneumococcal vaccine

should also be tested for *Strongyloides* and *Trypanosoma cruzi* if they have epidemiologic risks. Patients with evidence of syphilis, *Strongyloides*, or latent tuberculosis infection should be treated in the pretransplant period (see Table 11.2).

Vaccinations are an important component of disease prevention. Because of predictable decline in antibody titers posttransplant, it is recommended that recipients be revaccinated in the post-engraftment at the appropriate time (see Table 11.3) [195].

Prophylaxis in the posttransplant period is usually aimed at the most common and predictable organisms. A discussion of strategies to prevent CMV is beyond the scope of this chapter but includes either preemptive treatment in cases of CMV viremia or universal prophylaxis for those at risk for CMV reactivation. Recipients not at risk for CMV should receive acyclovir for HSV prophylaxis. PCP and *Toxoplasma* prophylaxis is accomplished with sulfamethoxazole/trimethoprim for 6–13 months, although this practice varies when taking into consideration the myelosuppressive effects of

this drug combination. Dapsone, atovaquone, and pentamidine are alternatives for PCP prophylaxis. Of those, only atovaquone has activity against *Toxoplasma* as well. Many centers also institute bacterial and fungal prophylaxis in the peri-transplant period until neutropenia resolves.

Complications Arising from Preparatory Conditioning Regimens for Stem Cell Transplantation

12

Jasmine Zain, Merav Bar, and Amar Safdar

Introduction

Hematopoietic stem cell transplantation (HSCT) is performed to provide long-term cures for patients with advanced hematological malignancies and other nonmalignant disorders. However, transplantation procedures can result in complications that can affect any organ system in the body. Many factors may contribute toward these complications including direct effects of old and newer modalities in transplant conditioning, severe and prolong pancytopenia, immunosuppressive antineoplastic drugs, graft-versus-host disease (GVHD), and infections, especially opportunistic viral, bacterial, and fungal infections. Factors that may help elucidate complications related to pretransplant conditioning include the following: (1) the incidence of complications appears to be similar between autologous and allogeneic stem cell transplants, (2) complication occurs less frequently in the setting of reduced-intensity conditioning (RIC), and (3) complications associated with radiation therapy (XRT) and total body irradiation (TBI) are mostly abrogated when nonradiation-based preparatory regimen is administered. The differences between the risk for various complications among autologous and allogeneic stem cell graft recipients may not only represent toxicity from the conditioning regimen; patients undergoing allograft transplantation are also given immunosuppressive drugs for prevention and treatment of acute and/or chronic GVHD. Introduction of RIC may further assist in elucidating complications arising from drugs used for prevention and treatment of GVHD during the post-transplant period. Adults undergoing cord blood stem cell transplantation experience prolonged periods of pancytopenia, thereby placing such patients at an increased risk for infection and hemorrhagic complications. In this chapter a focused discussion includes systemic toxicities related with various preparatory regimens among adult patients undergoing stem cell transplantation based on aforementioned principles is presented [1, 2]. Where possible, the authors intend to identify effects of GVHD and/or underlying immune suppression that may have contributed toward various systemic complications.

Conditioning Regimens

Preparatory conditioning regimens given prior to HSCT have two main functions: (1) to provide tumor cytoreduction and (2), in allogeneic HSCT, to suppress hosts' immune response against the allograft and to prevent early graft rejection. Traditionally, preparatory regimens consist of high-dose chemotherapy and/or chemotherapy plus total body irradiation (TBI) with the objective for near-total eradication of cancer. However, high-dose, myeloablative conditioning regimens are associated with significant systemic toxicity including pancytopenia, injury to internal organs and skin. The regimen-related toxicity (RRT) poses a major obstacle in achieving successful transplant outcome. Modifications in traditional myeloablative conditioning include reduced-intensity conditioning regimens (RIC). Patients undergoing RIC are given lower doses of chemotherapy, and containment of cancer in the recipients mainly relies upon the donor graft-mediated anticancer cellular immune response known as "graft-versus-tumor" (GVT) or "graft-versus-leukemia" effect. RIC transplants are better tolerated and may be offered to older patients, patients with medical comorbidities, or "heavily pretreated patients" in whom multiple courses of

Table 12.1 Toxicities of common agents used in HSCT conditioning regimens

Agent	Known MTD	Acute DLT	Chronic DLT	Mechanism of injury	Treatment
Cyclophosphamide	200 mg/kg	Nausea, hemorrhagic myocarditis, acute CHF, SIADH, Cardiac arrhythmias, hemorrhagic cystitis resulting from secretion of active drug metabolites into the bladder	CHF	Direct myocardial toxicity due to leakage of drug from damaged endothelium; and renal tubular injury	Supportive care, use of Mesna to prevent hemorrhagic cystitis, and bladder irrigation
Melphalan	200 mg/m^2	Mucositis, GI toxicity, SOS, diffuse pulmonary alveolitis, and SIADH			
Busulfan	20 mg/kg given over 4 days, steady-state PKs over 4 days more predictable of toxicity than actual dose	SOS, neurotoxicity characterized by seizure; mucositis, radiation recall and pulmonary fibrosis, and gonadal toxicity	Ovarian failure, infertility, and azoospermia		
Thiotepa	1135 mg/m^2	CNS toxicity including somnolence, confusion and coma; oral and esophageal mucositis, enterocolitis, liver toxicity and SOS, acute dermatitis manifested as desquamating dermatitis; interstitial pneumonitis and cardiac toxicity			
1,3-bis (2-chloroethyl)-1-nitrosourea (BCNU)	900–1200 mg/m^2	Pulmonary toxicity, SOS, hypotension, myocardial ischemia, renal toxicity, and encephalopathy		Depletion of pulmonary glutathione reductase	
Cisplatin	300 mg/m^2	Renal dysfunction including electrolyte wasting; ototoxicity and high-frequency hearing loss; peripheral neuropathy; nausea and vomiting			
Carboplatin	1600–2400 mg/m^2	Liver toxicity, mucositis, peripheral neuropathy, ototoxicity, nephrotoxicity			
Etoposide	25–60 mg/kg or 2400 mg/m^2	Mucositis, GI toxicity	Secondary leukemias		
Doxorubicin	150–165 mg/m^2 delivered over 96 h as a CI	Cardiac toxicity (cumulative for doses above 350–400 mg/m^2, this may be lower in patients with existing cardiac risk factors), orointestional mucositis resulting in stomatitis, diarrhea, and typhlitis	Secondary malignancies		
Paclitaxel	725–750 mg/m^2	Peripheral neuropathy, and mucositis	Secondary malignancies		
Bortezomib		Peripheral neuropathy			
Bendamustine					
Fludarabine		Neurologic toxicity			
Clofarabine					
Ifosfamide	18–20 mg/m^2	Renal, and urinary bladder toxicity; neurotoxicity may present as somnolence, lethargy, confusion, and seizures			Mesna infusion
Cytarabine	36 gm/m^2 for 4–12 doses at 12 h intervals	Neurotoxicity, particularly cerebellar			
TBI	10–16 Gy	GI toxicity includes severe mucositis; hepatic and pulmonary toxicity	Growth retardation, chronic pulmonary insufficiency, secondary malignancies, and cataracts		Shielding of internal organs; targeted delivery of radiation like total marrow irradiation or total lymphoid irradiation

antineoplastic therapy have been given for the treatment of recurring or relapsed cancer; in the past such patients were considered high risk for traditional myeloablative HSCT. Recent advances in targeted antineoplastic drugs like radioimmunotherapy, proteasome inhibitor, and monoclonal antibodies are being incoorporated in preparatory regimens with the intent to minimize systemic toxicity. Table 12.1 provides an outline of adverse events associated with commonly used modalities for conditioning given in preparation for stem cell transplantation.

Orointestinal Complications

Damage to the mucosa of orointestinal tract is common in patients undergoing HSCT. The ensuing mucositis may be severe after myeloablative stem cell allograft transplantation. It is important to note that mucosal damage resulting from conditioning regimens can overlap with orointestinal acute GVHD and enterocolitis due to opportunistic cytomegalovirus or adenovirus infection. Therefore, it is essential to thoroughly evaluate the patients, especially if symptoms appear more than 2 weeks post-transplantation. Following are the common presentations of orointestinal toxicities among patients undergoing HSCT.

Emesis and Anorexia

Most conditioning regimens are associated with emesis and anorexia [3, 4]. The pathogenesis of chemotherapy-induced emesis includes direct drug-induced stimulation of central vomiting center and local injury to cell lining of the orointestinal tract. Nausea and vomiting in such cases can last for up to 3 weeks after transplant procedure [5]. The main process during days 1-10 following transplantion is damage to the mucosal lining, resulting in systemic translocation of bacteria and bacterial endotoxins, triggering various aspects of innate immune response that includes acute-phase protein, and local release of proinflammatory cytokines. Cytokines such as interleukin-1, interleukin- 6, and tumor necrosis factor alpha via systemic circulation penetrate the blood-brain barrier suppressed brain regulation of appetite may result in devestating anorexia. Conditioning-induced anorexia is prominent during the first 3 weeks after transplantation.

Mucositis

Oral mucositis is a common transplant-related complication, usually seen during the first 2–3 weeks after HSCT. Mucositis may affect up to 80% of transplant recipients and frequently associated with myeloablative regimens that include radiation [6]. Mucositis occurs in phases starting with erythema and atrophy progressing to ulceration and the final, healing phase. Mucositis is common with cytarabine, etoposide, high-dose melphalan, and treatement with multiple alkylating agents [7, 8]. Preexisting periodontal disease and prior radiation to the head and neck area increase the risk for mucositis. Chemotherapy-induced symptomatic mucositis usually starts 5–10 days after initiation of the conditioning and may take up to 3 weeks to heal. The healing phase can be delayed if additional factors like methotrexate used as GVHD prophylaxis, bacterial and fungal infections, and in patients with recrudescence of oral HSV infection. Morbidity and risk of death due to mucositis include severe oral pain and dysphagia with marked decline in oral calorie intake, recurrent bleeding, superimposed viral (HSV), bacterial and fungal (*Candida*) infections, edema of the upper airway, and airway obstruction. The extent and severity of oral mucositis correlates with the risk for infection, prolonged hospital stay, and hospital mortality [9]. Treatment is usually supportive and includes analgesia, oral rinsing solutions, and parenteral nutrition. Severe mucosal swelling and upper airway edema may require endotracheal intubation to secure patients' airway. Prevention strategies are developed to minimize the risk for mucositis. Palifermin, a recombinant human keratinocyte growth factor, it was approved by FDA for prevention of mucositis in patients undergoing autologous and allogeneic HSCT. Preclinical data in mice showed protective effects of palifermin against chemotherapy and radiation-induced mucositis [10–12] and led to clinical trials [13, 14]. Phase III study in patients following autologous transplants after TBI conditioning demonstrated a decreased incidence and duration of grade III–IV mucositis. Goldberg et al. conducted a retrospective study in 251 patients undergoing allogeneic HSCT, 154 of whom received palifermin during peritransplant period. In all patients, treatment with palifermin significantly reduced the number of days needed for (1) total parenteral nutrition (TPN; 13 vs. 16 days; $P = 0.006$), (2) patient-controlled analgesia (PCA; 6 vs. 10 days; $P = 0.023$), and length of hospitalization (32 vs. 37 days; $P = 0.014$). However, the effect of palifermin was only significant in patients who received TBI; this benefit was not evident in patients given busulfan-based conditioning [15].

Injury to mucosal barrier may also result in diarrhea, gastrointestinal bleeding, susceptibility to infections, and risk of death [16, 17]. Typhilitis is a particularly serious complication. Cecal edema, mucosal friability, and mucosal ulceration, accompanied with fever, abdomonal pain, and diarrhea are salient features; polymicrobial infections may reasult in severe sepsis [3]. The pathophysiology of neutropenic typhlitis is not fully understood; it is hypothesized that an acute mucosal injury caused by cytotoxic drugs serves as a trigger, followed by secondary infection of the bowel wall, progressing to systemic infection and sepsis with increased risk for bowel perforation [18]. Typhlitis may progress rapidly and

mortality rate of up to 20% may be seen in high-risk patients. High index of suspicion, early diagnosis and timely institution of aggressive medical therapy that includes complete bowel rest, broad-spectrum antimicrobials, elecrolyte, mineral, and intravascular homeostasis among other supportive measures is essential for improve outcome [19].

Diarrhea

Diarrhea is seen in nearly half of patients receiving high-dose chemotherapy and radiation-based conditioning as a result of mucosal damage, which usually resolves within 3 weeks after transplantation [4, 20]. Patients with other complications such as superimposed infections or GVHD involving the orointestinal tract, the duration of diarrhea my be prolonged. Preparatory regimen with radiation, alkylating agents, cytarabine, high-dose melphalan, or busulfan frequently result in diarrheal illness. Radiation- or chemotherapy-induced diarrhea is classified as osmotic or secretory diarrhea [21, 22]. The underlying processes include (1) damage to the intestinal mucosa and crypts resulting in reduced chloride absorption causing an osmotic load, (2) alteration in gut motility with reduced transit time due to direct effect of chemotherapy, and (3) mucositis resulting in decreased water absorption. Additionally, chemotherapy and radiation change the composition of the native intestinal microbiota, which may also contributes to diarrhea following HSCT; intestinal yeast overgrowth may play a role in some patients. Organisms that may cause diarrhea in stem cell transplant recipients include infection due to exotoxin producing *Clostridium difficile* and, less commonly, tissue-invasive disease due to *C. perfringens*, and *C. septicum.* It is important to recognize that enterocolitis due to opportunistic viral infections such as CMV, and adenovirus are difficult to distinguish clinically from other causes of diarrheal illness in such patients.

Conditioning-Induced Liver Complications

Hepatic complications are a major cause of morbidity and mortality following HSCT. The frequency and severity of liver complications however, have declined in the recent years [23]. Hepatotoxicity due to pre-transplant conditioning is usually seen within the first 3 weeks after transplants [24]. Sinusoidal obstruction syndrome (SOS) or veno-occlusive disease (VOD) is the main complication. Treatment-induced damage to the endothelial cells in the hepatic sinusoids clinically presents as tender hepatomegaly, fluid retention, weight gain, and elevated serum bilirubin level [25–27]. SOS is a direct manifestation of conditioning-related hepatotoxicity. The major risk factors are radiation and specific chemotherapy agents used in high doses particularly cytoxan (Cy) and busulfan (Bu). Combination regimens with chemotherapy and TBI has shown a correlation between cytoxan and TBI dose. The incidence of SOS after conditioning regimens that include cyclophosphamide at a dose of 120 mg/kg plus TBI greater than 14 Gy can be as high as 50% [24]; however, the incidence of SOS can be minimized with reduced-intensity regimens [28]. In the past, gemtuzumab ozogamicin exposure was associated with the risk of SOS in patients undergoing myeloablative allogeneic HSCT [29]. Additional risk factors for SOS include: (1) variations in the metabolism of cyclophosphamide and other chemotherapy drugs [30, 31]; (2) underlying fibroinflammatory liver diseases [32], and (3) concomitant use of drugs during and after conditioning therapy that either affect the metabolism of cytotoxic drugs such as triazole-based antifungals, or cause concomitant liver injury like sirolimus (Table 12.1). During the 1990s, the overall incidence of SOS at Fred Hutchinson Cancer Research Center was 38% with 7% of the patients having severe disease after cyclophosphamide and TBI preparatory regimen. A favorable reduction (12% with 2% severe disease) was noted after oral busulfan plus cyclophosphamide combination was introduced [31, 33]. There has been an appreciable decline in the frequency and severity of SOS during the past decade and probably represent (1) lower doses of TBI being used, (2) replacement of cyclophosphamide with fludarabine, (3) conditioning regimens that do not contain either cyclophosphamide or high-dose TBI, and (4) therapeutic drug monitoring that allows individualized dosing of chemotherapeutic drugs adjusted for variability of drug metabolism [24]. Prevention of severe sinusoidal liver injury begins with an assessment of patients risk due to underlying liver disease (Table 12.2) and tailoring appropriate conditioning regimen for select group of at-risk patients [25, 31, 34]. There are no satisfactory treatments for SOS; however complete recovery from SOS occurs in more than 70% of patients with supportive care, that include management of sodium and water balance, preservation of renal blood flow, and paracenteses, as needed. Patients with poor prognosis are recognized by a steep rise in total serum bilirubin level, increase body weight, serum ALT level of greater than 750 U/L, portal pressure greater than 20 mm Hg, development of portal vein thrombosis, and development of multi-organ failure [24]. However, liver failure is an uncommon cause of death in patients with SOS; most patients die from secondary renal and cardiopulmonary failure, or both [26, 35]. Treatment with defibrotide, a compound porcine oligodeoxyribonucleotides with procoagulant and fibrinolytic properties may ameliorate SOS disease in select group of patients [36, 37]. Recent observation that octerotide prophylaxis may reduce the incidence of SOS after HSCT was interesting and needs further evaluation [38].

Table 12.2 Risk factors for SOS in patients undergoing HSCT [24]

Liver diseases at baseline	Specific conditioning regimens	Concomitant drugs during conditioning therapy
Inflammatory diseases	Cyclophosphamide-based	Itraconazole
Chronic hepatitis B or C	CY 120 mg/kg plus TBI (greater risk with higher TBI dosing)	Sirolimus (rapamycin)
Nonalcoholic steatohepatitis	BCV (BCNU + CY + VP-16)	Norethisterone
Alcoholic hepatitis	BU + CY (greater risk without therapeutic drug monitoring of BU)	
Fibrotic diseases	Melphalan-based	
Cirrhosis	BU + MEL + thiotepa	
Lobular fibrosis	BU + MEL	
Extramedullary hematopoiesis with sinusoidal fibrosis		
Cholestatic disorders	Other regimens	
Jaundice caused by intrahepatic cholestasis	BU + TBI (greater risk with higher TBI dosing)	
Past history		
Prior SOS from conventional chemotherapy	Gemtuzumab ozogamicin-containing myeloablative regimens	
Recent exposure to gemtuzumab ozogamicin	High-dose radiolabeled antibody myeloablative regimens	
Prior liver irradiation		
Prior myeloablative hematopoietic cell transplant

Conditioning-Induced Renal Complications

Acute Renal Failure

Acute kidney injury (AKI) is a common complication in patients undergoing HSCT, and usually seen within the first 3 months after transplantation [39]. The incidence, timing and severity is different among patients following myeloablative versus RIC preparatory regimen, thereby emphasizing differential nephrotoxic potential of conditioning regimens. In 1989 Zager et al. reported that 53% of patients who underwent myeloablative HSCT developed AKI after a mean 14 days post-transplantation [40]. Since then several studies have evaluated renal injury in patients undergoing myeloablative transplantation [35, 41–48]. First 3 months after transplantation is when most episodes of AKI are observed; the incidence range between 21% and 73% after myeloablative allogeneic transplants; it is 12–19% for patients undergoing autologous stem cell graft transplantation. The cause of AKI include: (1) direct renal toxicity from cytotoxic drugs; (2) indirect damage sustained from intense conditioning regimens, i.e., patients with SOS; (3) GVHD via cytokine- and immune-related kidney injury; (4) nephrotoxicity from calcineurin inhibitors such as cyclosporine and tacrolimus; (5) dehydration and other conditions with depletion of intravascular volume; and (6) opportunistic CMV, or adenovirus infections that may involve the kidneys. Myeloablative conditioning is an independent risk factor for the development of AKI [43]. Severe AKI was shown to be more frequent in patients undergoing myeloablative HSCT compared with those treated with RIC [41, 43, 44, 46, 49, 50]. Several studies have evaluated the incidence and time of occurrence of AKI in patients given RIC and ranges from 29% to 56%; most cases are observed during the 2nd month after transplantation [42, 43, 46, 49–55]. Factors shown to increase the risk of AKI in RIC transplant recipients include, requirement for mechanical ventilation [50], previous autologous SCT, preexisting chronic kidney disease (CKD) [56, 57], acute GVHD, CMV reactivation [49], incomplete HLA-matched stem cell allograft transplantation, presence of sepsis [55], methotrexate given for GVHD prophylaxis, three or more antineoplastic treatments before transplantation, and patients with preexisting diabetes mellitus [54].

Chronic Renal Failure

AKI in the early post-transplant period is a risk factor for CKD. In a retrospective study, 158 adults received myeloablative allogeneic HSCT [58], proteinuria was noted in 23% of patients; prevalence of stage 3 or stage 4 CKD was 17%. Initiation of chronic renal replacement therapy or kidney transplantation for end-stage kidney disease was performed in 4% after an average 11 years following transplantation. In this study, presence of AKI after transplant was significantly associated with the risk for severe CKD (≥ stage 3). Another large study included 1,635 adult and pediatric patients who underwent myeloablative or RIC HSCT at the Fred Hutchinson Cancer Research Center between 1991 and 2002 [59]. A total of 23% developed CKD at a median of 191 (range, 131–516) days after transplantation. Presence of AKI was a prominent risk for CKD in the late transplant period [59]. Lack of resolution of structural and functional renal abnormalities back to the baseline after AKI episode and persistence of reduced renal reserves predicted the risk for CKD [60, 61]. AKI after transplant was associated with a higher risk for hypertension, which further increased the risk for CKD [62]. RIC regimen did not reduce the incidence of CKD. In an another retrospective study, the risk for CKD was 55% at 6 months, 50% at 9 months, and 45% at 12 months after RIC transplants [63]. Overall, 66%

of the patients developed CKD within 1 year following RIC transplantation. AKI during the first 3 months following transplantation was associated with the risk for CKD. Hingorani et al. reported albuminuria (ACR >30 mg/gm and proteinuria as >300 mg per day) on day 100 was associated with greater risk of CKD 1 year after HSCT; they also found that overt albuminuria was associated with an increase risk of non-cancer relapse death, and reduced 1 year post-transplant survival [64].

Immune System Complications and Immune Reconstitution

Conditioning regimens are designed to suppress hosts' immune response in order to allow the donor hematopoietic stem cells to establish stable engraftment. After HSCT, there is a prolonged period of immune deficiency affecting both the innate and the adaptive component of immune system thereby enhancing hosts' vulnerability to a variety of infections and other complications. Several factors contribute to immune deficiency state after HSCT, including: advance age, preparative regimen like myeloablative vs RIC; source of stem cell graft such as bone marrow, vs. G-CSF-mobilized peripheral blood stem cells, or stem cells derived from umbilical cord blood; graft manipulation, donor-recipient human leukocyte antigen (HLA) and non-HLA (minor) antigen mismatch; drug-induced immune suppression, and presence of acute or chronic GVHD [65].

Innate Immunity

Epithelial barriers are an important component of innate immune defense that are compromised on account of chemotherapy and/or radiation-induced mucositis or mucosal disruption resulting from acute or chronic GVHD. Direct injury to epithelial cells and cell-cell junctions or desmosomes facilitate systemic translocation of pathogens and microbial byproducts through the skin intergumentary system, respiratory, orointestinal, and genitourinary tracts. The epithelial barriers often recover quickly after transplant, however, presence of secretory acellular antimicrobial components such as cationic peptides, lyzosome, secretory immunoglobulins may remain subnormal for a potentially extended duration, especially in patients with GVHD [66, 67]. Cells of the innate immunity, including neutrophils, natural killer (NK) cells, monocytes, macrophages, and dendritic cells including antigen-presenting cells (APCs), are destroyed by the conditioning regimen in patients undergoing autologous and allogeneic HSCT. Various classes of immune cells originating from the hematopoietic progenitor cells start the process of recovery within weeks after transplantation [68–70]. However, despite recovery of the innate cell counts, some of the cell functions may not recover fully for months after transplantation [65]. NK cells reach normal levels within 3 months after transplantation and regain their ability to destroy malignant cells early in the post-transplant period [71, 72]. Additional events like GVHD, opportunistic viral infections such as CMV, and medications particularly high-dose systemic corticosteroids may further dampen prospects of immune recovery.

Adaptive Immunity

Myeloablative preparatory conditioning regimens comprises of agents that have myeloablative capacity resulting in destruction of hosts' adaptive immune system. Restitution and recovery of adaptive immune response in recipients after allogeneic stem cell grafts transplantoriginates from mature lymphoid cells from the donor derived effecter immune cells. The newly engrafted stem cells differentiate into common lymphoid progenitors (CLP) a common precursor to both T and B lymphocytes. If T-cell depletion methods are not used, the graft also contains antigen-specific T cells and naïve T cells that undergo peripheral expansion outside the thymus; lacking capacity for self-recognition. The proliferation, maturation, and differentiation of the donor-derived T cells into a diverse immune repertoire are dependent on adequate thymic function in recipients and controlled by the expression of surface molecules on thymic stromal cells and cytokines secreted by these important regulatory cells [73]. Immune regulatroy thymic activity is a complex process; dependent upon the patient age and prior treatments at the time of transplantation. Chemotherapy and radiation before HSCT and as preparatory conditioning regimen results in thymic dysfunction causing delayed T-cell immune reconstitution [74]. B cells derived from the common lymphoid progenitors undergo differentiation in the bone marrow, and the number of B cells usually returns to normal levels within 1–2 months after HSCT; however, serum immunoglobulin levels may remain subnormal for several months after transplantation [75]. The maturation process of B cells is dependent on the interactions with antigen-specific T lymphocytes. Therefore, defects in T-cell maturation due to inadequate thymic function or ongoing iatrogenic immunosuppression may also adversely affects B-cell maturation and B-cell function. Plasma cells are relatively resistant to chemotherapy and irradiation; studies have shown that persistence of antibody producing residual plasma cells of hosts origin may linger for a year after HSCT [76, 77]. However, a durable source of antibody production requires both antigen-specific donor T cells and mature B donor-derived lymphocytes. RIC regimens are immunosuppressive rather than immunoablative, and the

immunological outcome in RIC transplant recipients' depends upon the degree of elimination of the residual recipients' immune system following donor-derived T lymphocytes repopulation and functional recovery. The immune reconstitution after RIC HSCT is not significantly different from the immune reconstitution after myeloablative HSCT, although this occurs early after RIC transplants compared with patients undergoing myeloablative HSCT [78]. In most cases, T lymphocytes are all from donor origin within 3–4 months after RIC transplantation [79]. In patients following autologous HSCT, the number and function of NK cells return to normal as early as day 14 after transplantation; the quantitative and functional B-cell recovery may be delayed up to 18 months after HSCT, and T-cell subsets' (CD3, CD4, and CD8) recovery does not return to normal for a year or in some cases longer after transplant procedure [80].

The prolonged immunodeficiency state after allogeneic HSCT results in significant morbidity due to potentially life-threatening bacterial, viral, fungal and protozoal infections, this may also have a negative influence on the much desired graft-versus-tumor effect [81]. Since the immune reconstitution process after autologous HSCT is more rapid, opportunistic infections are not as common in patients undergoing these procedures [78].

Neurologic Complications

Conditioning regimens can lead to both short- and long-term neurologic complications in patients undergoing HSCT. In addition, patient may experience neurological symptoms due to neurotoxicity from immunosuppressive drugs or infections that directly or indirectly affect the nervous system. Up to 3% of patients will have neurological complications after autologous transplants; whereas 44% after allogeneic transplants may experience these complications [82, 83].

Neurologic Toxicity

Direct neurotoxic effects of specific chemotherapeutic agent and radiation can result in acute encephalopathy, and new-onset seizures, as well as long-term complications such as peripheral neuropathy and cognitive impairment may adversly impact patients' quality of life. Among the common chemotherapeutic agents used in conditioning, busulfan and carmustine (BCNU) are most likely to cause seizures as they readily cross the blood-brain barrier. About 10% of patients receiving high-dose busulfan, defined as 4 mg/kg for 4 days, will experience generalized seizures [84]. BCNU typically used in conditioning regimens for lymphoma and Hodgkin's disease may result in seizures at doses of 300 mg/m^2. Anticonvulsant prophylaxis is recommended when these medications are being administered. Oral phenytoin and levetiracetam are commonly used for this purpose, and it is imperative that a therapeutic level of the anticonvulsant be achieved before chemotherapy is commenced. Other agents associated with acute CNS toxicity include ifosfamide as part of high-dose ICE regimens that may result in seizures, confusion, mutism, disordered sensorium, and even comma. Ifosfamide neurotoxicity results due to the accumulation of chloroacetaldehyde, a chloral hydrate-like compound which is an important metabolite of the drug. There is no prophylaxis, but methylene blue has been used to treat neurological toxicity in select cases [85]. High-dose mechlorethamine used with TBI and fludarabine is also associated with encephalopathy; fludarabine-associated encephalopathy may present late in some patients. High-dose cytarabine used in BEAM and other conditioning regimens given for lymphoproliferative disorders is associated with cerebellar symptoms in over 10% of cases; permanent Purkinje fiber damage observed in nearly 3% of cases [86]. This can also result in seizures and transient encephalopathy. High-dose Ara-C can cause peripheral neuropathy and demyelinating polyneuropathy similar to Guillain-Barre syndrome [87]. Cisplatin and VP-16 are associated with a delayed axonal neuropathy that develops approximately 2 months after the administration of these drugs, and recovery is gradual and protracted [88]. Cisplatin neurotoxicity involves large sensory fibers resulting in a deficit in proprioception with preserved tactile and pain sensations without motor deficits. It correlates with cumulative toxicity with symptoms usually occurring at doses of 300–600 mg/m^2. Other problems include ototoxicity that involves high-frequency hearing loss, and ultimately speech frequency hearing loss may occur with continued drug exposure. Cisplatin has also been reported to result in CNS toxicity including Lhermitte phenomenon, which is presented as cortical blindness and seizures [89]. By contrast VP-16 and paclitaxel neuropathies affect all sensory fibers. Manifestations can include paresthesia and sensory disturbances of the distal extremities; cases of motor and autonomic neuropathy have also been described. Prior exposure to other neurotoxic agents like vincristine can exacerbate such symptoms. High-dose paclitaxel at a minimum dose of 625 mg/m^2 used in some conditioning regimens for solid tumors is associated with a high incidence of peripheral sensory neuropathy within 5 days after the drug is given [90]. High-dose methotrexate (5 gm/m^2) may be associated with transient leukoencephalopathy [91], while the use of intrathecal methotrexate can rarely result in hemiparesis. A delayed onset chronic leukoencephalopathy may result in patients after intrathecal MTX and whole brain radiation [92]. Neurologic signs develop within 4–5 months after transplantation and progress to dysarthria, ataxia, dysphasia, spasticity, upper motor neuron weakness, spasticity, seizures,

confusion, and eventually death. The combination of TBI and amphotericin B has also been reported to lead to a similar leukoencephalopathy. Intrathecal cytarabine and the depot version are associated with a predictable aseptic meningitis due to meningeal irritation. Concomitant use of steroids either given intrathecally or systemically may ameliorate symptoms [86]. Some of the newer agents that are being used in conditioning regimens like bortezomib may cause peripheral neuropathy [93]. This is usually reversible with dose modification or discontinuation of the drug.

Central Nervous System Infections

Conditioning regimens lead to a period of pancytopenia and immune suppression that increases the risk for infections involving the CNS. Most of these present in the immediate post-transplant period, and late infections can also occur in patients with prolonged immunosuppression due to GVHD or graft dysfunction. The incidence of CNS infections is 5% in allogeneic transplants and as high as 8–15% in autopsy series [94]. The presenting symptoms are altered mental status, delirium, and altered sensorium. Meningeal signs or focal neurologic deficits are less common. Workup should include imaging studies and spinal fluid examination once intracranial mass lesion(s) with potential for herniation is ruled out. Aspergillosis was the most common infection accounting for 30–50% of CNS infections [94]. The newer mold-active triazole drugs like voriconazole have better CNS penetration as compared to other antifungals and currently recommended for the treatment of CNS aspergillosis. Systemic candidiasis in patients with fungemia can result in CNS involvements in nearly 3% of cases; seen in up to 15% in autopsy series [95]. Protozoal infections that include *Toxoplasmosis gondii* CNS disease mostly noted in the early post-transplant period, especially if patients, in whom prophylaxis with trimethoprim-sulfamethoxazole was deferred [94].

Bacterial infections are less common in the era of aggressive antibacterial prophylaxis and routine antimicrobial therapy for suscepted or porven infections. However, cases of meningitis due to *Listeria monocytogenes*, penicillin-nonsusceptible *Streptococcus pneumoniae*, and *Stomatococcus mucilaginous* have been reported in patients after allogeneic and autologous stem cell transplants; these infections are usually seen during the early post-transplant period. However, in patients with chronic GVHD, such infections may present late after HSCT. CNS mycobacterial infections are rare in patients undergoing HSCT [94].

CMV reactivation is a common and serious complication after allograft transplants. Unlike patients with HIV/AIDS, CMV chorioretinitis is seldom seen in patients following HSCT for reasons still not well understood [96]. Similarly, herpes simplex encephalitis is rare in post-transplant setting despite up to 80% of seropositive patients may experience high-level viral reactivation after undergoing stem cell transplantation. There are few reports in literature; the presentation and findings in HSCT recipients are mostly diffuse brain involvement that is not limited to the temporal lobe. EEG shows periodic lateralized epileptiform discharges characteristic of herpetic encephalitis and may precede before radiographic changes become evident [96]. Activation of VZV mainly as mucocutaneous disease is seen 4–5 months after transplantation; viral encephalitis may seldom occur. Postherpetic neuralgias can develop in up to 25% of patients despite antiviral therapy and secondary prophylaxis. Cranial nerves can be involved resulting in symptoms of facial palsy, hearing loss, and unusual features like arm weakness from cervical neuralgia or a neurogenic bladder from the involvement of lumbosacral plexus [97]. Adenovirus and other herpes viruses like Epstein-Barr virus or human herpesvirus 6 can cause fatal meningoencephalitis during the periods of pancytopenia and severe cellular immunosuppression. Progressive multifocal leukoencephalopathy (PML) caused by JC virus is a rare complication that may present late after allogeneic transplantation and even rare among patients in whom autologous stem cell transplantation was performed years prior to PML presentation [98, 99].

Vascular Complications

In the early post-transplant period following myeloablative conditioning, patients are typically pancytopenic for nearly 2 weeks and are at risk for intracranial bleeding due to severe thrombocytopenia. Subdural hematoma may occur, whereas intracerebral hemorrhage is often fatal. Subdural hematomas are the most common form of intracranial hemorrhage in this group of patients; clinical presentation includes mental status changes without acute localizing neurologic signs [100, 101]. Treatment requires maintenance of platelet count of greater than 75,000/mm^3, correction of any coagulation abnormalities, and surgical treatment, as necessary [102]. The clinical presentation for intracerebral hemorrhage reported in up to 3% of allogeneic transplant recipients may present with an acute localizing neurologic event accompanied by decreased sensorium. Fatal transtentorial herniation may occur if not recognized and treated promptly with surgical decompression. Cerebellar bleeds may present with more subtle signs of gait abnormalities and nystagmus, which can progress to changes in sensorium.

Ischemic strokes can also occur in the early post-transplant period. These can arise from thrombotic emboli in patients with infectious and noninfectious endocarditis or a hypercoagulable state resulting from disseminated intravas-

cular coagulation in patients with multi-organ failure (MOF) or severe sepsis [103, 104]. Rare cases of vasospasm associated with the infusion of cryopreserved stem cells have been reported [105]. Intracranial infections and meningitis can lead to endarteritis, resulting in an ischemic events; a compication occasionally seen in patients with CNS aspergillosis. Sinusoidal infections either bacterial or fungal may extend into the carotid artery and the venous cavernous sinus causing vascular compromise and stroke. Conditioning chemotherapy can lead to endothelial damage, which may be exacerbated by calcineurin inhibitors. The hypercoagulable state and non-bacterial thrombotic endocarditis carries a high risk for stroke. Thrombotic microangiopathy seen in 5–15% of stem cell transplant patients can also cause acute mental status changes. The presence of fragmented RBCs, elevated LDH, and renal insufficiency are the classic features. Treatment consists of discontinuation of calcineurin inhibitors, infusion of cryoprecipitate poor plasma, or plasmapheresis [104].

Metabolic Encephalopathy

Acute metabolic complications after conditioning regimens can lead to acute mental status changes that present as altered sensorium. The leading causes include sepsis, use of sedatives and other neurotrophic medications, hypoxia from various respiratory complications; uremia and liver failure [106]. Multi-organ failure (MOF) is a significant cause of mortality in patients undergoing transplantation. Severe CNS dysfunction is a salient feature of this syndrome, which is thought to reflect an excessive systemic inflammatory response. Prolonged critical care unit stay in transplant patients may result in critical care polyneuropathy that is thought to occur due to impaired blood flow to the peripheral nerves [107]. Vasogenic edema with characteristic radiologic findings has been associated with the use of calcineurin inhibitors. Radiation-based conditioning regimens and the use of high-dose chemotherapy may contribute to the breakdown of blood-brain barrier resulting in the release of endothelin and other vasoactive peptides that may trigger vascular and neurological changes well documented with calcineurin inhibitors [108].

Delayed Neurologic Complications

Intensive chemotherapy and radiation are well-recognized cause for chronic neurologic sequelae. Ongoing immunosuppression, GVHD, and infections may beother contributing factors. Both the central and peripheral nervous system may be involved; In general, the neurologic complications are less frequent among recipients of autologous stem cell graft compared with those undergoing allogeneic transplants. Leukoencephalopathy can arise in the setting of aggressive intrathecal chemotherapy in combination with cranial irradiation with TBI dose of 1800–2400 cGY or higher. This is an irreversible complication and can leave a patient in a permanent vegetative state. Adequate shielding of cranium and judicious use of intrathecal chemotherapy has reduced the risk for this devastating complication [109]. Vasculitic changes in the CNS as well as peripheral neuropathy have been described in the setting of GVHD. Cognitive impairment, memory dysfunction, and shortened attention span are reported in patients, particularly children after stem cell transplantation; these CNS complications may or may not be directly attributed to preparatory pre-transplant conditioning particularly patients receiving cranial irradiation [110, 111]. Radiation-induced neurocognitive impairment due to brain irradiation in patients with CNS lymphoma or leukemia, presents as a biphasic illness; a subacute transient decline that peaks around 4 months and a late irreversible neurocognitive dysfunction that becomes evident several months to years after brain irradiation was given [112].

Cardiovascular System

Cardiac complications occur at a rate of 2–28% despite aggressive pre-transplant screening and implementation of reduced-intensity conditioning regimens. They are an increasing problem as stem cell transplants are being offered to older patients. Congestive heart failure, and arrhythmias are common; pericardial effusions, and rarely, infectious or noninfectious endocarditis may be seen [113].

Acute Cardiac Complications

High-dose cyclophosphamide, prior history of anthracycline use, chest and mediastinal radiation are risk factors for CHF. This is exacerbated in patients with pancytopenias, particularly severe anemia, fluid overload, and renal dysfunction. Cyclophosphamide can result in cardiac toxicity within 3 weeks following administration. This occurs at doses above 150 mg/kg. Besides CHF, it can also cause pericardial effusion and cardiac tamponade. Pathophysiology of cyclophosphamide-related cardiac injury is related to endothelial damage resulting in extravasation of active drug metabolites into the myocardium causing direct cellular injury by severe depletion of cardiac thiol stores. Fractionated cyclophosphamide can reduce the incidence of cardiac injury. The risk of cardiac toxicity is increased by concomitant administration of cytarabine or mitoxantrone [114]. Melphalan and fludarabine, commonly

used for reduced-intensity conditioning, are associated with a 2–14% incidence of cardiac toxicity in the acute setting [115]. Pancytopenia, particularly severe neutropenia following pre-transplant conditioning can lead to infections, which may present as pericarditis with pericardial effusions, and less commonly, endocarditis with or without valvular dysfunction. Cardiac arrhythmias can also be a manifestation of acute cardiac injury associated with conditioning regimens. Rituximab, cyclophosphamide, and melphalan are the most common agents associated with cardiac arrhythmias [116].

Delayed Cardiac Complications

Several antineoplastic agents that are part of pre-transplant conditioning can result in long-term cardiac complications. Late effects consist of arrhythmias, congestive heart failure, myocardial infarction, hypertension, angina, pericarditis, and valvular heart disease. In a study of 248 patients with chronic myeloid leukemia, the incidence of delayed cardiac complications was 33% compared with age-controlled general population, and the degree of cardiac impairment was greater after unrelated donor stem cell transplants (48%) as compared with 29% in related donor HSCT and 18% in patients following autologous transplants [117]. Other than direct cardiotoxicity from chemotherapeutic agents, GVHD appears to be a major factor associated with cardiovascular complications. There is an increased incidence of coronary artery disease in survivors of stem cell transplantation due to the delayed effects of chest radiation, hyperlipidemia associated with calcineurin inhibitor therapy, corticosteroid use, endocrine dysfunctions, physical inactivity, and overall physical deconditioning. Vascular sequelae of the seldom seen infective and non-infective endocarditis can lead to permanent valvular dysfunction; it is important ot note that sudden, severe aortic valve regurgitation is a life-threatneing cardiac emergency [118].

Pulmonary Complications

In nearly 60% of transplant recipients, pulmonary complications are expected and may result in 30% of deaths attributed to non-(cancer) relapse mortality (NRM) [119]. Pulmonary complications after transplant may have various causes such as infections, direct effects of the drugs or radition used in pre-transplant conditioning, non-cardiogenic pulmonary edema, fluid overload states, diffuse alveolar hemorrhage, and idiopathic pneumonia syndrome, as well as late obstructive and restrictive lung disease each with unique clinical and diagnostic features. GVHD also affects the respiratory tract [120, 121].

Infections

Severe neutropenia following high-dose conditioning regimens substantially increases the risk for acute pulmonary infections. Pneumonia is the leading cause of death after HSCT. In the first 30 days, patients are most susceptible to bacterial pneumonia with an incidence up to 15%. Myeloablative conditioning regimens are more likely to cause bacterial pneumonia compared with reduced-intensity regimens. Atypical clinical presentation and absence of consolidation on CXR is not uncommon in neutropenic patients with penumonia. Bacterial pneumonia can be a rapidly progressive illness resulting in acute respiratory failure and death. Therefore, high-index of suspicion is of paramount importance in managing patients during pre-engraftment neutropenia, in particular those with fever without localizing sign(s) of infection.

Respiratory viral infections due to respiratory syncytial virus, influenza, parainfluenza, and adenovirus can lead to debilitating acute illness in the early post-transplant period and in patients with GVHD-related prolonge immunosuppression [122, 123]. CMV reactivation and viral pneumonitis among other CMV manifestations of systemic disease are usually seen after engraftment, herald by recovery in peripheral blood cell count usually between day 30 and day 100 after transplantation. This is related to the ongoing immunosuppression in the post-transplant period rather than conditioning regimen-associated complication; furthermore, CMV end-organ disease is rarely seen in patients following autologous stem cell transplants [124].

Prolonged neutropenia, and continued immunosuppression increases the risk for invasive fungal disease (IFD); aspergillosis mostly involve lungs and less frequently paranasal sinuses with the risk for intraorbital and intracranial extension. These neurotropic filamentous fungi may cause intracranial infection via hemtogenous seeding. In recipients of cord blood stem cells, the incidence of invasive fungal infections is highest among adults undergoing allogenic HSCT; which in most part is a reflection of delayed hematopoietic engraftment and therefore, extended duration of neutropenia [125]. Chronic GVHD and drug-induced cellular immune suppression also places the patient at risk for invasive fungal disease. Dyspnea and cough are usually present. CT scan of chest should be obtained early and findings such as pulmonary nodules with the classic "Halo sign" indicating hemorrhage in the adjoining lung tissue that tends to disapper after first week of infection; dense areas of consolidation in peripheral lung, near pleura, or thick wall cavitation with seldom seen “air crescent sign” are highly suggestive of pulmonary IFD. Hyphae seen in bronchoalveolar lavage samples have a positive predictive value of 80%; however it has low sensitivity. Voriconazole and other mold-active triazole drugs such as posaconazole and isavuconazonium sulfate have replaced amphotericin B as

the gold standard of therapy for most cases of pulmonary fungal disease. Echinocandins and lipid formulations of amphotericin B may still be used in select cases. The incidence of *Pneumocystis jirovecii* pneumonia was up to 15% in patients undergoing transplantation. Routine prophylaxis with trimethoprim-sulfamethoxazole has almost eliminated this serious fungal lung disease in the susceptible population. BAL is the diagnostic procedure of choice, with a yield of nearly 90%. Treatment consists of high-dose trimethoprim-sulfamethoxazole; corticosteroids are reserved for patients with severe hypoxemia.

Idiopathic Pneumonia Syndrome

Also known as interstitial pneumonia, is an acute pulmonary syndrome with widespread alveolar injury, with multilobar infiltrates, increased alveolar to arterial oxygen gradient, and restrictive pulmonary dys function in the absence of infection or cardiogenic lung disease. The histopathologic findings consist of interstitial pneumonitis; diffuse alveolar damage; cryptogenic organizing pneumonia (COP), formerly bronchiolitis obliterans organizing pneumonia (BOOP); and lymphocytic bronchitis. The incidence is 3–15% and associated with high-dose conditioning regimens compared to RIC; suggesting toxicity from pre-transplant preparatory regimen as a contributing factor. The incidence is also higher in patients who undergo allogeneic transplantation compared with patients given autologous stem cell grafts [126]. Symptoms occur early in the post-transplant period, usually within the first 100 days and are fairly typical for pneumonia such as dyspnea, fever, hypoxemia, and mostly non-productive cough. Infections need to be ruled out, and treatment consists of high-dose corticosteroids. This condition may rapidly progress to respiratory failure requiring assisted mechanical ventilation [121, 127]. COP is usually seen as a complication of GVHD within the first 1–3 months after HSCT. Pathologically it consists of small airway injury and interstitial inflammation with granulation plugs in the small airways. Patients with COP respond to high-dose steroids; however, long-term respiratory complications in such patients are not uncommon.

Diffuse alveolar hemorrhage (DAH) is seen in 5% of HSCT recipients. The characteristic features include fever, cough, and respiratory compromise during the early post-transplant period usually within the first 30 days. Diffuse ground-glass infiltrates are suggestive, by no means diagnostic. Diagnosis requires progressively bloodier return of BAL aliquots and 20% or more blood-laden macrophages. Patients may need mechanical ventilation, and treatment consists of corticosteroids given in high doses such as 125 or 250 mg of methylprednisolone every 6 h for 4–5 days followed by a gradual tapering steriod dose schedule. Mortality is high, up to 60% at 6 months. Risk factors for DAH include high-dose conditioning regimen, total body irradiation, renal insufficiency, older age, and previous history of GVHD [128–130].

Late-Onset Pulmonary Complications

Late complications affecting the airways and lungs are seen in 7–26% of patients undergoing HSCT; common causes are lung infections, TBI-based conditioning regimen, and GVHD [131, 132]. Mucositis due to aggressive preparatory conditioning reduces mucociliary clearance and mucous retention in the respiratory tract. Chronic inflammation ensues, alveoli and pulmonary interstitium are both affected, recurring or perisstent hemorrhage, and edema promotes fibrosis resulting in chronic obstructive and/or restrictive lung disease. High-dose regimens containing carmustine are known to cause delayed pulmonary syndrome seen approximately 10 weeks after transplantation. Symptoms consist of dyspnea, nonproductive cough, and fever. PFT show a mild restrictive defect although severe defect in lung diffusion capacity becomes evident. Radiographic presentation comprises of scattered diffuse ground-glass infiltrates. Patients respond to corticosteroids; however, progressive respiratory failure and death may occur in nearly 8% of patients [133, 134].

Bronchiolitis obliterans is seen as a late complication and often associated with chronic GVHD. Methotrexate and respiratory viral infections within first 100 days after transplants increases the risk of bronchiolitis obliterans. Some patients may progress to obstructive lung disease and respiratory failure [135].

Late idiopathic pulmonary syndrome (IPS) defined as a noninfectious interstitial pneumonitis may occur in 6–18% of HSCT recipients between 3 and 24 months after transplantation. It is characterized by thickening of the interstitial space with a cellular infiltrate, accumulation of fluid, and fibrotic tissue. Radiographic studies show diffuse pulmonary infiltrates, and the symptoms consist of progressive dyspnea, hypoxemia, and fevers. High-dose radiotherapy and GVHD are the risk factors associated with this complication. Treatment includes high-dose corticosteroid therapy [136–138].

Patients undergoing HSCT are at increased risk for secondary malignancies including lung cancer, head and neck cancers that are usually seen 2 years after transplantation. Total body irradiation during preparatory conditioning is a well-described risk factor.

Hematologic Complications

Myeloablative conditioning regimens are designed to erode marrow function completely; recovery of the resultant pancytopenia requires successful engraftment, which is an amalgam of variables such as stem cell graft source i.e., autologous vs. allogeneic; dose of nucleated stem cells; marrow-derived vs. PBSC vs. cord blood-derved; donor factors i.e., related vs. unrelated; ABO blood type,

major, and minor HLA antigen compatibility. RIC is designed to creat a hosts' milieu of immune suppression rather than myelosuppression. Therefore, as expected RIC is associated with low systemic and myelotoxicity. The duration of pancytopenia is shorter and conceivably less infectious, and non-infections complications, including the need for transfusions.

Conditioning regimens are associated with hemolytic complications secondary to thrombotic microangiopathy (TM); a Coombs' negative hemolysis associated with RBC fragmentation, thrombocytopenia; renal and neurologic abnormalities [139, 140]. The incidence varies from 1% in autologous transplants and up to 70% in small series of patients following allogeneic transplants particularly where tacrolimus and sirolimus was used for GVHD prophylaxis [141, 142]. RIC is associated with 15–23% incidence of TM, with the highest risk in patients with prior myeloablative transplant (<6 months), suggesting a potential role of cytotoxic conditioning therapy for this syndrome [104, 143]. The majority of TM cases occur within the first 3 months after transplants. Unlike thrombotic thrombocytopenic purpura, ADAMTS13 deficiency or a decrease in the von Willebrand multimers cannot be demonstrated in the transplant-related TM. Mortality can be as high as 50–90% [144–146]. Pathophysiology of transplant-related TM consist of injury to the vascular endothelium from irradiation, dose-intense chemotherapy, as well as injury due to calcineurin inhibitors. Certain viral infections such as HHV6, parvovirus B19, CMV, or adenovirus; possibly aspergillosis may act as a trigger for post-HSCT TM. Treatment consists of supportive care, removal of offending agents, and potential role of the compliment inhibitor such as eculizumab [147–149]. Among long-term hematologic complications also include increased risk of MDS and acute leukemia during the late transpant period.

Endocrine Complications

The effect of pre-transplant conditioning on endocrine dysruption involves growth and skeletal development, metabolic function, gonadal and sexual function, and fertility. Radiation-based conditioning exposes the hypothalamic-pituitary axis to the effects of radiation at doses of 10–14 Gy [150]. The degree of damage is directly proportional to the cumulative radiation dose received with hypopituitarism observed with > or equale to 20 Gy. At the standard doses of 12 Gy used in TBI, the damage to the hypopituitary axis is minimal, however, concomitant or prior use of systemic and intrathecal chemotherapy may lower this threshold particularly in patients given high-dose methotrexate [151].

Growth Hormone Dysfunction

Children undergoing HSCT are highly susceptible; the incidence of short stature may range from 4–60% and correlates with young age at the time of transplantation. TBI and cranial irradiation are the strongest predictors for growth retardation due to: skeletal dysplasia of the spine by direct effects of chemotherapy and irradiation, radiation-induced hypopituitarism, hypothyroidism, and possibly precocious puberty resulting in early closure of bone epiphysis. In addition, use of glucocorticoids can blunt the secretion of growth hormone (GH), and direct effects of Bu and Cy on the epiphyseal growth plate may also contribute to growth retardation in children given radiation sparing preparatory regimen [152, 153]. In adults, there are no clearly recognizable syndromes associated with GH deficiency. However, GH deficiency may be associated with lean body mass and muscule wasting and increased body fat; cardiovascular adverse events and reduced bone mineral density [154].

Bone Metabolism and Osteoporosis

Patients undergoing HSCT exhibit bone loss particularly within the first 6 months [155, 156]. Typically, 5–15% bone loss is expected in lumbar spine and femoral neck within the 1st year after HSCT; osteopenia is noted in 50–60% and osteoporosis in 20% of stem cell transplant recipients [157]. The pathogenesis of bone loss in is multifactorial. Prolonged use of glucocorticoids, alterations in calcium and magnesium homeostasis in patients given calcineurin inhibitors contribute to bone loss [158, 159]. It is prudent to be aware of this complication, assess bone density by DEXA scans at regular intervals, and replenish calcium, vitamin D; and bisphosphonate therapy as indicated.

Thyroid Dysfunction

Thyroid dysfunction is seen 2–56%, and effects both autologous and allogeneic stem cell graft recipients [160, 161]. Conditioning regimen is thought to play a role, as expected, radiation-based conditioning would elicit direct damage to the thyroid tissue and to the hypothalamus and pituitary gland. The incidence of thyroid dysfunction after single dose irradiation is higher (23–73%) compared with 10–28% seen with fractionated dose therapy [162]. Similarly, patients undergoing allogeneic vs. autologous HSCT have higer risk for thyroid dysfunction as a result of immunosuppressive drugs [163, 164]. In the post-transplant period, thyroid dysfunction presents as euthyroid sick syndrome (ETS), hypothyroidism, autoimmune disease, or a thyroid nodule.

ETS is the most common thyroid dysfunction observed during first 3 months following HSCT. It is characterized by low free T3 and free T4 and a normal or low TSH; and regarded as an indicator for poor overall prognosis. Hypothyroidism is a common long-term thyroid complication after transplantation, with a cumulative incidence of 48% after 5 years and 67% after 8 years; however, median time to diagnosis is 4 years post-HSCT. Single-dose TBI carries higher risk for hypothyroidism (50%) compared with fractionated TBI (15%). The incidence of hypothyroidism is lower (11%) in patients given non-radiation conditioning. In this case the mechanism appears to be related to the effects of chemotherapy on the cytokines that control thyroid function; in addition GVHD may elicit thyroid dysfunction via immune/inflammatory pathway [163, 165, 166]. The incidence of thyroid nodules is higher in patients undergoing HSCT (27%) compared with the general population (4%) [162]. Although most patients with thyroid nodules have no symptoms, although 5–10% may be malignant, therefore, rigorous evaluation should be performed at the time of initial diagnosis and follow up. Patients, particularly children undergoing HSCT, have an increased risk for thyroid cancers compared with the general population, with an overall incidence of 0.2%. Radiation (TBI)-associated relative risk for nodules and thyroid malignancies is estimated between 0.6–14.9 and 3.6, respectively [167, 168].

Secondary Malignancies After HCT

Secondary malignancies are a rare and usually late complication; total body irradiation and chronic GVHD appears to be the strongest risk factors [169].

Solid Tumors

Secondary solid cancer following HSCT was performed by the Center for International Blood and Marrow Transplant Research (CIBMTR) [170]. Risk factors for solid cancers in a multi-institutional cohort of 28,874 allogeneic transplant recipients, who underwent myeloablative transplantation was assessed. Approximately 70% had received TBI-based conditioning. New solid tumors were reported in 153 transplant recipients, with a cumulative incidence of 1% after 10 years, 2.2% after 15 years, and 3.3% 20 years after transplantation. In this study, transplant recipients developed solid organ malignancies twice the rate of age- and gender-matched general population. Risk for tumors involving the oral cavity, liver, thyroid, bone, soft tissue, melanoma, brain and CNS were prominent. Risk for invasive solid tumor cancers was strongly related with age at time of transplant, exposure to radiation as part of the conditioning regimen, and development of moderate-to-severe chronic GVHD. However, risk factors for solid tumors differed by the type of tumor. Radiation was found to be a major factor for non-squamous cell carcinoma (SCC), especially among patients who had survived 5 years or longer after transplant. Whereas, chronic GVHD was associated with an increased risk for SCC, during both early and late post-transplant period [170]. The overall risk for secondary solid tumor was twofold higher in patients in whom radiation was a part of pre-transplant conditioning compared with patients given radiation sparing prepartory regimen. The increased solid tumor risk with radiation was most significant for patients younger than 10 years of age at the time of transplantation and remained high up to the age of 30 years. Patients 30 years and older at the time of transplant did not display higher risk for secondary solid organ malignancies despite receiving TBI conditioning.

The risks of secondary solid organ malignancies in nonradiation-based HSCT conditioning, with busulfan-cyclophosphamide was evlauted in 4,318 patients [171]. The cumulative incidence of solid cancers was 0.8% after 5 years and 2% after 10 years following transplantation. HSCT recipients had 1.4× higher rate of solid organ cancer compared with age- and gender-matched general population. Lung cancer was common, followed by breast cancer; significantly elevated risk was also observed for tumors involving the oral cavity, esophagus, soft tissue, and brain. On multivariate analysis, old age, lower performance status at time of transplantation, and chronic GVHD were important predictors for such cancers [171]. It is hypothesized that busulfan can cause pulmonary injury and fibrosis [172]; exposure to alkylator chemotherapy and particularly in patients with history of smoking increases the risk for lung cancer [173]. There might have been a synergistic carcinogenic effect of smoking and busulfan-cyclophosphamide lung cancer in non-TBI HSCT study [170, 171, 174–177].

The pathophysiology of secondary solid organ malignancies after allogeneic HSCT is not well understood and most likely a culmination of number of factors. Differences in type of malignancies related with TBI exposure versus busulfan-cyclophosphamide preparatory therapy or chronic GVHD suggest divergent carcinogensis pathways. Radiation may increase the risk of post-transplant malignancies by inhibiting DNA repair mechanisms resulting in gene translocation and gene instability due to breaks in double-strand DNA. Chronic GVHD and prolong exposure to immunosuppressive drugs likely increase the risk for secondary malignancies by inhibiting cancer-protecting immunologic defense mechanisms; for example, increased incidence of SCC involving female genital tract or head and neck cancer due to infection with human papilloma virus is related with chronic GVHD and prolonged immunosuppressive therapy [170, 171, 177–179].

Post-Transplant Lymphoproliferative Disorder

Post-transplant lymphoproliferative disorder (PTLD) is a serious complication in patients undergoing solid organ transplants (SOT) and allogeneic HSCT. PTLD is a heterogeneous group of lymphoproliferative diseases with a wide-spectrum of underlying pathology and clinical manifestations that range from benign lymphoid hyperplasia to aggressive lymphoma [180]. The incidence of PTLD is 1–10% after SOT and 0.5–1% after HSCT [181–185]. Most SOT-related PTLD is of host origin [186], whereas PTLD in allogeneic HSCT recipients is predominately of donor origin [187]. The highest risk for PTLD is in patients with drug-induced severe immune suppression for prevention and treatment of solid organ allograft rejection; rate between 10% and 25% are observed in SOT subgroup that require high doses of antirejection therapy that is commonly given for a prolong duration after heart, lung, and multivisceral transplants [181, 182, 188]. The incidence rates are lower (1% and 5%) after kidney and liver transplantation, as these patients in most cases, do not require intense drug-induced immunosuppressive state [184, 188]. An estimated 50–70% of all PLTD cases are associated with EBV infection [189–191], the risk is higher in EBV-negative recipient given allograft from EBV-positive donor [190, 192].

In HSCT recipients, the main risk factors for PTLD are T-cell depletion (TCD), and HLA mismatch, unrelated donor graft transplants. Severity of GVHD, and transplantation for primary immune deficiency disorders are additional contributing factors [185, 187, 193]. The median time from transplantation for PTLD in SOT patients varies from 30 to 72 months [183, 189, 194–197]. Among HSCT recipients, PTLD has a more rapid onset with a median time between 4 and 6 months after transplantation [185, 187, 198].

The incidence of EBV-negative PTLD is 10–20%; it usually occurs late and responds poorly to treatment [169, 196, 197]. PTLD have a diverse clinical presentation based on location and the degree an organ is involved. Presenting symptoms include fever, lymphadenopathy, weight loss, anorexia, fatigue, sepsis-like syndrome, and multi-organ dysfunction. Extra-nodal involvement is relatively common; sites such as the gastrointestinal tract, lung, skin, bone marrow, and central nervous system are frequently affected [183, 189, 194, 197, 199, 200]. PTLD in patients after HSCT usually has an aggressive course with extensive disseminated disease, involving multiple organs [201]. Prognostic factors associated with poor survival include older age, elevated LDH, presence of B symptoms, multi-organ involvement, decreased performance status, advanced stage of the disease, involvement of the allograft in solid organ recipients, >1 extra-nodal sites, and CNS or bone marrow involvement [202, 203]. At present there is no consensus on standard treatment for PTLD; reduction in immune suppression, when possible is the main treatment strategy. Additional therapeutic options include rituximab, chemotherapy, antiviral therapy, cytokine therapy, adoptive immunotherapy, surgery, and radiation [202, 204]. Given the heterogeneity of PTLD, survival is variable with an overall median survival range between ~1.5 and 8 years [180]. Mortality rate may be high (70–90%) in patients following high-risk allogeneic HSCT [185].

Secondary Myelodysplastic Syndrome and Leukemia

Recipient-Derived Myelodysplastic Syndrome and Acute Myelogenous Leukemia

Treatment-related myelodysplastic syndrome (MDS) and acute myelogenous leukemia (AML) may occur after autologous HSCT. Up to 10% of patients with lymphoma treated with either conventional or high-dose antineoplastic therapy, and those after autologous stem cell transplants may develop treatment-related MDS or AML within 10 years after the primary therapy [205, 206]. Main risk factors are prior exposure to alkylating agents and the purine nucleotide analog like fludarabine, and TBI as part of the preparatory regimen [205, 206]. Cases of treatment-related MDS/AML have been reported in patients who were treated with radioimmunotherapy; however the possible contribution of radioimmunotherapy to the risk for secondary malignancies is still unclear since most patients had been previously treated with alkylating agents [207]. The pathogenesis of alkylating drug and TBI-induced MDS/AML is a result of chromosomal damage of hematopoietic precursors; possibly other yet unknown tumor promoting external elements and unrecognized hosts' genetic haecceity may also play a role. The neoplastic transformation of the hematopoietic stem cells is a multiple step process, which is most likely initiated by prior exposure to cytotoxic drugs and accelerated by high-dose chemo- and radiation therapy used in transplant conditioning. Therefore, patients undergoing autologous HSCT should be carefully evaluated for pre-transplantation risk(s) for secondary MDS/AML, and selection of conditioning regimen must be tailored accordingly.

Donor-Derived MDS and AML

In the allogeneic setting, secondary MDS and AML after HSCT are thought to occur as a result of oncogenic transformation of the apparently normal donor hematopoietic stem cells exposed to a foreign environment [208]. Donor-derived MDS/AML is a rare complication after HSCT, and its incidence has been reported between 0.12% and 5% [208–210]. Alteration of the bone marrow microenvironment following allogeneic stem cell transplantation resulting from high -doses cytotoxic and immunosuppressive

drugs may influence normal hematopoietic progenitor cells to undergo leukemic transformation via a complex mechanism(s) that may involve interaction between donor hematopoietic progenitor cells, and recipients' unique stromal cells and signalling milieu, influence of growth factors, selective impact via cytokines and chemokine dysregulation, among others [208]. In large survey conducted by European Group for Blood and Marrow Transplantation (EBMT), 14 donor-derived leukemia were reported among 10,489 allogeneic HSCT recipients. The median time to onset was 17 months, with a range of 4–164 months after transplantation. No specific risk factors, such as type of conditioning regimen, donor graft manipulation, or type and degree of recipients' immune suppression were identified [209]. It is important to differentiate secondary leukemia after allogenic transplant from relapse of the original disease, which is an important cause of death in patients undergoing allogeneic stem cell transplantation [211].

The current understanding of secondary malignancies after HSCT is based on studies that evaluated mainly patients who have received myeloablative conditioning. Less is known about the repertoire and risks for secondary malignancies after reduced-intensity HSCT recipients; long-term follow up studies are needed to assess post-transplant cancer risk this population.

Conclusion

HSCT is an effective life-saving treatment modality for many hematologic malignancies and a growing number of nonmalignant hematologic and autoimmune disorders. However, as discussed in the aforementioned text, there are a number of short- and long-term complications associated with preparatory regimens given prior to transplantation. In this chapter, we have enumerated common and less frequently noted complications attributed to various conditioning regimens used to achieve cytoreduction, antitumor effect, myeloablation, and immunosuppression. Additional complications and toxicities may occur as a result of GVHD, opportunistic infections, and disruption in various aspects of hosts' immune response. Whenever the transplant procedure is performed, a life is at risk, and the question of risk vs. benefit needs to be discussed in great detail with the patient along with quality of life issues and reasonable expectations in near and far post-transplant period. The goal always is to minimize transplant-related risks, which can be achieved with better understanding of such complications. As we move forward into the era of targeted and molecular biologics, it remains imperative that feasiability of new agents with better therapeutic index and safety profiles be incorporated in next generation preparatory regimens with the aim to reduce the burden of complications and achieve sustained cancer remission following hematopoietic stem cell transplantation.

Intravascular Catheter and Implantable Device Infections in Transplant Patients

13

Nasia Safdar, Cybele Lara R. Abad, and Dennis G. Maki

Introduction

The use of intravascular devices for administration of drugs, fluids, blood products, and nutritional support is essential to medical care. Unfortunately, these intravascular devices have a significant potential to produce iatrogenic disease, especially bloodstream infection originating from colonization of the device used for access or from contamination of the infusate administered through the device [1–4]. Over two-thirds of all healthcare-associated bacteremia originate from devices used for vascular access [5]. Patients with hematologic malignancies undergoing stem cell transplantation (SCT), who have inherently compromised immune function because of their malignancy and are further incapacitated due to the preparative regimen or graft-versus-host disease (GVHD), are particularly prone to device-related infections [6].

Every year more than five million central venous catheters (CVC) are inserted in the United States [7]. More than 250,000 intravascular catheter-related bloodstream infections (IVDR BSI) occur annually with an associated mortality of 12–25% [7]. A recent meta-analysis found mortality to be significantly increased in intensive care unit (ICU) patients who had IVDR BSI compared with those without IVDR BSI (odds ratio [OR], 1.96; 95% confidence interval [CI], 1.25–3.09) (Fig. 13.1) [8]. Each episode of IVDR BSI significantly increases hospital length of stay, and the added healthcare costs range from $4,000 to $56,000 per episode [9–11].

Probably more than any other healthcare-associated infection, IVDR BSI is preventable [5, 12–15].

This chapter focuses on the epidemiology and prevention of IVDR BSI in transplant patients. Given the paucity of data specific to the transplant population, we extrapolate from studies in other populations, particularly the critically ill and patients with cancer.

The first step to preserve vascular access is a highly effective institutional program for prevention of IVDR BSI. In recent years, a large volume of high-quality research studies have delineated key measures for prevention, and IVDR BSI rates in the ICU have declined markedly in most institutions [13, 16–27]. However, despite adherence to best practices, IVDR BSI continues to pose formidable challenges, especially in solid organ and stem cell transplant patients [28].

Pathogenesis of IVDR BSI

There are two major sources of IVDR BSI: (1) colonization of the IVD, or device-related infection, and (2) contamination of the fluid administered through the device, or infusate-related infection [29]. Contaminated infusate is the cause of most epidemic intravascular device-related BSI [4, 30]; in contrast, catheter-related infections are responsible for most *endemic* device-related BSI. A major route of BSI in transplant patients may be translocation of gut and oral flora into the bloodstream as a result of mucositis, called mucosal barrier injury-related BSI. These infections may be mistakenly classified as IVDR BSI if the patient has an IVD in place at the time of positive blood culture.

Understanding the pathogenesis of IVDR BSI is fundamental to devising effective strategies for prevention and treatment of these infections; however, relatively few published studies have determined the mechanism of IVDR colonization and infection using sophisticated molecular techniques to prove or disprove potential routes of infection [31–37].

In order for microorganisms to cause catheter-related infection, they must first gain access to the extraluminal or intraluminal surface of the device where they can adhere

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_13

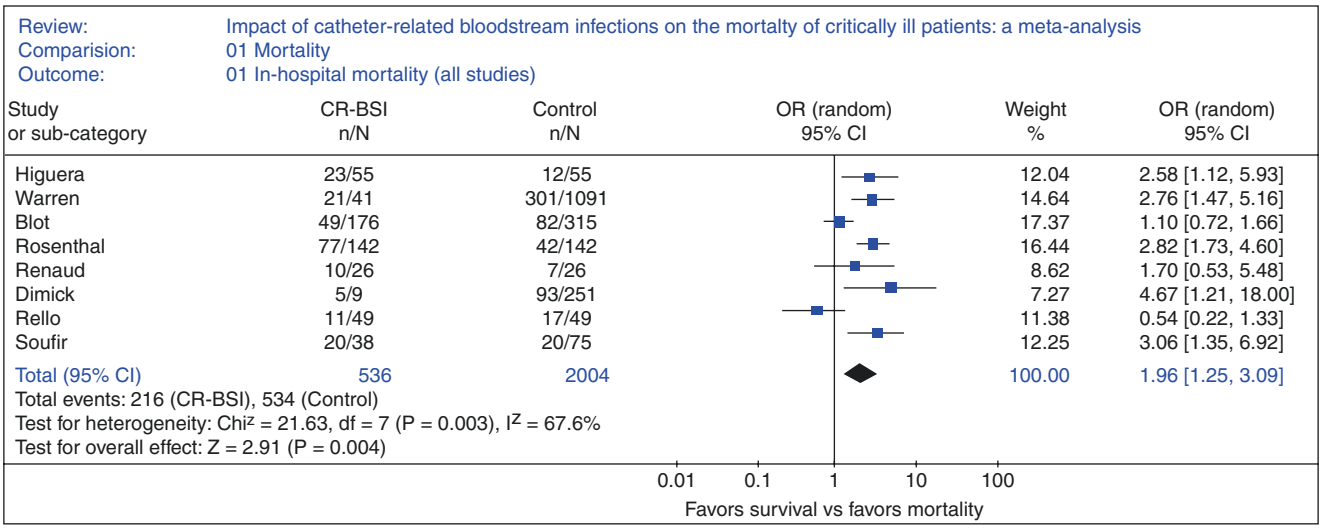

Fig. 13.1 Attributable mortality of IVDR BSI in critically ill patients [8]. (Reprinted from Siempos et al. [8], © 2009, http://journals.lww.com/ccmjournal/Abstract/2009/07000/Impact_of_catheter_related_bloodstream_infections.22.aspx, with permission from Wolters Kluwer Health, Inc.)

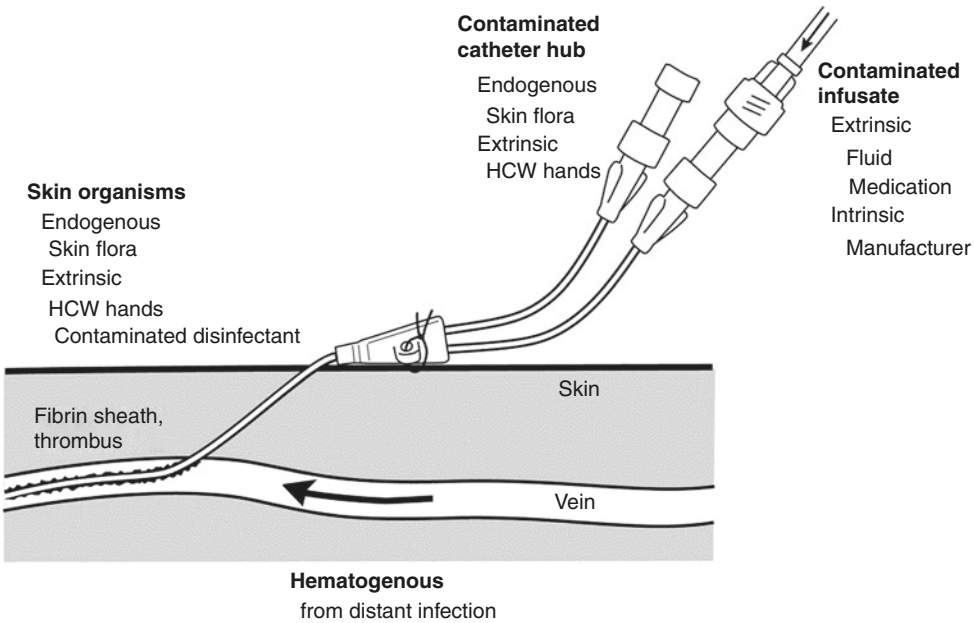

Fig. 13.2 Potential sources of infection of a percutaneous IVD: the contiguous skin flora, contamination of the catheter hub and lumen, contamination of infusate, and hematogenous colonization of the IVD from distant, unrelated sites of infection [42]. (Reprinted from Crnich and Maki [42], by permission of Oxford University Press)

and become incorporated into a biofilm that allows sustained colonization and ultimately hematogenous dissemination [38]. Microorganisms gain access to the implanted IVD by one of three mechanisms: (1) skin organisms invade the percutaneous tract, probably facilitated by capillary action [39], at the time of insertion or in the days following; (2) microorganisms contaminate the catheter hub and lumen when the catheter is inserted over a percutaneous guidewire or later manipulated [40]; or (3) organisms are carried hematogenously to the implanted IVD from remote sources of local infection, such as a pneumonia [41] or from gut or mouth translocation due to inflammation or mucositis (Fig. 13.2) [42].

With short-term IVDs that are in place <14 days, such as peripheral IV catheters, arterial catheters, and non-cuffed, non-tunneled CVCs, most catheter-related BSIs are of cutaneous origin, from the insertion site, and gain access extraluminally or occasionally intraluminally [37, 43, 44]. For long-term catheters, such as tunneled, cuffed CVCs, totally implantable ports, and peripherally inserted central catheters (PICCs), luminal colonization has been shown to be the major mechanism leading to BSI [45, 46]. A characteristic pulsed-field gel electrophoresis image obtained from a short-term non-cuffed CVC causing BSI is shown in Fig. 13.3 and from a long-term catheter (PICC) in Fig. 13.4.

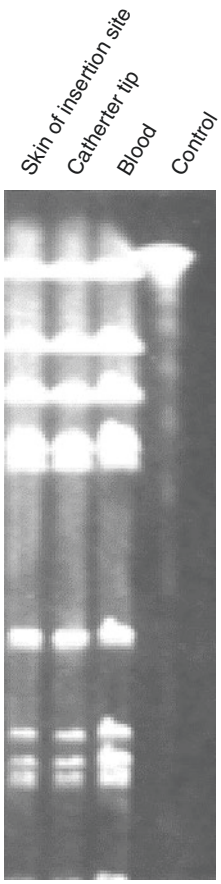

Fig. 13.3 Pulsed-field gel electrophoresis image showing the probable pathogenesis of a CVC-related bacteremia with coagulase-negative Staphylococcus. The isolates from the skin of the insertion site, catheter tip, and blood and were concordant, indicating an extraluminal route of infection [37]. (Reprinted from Safdar and Maki [37], with permission of Springer)

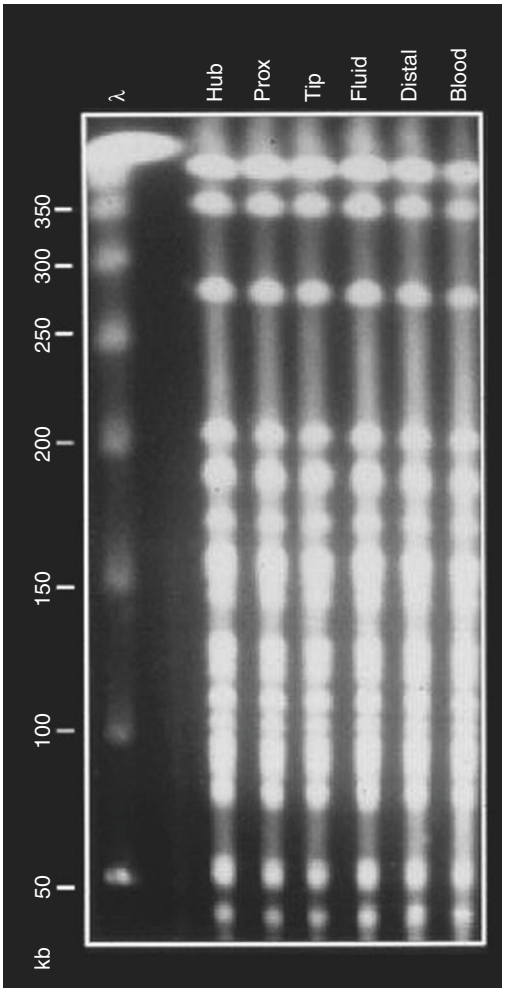

Fig. 13.4 Pulsed-field gel electrophoresis image showing the probable pathogenesis of a PICC-related bacteremia with *Serratia marcescens*. The isolates from the catheter tip, blood, hub, and fluid were all concordant, indicating an intraluminal route of infection

Microbiology

Antimicrobial resistance, now considered to be at global-crisis levels, continues to loom large, and the organisms implicated in IVDR BSI are no exception. In the past two decades, the proportion of IVDR BSI caused by multidrug-resistant (MDR) organisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA) and fluconazole-resistant *Candida* species, has risen inexorably [7, 47–49]. Overall, the organisms encountered most frequently in IVDR BSI are coagulase-negative staphylococci (CoNS) (31%), *Staphylococcus aureus* (20%), enterococci (9%), and *Candida* species (9%) [25–27, 47, 50].

In one large prospective surveillance study using data from SCOPE (Surveillance and Control of Pathogens of Epidemiological Importance), comprising 24,179 cases of nosocomial BSI reported over a 7-year period from 49 hospitals, the rates of MRSA infection increased from 22% of all *S. aureus* BSI in 1995 to 75% in 2001 ($p < 0.001$), and resistance to vancomycin was found in 60% of *Enterococcus faecium* isolates [47].

There is a paucity of data on the epidemiology and microbiology of IVDR BSI in the transplant population. However, a large multicenter study among 38 acute care hospitals, the majority of which were oncology and bone marrow transplant-capable centers, recently implemented the National Healthcare Safety Network (NHSN) surveillance definition of mucosal barrier injury laboratory-confirmed bloodstream infection (MBI-LCBI). In a study by See et al. [51], among 168 central line-associated bloodstream infections (CLABSI) from patients who met one of the two patient criteria of the MBI-LCBI definition, *E. faecium*, *E. coli*, and CoNS (16.0%, 12.6%, 12% of organisms, respectively) were the organisms most commonly reported. In comparison, among 121 cases of CLABSI from patients who did not meet the MBI-LCBI definition's patient criteria, CoNS and *S. aureus* were the top organisms isolated, and both *E. faecium* and *E. coli* organisms were less commonly reported, with a joint rank of sixth (7.2% of organisms). This difference in the underlying etiologic organism favors the addition of mucosal

barrier injury-related BSI as a separate entity from CLABSI particularly for the neutropenic transplant population, as the pathogenesis of bacteremia in this group of patients can arise from a wholly different mechanism.

Diagnosis

Accurate and early diagnosis of IVDR BSI is essential in guiding management decisions, and a variety of diagnostic tests have been developed to help guide therapy. These tests are broadly categorized as methods that require removal of the IVD and those that do not. In general, those that require removal involve quantitative or qualitative cultures of the catheter segment, and those that do not require removal involve paired blood cultures or cytospin examination (Table 13.1) [52].

A meta-analysis by Safdar et al. examined the eight most common diagnostic methods used to evaluate catheter-related bloodstream infection, including qualitative catheter segment culture, semiquantitative catheter segment culture, or quantitative catheter segment culture, each in concordance with results of concomitant blood cultures; qualitative blood culture drawn through an IVD; quantitative blood culture drawn through an IVD, paired quantitative peripheral, and IVD-drawn blood cultures; acridine orange leukocyte cytospin testing; and differential time to positivity. Overall sensitivity was highest for the qualitative catheter segment culture (0.9), followed by IVD-drawn qualitative blood culture and paired quantitative blood cultures (both 0.87). The acridine orange cytospin test had the lowest sensitivity (0.72). Among all the tests, the paired quantitative cultures had the highest specificity (0.98), whereas the qualitative segment culture had the lowest (0.72). However, most methods had acceptable sensitivity and specificity, and the commonly used differential time to positivity test is the preferred method [52].

Notably, in this meta-analysis, only a few studies included immune-compromised patients [53–60], and none exclusively studied the transplant population. Since, there have been only a few additional studies involving the transplant population [61–63]. All these studies evaluated the use of a catheter removal sparing method, the acridine orange leukocyte cytospin (AOLC) test. In a study by Abdelkefi et al., among 26 of 245 hematopoietic stem cell transplant recipients who had a positive differential time to positivity test, the cytospin test was only positive in two of the 26 patients and had a very low sensitivity of 7% [63]. A study by Farina et al. showed similar results, with AOLC testing negative despite positive culture results [62]. In contrast, a smaller study by Krause et al. involving 16/51 hematopoietic stem cell transplant patients showed conflicting results, with much higher sensitivity at 70% and a 100% positive predictive value and a 88% negative predictive value [61]. Certainly, more information regarding the applicability of these and other methods of diagnoses in this particular population is needed.

Table 13.1 Major diagnostic methods for IVDR BSI [52]

Diagnostic method	Description	Criteria for positivity
Methods requiring device removal		
Qualitative catheter segment culture	A segment from the removed catheter is immersed in broth media and incubated for 24–72 h	Any growth
Semiquantitative catheter segment culture	A 5-cm segment of the catheter is rolled four times across a blood agar plate and incubated	≥15 CFU
Quantitative catheter segment culture	A segment from the removed catheter is flushed with broth or sonicated in broth, followed by serial dilutions, surface plating on blood agar, and incubation	≥1000 CFU
Methods not requiring device removal		
Qualitative blood culture through the device	One or more conventional blood cultures are drawn through the device	Any growth
Quantitative blood culture through the device	A blood culture drawn through the device and processed by pour-plate methods or a lysis-centrifugation technique (Isolator, Wampole Laboratories, Cranbury, New Jersey)	≥100 CFU/mL
Paired quantitative blood cultures	Concomitant quantitative blood cultures are drawn through the device and percutaneously and are monitored continuously	Cultures are positive from both sites and the concentration of microorganisms in the culture from the device is 3- to 5-fold greater than in the peripherally drawn culture
Differential time to positivity	Concomitant conventional blood cultures are drawn through the device and percutaneously and are monitored continuously	Both blood cultures are positive and the catheter-drawn blood culture turns positive ≥2 h earlier than the peripherally drawn culture
Acridine orange leukocyte cytospin	Approximately 1 mL of blood is aspirated from the catheter; the cells are lysed with sterile water; and the specimen is centrifuged, stained with acridine orange, and examined microscopically	Visualization of any microorganisms

Abbreviation: CFU colony-forming units

Table 13.2 Recommendations for prevention of IVDR BSI, 2011 CDC HICPAC Guideline [7, 64, 65]

Recommendation	Rating[a]
Education, training, staffing	
Educate all relevant healthcare personnel regarding indications for IVC use, proper procedures for insertion and maintenance, and infection-control measures	IA
Ensure appropriate nursing staff levels in ICUs	IB
Surveillance	
Conduct institutional surveillance for rates of IVDR BSI, monitor trends, identifying lapses in infection-control practices	IA
Express ICU data as number of IVDR BSIs per 1000 catheter days	IB
Antisepsis	
Maximal sterile barrier precautions during catheter insertion: cap, mask, sterile gown, sterile gloves, and large sterile sheet	IB
Hand hygiene: wash hands with antiseptic-containing soap and water or waterless alcohol-based product: before insertion or any manipulation of any IVC	IB
Gloves: required for any manipulation of any IVC	IB
Sterile gloves required for arterial and central catheters	
Clean gloves acceptable for peripheral IVCs if site not touched after application of skin antiseptics	
Cutaneous antisepsis: use before insertion and during dressing changes: 2% chlorhexidine is preferred, an iodophor or 70% alcohol are acceptable	IA
Insertion	
When possible, use subclavian site when using a non-tunneled CVC	IB
Use ultrasound guidance and designated personnel for insertion and maintenance of IVCs	IB
Use sterile gauze or sterile, transparent semipermeable dressing	IA
Do not give prophylactic antibiotics to prevent catheter colonization or BSI	IA
Maintenance	
Change dressing at least weekly	IIII
Monitor site visually or by palpation through intact dressing on regular basis and remove dressing for full exam if tender, fever without obvious source, or other manifestations suggesting local or BSI	
Do not routinely culture catheter tips	IB
Do not use topical antibiotic ointments or creams (except with dialysis catheters)	IB
Remove IVCs as soon as not necessary	IB
Do not routinely replace CVCs, PICCs, HD catheters or pulmonary artery catheters to prevent IVDR BSI	
Replace peripheral venous catheters at least every 72–96 h in adults	IB
Replace administration sets no more frequently than at 72 h unless infection or unless infusing blood products or lipid emulsions	
If after implementing a comprehensive strategy to reduce rates of IVDR BSI and rates remain high, use antimicrobial or antiseptic-impregnated CVC in adults if CVC is expected to remain >5 days	IB
Other strategies recently addressed in current guidelines	
Consider antimicrobial lock solutions for use in all long-term devices	II
Chlorhexidine-impregnated dressings (Biopatch®) should be used with all short-term catheters	IA
A sutureless catheter securement device (StatLock®) is preferred to sutures	II
Adhere to the IHI bundle for CVCs	IA
Chlorhexidine bathing in the ICU	II

[a]CDC categories of evidence: IA: Strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies, IB: Strongly recommended for implementation and supported by some experimental, clinical or epidemiologic studies, and a strong theoretical rationale, IC: Required by state or federal regulations, rules, or standards, II: Suggested for implementation and supported by suggestive clinical or epidemiologic studies or a theoretical rationale [7]

Prevention of IVDR BSI

In 2002, the Healthcare Infection Control Practices Advisory Committee (HICPAC) of the CDC published a comprehensive guideline for the prevention of IVDR BSI [7]. This guideline was recently updated in 2011 [64] and provides recommendations for: all healthcare workers on best practices for catheter insertion and care; the surveillance of infection rates; practicing maximal antisepsis, including hand hygiene and barrier precautions; choosing the optimal insertion site and dedicated insertion personnel; and removing the device as soon as it is deemed unnecessary [64]. Table 13.2 summarizes the recommendations of the guideline [7, 64, 65]. Highlighted below are topics of importance in prevention as well as other strategies recently addressed in the guideline (Table 13.3) [66–78]. The recommendations are rated based on the strength of evidence supporting them as follows: IA, strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies; IB, strongly recommended for implementation and supported by some

Table 13.3 Novel strategies for the prevention of catheter-related bloodstream infections [66–78]

Strategy	Study	Design	Technology	Outcome
Antimicrobial lock solutions				
	Safdar et al. (2006) [67]	Meta-analysis	Vancomycin-containing locks versus heparin	50% risk reduction (RR, 0.49; 95% CI, 0.26–0.95)
	Yahav et al. (2008) [68]	Systematic review and meta-analysis	Various antibiotics[a]	*Antibiotic solutions:*
			Antibiotic plus antiseptic[b]	RR, 0.44 (95% CI, 0.38–0.5)
			Antiseptic[c]	*Non-antibiotic antiseptic solutions alone*:
				RR, 0.9 (95% CI, 0.48–1.69)
				Non-antibiotic antiseptic solutions + other prevention methods[d]*:*
				RR, 0.25 (95% CI, 0.13–0.5)
	Sanders et al. (2008) [69]	Double-blind randomized trial	Ethanol-containing locks versus heparin	OR, 0.18 (95% CI, 0.05–0.65)
Antimicrobial catheters				
	Veenstra et al. (1999) [70]	Meta-analysis	Antiseptic-impregnated CVCs[e]	OR, 0.56 (95% CI, 0.37–0.84)
	Ramritu et al. (2008) [71]	Systematic review	Antibiotic-impregnated CVCs[f]	RR, 0.39 (95% CI, 0.17–0.92)
	Crnich et al. (2002) [66]	Meta-analysis	Silver-impregnated CVCs	RR, 0.40 (95% CI, 0.24–0.68)
	Ramritu et al. (2008) [71]	Systematic review	Antibiotic versus first-generation antiseptic-impregnated CVCs	RR, 0.12 (95% CI 0.02–0.67)[g]
	Hockenhull et al. (2009) [72]	Meta-analysis	Anti-infective CVCs (all types)	OR, 0.49 (95% CI 0.37–0.64)[h]
Chlorhexidine dressings				
	Maki et al. (2000) [73]	Randomized, controlled trial	Chlorhexidine-impregnated sponge dressing	IVDR BSI: RR 0.37 (0.17–0.80)
	Ho et al. (2006) [74]	Meta-analysis	Chlorhexidine-impregnated dressing versus placebo or povidine-iodine dressing	Catheter or exit site colonization: 14.3% vs 27.2%; OR, 0.4 (95% CI, 0.26–0.61)
				IVDR BSI: 2.2% vs 3.8%; OR, 0.58 (95% CI, 0.29–1.14, $p = 0.11$)
	Timsit et al. (2009) [75]	Randomized, controlled trial	Chlorhexidine-impregnated dressing versus standard dressing	IVDR BSI: 0.4 vs 1.3 per 1000 catheter days; HR, 0.024 (95% CI, 0.09–0.65; $p = 0.005$)
Cutaneous antisepsis				
	Chaiyakunapruk et al. (2002) [76]	Meta-analysis	Chlorhexidine versus povidone-iodine	RR, 0.49 (95% CI, 0.28–0.88)[i]
	Maki et al. (1991) [77]	RCT	Chlorhexidine vs alcohol versus povidone-iodine	IVDR BSI RR 0.16, $p = 0.04$
Mupirocin prophylaxis				
	Tacconelli et al. (2003) [78]	Meta-analysis	Mupirocin prophylaxis in dialysis patients[j]	Decrease in *S. aureus* bacteremia in hemodialysis patients by 78%; RR 0.22 (95% CI, 0.11–0.42)

Abbreviations: CI confidence interval, *EDTA* ethylenediamine tetraacetic acid, *HR* hazard ratio, *IVDR BSI* intravascular catheter-related bloodstream infection, *OR* odds ratio, *RR* relative risk

[j]Six studies used intranasal mupirocin two to three times daily for 5–14 days with various maintenance schedules; four studies used mupirocin applied to catheter exit site

experimental, clinical, or epidemiologic studies and a strong theoretical rationale; IC, required by state or federal regulations, rules, or standards; and II, suggested for implementation and supported by suggestive clinical or epidemiologic studies or a theoretical rationale [7].

Cutaneous Antisepsis

Iodophors, such as 10% povidone-iodine, or 70% alcohol were historically the most widely used agents for cutaneous antisepsis of the insertion site in US centers [79, 80].

However, several studies, including a meta-analysis, have shown that 2% chlorhexidine (CHG) is unequivocally superior for preventing IVDR BSI [76, 77] and is now recommended by the HICPAC Guideline as the agent of first choice (rating IA) [7, 64, 77, 79].

Topical Antimicrobials

The HICPAC Guideline specifically recommends against the application of topical antimicrobial ointments or creams to the IVD insertion site, except in the case of hemodialysis catheters [7] to avoid promotion of fungal infection and antimicrobial resistance (rating IA). The Guideline also discourages the use of intranasal mupirocin for staphylococcal decolonization before IVD insertion or during the use of an IVD as a means to prevent colonization or IVDR BSI (rating IA) [7]. A meta-analysis of mupirocin prophylaxis to prevent *S. aureus* infections in patients undergoing dialysis showed a 63% reduction (95% CI, 50–73%) in the rate of overall *S. aureus* infections [78]. The study population included both hemodialysis and peritoneal dialysis patients. Of the ten studies, six used intranasal mupirocin two to three times daily for 5–14 days, with various maintenance schedules, and four used mupirocin applied to the catheter exit site. In patients undergoing hemodialysis, *S. aureus* bacteremias were reduced by 78% (relative risk [RR], 0.22; 95% CI, 0.11–0.42). However, the differences in site, frequency, and duration of mupirocin treatment in these studies and the resulting clinical heterogeneity make it difficult to offer robust recommendations [78].

A randomized, double-blind, placebo-controlled trial evaluating mupirocin prophylaxis for nosocomial *S. aureus* infections in nonsurgical patients found that restricting the use of intranasal mupirocin to patients shown to be carriers on admission did not prevent nosocomial *S. aureus* infections [81]. Increasing reports of mupirocin resistance [82–87] has called decolonization with mupirocin into question as a strategy to prevent IVDR BSI, even in hemodialysis centers, and we do not recommend topical or intranasal mupirocin for prevention of IVDR BSI.

The early promise of mupirocin has suggested that other topical approaches to preventing IVDR BSI bear study. One such agent is honey, which has long been known to have antibacterial properties. In a randomized, controlled trial (RCT) to compare the effect of thrice-weekly application of Medihoney (commercially available; pooled antibacterial honeys including *Leptospermum* species honey; Medihoney Pty Ltd., Brisbane, Australia) to the IVD exit site versus mupirocin in 101 patients receiving hemodialysis through tunneled and cuffed CVCs, catheter-associated bacteremia rates in the two arms were similar (0.97 versus 0.85 episodes per 1000 catheter days; $p > 0.05$) [88]. Although these results are promising, a larger trial powered to show equivalence or superiority is needed to establish the utility of Medihoney for the prevention of IVDR BSI in patients receiving hemodialysis through cuffed and tunneled CVCs.

Maximal Barrier Precautions

The use of maximal barrier precautions, including cap, sterile gown, mask, large sterile drape, and sterile gloves, significantly reduces the rate of IVDR BSI when used during catheter insertion [7, 89, 90]. In an RCT, Raad et al. compared maximal barrier precautions with minimal precautions such as sterile gloves and a small fenestrated drape, and found the CVC-related BSI rate to be 6.3 times higher in the control group ($p = 0.06$) [89]. The HICPAC Guideline recommends that maximal barrier precautions be used for all central IVD insertions, including PICCs (rating IB) [64].

Insertion Site

According to the HICPAC Guideline, the preferred site for insertion of non-tunneled CVCs in adult patients is the subclavian vein (rating 1B) [7]. However, the subclavian site is typically avoided in hemodialysis patients and patients with advanced kidney disease to avoid stenosis (1A). The femoral site has been reported to be associated with higher rates of catheter colonization as well as an increased risk of deep vein thrombosis compared to cephalad sites in adults [7, 43, 91–93]. In an RCT with uncuffed CVCs comparing femoral with subclavian sites, catheters inserted in a femoral site were associated with a higher incidence of infectious complications (19.8% vs 4.5%; $p < 0.001$) [93].

The internal jugular vein site has also been associated with higher rates of IVDR BSI than the femoral or subclavian sites in several studies [7, 43, 94]. However, a recent RCT comparing the jugular and femoral sites found no difference in the risk of infection between the two sites (2.3 vs 1.5, $p = 0.42$) [95]. A prospective, observational study comparing the subclavian, internal jugular, and femoral insertion sites found colonization lowest at the subclavian site but no difference in rates of infection between sites [95, 96].

Using real-time ultrasound guidance for catheter insertion significantly reduces mechanical complications deriving from catheter insertion and catheter infection [7, 97, 98]. In a randomized study, real-time ultrasound guidance versus the landmark technique for catheter placement in the internal jugular vein resulted in significantly fewer complications, including fewer IVDR BSI ($p < 0.001$) [98]. A meta-analysis found that the use of ultrasound for insertion at internal jugular and subclavian vein sites reduced cannulation failure (RR, 0.32; 95% CI, 0.18–0.55), the need for multiple placement attempts (RR, 0.60; 95% CI, 0.45–0.79), and complications during catheter placement (RR, 0.22; 95% CI,

0.10–0.45) in comparison with insertions using anatomic landmarks [97].

Although no RCT to date has compared the three insertion sites, based on the available data we recommend the subclavian site as the first preferred site for CVC insertion and routinely employing real-time ultrasound to minimize mechanical complications.

Simulation-Based Training

A recent observational study, completed in an urban teaching hospital, evaluated the impact of a simulation-based educational intervention on the rates of IVDR BSI in a medical ICU [99]. As part of this study, 92 second- and third-year internal medicine and emergency medicine residents completed the educational program, which included a pretest, an informational video demonstrating proper CVC insertion technique, training with ultrasound and hands-on practice using a simulator device, and a posttest with a required minimum score [99]. There were 3.2 infections per 1000 catheter days in the 16 months prior to the educational intervention in this medical ICU, and 4.9 infections per 1000 catheter days in a comparator unit in the same hospital, the surgical ICU, during the pre-intervention period. The rate of IVDR BSIs in the medical ICU during the 16-month intervention period, when all of the second- and third-year residents had completed the training, decreased to 0.5 per 1000 catheter days. The rate in the surgical ICU, where no rotating residents completed the simulation training, remained stable at 5.3 per 1000 catheter days during the same 16-month interval [99]. This study highlights the value of cutting-edge programs for training healthcare personnel in proper CVC insertion techniques, addressing a priority recommendation in the CDC HICPAC Guideline for the Prevention of IVDR BSI [7].

Chlorhexidine-Impregnated Insertion Site Dressings

The application of a chlorhexidine (CHG)-impregnated sponge dressing (BioPatch®, Johnson & Johnson Gateway) over the CVC insertion site has been shown to greatly reduce the incidence of IVDR BSI in several randomized trials [5, 73, 75, 79, 100, 101]. A large, randomized, open, controlled trial compared this dressing to standard sterile dressings in 601 chemotherapy patients, with 9,731 catheterization days, and showed a significant reduction in IVDR BSI in the intervention group (6.4%, 19 of 300) compared to the control group (11.3%, 34 of 301; $p = 0.016$, RR, 0.54; 95% CI, 0.31–0.94) [101]. In ICU patients, the use of CHG-impregnated dressings led to significantly fewer IVDR BSIs when compared with standard sterile dressings, in a large, multicenter RCT ($p = 0.005$, HR, 0.024; 95% CI, 0.09–0.65) [75, 100].

The latest 2011 guideline recommends the use of CHG-impregnated dressings for short-term catheters in patients older than two months of age if the CLABSI rate is not decreasing despite adherence to basic multimodal prevention measures (IB). However, there is considerable emerging data indicating that CHG-impregnated dressings are effective in reducing IVDR BSI, and we recommend their use as part of standard care [73, 75, 79, 100, 101].

Chlorhexidine Bathing

Daily bathing with liquid CHG or the use of CHG-impregnated washcloths has been studied extensively in the past few years [102–104] for its impact on reducing healthcare-associated infections. A meta-analysis by O'Horo et al. which included 12 studies examined the efficacy of daily bathing with CHG, focusing mainly on healthcare-associated BSIs, including CLABSI [102]. Ten of the 12 studies were carried out in the ICU setting, and none included the transplant population. The results showed that 291 patients in the CHG arm developed BSI over 67,775 days compared to 557 patients in the control arm who developed BSI over 69,617 days (OR, 0.44; 95% CI, 0.33–0.59; $p < 0.0001$).

Data regarding the use of CHG bathing among transplant recipients is lacking. The study by Climo et al., a multicenter cluster-randomized, crossover trial, involved a total of nine units, of which one was exclusively bone marrow transplant patients [105]. However, results specific to the bone marrow population were not provided. Overall, the risk of acquiring primary BSI was significantly lower among patients bathed with CHG than among those bathed with non-antimicrobial cloths. In addition, the longer the length of stay in the unit, the lower the risk for a primary BSI among those bathed with CHG; for example, RR at day 7 was 0.69 compared to 0.51 at 14 days.

Anti-infective-Impregnated Catheters

The HICPAC Guideline recommends the use of anti-infective-coated CVCs if the catheter is expected to remain longer than five days and is used in combination with a comprehensive IVDR BSI reduction strategy (rating IB) [7]. However, the majority of studies have focused on the use of antimicrobial-coated CVCs used as short-term devices, and few data have been published on their use as long-term devices [71, 79]. Several types of catheters are available: catheters coated either externally, the first generation, or externally and internally, the second generation, with

chlorhexidine and sulfadiazine silver (CSS); catheters coated with minocycline or rifampin; and silver-impregnated catheters [5]. Silver-coated catheters include silver-, platinum-, and carbon-coated catheters and silver ion/alloy catheters.

A recent comprehensive meta-analysis of anti-infective-coated catheters included clinical trials comparing antimicrobial-coated CVCs with either a standard CVC or another antimicrobial-coated CVC [106]. The main outcomes were catheter colonization and catheter-related BSI. The first-generation CSS CVCs were shown to reduce colonization (OR, 0.51; 95% CI, 0.42–0.60) and catheter-related BSI (OR, 0.68; 95% CI, 0.47–0.98). Minocycline-rifampin-coated CVCs also reduced catheter colonization (OR, 0.39; 95% CI, 0.27–0.55) and catheter-related BSI (OR, 0.29; 95% CI 0.16–0.52) and performed better than the CSS CVCs for reducing catheter colonization and BSI (OR, 0.18; 95% CI, 0.07–0.51). A small retrospective study among kidney transplant patients also showed that silver ion (AgION)-coated polyurethane catheters were less likely to be colonized with bacteria (58% vs 6.6%), compared to plain polyurethane catheters [107].

The choice of which catheter to use is governed by many factors including efficacy, cost, cost-effectiveness, and risk of promoting drug resistance. A recent analysis (2008) found an estimated cost savings of £138.20, approximately $227, for every anti-infective catheter inserted [11]. Antibiotic resistance is a particular concern with antibiotic-impregnated catheters, although trials assessing the efficacy of minocycline-rifampin-coated catheters have not found evidence of emergence of drug resistance to date [71].

Anti-infective Lock Solutions

The major mechanism of IVDR BSI in long-term IVDs is intraluminal colonization. For this reason, antimicrobial lock solutions have been a logical step to prevent colonization of the intraluminal surfaces of long-term IVDs to prevent IVDR BSI. A small volume of the antimicrobial solution is instilled into the lumen of the IVD and allowed to dwell for a prescribed period, after which it is either removed or flushed into the patient's bloodstream.

A meta-analysis of seven RCTs, involving mostly cancer patients, comparing a vancomycin-containing lock solution with sterile saline showed a significantly reduced risk of IVDR BSI (RR, 0.49; 95% CI, 0.26–0.95) [67]. Ethanol has also recently been shown to be safe and effective as an antimicrobial lock solution [69, 79, 107]. A recently published prospective, double-blind RCT comparing ethanol with heparinized saline in granulocytopenic hematology patients showed a four-fold reduction in IVDR BSI in the ethanol group compared to controls (OR, 0.18; 95% CI, 0.05–0.65) [69]. In contrast, a similar study comparing heparinized saline with 70% ethanol locks in patients with hematologic malignancies and tunneled CVCs did not show a reduction in device-associated infection with the use of ethanol locks [108].

A recent meta-analysis of 23 studies [109] published in 2014 reported data on a variety of lock solutions and involved a total of 2,896 patients, including patients on hemodialysis, adult and pediatric oncology patients, critically ill neonates, and patients receiving total parenteral nutrition. The use of antimicrobial lock solutions led to a 69% reduction in CLABSI rate (RR, 0.31; 95% CI, 0.24–0.40) and a 32% reduction in the rate of exit site infections (RR, 0.68; 95% CI, 0.49–0.95) compared with heparin, without significantly affecting catheter failure due to noninfectious complications (RR, 0.83; 95% CI, 0.65–1.06).

While a number of new antibiotics show promise as lock solutions based on in vitro studies [110], further research of their efficacy in clinical trials is mandatory.

Given the promising data, we recommend the use of anti-infective lock solutions for prevention of IVDR BSI with long-term IVDs in patients at high risk for IVDR BSI, such as those receiving hemodialysis. In general, antiseptic lock solutions are preferable to antibiotic lock solutions because of their greater spectrum of activity and lower risk of promoting antibiotic resistance.

Anti-infective Luer-Activated Devices

In addition to the above novel technology-based strategies for prevention of IVDR BSI, an emerging role of needleless connectors in the pathogenesis of IVDR BSI must be mentioned, with conjecture of possible preventive strategies.

Needleless connectors were developed in response to demands for enhanced safety for healthcare workers, to prevent needlestick injuries universally, and are an integral component of infusion systems in use across North America. Although needleless connectors, when properly used, clearly reduce the risk for needlestick injuries during access of an IVD or injection port [111–115], some reports published over the past decade have raised concerns about a potential increased risk of iatrogenic IVDR BSI associated with the use of luer-activated, valved connectors [43, 116–120]. Most of these studies have been retrospective and uncontrolled, and suboptimal manipulation of the device, rather than the device itself, may have been responsible for some of the increased incidence of BSI in some settings. However, many hospitals experienced sharp increases in primary BSI following introduction of a new connector, and intensified infection control practices had no impact; only after removing the new connector from the hospital did rates of CVC-associated BSI return to baseline levels [121]. Most notably, multiple commercial valved connectors have been implicated, indicating

that these devices can become contaminated and result in iatrogenic BSI.

Typically, healthcare personnel disinfect the connector before accessing with 70% (v/v) isopropyl alcohol. Although needleless connectors appeared to reduce contamination in comparison with standard caps [122], a recent study by Menyhay and Maki found that conventional methods of disinfection of the membranous septum may not prevent microbial entry if the membrane of the luer-activated device (LAD) is heavily contaminated, which may account for the increased risk for CVC-associated BSI seen in some centers [123].

This issue has been addressed with the development of a new technology. The V-Link with VitaShield (Baxter Healthcare) is a LAD protected with interior and exterior antimicrobial coating and was recently approved by the FDA. The V-Link with VitaShield is effective against 99.9% of pathogens known to cause IVDR BSI in in vitro testing and was recently shown in a simulation study to prevent internal contamination, even with heavy contamination of the membranous septum [124].

Saralex-cl (Menyhay Healthcare Systems), another promising device, is an antimicrobial barrier cap that threads onto the end of a needleless LAD system. A recent prospective in vitro study compared standard disinfection of common LADs using 70% isopropyl alcohol with the new antiseptic barrier cap [125]. This new antiseptic cap which bathes the connector septum with 0.25 mL of 2% CHG in 70% isopropyl alcohol is almost totally effective in preventing transmission of pathogens across the membranes of pre-contaminated LADs when compared to standard techniques (positive control, 100% transmission; standard disinfection with 70% alcohol, 20 transmissions in 30 trials, 67% transmission; Saralex-cl, 1 transmission in 60 trials, 1.6% transmission; $p < 0.001$) [120]. Data on the clinical efficacy of antimicrobial-coated LADs and antimicrobial barrier caps based on RCTs is needed.

Catheter Securement

Choices for securement of a percutaneous uncuffed CVC or PICC include sutures, tape, or novel catheter securement devices, such as StatLock® (Venetec International, a subsidiary of CR Bard). Sutures are often painful for the patient, pose the risk of needlestick injury to the provider placing them, and foster infection at the catheter insertion site, increasing the risk of catheter-related BSI. StatLock®, a sutureless catheter securement device, reduces catheter-related complications including IVDR BSI [126–128]. A randomized trial comparing suture securement to the StatLock® with peripherally inserted central catheters showed a significant reduction in the number of catheter-related BSIs in the StatLock® group (2 vs 10; $p = 0.032$) [127]. We recommend the use of a sutureless securement device for peripheral IV and extended dwell catheters, such as non-cuffed CVCs and PICCs.

Intensive Insulin Therapy

Glycemic control in critically ill ICU patients is essential for prevention of IVDR BSI. However, the optimum level of glycemic control is controversial. A large, RCT in 1,548 critically ill patients in a surgical ICU, the majority of whom had undergone surgical procedures, compared intensive insulin therapy for the maintenance of blood glucose level between 80 and 110 mg/dL by using continuous insulin infusions with conventional subcutaneous insulin therapy given only if blood glucose levels exceeded 215 mg/dL, striving to maintain levels between 180 and 200 mg/dL [129]. The study found a markedly reduced ICU and hospital mortality with intensive glycemic control [8% with conventional treatment vs 4.6% with intensive treatment ($p < 0.04$)]. The greatest reduction in mortality was seen in patients with multi-organ failure due to a septic focus [129]. Most noteworthy, the incidence of nosocomial BSI was cut in half from 8% to 4%. A similar study in medical ICU patients found no reduction in mortality or difference in bacteremia rates with intensive control [130].

A meta-analysis which included 29 RCTs and 8,432 patients found no difference in hospital mortality with tight glucose control versus moderate control (21.6% vs 23.3%; RR, 0.93; 95% CI, 0.85–1.03), and the results did not change when patients were stratified by type of ICU: surgical, medical, or medical-surgical. However, tight glucose control was associated with a reduced risk of septicemia of 10.9% vs 13.4% in the moderate control group (RR, 0.76; 95% CI, 0.59–0.97) [130].

In the NICE SUGAR study, a large RCT of 6,104 adult ICU patients, intensive glycemic control (goal 81–108 mg/dL) was associated with increased mortality compared to conventional control (goal ≤180 mg/dL) (OR, 1.14; 95% CI, 1.02–1.28; $p = 0.02$) [131]. The study population included more medical than surgical ICU patients. The intensive group had 36.9% surgical and 63.1% medical patients, whereas the conventional group included 37.2% surgical and 62.8% medical ICU patients. Severe hypoglycemia, defined as ≤40 mg/dL was significantly more common in the intensive control group (6.8% vs 0.5%; $p < 0.001$) [131].

A recent meta-analysis of 26 trials involving a total of 13,567 patients, including the data from the NICE SUGAR trial, found no mortality benefit to intensive insulin therapy in critically ill patients; the pooled RR of death with intensive therapy using insulin drip as compared with moderate control using subcutaneous insulin was 0.93 (95% CI, 0.83–1.04) [132]. However, when analyzed separately, sur-

gical ICU patients experienced significant benefit (RR, 0.63; 95% CI, 0.44–0.91), while patients in nonsurgical ICUs did not.

Based on these studies, all hospitalized patients are likely to benefit from moderate glycemic control, and we recommend the use of intensive glycemic control with an insulin drip in surgical ICU patients to reduce the risk of healthcare-associated infections, particularly BSI. However, stringent monitoring to avoid severe hypoglycemia is critical, and a glycemic target that can be achieved safely should be chosen, generally 120–130 mg/dL.

Achieving High-Level Compliance with Essential Control Measures Through Institutional Systems

A multifaceted approach with near-100% compliance is essential to consistently and maximally reduce the risk of IVDR BSI. The Institute for Healthcare Improvement (IHI) has developed the concept of "bundles" to aid in risk reduction. A bundle, according to the IHI, is a structured way of improving the processes of care and patient outcomes using a set of practices, generally three to five, which when performed collectively and reliably have been shown to improve patient outcomes [133]. The IHI-recommended evidence-based bundle for CVC care includes the following: (1) hand hygiene before IVD insertion; (2) maximal barrier precautions during the insertion procedure; (3) cutaneous antisepsis with CHG; (4) optimal catheter insertion site selection, with the subclavian vein the preferred site for CVCs; and (5) daily review of continued need for the catheter, with immediate removal when no longer needed [133]. In a pre-post trial in 100 Michigan hospitals, Pronovost et al. showed that development of effective systems within the hospitals which assured a very high level of compliance with the bundle for every CVC insertion resulted in a striking reduction in IVDR BSI in the individual hospitals over 18 months, with a reduction from pre-study baseline at 0–3 months of 0.62 (95% CI, 0.47–0.81) and at 16–18 months of 0.34 (95% CI, 0.23–0.5) [13]. These numbers represented an overall 66% reduction in rates of IVDR BSI, which was maintained for several months [15].

Bhutta et al. undertook a prospective quasi-experimental study in a children's hospital which included the stepwise introduction of interventions over a 5-year period [134]. The interventions included maximal barrier precautions, a transition to antibiotic-impregnated CVCs, annual hand washing campaigns, and the use of CHG in lieu of povidone-iodine. Significant decreases in rates of infection occurred over the intervention period and were sustained over a 3-year follow-up. Annual rates of CVC-associated BSI decreased from 9.7 per 1000 days in 1997 to 3.0 per 1000 days in 2005 (RR, 0.75; 95% CI, 0.35–1.26). The investigators found that multifaceted interventions of this nature and development of systems to achieve uniformly high compliance reduce IVDR BSI but require strong institutional support.

The recent implementation of a multifaceted approach in a pediatric cardiac ICU, which included CVC insertion and maintenance bundles, CHG-impregnated dressings, nurse and physician education, and the addition of a unit-based infection control nurse, resulted in a reduction in the rate of IVDR BSI from 7.8 to 2.3 infections per 1000 catheter days over a period of less than 2 years [135]. Pronovost et al. have outlined the essential steps to establishing an effective institutional system to achieve these recommended results [14].

A recent meta-analysis by Blot et al. also investigated the efficacy of quality improvement interventions, including personnel education, catheter care bundles, and checklists in decreasing CLABSI. Results among the 41 studies showed an infection rate decrease (OR, 0.39; 95% CI, 0.33–0.46; $p < 0.001$), which was more pronounced for trials implementing a bundle or checklist approach ($p = 0.03$) [136]. These results suggest that quality improvement interventions contribute to the prevention of CLABSI.

Summary

The use of intravascular devices is now standard of care for many patients, including transplant recipients. Unfortunately, these devices, especially when used in the long term, increase the risk of bloodstream infections through external or internal colonization of the lumen. The key to preventing device-related bloodstream infection is establishment of, and strict compliance with, a multifaceted approach to consistently and maximally reduce the risk of IVDR BSI. This approach has largely been streamlined into a few steps called the bundle of care and consists of hand hygiene, use of maximal barrier precautions, antisepsis, and removal of the line when it is no longer necessary.

In critically ill transplant patients where access is crucial and yet difficult to obtain, removal of the infected device may not be a feasible option, and catheter salvage is a viable alternative. Fortunately, there are now evidence-based recommendations from guidelines and several recent studies that have evaluated the use of salvage therapy, both for prevention and treatment of device-related bacteremia. Among the options, the use of antibiotic or antiseptic lock solutions in combination with systemic therapy appears to be the most promising. Data among the transplant population remains scant at this time, and more prospective, randomized controlled trials are needed in the future to evaluate whether current recommendations for the general population are applicable to this population.

Surgical Site Infections: Wound and Stump Infections

14

Nasia Safdar, Sara A. M. Zerbel, and Elizabeth Ann Misch

Background and Prevalence

Surgical site infections (SSI) following transplantation have been linked to increased mortality, graft rejection, increased length of stay, and increased resource utilization [1, 2]. SSIs can be categorized by the anatomical depth at which the infection occurs. Superficial SSIs involve the skin and subcutaneous tissue of the surgical incision only. Deep SSIs involve the deep soft tissues (e.g., fascia and muscle). Organ/space infections involve tissue beyond the fascia and muscle including the intra-abdominal cavity, solid organs, bone, mediastinum, and spinal tissue (see Fig. 14.1). The Centers for Disease Control and Prevention's (CDC) National Healthcare Safety Network (NHSN) defines the time frame for superficial, deep and organ/space SSIs as occurring within the 30 days after surgery for select procedures such as if no implant is present. For other procedures, such as if an implant is present, deep and organ/space infections can be linked back to a surgical procedure for up to 90 days after surgery. See Table 14.1 for detailed NHSN definitions of SSI. Rates of SSI vary and can reach as high as 37% for some transplant procedures [3]. The risk of infection depends greatly on type of surgery and patient-specific factors. A number of factors predispose transplant patients to SSI including immunosuppression, reoperation, diabetes, and obesity [4–13]. The route of infection is dependent on the type of transplant surgery and may be both endogenous and exogenous sources. Microorganisms in posttransplant SSIs are primarily bacterial; however, fungal infections may also play a role [14–16]. Multidrug-resistant organisms are an increasingly common culprit in SSI [9–11] in this population due to a heavy exposure to the healthcare system, use of prophylactic antibiotics, and immunosuppression. There are few guidelines to direct therapy. In general, management with debridement alone is not sufficient in the transplant population, due to impaired host defenses. Culture or PCR of tissues is critical to diagnose resistant or unexpected pathogens. Depending upon local epidemiology and site of infection, antibiotics to target resistant Gram-positive and Gram-negative organisms (including *Pseudomonas*), *Candida*, and, on occasion, *Aspergillus*, may be necessary. Measures to prevent SSI during the preoperative, intraoperative, and postop-

Table 14.1 CDC's NHSN definition of SSI [17]

A *superficial incisional SSI* must meet each of the following criteria:
1. Infection occurs within 30 days after operative procedure
2. Involves only skin and subcutaneous tissue of the incision
3. Patient has at least one of the following:
a. Purulent drainage from the superficial incision
b. Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision
c. At least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat, and superficial incision are deliberately opened by surgeon and are culture-positive or not cultured. A culture-negative finding does not meet this criterion
d. Diagnosis of superficial incisional SSI by the surgeon or attending physician
A *deep incisional SSI* must meet each of the following criteria:
1. Infection occurs within 30 days after the operative procedure for select procedures or within 90 days for others (such as if an implant is in place) and the infection appears to be related to the operative procedure
2. Involves deep soft tissues (e.g., fascial and muscle layers) of the incision
3. Patient has at least one of the following:
a. Purulent drainage from the deep incision but not from the organ/space component of the surgical site
b. A deep incision spontaneously dehisces or is deliberately opened by a surgeon and is culture-positive or not cultured, and the patient has at least one of the following signs or symptoms: fever (>38 °C), or localized pain or tenderness. A culture-negative finding does not meet this criterion
c. An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiographic examination
d. Diagnosis of a deep incisional SSI by a surgeon or attending physician
An *organ/space SSI* must meet each of the following criteria:
1. Infection occurs within 30 days after the operative procedure for select procedures e or within 90 days for others (such as if an implant is in place) and the infection appears to be related to the operative procedure
2. Infection involves any part of the body, excluding the skin incision, fascia, or muscle layers, that is opened or manipulated during the operative procedure
3. Patient has at least one of the following:
a. Purulent drainage from a drain that is placed through a stab wound into the organ/space
b. Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space
c. An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination
d. Diagnosis of an organ/space SSI by a surgeon or attending physician

erative period should be evidence-based and incorporated into hospital quality control initiatives.

The incidence of SSI as published by NHSN is 3.28% in patients undergoing heart transplant, 3.67–6.57% for kidney transplant, and 11.61–20.10% for liver transplant [18] (Table 14.2). A prospective study of 113 living-donor liver transplant recipients showed an SSI rate of 37%, with intra-abdominal abscess and peritonitis as the most common infections [3].

Table 14.2 Posttransplant SSI rates [3, 18]

Organ transplanted	Published SSI range	Source
Living-donor liver transplant	37%	Iinuma et al. [3]
Liver transplant	11.61–20.10%	NHSN [18]
Heart transplant	3.28%	NHSN [18]
Kidney transplant	3.67–6.57%	NHSN [18]

Major Risk Factors for SSI

Patients undergoing solid organ transplant are at an increased risk for development of SSI. A number of factors are known to increase the risk for infection in the transplant population including immunosuppression, recurrent rejection, reoperation, diabetes mellitus, and obesity [3, 8–11, 19–21]. The CDC uses the following equation to estimate risk for SSI:

$$\frac{\text{Dose of bacterial contamination} \times \text{virulence}}{\text{Resistance of the host patient}} = \text{Risk of SSI}$$

Immunosuppression

The last two decades have witnessed tremendous advances in transplantation including the development of drugs that suppress the body's immune system to aid the transplant and long-term acceptance of allogeneic tissue. However, these drugs simultaneously create an environment within the body that allows invasion by opportunistic pathogens [4, 22]. Environmental and skin organisms that offer little risk to patients with intact immune systems may colonize and infect immunosuppressed patients. In addition, due to immunosuppression, symptoms and signs of SSI may be attenuated in transplant patients. With a suboptimal immune response, redness, heat, and swelling may not be present as they would be in a patient with an intact immune system. With a lack of early symptoms, SSIs in immunosuppressed transplant patients are at risk for staying undetected until they become more severe. Patients undergoing transplant of cadaveric allografts are additionally at an increased risk for infection due to the elevated level of immunosuppression required for acceptance of the transplanted organ. Because of the high risk of infection in immunosuppressed patients, it is advisable to complete a comprehensive preoperative physical to evaluate for sources of potential current or previous infection and successfully treat any infections prior to surgery.

Repeat Surgery

Each time a surgical incision is made, there is a risk for contamination with endogenous organisms which consequently increases the risk for infection. Reoperation at the allograft site presents a unique risk for SSI [10, 23]. Patients undergoing reoperation for transplantation are more likely to be highly immunosuppressed in an effort to save the transplanted organ. They are also very likely to have a number of comorbidities that will impact wound healing. In addition, rejection of a transplanted organ often leads to tissue necrosis which can fuel an organ/space infection at the site of the transplant. Anastomotic leaks followed by repeat surgery have also been shown to greatly increase the risk of infection in liver transplant patients [1].

Diabetes Mellitus

Diabetes mellitus adds to the risk of SSI, and with a high incidence in renal and pancreas transplant patients, it can be a common factor in many transplant patients. In a retrospective study of 680 liver transplant patients, Park et al. found that severe hyperglycemia was independently associated with SSI following liver transplantation [24]. Additionally, a prospective study of 1400 kidney transplant patients showed that diabetic patients were at increased risk of developing incisional SSIs after surgery [20]. Although diabetes mellitus is an immutable patient factor, perioperative blood glucose levels can be monitored and strictly controlled, which may reduce SSI and improve outcomes.

Obesity

Many studies have linked obesity with a number of comorbidities, including heart disease, diabetes, cancer, vascular disease, hypertension, and, with these, an increased risk of postoperative wound infection. In addition to the comorbidities that often coexist with obesity, there is an increased risk of suboptimal or underdosing of preoperative antibiotic prophylaxis, as well as concerns regarding postoperative wound care. A review by Holley et al. showed that the most frequently reported postrenal transplant complication in obese patients (BMI ≥30) was wound infection and wound disruption [13]. In another review by Johnson et al., obese patients (BMI >30) were more likely to experience postrenal transplant superficial wound breakdown and wound dehiscence [19]. Due to the increased risk for postoperative wound infection in obese patients, an attempt at significant weight reduction prior to surgery may be indicated for optimal outcomes.

Mechanism of Surgical Site Infection

Type of Transplant

Risks for SSI vary greatly depending on the type of transplant procedure (Table 14.2). Surgery at a sterile body site as in heart transplant is generally lower risk for a SSI than surgery at body sites that can be more easily contaminated by the endogenous bacteria of the gastrointestinal tract, respiratory tract, or genitourinary tract. The CDC describes four types of wound classifications: (1) clean, (2) clean contaminated, (3) contaminated, and (4) dirty/infected (see Table 14.3) [17]. Heart and pancreas transplants are generally considered clean wounds. However, lung, kidney, intestine, and liver transplants are generally considered clean contaminated. If bile or urine is infected, then a liver or kidney transplant, respectively, is considered contaminated. This risk for infection is lowest for clean wounds and highest for dirty wounds.

Endogenous Sources

As described previously, the risk for SSI is directly related to the level of microorganism contamination at the wound site.

Table 14.3 Surgical wound classification [17]

Wound class	Definition
Class I/clean	An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or uninfected urinary tract is not entered. In addition, clean wounds are primarily closed and, if necessary, drained with closed drainage. Operative incisional wounds that follow non-penetrating (blunt) trauma should be included in this category if they meet the criteria
Class II/clean-contaminated	An operative wound in which the respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered
Class III/contaminated	Open, fresh, accidental wounds. In addition, operations with major breaks in sterile technique (e.g., open cardiac massage) or gross spillage from the GI tract, and incisions in which acute, non-purulent inflammation is encountered are included in this category
Class IV/dirty-infected	Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera. This definition suggests that the organisms causing postoperative infection were present in the operative field before the operation

Reprinted from Mangram et al. [17], © 1999, with permission from Elsevier

When a SSI does develop after a clean wound procedure, the infecting organism is much more likely to be endogenous normal skin flora. In particular, Gram-positive bacteria and especially *Staphylococcus species* dominate as the causative agent of infections after clean procedures. Alternatively, with clean-contaminated procedures, the causative agent is much more likely to be endogenous flora of the respiratory, gastrointestinal, or genitourinary tract depending on the type of surgery. The antibiotic chosen for surgical prophylaxis must take into consideration the wound class as well as the type and location of surgery.

Exogenous Sources

Most sources of SSI originate from endogenous normal flora and asymptomatic and symptomatic infections that are present at the time of surgery. However, lapses in surgical technique, hand hygiene compliance, postoperative wound care procedures, and postoperative infections from invasive devices are also contributing factors to the risk of SSI. Given the depressed immune status of the transplant patient, any number of exogenous sources could lead to a postoperative wound infection.

Early Onset

In general, infections that occur within the first week of surgery and are organ/space infections are a result of anastomotic leaks or other contamination of the open surgical site during surgery by endogenous or exogenous sources. These types of infections generally require, at minimum, drainage of fluid collections and possibly repeat surgery. Since the symptoms of SSI can be obscured by immunosuppression, there should be a high level of suspicion for SSI if a patient develops even a slightly elevated white blood cell count or fever.

Late Onset

SSIs that develop after the first two postoperative weeks can have a variety of sources. Postoperative wound care in combination with immunosuppression therapy can play an important role in these late-onset infections. Late-onset organ/space infections in posttransplant patients could be related to rejection of the transplanted organ. In addition, for surgery that involves an implant, deep and organ/space infections may develop as far out as several weeks after surgery. An example of late onset SSI might be a deep sternal wound infection and mediastinitis after heart and lung transplant, since sternal wires are considered implants by the CDC definition.

Diagnosis

The clinical presentation of SSI in immune-compromised (IC) patients may be attenuated in comparison to the normal host. In heart transplant patients, for example, sternal dehiscence, fever (approximately 25–30% of patients), or pain out of proportion to that expected following a sternotomy incision may be the only indicator of an infection at the operative site [9, 25, 26]. In a series of liver transplant recipients, leukocytosis and fever were seen in only 53% and 34%, respectively, of patients [12]. Clinicians should be aware that the differential diagnosis of skin and soft tissue infection in IC patients includes routine (*Staphylococcus*, *Streptococcus*, Gram-negative organisms, *Clostridium*) as well as atypical pathogens (yeasts, mold, mycobacteria) [27–32] and systemic, noninfectious syndromes (drug eruption, pyoderma gangrenosum, and Sweet's syndrome, among others) [33–35]. Thus, patients who fail to respond to empiric antibiotics may require biopsy of the involved tissue to direct therapy toward a proven pathogen or establish an alternate diagnosis. Material can be obtained during debridement or through a separate procedure (punch biopsy) and should be sent for bacterial Gram stain and stains for fungal, acid-fast, and modified acid-fast organisms. Tissue should be submitted separately to the microbiology laboratory, for bacterial, fungal, and mycobacterial culture, and to pathology (fresh frozen section and fixed sections). Immunohistochemistry, PCR, and special stains can be added onto fresh or fixed tissues and may permit more rapid diagnosis of pathogens (e.g., cytomegalovirus, fungi, mycobacteria). Histological evidence of inflammation may be scant even in cases of proven infection.

Microbiology

Recent case series of SSIs in liver transplant recipients emphasize a shift toward a predominance of Gram-negative pathogens, *Enterococcus* (often vancomycin-resistant), and drug-resistant Gram-positive and Gram-negative bacteria. *Candida* species are also reported [36–39]. In patients who received either small bowel or multivisceral transplant, 57% experienced an SSI within 30 days of surgery, with Gram-negative and Gram-positive organisms and *Candida* represented [40]. SSIs in kidney transplant recipients frequently involve Gram-positive bacteria, specifically, S*taphylococci* and *Enterococci* [8, 23, 41]. Frequent rates of Gram-positive organisms and *Candida* are reported in some series of postoperative wound infections in kidney-pancreas transplant patients [21, 42], while a predominance of Gram-negative organisms has been reported in others [20]. Heart transplant patients have high rates of SSIs, with incidences of 8–15% [38, 43]. *Staphylococci*, methicillin-resistant *Staphylococcus*

aureus, and *Candida* species are commonly isolated, but Gram-negative organisms are also encountered [9, 25, 44–46]. Microbiological data on SSIs in the lung transplant population is particularly lacking. In a single study of 31 "deep" SSIs occurring after lung transplantation [47], MSSA, MRSA, *Enterococcus*, *Pseudomonas*, and other Gram-negative bacteria, mycobacteria, and molds were identified.

Treatment

Most of the studies cited above are retrospective and offer few insights as to the comparative effectiveness of different antibiotic regimens for prophylaxis or treatment of SSIs. Treatment of SSIs in transplant patients is not standardized, in part because the microbiology is different than for non-transplant surgery and has not been as systematically surveyed. Existing guidelines for the treatment of SSIs in general surgical patients [48] may not be fully applicable to the transplant setting, where methicillin-resistant *Staphylococci*, vancomycin-resistant *Enterococci* SSIs, and multidrug-resistant pathogens are frequently encountered and mortality rates can be as high as 30% [44]. For immunocompetent patients, opening and draining the wound is the cornerstone of management. Antibiotics are then added if there is evidence of a "significant systemic response," such as redness, tissue induration, fever, tachycardia, or leukocytosis [48]. By contrast, in transplant patients the inflammatory response is markedly blunted in the first 30 days after transplant. Since systemic signs may be masked in this population, antibiotics are considered mandatory for the treatment of SSI. In general, tissue should be promptly sampled and treatment should be guided by organisms recovered on culture. When empiric, antibiotic selection should be broad and informed by the available epidemiology. For example, given that Gram-positive bacteria, including MRSA, *Candida*, and Gram-negative bacteria are reported in SSI series of heart transplant patients, an empiric antibiotic regimen could reasonably include vancomycin, linezolid, daptomycin, telavancin, or ceftaroline, an antifungal agent (an echinocandin or fluconazole), and an extended-spectrum beta-lactam, third- or fourth-generation cephalosporin, or antipseudomonal carbapenem for Gram-negative pathogens. If institution-specific epidemiology suggests high rates of MDROs, antibiotic coverage of Gram-negative organisms should be designed using local antibiograms.

Other critical aspects of management include drainage of associated collections (by catheter, needle aspiration, or surgery), repair of anastomotic leaks, and the debridement of necrotic or unviable tissue. Infrequently, the dose of immunosuppressive medications may need to be reduced, raising the prospect of graft loss.

Prevention

Despite the increased risk for SSI associated with transplant surgery, there are measures that can be taken to reduce the incidence of SSI in this patient population. Dosing and choice of preoperative antibiotic, careful surgical technique to minimize tissue damage, nutritional support, surgical site antisepsis, and postoperative wound care are among the key areas for SSI prevention.

Preoperative

Screening for Infection and Colonization

A thorough preoperative history and physical should be completed to inspect for active infections at surgical or remote body sites. If possible, surgery should be delayed until infections are treated. Transplant centers should routinely evaluate transplant candidates for potential colonization with multidrug resistant organisms. Individuals who have had recent lengthy hospitalizations, live in a long term care environment, have been on multiple courses of antibiotic treatment, or have been incarcerated are all at higher risk for colonization with drug-resistant organisms. A patient with a history of MRSA could undergo a decolonization protocol prior to surgery to reduce the risk of infection with the colonizing organism [49]. Active screening for MDROs may be indicated when protocols for decolonization of known carriers are in place. Type of surgery and sources for potential infection should be considered when developing such protocols. Generally MRSA decolonization protocols are more effective when used for clean procedures in which *Staphylococcal* species are more likely to cause infection.

Antiseptic Preoperative Bath or Shower

Some studies have shown a benefit of preoperative skin bathing with the antiseptic agent chlorhexidine gluconate (CHG). Bathing with CHG the night before and the morning of surgery has been shown to decrease risk of bacterial colonization at the site, but studies have not consistently found a major effect on SSI [50]. Additionally, some studies support the use of a CHG-impregnated cloth, which is used to apply CHG to the skin where it is then left to dry. Leaving the CHG on the skin may have an increased benefit as compared to washing it away, especially in clean procedures where normal skin flora is often the etiological agent of SSI.

Preoperative Hair Removal

A number of studies confirm that hair removal should not be performed unless the hair at the surgical site will interfere with the operative procedure. If the hair must be removed, it should not be shaved. Shaving produces small nicks and cuts

in the skin that can serve as a portal of entry for microorganisms. Clipping the hair or using depilatory creams has been shown to lower the risk of SSI as compared to shaving. Furthermore, the Association for Perioperative Registered Nurses (AORN) guidelines state that preoperative hair removal should take place outside the operating suite to prevent contamination of the sterile field.

Tobacco Cessation

A link has been shown between the use of nicotine and an increased risk of SSI through delayed wound healing. Tobacco cessation should be encouraged preoperatively. The CDC recommends that patients be instructed to abstain from products containing nicotine for at least 30 days before elective operation.

Wash and Prep the Incision Site

In an effort to reduce bacterial load on the skin prior to surgery, the patient's skin should be washed and cleaned around the incision site. This should be followed with the application of a surgical prep that is allowed to dry on the skin. The use of products containing alcohol in addition to CHG or povidone iodine has shown superior results in prevention of SSI in comparison to aqueous povidone iodine alone [51].

Prophylactic Antibiotic Choice and Timing

The most effective time for antibiotic administration is within 30 min prior to incision. Between 1 and 2 h prior to incision is effective for vancomycin and fluoroquinolones. Prophylactic antibiotic choice depends primarily on the sight of infection and likely bacterial contaminants. For clean procedures, it is important to cover for Gram-positive organisms, whereas clean-contaminated procedures that could involve gastrointestinal flora should cover for Gram-negative anaerobes. Antibiotic dosing will depend on patient's weight and creatinine clearance [52].

Intraoperative

Antibiotic Re-dosing

Antibiotic re-dosing should be completed as appropriate for long surgeries. Generally re-dosing is indicated when the half-life of the given prophylactic antibiotic is reached. Antibiotic re-dosing is also indicated when there is a high volume of blood loss (>1500 mL) and should also take into account patient renal function [52].

Temperature Management

Research has shown that the incidence of SSI is significantly increased in hypothermic patients undergoing surgery [53]. Hypothermia, even when mild, results in subcutaneous vasoconstriction which causes tissues hypoxia. When the cells of the immune system cannot reach the tissue, the risk for infection is elevated. All efforts should be made to maintain a minimum body temperature of 36 °C. This can be achieved through advanced technology in active warming devices such as a Bair Hugger or similar device.

Technique

In a retrospective review of 166 liver transplant patients who developed SSI at a single hospital from 2003 to 2008, Hellinger et al. found an association between SSI rate and surgeon that was independent of all other risk factors evaluated [54]. Wound closure technique can play a role in risk for SSI. Tissue damage can also impact the rate of SSI. Excessive tissue injury, which can be caused by overuse of electrocautery, has been shown to elevate the risk for SSI. Surgical techniques such as multilayered wound closure that prevent the occurrence of dead spaces have also been shown to decrease the risk of wound infection.

Postoperative

Control of Serum Blood Glucose

A number of studies have linked diabetes mellitus to poor wound healing and an increased risk for postoperative wound infection [5]. Taking this one step further, research in diabetic patients showed that controlled serum blood glucose levels after open heart surgery are linked to a reduction in SSI [7]. Efforts should be made to control blood glucose perioperatively at a level less than 200 mg/dl.

Wound Care

Protecting the surgical wound from contamination leads to a decreased risk of SSI. Surgical wounds that have been closed primarily should be covered with a sterile dressing for 24–48 h. Hand hygiene should be performed before and after dressing changes. Sterile technique should be used when changing surgical incision dressings. The patient and family should be educated regarding proper wound care and symptoms of SSI prior to discharge from the hospital.

The Role of the Environment

The preoperative, intraoperative, and postoperative environment should be a particular focus for transplant patients due to their diminished immune response. Preoperatively, patients with suppressed immune systems should be roomed in a protective environment with HEPA-filtered positive pressure airflow whenever possible to prevent opportunistic infections prior to surgery. In the OR suite, as with any surgical procedure, the air should be HEPA-filtered and air flow should be positive to the hall, with minimal traffic into the

OR during the case. After surgery, the patient should ideally return to a protective environment where environmental contamination can be kept to a minimum. Protective precautions policies for immunosuppressed patients should incorporate HVAC controls and the use of personal protective equipment for the patient and staff, and prohibit plants and flowers from the patient's environment.

Summary

Advances in immunosuppressive therapies have led to success in transplantation outcomes. However, infections remain a challenge for this population. SSIs are a common complication of transplantation and can range from superficial skin and subcutaneous tissue infections to deep and organ/space infections. Multiple factors play a role in the increased risk of SSI among transplant patients, including immunosuppression, repeat surgeries, diabetes mellitus, and obesity. The mechanism of post-transplant SSI can vary depending on the organ, with the possibility of both endogenous and exogenous sources for bacterial and fungal contamination. SSIs generally present within the first 30 days after transplant and can be related to contamination with normal body flora during incision or leaks at the site of anastomosis. Organisms involved in SSIs are generally bacterial, but fungal organisms also play a role. Multidrug-resistant organisms are increasingly common in the transplant population. Guidelines for antibiotic therapy are lacking. We believe tissue sampling is essential to direct antibiotic selection. Empiric regimens should be broad and cover resistant Gram-positive (MRSA, VRE), resistant Gram-negative organisms and, depending upon the site of infection, fungal pathogens. Prevention of SSIs should focus on preoperative, intraoperative, and postoperative periods and use evidence-based practices, including preoperative assessments for infection and colonization with pathogenic organisms, surgical site preparation, tobacco cessation, antibiotic prophylaxis, surgical technique, and wound care.

Endovascular Infections and Endocarditis

15

Walter Zingg and Didier Pittet

Introduction

Acute bloodstream infection (BSI) is one of the most severe forms of infection. BSI may be primary or secondary and community-acquired or healthcare-associated. BSI is frequently observed among immunocompromised and critically ill patients, but is rarely asymptomatic and may be associated with multiple organ failure [1–3]. Infective endocarditis (IE) is either acute or subacute, the latter being more common with underlying vascular disease.

The term "bloodstream infection" includes all forms of microbiologically confirmed or non-confirmed bacteremia and fungemia. Acute BSI should be distinguished from *septicemia, clinical sepsis*, and *sepsis*, which refer to clinical syndromes. Definitions are summarized in Table 15.1 [8]. Strictly speaking, IE is a BSI variant, but for practical reasons, it is often considered a separate entity. Diagnosis of IE follows the modified Duke criteria as outlined in Table 15.2 [9].

Table 15.1 Definitions of bloodstream infections [4–6]

Type	Criteria
Positive blood culture	Pathogens identified from one or more blood cultures
Laboratory-confirmed BSI	One or more positive blood cultures with a recognized pathogen; or common skin contaminant (diphteroids, *Bacillus* spp., *Propionibacterium* spp., coagulase-negative staphylococci, or micrococci) cultured from two or more blood cultures obtained on separate occasions, and at least one of the following signs or symptoms: fever (>100.4 °F [38 °C]) or hypothermia (<98.6 °F [37 °C]); chills; low blood pressure (systolic blood pressure ≤90 mm Hg or a decrease >40 mm Hg from baseline)
Primary BSI	Laboratory-confirmed BSI occurring without a documented distal source of infection, but including those associated or related with an intravascular device
Secondary BSI	Laboratory-confirmed BSI occurring in the presence of a documented distal source of infection
Catheter-associated BSI	Primary BSI and presence (>2 calendar days) of an intravascular device
Catheter-related BSI	Primary BSI and at least one of the following: positive semiquantitative culture of the catheter (>15 CFU/catheter segment) with the same organism; [4] positive quantitative culture of the catheter (>10^3 CFU/catheter segment) with the same organism; [7] quantitative blood cultures obtained from the catheter and a peripheral vein with a ≥5: 1 ratio (catheter versus peripheral vein); [5] or differential time to positivity >2h of blood cultures simultaneously obtained from the catheter and a peripheral vein [6]

BSI bloodstream infection, *CFU* colony-forming unit

Epidemiology

Severe sepsis is not rare (3/1000 population; 2.3/100 hospital discharges), and particularly frequent in the elderly with an incidence increasing by >100-fold with age (0.2/1000 in children compared to 26.2/1000 in persons >85 years old) [10]. It is an expensive (US$ 22,100/case) and potentially fatal condition (28.6%). Laboratory-confirmed BSI accounts for 30–40% of all cases of severe sepsis and septic shock. In the healthcare setting, BSI contributes to 12–15% of all healthcare-associated infections (HAI) as reported in the European Prevalence of Infection in Intensive Care (EPIC) studies [11–13]. Almost half of all positive blood cultures in the hospital setting are due to healthcare-associated BSI [14]. Of these, most are primary and associated with central catheter use [15].

Most surveillance systems today, such as the United States National Healthcare Safety Network (NHSN), the German Krankenhaus Infektions Surveillance System (KISS), or the International Nosocomial Infection Control Consortium (INICC), focus on catheter-associated, laboratory-confirmed, primary BSI (CLABSI), with rates

Table 15.2 Infective endocarditis: modified Duke criteria

Major criteria
Blood culture positive for IE
Typical microorganisms consistent with IE from 2 separate blood cultures:
Viridans streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*
Community-acquired enterococci in the absence of a primary focus
Microorganisms consistent with IE from persistently positive blood cultures, defined as follows:
At least 2 positive cultures of blood samples obtained >12 h apart
All of 3 or a majority of >4 separate cultures of blood (with first and last sample obtained at least 1 h apart)
Single positive blood culture for *Coxiella burnetii* or IgG antibody titer >1: 800
Evidence of endocardial involvement
Echocardiogram positive for IE (TEE recommended in patients with prosthetic valves, rated at least "possible IE" by clinical criteria, or complicated IE [paravalvular abscess]; TTE as first test in other patients), defined as follows:
Oscillating intracardiac mass on valve or supporting structures in the path of regurgitant jets or on implanted material in the absence of an alternative anatomic explanation
Abscess
New partial dehiscence of prosthetic valve
New valvular regurgitation (worsening or changing of pre-existing murmur not sufficient)
Minor criteria
Predisposition, predisposing heart condition, or injection drug use
Fever (temperature >38 °C)
Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions
Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor
Microbiological evidence: positive blood culture, but does not meet a major criterion as noted above[a] or serological evidence of active infection with an organism consistent with IE
Echocardiographic minor criteria eliminated
Definite infective endocarditis
Pathologic criteria
1. Microorganisms demonstrated by culture or histologic examination of a vegetation, a vegetation that has embolized or an intracardiac abscess specimen
2. Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis
Clinical criteria
1. 2 major criteria
2. 1 major criterion and 3 minor criteria
3. 5 minor criteria
Possible infective endocarditis
1. 1 major criterion and 1 minor criterion
2. 3 minor criteria
Rejected
1. Firm alternate diagnosis explaining evidence of infective endocarditis
2. Resolution of infective endocarditis syndrome with antibiotic therapy for <4 days
3. No pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for <4 days
4. Does not meet the criteria for possible infective endocarditis as detailed above

[a]Excludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis HACEK Haemo philus parainfluenzae, H. aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium homi nis, Eikenella corrodens, and Kingella kingae, *IE* infective endocarditis, *TEE* trans-esophageal echoca rdiography, *TTE* trans-thoracic echocardiography

reported as episodes per 1000 device-days. CLABSI incidence density rates are known to be high in the intensive care unit (ICU), but non-ICU settings may have similar rates (Table 15.3) [16–29, 31–35]. The large differences among studies reporting on CLABSI are due to variable definitions and reporting systems. Thus, comparison and benchmarking should be performed with caution [36, 37].

Severe sepsis and septic shock are associated with increased morbidity, end-organ dysfunction, and risk of death [38]. Clinical sepsis has been reported to represent up to two-thirds of CLABSI, and focusing on microbiologically documented BSI may underestimate true CLABSI rates [15]. However, surveillance of clinical sepsis has been mostly abandoned because the definition of this infection leaves too much room for interpretation and is resource demanding [15]. The exception to this rule is BSI-surveillance in the neonatal intensive care unit (NICU) because blood cultures from neonates are often unreliable [39]. In adults, false-negative blood cultures are most likely due to previous antibiotic treatment.

Table 15.3 Incidence of healthcare-associated bloodstream infections in various healthcare settings [16–30]

[a]Both community-acquired and healthcare-associated infections were reported together

Patients with BSI have higher mortality compared to those without BSI [17, 40]. Attributable mortality from CLABSI is between 2% and 35% [41]. Healthcare-associated BSI, particularly CLABSI, is associated with morbidity, prolonged length of hospital stay, and increased resource utilization in almost all groups of patients [1, 16, 17, 31–33, 41–51]. Interestingly, mortality from secondary BSI is higher compared to primary BSI (29–45% vs. 18–29%, respectively). Furthermore, mortality from CLABSI is lower than mortality from other primary BSI (15–26% vs. 18–29%, respectively) [17, 40]. Although the reason for this remains unclear, delayed antibiotic therapy for community-acquired BSI and serious comorbidities in the context of secondary BSI may partially explain such trends. Microbiological factors have been found to be important in the context of mortality among patients with healthcare-associated BSI, even after adjustment for major confounders such as patients' underlying conditions [40]. Pathogens independently associated with mortality include *Candida* spp. and *Pseudomonas aeruginosa*. Coagulase-negative staphylococci (CoNS) are less associated with mortality compared to other pathogens, although they are the most frequently isolated [40].

BSI is the most frequent type of infection in patients after hematopoietic stem cell transplantation (HSCT) with rates of approximately 11–19 per 1000 neutropenic days [52, 53]. Most BSI occur within the first 30 days after transplantation. In this period, there is no difference in BSI between allogeneic and autologous transplants, most likely due to neutropenia, which is similar in both groups [54]. Prolonged neutropenia is the most important risk factor for BSI and attributable mortality [54–56]. In the long term, BSI occurs almost exclusively in allogeneic transplant patients because of the prevention and treatment of graft-versus-host disease with immunosuppressive drugs [57].

IE accounts for about 1% of all cases of severe sepsis [10]. The estimated incidence is 3–10/100,000 patient-years with a low incidence in childhood and a peak incidence up to 15/100,000 patient-years in the elderly [58–66]. The incidence among children has been estimated at around 0.2–1.25/1000 hospital admissions, with an average age of 5–13 years [67–70]. Historically, the most important reason for IE was rheumatic heart disease. However, it has been estimated that the proportion of IE patients with this disease has decreased by 12% per decade, while the proportion of IE patients after valve surgery has increased by 9% in the same period [71]. Mortality from IE is approximately 20–25% during hospitalization, and up to one-third in the 1st year [10, 59, 63–65, 72]. Immunosuppressed and hemodialysis patients are particularly at risk [64]. In general, IE is a rather rare event after solid organ transplantation (SOT), but the overall incidence is still higher compared to the general population [73–75]. By contrast, IE is frequent (1.5%) after heart transplantation with an exceptionally high mortality of up to 80% and a dramatic reduction of the survival rate from 9.3 to 1.4 years [76]. The annual incidence of IE among prosthetic valve recipients is 1–4% [77]. Patients with prosthetic valves and a history of past IE have the highest risk for recurrent IE. Other risk factors for IE include congenital malformations, rheumatic fever, degenerative valve lesions, and even mitral valve prolapse [78]. Although the individual risk of IE from mitral valve prolapse is small, the high prevalence of this heart condition in the general population makes it relevant. Among congenital malformations, the ventricular septal defect is particularly of risk due to high blood flow and pressure gradients [81]. In recent years, intravenous drug use and healthcare-associated bacteremia have been recognized as emerging risk factors for IE [79, 80].

Pathogenesis

Microorganisms are not likely to attach to the vascular endothelium. However, host factors and cofactors such as fibrinogen, fibronectin, calcium, magnesium, and iron facilitate bacteria attachment on foreign material, such as intravascular catheters [82–92]. Streptococci possess fibronectin-binding proteins, platelet-aggregating factors and glucans, which facilitate adherence to endocardial lesions and vegetations [93]. *Staphylococcus aureus* adheres to host-tissue ligands, such as fibrinogen, via genetically defined microbial surface proteins, commonly referred to as "microbial surface components recognizing adhesive matrix molecules" (MSCRAMM) [94–96]. After adherence, the attachment becomes irreversible, and the microorganisms start to produce an extracellular matrix. This matrix protects microorganisms from host defense mechanisms and antibiotics, and allows them to proliferate in a protected environment. This process is called biofilm formation [97]. Thrombus formation around the catheter is thought to further increase the risk of catheter-related BSI, [98] although clinical evidence on this topic is controversial [99–101]. Main risk factors for catheter-related BSI include catheter dwell time [102], femoral rather than the subclavian access site [103, 104], parenteral nutrition [105–107], guidewire exchange [108, 109], multi-lumen catheters [110], and previous HSCT [111, 112].

The pathogenesis of IE is initiated by turbulent flow and pressure gradients creating stress on endocardial tissue. Such stress is maximal on the atrial surface of the atrioventricular valves and the ventricular surface of the semilunar valves. In valve insufficiency, flow jets damage structures, such as the mitral chordae (aortic insufficiency), the atrial wall (mitral regurgitation), or the septal leaflet of the tricuspid valve (ventricular septal defect) [113, 114]. Defects in the endocardium provoke the deposition of fibrin and platelets [115], an ongoing process resulting in thrombus formation. At any time, such a thrombus may become colonized by microorganisms due to transient bacteremia or fungemia. Once attached, microorganisms are covered by further deposition of fibrin and platelets and proliferate in a protected environment. This cycle of fibrin and platelet deposition, together with the proliferation of microorganisms in the presence of pressure gradients and sheering forces, results in the formation of the typical IE vegetations. Gradually, the process triggers an inflammatory response that is exemplified by elevated levels of inflammatory markers, such as C-reactive protein, tumor necrosis factor alpha, immune complexes, the rheumatoid factor, and increased the erythrocyte sedimentation rate [116]. The deposition of immune complexes can result in kidney amyloidosis.

Microbiology

The distribution of microorganisms causing intravascular infections varies according to source, age (neonates, children, adults), and resources [16, 17, 20–22, 25, 30–33, 117–126]. Healthcare-associated BSI are mainly due to Gram-positive organisms in high-income countries (Table 15.4) [25, 30, 128, 129]. In countries with limited resources, Gram-negative pathogens and among these, non-fermentative organisms such as *Pseudomonas* spp. and *Acinetobacter* spp., are predominant (Table 15.4) [119–123]. This may be the result of breaches in basic infection control procedures, such as the multiple use of infusates or handling of catheteres without complying with aseptic procedures [120, 130]. The shift toward Gram-positive cocci in high-income countries is mainly due to coagulase-negative staphylococci (CoNS), and is a consequence of the abundant use of central catheters and the fact that the proportion of patients with risk factors, such as neutropenia, SOT, HSCT, prematurity, or the use of immunosuppressive agents, has increased in the past years [131]. The mean interval between admission and infection depends on the microorganism and is shortest (13 days) for *Escherichia coli*, followed by *S. aureus* (16 days), *Candida* spp. and *Klebsiella* spp. (22 days), enterococci (23 days), and *Acinetobacter* spp. (26 days) [129].

The proportion of *Candida* spp. has increased over the years due to the use of broad-spectrum antibiotics, intravascular devices, total parenteral nutrition, and prolonged neutropenia in patients with chemotherapy [132–139]. But only recently, first reports suggested no further increase and even trends toward a reduction of *Candida* infections, at least in North America [140, 141]. By contrast, an important shift in the epidemiology of *Candida* BSI has occurred over the past decades with decreasing infections due to *C. albicans*, but increasing infections due to non-albicans species, in particular *C. glabrata* [142]. The emergence of this species is a problem because it is often resistant to fluconazole [143]. BSI due to *Candida* spp. has a poor prognosis. Mortality from BSI with this microorganism ranges between 15% and 55%, particularly when antifungal treatment is delayed or intravascular catheters are left in place [132, 144].

CoNS are the most common pathogens isolated from blood cultures, particularly in primary BSI [14]. They are mostly contaminants, but the detection of CoNS may not always be harmless, and mortality up to 12% has been reported, particularly in neutropenic patients [14, 145]. By contrast, mortality from *S. aureus* BSI ranges between 13% and 25% with higher proportions in healthcare-associated compared to community-acquired infections [146, 147]. Detection of *S. aureus* on a catheter tip is a predictor for subsequent bacteremia, even in the absence of clinical signs and negative blood cultures at the time of catheter removal [148–150].

CoNS coagulase-negative staphylococci, HSCT Hematopoietic stem cell transplantation
[a]Including methicillin-resistant *Staphylococcus aureus* (MRSA)

The distribution of pathogens in SOT demonstrates a predominance of Gram-positive bacteria similar to healthcare-associated BSI in HSCT (Table 15.5). Emerging BSI in SOT due to *Candida* spp. are the result of antifungal prophylaxis [164]. In addition, rare causes such as *Mycobacterium avium intracellulare*, and *Listeria* spp. have been reported [165, 166]. Vascular infections due to donor organs are not frequent, although donor organs may be contaminated with CoNS, *S. aureus*, *Streptococcus pyogenes*, *Enterobacteriaceae*, *Enterococcus*, *Pseudomonas*, *Candida* spp., and *Aspergillus* [167, 168]. Recently however, infections including BSI due to donor organs colonized with carbapenem-resistant Gram-negative organisms such as *K. pneumoniae* or *A. baumannii* after lung, liver, kidney, or heart transplantation have been described [169–171]. Independent from donor organ contamination, patients after SOT and HSCT are at increased risk for BSI.

In bone marrow transplant patients, time from transplantation to first positive blood culture is between 5 and 10 days [172]. Most pathogens are Gram-positive bacteria with a large proportion of viridians streptococci and enterococci [159, 173]. Mucositis is a risk condition for BSI due to enterococci and anaerobes such as *Fusobacterium* and *Clostridium* spp. [159, 174]. The incidence of pre- and post-engraftment BSI is similar in allogeneic HSCT recipients (22% and 19.5%, respectively). Pre-engraftment rates are highest for viridans streptococci (58), *Enterobacteriaceae* (39), and *E. faecium* (34) [173]. Attributable mortality from BSI is low except for infections due to *P. aeruginosa, Enterobacter* spp., *Serratia*, and *Citrobacter* spp. [172]. No significant difference in the distribution of pathogens was identified in neutropenic and non-neutropenic patients with hematological malignancies or solid neoplasms and BSI [175].

IE is largely due to Gram-positive bacteria, mostly *S. aureus* and streptococci, predominantly from the viridians group; however, enterococci or *S. pneumoniae* have been described as well. CoNS rarely cause IE, particularly on native valves [176]. Overall, a third of native valve IE are due to *S. aureus* [177]. Mortality from *S. aureus* IE is 20% [178], and patients are more likely to experience an embolic event (61%) or to have a central nervous system complication. More than half of the cases occur in patients with intravascular devices. IE due to other Gram-positive bacilli such as *Corynebacterium* spp., *L. monocytogenes,* or *Lactobacillus*

are very rare. Gram-negative bacteria only cause few IE (4–5%) with a predominance of bacteria from the HACEK group (*Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingae*). In a large study of 2761 patients with definite IE according to the Duke criteria, only 49 (1.8%) had endocarditis (20 native valve, 29 prosthetic valve or device) due to non-HACEK Gram-negative bacilli, with *E. coli* and *P. aeruginosa* being the most common pathogens [179]. Most IE due to non-HACEK Gram-negative bacilli were healthcare-associated and in patients with implanted intravascular devices.

IE after SOT is infrequent but the microorganisms differ from non-transplant patients. *S. aureus*, *Candida*, and *Aspergillus* spp. are predominant, but viridians streptococci remain rather rare (4%) [75]. Other pathogens found in this group include *Coxiella burnetii*, *Nocardia*, *Listeria* spp., *Pseudomonas* spp., *Enterococcus* spp., *Oerskovia xanthineolytica*, and *Weissella confusa* [74, 180–184]. Most fungal IE are due to *Candida* spp. with *C. albicans* being the most common microorganism, but other *Candida* spp. such as *C. krusei*, *C. parapsilosis*, *C. tropicalis*, or *C. guillermondii* have been reported as well. *Aspergillus* spp., including *A. fumigatus*, *A. flavus*, *A. terreus*, and *A. niger*, are isolated particularly in lung transplant recipients after cystic fibrosis, and IE due to these pathogens are associated with a poor prognosis [75, 76, 185, 186]. Fungal infections predominate in the first 30 days after transplantation (20%), while bacteria are responsible for most infections (80%) after this period [75].

The most common organism in "culture-negative" IE is *Coxiella burnetii*. Other pathogens such as *Bartonella* spp., *Brucella* spp., *Chlamydia* spp., *Mycoplasma hominis*, *Legionella pneumophila*, rickettsiae, and *Tropheryma whipplei* have been rarely described [187].

Clinical Signs

Fever is the hallmark of all vascular infections. Fever in the absence of other symptoms and, in particular, in the presence of an intravascular device must be considered a BSI until proven otherwise. Sepsis is characterized additionally by hemodynamic abnormalities. The symptoms of IE relate to systemic infection, (septic) emboli, metastatic infective foci, congestive heart failure, or immune complex-associated lesions [188]. Acute IE is characterized by fever, new or changed heart murmurs, and skin manifestations such as splinter hemorrhages, Osler nodes, Roth spots, or Janeway lesions. Subacute IE may present less typically without or with moderate fever only, but with malaise, anorexia/weight loss, heart failure, arthralgia, splenomegaly, or glomerulonephritis.

Diagnosis

Blood cultures should be obtained from patients with clinical signs suggestive for BSI. Severe sepsis and septic shock are associated with increased morbidity, mortality, and end-organ dysfunction [38]. Accordingly, when sepsis is suspected, it is not possible to wait until the results of blood cultures are available, and empirical antimicrobial treatment is initiated as soon as possible. Positive blood culture results with a recognized pathogen are sufficient to diagnose BSI, particularly when clinical signs such as fever, hypothermia, chills, or low blood pressure are present. BSI due to skin contaminants need confirmation with additional blood cultures and the presence of clinical signs. The classification into primary or secondary, and catheter-associated or catheter-related BSI, can be done based on additional clinical signs and laboratory findings, and whether a catheter is in place (Table 15.1). Inappropriate blood culture sampling may produce false-positive results, particularly when skin contaminants are identified [189]. If CLABSI is suspected and the catheter is removed, the tip should be cultured either by using the Maki roll-plate technique or the Brun-Buisson vortex method [4, 190, 191]. Alternatively, if the catheter is left in place, two blood culture samples – from the catheter and from a peripheral vein – should be obtained simultaneously to measure the differential time to positivity [192]. To avoid missing infections, all lumens of a multi-lumen catheter should be tested [193].

The diagnosis of IE follows the modified major and minor Duke criteria distinguishing definite, possible, and rejected IE (Table 15.2). Prior antibiotic use may result in culture-negative IE, less likely to be classified as definite IE by the Duke criteria [194]. Clinical signs, such as fever, embolic complications, new or changed heart murmurs, and predisposing factors (e.g., rheumatic heart disease, congenital heart disease, mitral valve prolapse, or previous cardiac surgery) should raise suspicion for IE, even in the absence of positive blood cultures.

Laboratory Findings

Overall, only 10–15% of performed blood cultures turn positive. Even in the presence of a systemic inflammatory response syndrome, blood cultures are negative in 40–60% of cases [31]. Due to challenges of blood culture sampling in terms of technique, volume and availability of adequate blood culture bottles, the situation in neonates is even more pronounced [39]. The quality of blood cultures is better among older children but is not optimal either when compared to adults [189]. Prophylactic or preemptive antibiotic treatment at the time of sampling makes the interpretation of negative blood culture results difficult [195–197]. This can be bypassed by using nucleic acid testing with a multiplex polymerase chain reaction (PCR) identifying a wide range of microorganisms [198, 199]. However, most nega-

tive test results are true negative. After SOT and HSCT, blood cultures should be obtained generously from febrile patients in the first 30 days after transplantation. BSI is less frequent in autologous HSCT recipients after engraftment, and in SOT recipients once immunosuppressive therapy is less intensive.

Most patients with IE have positive blood cultures, but they may remain negative for a long time in subacute IE due to non-common pathogens such as *Candida* spp. or microorganisms of the HACEK group. However, blood cultures in IE are negative only in 10–15% of cases, although rates up to 31% have been described [200–204]. Potential reasons for blood culture-negative IE are (1) right-sided IE, (2) previous administration of antibiotics, (3) fungi, (4) viruses, and (5) pathogens that do not grow in regular culture conditions such as *Bartonella* spp., *Brucella* spp., *Chlamydia* spp., *Mycoplasma hominis*, *Legionella pneumophila*, rickettsiae, *Coxiella burnetii*, and *Tropheryma whipplei* [203, 205]. Pathogens of blood culture-negative IE can still be identified by serological tests and by PCR in valve tissue obtained by surgery [205, 208–214]. In particular, fungi are be detected more readily in biopsies [215]. Microbiological culturing of heart valves on the other hand, has a low sensitivity [206, 207]. By applying a range of methods (microbiology, serology, molecular techniques), a pathogen can be identified in up to 63% of culture-negative IE cases [187].

Upon IE suspicion, two blood culture bottles for aerobic and anaerobic cultures and a serum vial should be obtained immediately, the latter to search for rheumatoid factor and antibodies directed against *Coxiella burnetii*, *Bartonella* spp., *Brucella* spp., *Chlamydia* spp., *Mycoplasma pneumonia*, *Legionella pneumophila*, and *Aspergillus* spp. [204, 210]. Two additional samplings of blood culture bottles for aerobic and anaerobic cultures are obtained after 2 and 4 h.

Inflammatory markers such as C-reactive protein, procalcitonin, erythrocyte sedimentation rate, and tumor necrosis factor alpha are elevated in vascular infections. Presence or absence of rheumatoid factor can distinguish between patients with definite and rejected IE based on the modified Duke criteria [116]. Autoantibodies, such as antinuclear antibodies and anticardiolipin, can be present in IE, but they are less specific than the rheumatoid factor [216].

General Principles of Management

The management of BSI combines early antimicrobial treatment and the active search for a source of infection that might require specific therapeutic interventions. Either delayed or inappropriate antibiotic treatment is associated with higher mortality [34, 128, 217–219]. Similar results were observed for candidemia where mortality was significantly higher when antifungal therapy was delayed [144, 220, 221]. Conversely, inappropriate antibiotic treatment was not found to be a risk for developing septic shock in patients with positive blood cultures in one study, [31] but mortality of those requiring inotropic drugs was significantly higher – 85% vs. 75% and 58% vs. 24%, respectively.

The choice of antibiotics to start empiric therapy should be based on knowledge of the local epidemiology and susceptibility of pathogens, and the source of infection. A multidisciplinary approach, allowing close collaboration between the physician in charge of the patient, the infectious disease specialist, and the microbiology laboratory, improves the accuracy of empiric therapy. Once susceptibility testing of the microorganisms is available, antimicrobial treatment should be adjusted accordingly. In some conditions, pathogens identified from other body sites may also need to be taken into account for selecting the appropriate antimicrobials. In addition, specific measures such as abscess drainage , adequate surgical management of peritonitis, or removal of infected prosthetic material are necessary to control the infection. Follow-up of inflammatory markers can help to shorten antimicrobial treatment. Procalcitonin-based de-escalation of antimicrobial therapy can reduce exposure to antibiotics by almost 30% [222–224].

In the case of primary BSI or sepsis, central lines should be removed if in place at the time of infection. Catheter retention may result in a severalfold increase in risk for recurrence of BSI. However, recent data suggest that antibiotic locks in addition to systemic antibiotic therapy can be used as a salvage strategy if CLABSI involves long-term catheters, signs of exit site or tunnel infection are absent, and blood cultures reveal the presence of CoNS or enterococci [225, 226]. Removal of the catheter is mandatory in severe or complicated infections, in the presence of shock, in case of recurrent BSI, and when microorganisms such as *S. aureus*, Gram-negative bacilli, or *Candida* spp. are isolated [227]. Relapse, continuous fever, or bacteremia despite catheter removal requires an active search for complications, such as metastatic abscesses, septic thrombophlebitis, or endocarditis. Following the completion of antimicrobial therapy, careful follow-up is mandatory owing to the frequent occurrence of late complications [228, 229]. Recovery of *S. aureus* on a catheter tip may suggest the initiation of therapy, even in the absence of clinical signs and negative blood cultures [148].

Antibiotic therapy is the cornerstone in the treatment of IE, with the addition of an aminoglycoside to an antibiotic regimen with activity against Gram-positive bacteria [210, 230, 231]. Although the addition of an aminoglycoside in the 1st weeks of treatment is recommended by international guidelines, clinical trials did not show that such combination therapies decrease mortality or bacteriological failure, or reduce the need for surgery [210, 232–235]. For IE due to methicillin-resistant staphylococci, vancomycin remains the therapy of choice. Other antibiotics such as linezolid or daptomycin have been shown to be effective, but have not been

proven to be superior to vancomycin [236, 237]. Furthermore, linezolid alone is bacteriostatic, but in the treatment of IE, a bacteriocidal substance is encouraged. Appropriate antibiotics must be initiated as early as possible in the treatment of IE because a delay in antibiotic therapy worsens the clinical outcome [210, 238, 239] e.g. IE-related stroke [240].

Heart surgery is necessary in 25–42% of patients with IE [62, 73, 241]. The two primary objectives of surgery are the total removal of infected tissue and reconstruction of the cardiac morphology [210]. Surgery can improve long-term survival, in particular for left-sided IE [242, 243]. However, a significant proportion of patients with a recommended indication does not receive cardiac surgery [244]. Because IE is a multifactorial event, a standardized management by a skilled multidisciplinary team is required for best outcome [245, 246].

Prevention

As for any other healthcare-associated infection, the prevention of BSI in the hospital relies on the basic principles of hygiene, particularly hand hygiene practices [247–249]. It has been shown that improved hand hygiene and good work organization prevents the transmission of pathogens [250]. For the prevention of device-associated infections, there is good evidence that multimodal strategies combining procedural and technical interventions are effective [29, 251–254]. "Procedural" interventions include the introduction of standardized, written procedures for catheter insertion and catheter care. "Technical" interventions include the use of alcohol-based chlorhexidine for skin antisepsis, devices (catheters, connectors, sponges, dressings) impregnated with chlorhexidine, chlorhexidine-silver sulfadiazine, silver and antibiotics, and the use of lock solutions with agents such as taurolidine, citrate, or EDTA. Alcohol-based, chlorhexidine-containing skin antiseptics have now become standard of care. The use of a chlorhexidine-impregnated sponge was found effective in two randomized controlled trials [255, 256]. Daily bathing with a chlorhexidine-containing solution in the ICU reduced bacteremia due to vancomycin-resistant enterococci (VRE), as well as VRE-colonization and methicillin-resistant *S. aureus* (MRSA) acquisition. This allowed to reduce colonization pressure and shows the importance of microorganism transmission in the pathogenesis of BSI with multidrug-resistant pathogens [257]. Two meta-analyses demonstrated that chlorhexidine-silver sulfadiazine-impregnated catheters are effective in reducing catheter colonization, but not CLABSI, while rifampicin-minocycline-coated catheters are effective in reducing both catheter colonization and CLABSI [258, 259]. Most studies with central venous catheters are conducted in the ICU, including catheters with relatively short dwell times. No data on the efficacy of antibiotic-coated devices are available for long dwell-times, and there is evidence that chlorhexidine-silver sulfadiazine impregnation is not effective in the long run [260]. The efficacy of lock solutions as a prevention strategy remains undetermined at present, although some studies show promising results [261–263]. A recent study among children reported that a taurolidine citrate lock solution was associated with a significant BSI reduction in immunocompromised pediatric patients [264]. Ethanol locks in CLABSI prevention on the other hand remain controversial. Although the substance worked well in vitro [265, 266] and among patients with long-term catheters, [267–269] three recent randomized controlled trials did not find any significant efficacy [270–272].

Educational programs or global preventive strategies based on the strict application of specific preventive measures and careful control of all factors associated with infection have been shown to be effective in reducing infection rates. Such programs must be multidisciplinary in preparation and multimodal in implementation in order to be effective [29, 251, 253, 273–277]. Education and training should use different modes such as bedside teaching, workshops, or simulator training [278–283]. Ex cathedra teaching or disseminating guidelines alone are not sufficient to change behavior of healthcare workers [284].

IE prophylaxis has produced contradictory results [285, 286] and has never been shown effective in clinical studies [113, 287, 288]. This is most likely due to the fact that IE is a rare event, even in the absence of prophylaxis. The procedure-related risk for IE due to dental procedures can be estimated as 1:14,000,000 for the general population and 1:95,000 for patients with previous IE [78, 289]. No potential index procedure can be associated with IE [63]. The existing evidence does not support the extensive use of antibiotic prophylaxis recommended in previous guidelines. Prophylaxis should be limited to patients at highest risk for IE or at high risk for adverse outcome from IE [231]. Compared to previous recommendations, all recent guidelines limit prophylaxis to clearly defined patients at risk and to dental procedures (Table 15.6) [231, 290] or do not recom-

Table 15.6 Patients at risk for infective endocarditis

1. Patients with a prosthetic valve or prosthetic material used for cardiac valve repair
2. Patients with previous infective endocarditis
3. Patients with congenital heart disease:
Cyanotic congenital heart disease, without surgical repair, or with residual defects, palliative shunts, or conduits
Congenital heart disease with complete repair with prosthetic material whether placed by surgery or by percutaneous technique, up to 6 months after the procedure
When a residual defect persists at the site of implantation of a prosthetic material or device by cardiac surgery or percutaneous technique

mend antibiotic prophylaxis at all [291]. However, all guidelines emphasize the importance of good oral hygiene in IE prevention [231, 290–293]. This is reasonable because it has been shown that transient bacteremia is associated most likely with tooth brushing, flossing, or chewing [294, 295]. IE prophylaxis is recommended only for dental procedures requiring manipulation of the gingival or periapical region or the teeth or perforation or the oral mucosa [231]. It is not recommended for any procedure of the respiratory, gastrointestinal, or urogenital tract, or for skin or soft tissue interventions. Prophylaxis is administered as a single dose 30–60 min before the dental procedure either with penicillin or ampicillin, or clindamycin in case of penicillin allergy.

Gastrointestinal Infections and *Clostridium difficile* Infection

16

Stephen Harold and Herbert L. DuPont

Introduction

Gastrointestinal infections developing before, during, and after organ transplant is one of the leading causes of treatment failures among transplant recipients. In addition to significant increase in morbidity and mortality, GI complications also escalate the cost of treatment due to prolonged periods of hospitalization [1]. In this chapter, we provide an overview of the gastrointestinal infections with special emphasis on the *Clostridium difficil*e (*C. difficile*) infection (CDI) in transplant recipients. In Fig. 16.1 we outline important factors in the development of CDI.

Transplants are broadly classified into hematopoietic stem cell transplant (HSCT), bone marrow transplant (BMT), and solid organ transplant (SOT). Recent changes in transplant immunosuppressant regimes have dramatically reduced the incidence of acute graft rejection. Newer immunosuppressive agents provide profound and sustained immunosuppression that effectively reduces the number of organ dysfunction or rejection and prolongs the survival of transplant recipient. On the contrary, it increases the risk of infection in this patient population due to disruption of the delicate balance between immunosuppression and host defense mechanism [2, 3]. The risk of infection in this subset of patients is due to interplay of multiple predisposing factors such as the type of transplant, conditioning regimens, use of antibiotics and immunosuppressive agents, and time period following transplantation [2]. Knowledge of the impact of immunologic state and therapies administered on the risk of infectious diseases including CDI can be critical to outcome in transplantation.

Clostridium difficile Infection (CDI)

CDI rates have tripled in hospitals in the United States (US) since the 1990s. Rates are rising due to changes in organism virulence but more importantly because of changing resistance of the host [4]. This review focuses on the problem of CDI in patients undergoing transplantation.

History

Bacillus difficilis was identified in 1935 by Hall and O'Toole as a common constituent of neonatal bowel flora [5]. The organisms, while now known as *C. difficile*, earned its appellation due to the difficulty experienced in the laboratory in characterizing the organisms' fermentation patterns. In the 1950s, pseudomembranous enterocolitis was thought to occur infrequently in surgical patients and was generally attributed to *Staphylococcus aureus* [6, 7]. The modern era of CDI began in the early 1970s with a prospective study of 200 patients treated with clindamycin, wherein 21% of the patients reported diarrhea and 10% were found to be suffering from pseudomembranous colitis (PMC) [8]. In 1977, a toxin produced by a *Clostridium* species was proposed as the cause of clindamycin-induced ileocecitis in hamsters [9], and in 1978, *C. difficile* was clearly identified as the causal agent of antibiotic-associated colitis in humans [10].

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_16

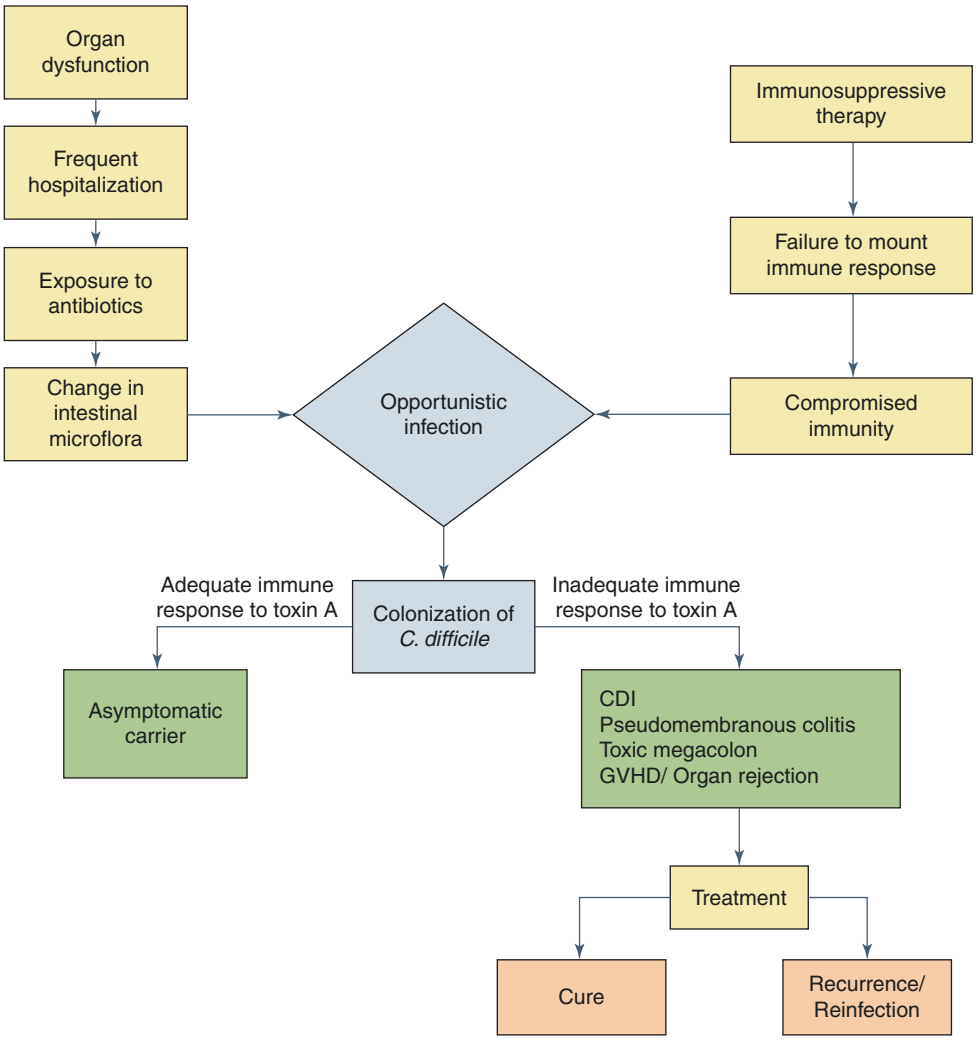

Fig. 16.1 An algorithm identifying risk factors associated with the development of *Clostridium difficile* infection in hospitalized patients including transplant recipients

Epidemiology

CDI is the most commonly identified cause of antibiotic-associated diarrhea found in 15–25% of cases [1, 11–13]. CDI was also reported in 5–7% of autologous BMT and 13–15% of allogeneic BMT patients [14–17]. Lung transplant recipients were shown to be more susceptible to CDI and were more likely to have severe CDI than all other SOT patients [18]. It is also the most common cause of enteric infections among liver transplant recipients [19]. The emergence of a so-called NAP1 hypervirulent strain further increased the incidence of CDI in some places of Canada, the US, and Europe since 2000 and is associated with increased morbidity and mortality where it occurs. The mortality rate due to CDI averages 1–2.5% of cases of infection [12].

Risk Factors

Most patients with CDI develop their infection when three factors are aligned: (1) elderly and infirm host, often immunosuppressed; (2) receipt of an antibiotic that dramatically alters colonic flora; and (3) exposure to *C. difficile* spores, often in a healthcare facility [4]. The specific antibiotic used in patients that leads to a disruption of normal bacterial flora is important [20, 21]. The antibiotics that are mostly associated with CDI are penicillins, cephalosporins, fluoroquinolones, and clindamycin [22–24]. Other predisposing factors for CDI are advanced age (greater than 65 years), severe underlying diseases, enteral feeding, use of proton pump inhibitors and chemotherapeutic agents, surgery, immunosuppression, and prolonged hospital stay leading to exposure to *C. difficile* spores [25, 26]. Most patients acquiring CDI have a combination of these risk factors.

Route of Transmission

C. difficile is a spore-forming gram-positive bacillus. *C. difficile* spores are non-vegetative forms that are acid and heat resistant. Spores of the organism are viable for prolonged period of time and are resistant to commonly used disinfec-

tants and antiseptics. Ten percent Clorox is the preferred disinfectant yet is poorly tolerated as a general hospital disinfectant. The major reservoirs of infection are patients with CDI or asymptomatic carriers of *C. difficile* that contaminate the environment. Transmission of *C. difficile* is through fecal-oral route. Exposure may occur through direct contact with contaminated surfaces or through oral inoculation via contaminated materials like thermometers. When ingested, the spores of *C. difficile* survive gastric acidity, germinate to vegetative forms when exposed to bile salts, and colonize the gut [27]. CDI mostly occurs after antimicrobial therapy that disrupts the normal bacterial flora of the colon, facilitating colonization of the gut by *C. difficile*. Depending on the immune status of the individual, the incubation period of illness varies from few days to 8 weeks, and they clinically manifest with varying degrees of severity [21, 28] (Fig. 16.1).

Pathogenicity of *C. difficile* Infection

Pathogenesis of the disease is due to elaboration of two virulent toxins, toxin A, an enterotoxin, and toxin B, a cytotoxin. These toxins are large antigenic proteins that mediate an acute inflammatory diarrhea, characterized by proteinaceous exudate containing large number of neutrophils. Toxin A, which is a 308-kD cytotoxin and enterotoxin, induces marked intestinal inflammation, fluid secretion, and mucosal injury, while Toxin B, which is a 270-kD cytotoxic protein, stimulates the release of inflammatory cytokines from monocytes. It also activates calcium influx required for actin disassembly during cytotoxicity [29, 30]. A third toxin, named CDT, is a member of the iota family of binary toxins, which comprises the *Clostridium botulinum* C2 toxin and iota toxin subfamilies. CDT comprises two independent unlinked protein chains, CDTa (the enzymic component) and CDTb (the binding component) [31, 32]. The binding component CDTb mediates entry of CDTa into the cell, which potentiates the ADP ribosylation of actin and leads to disorganization of the cytoskeleton [33]. The exact pathogenic role of the binary toxin CDT in *C. difficile* infections is still not fully understood although it is associated with the hypervirulent NAP1 strain. Since they act synergistically with other toxins and depolymerize the actin cytoskeleton by a complementary mechanism, they are considered to be an additional virulence factor that contributes to the increased morbidity and mortality [34, 35]. *C. difficile* toxins inflame and destroy the colonic mucosal lining and form the typical "pseudomembranes" [36, 37].

The surface layer proteins (SLPs) of *C. difficile* also play a significant role in activating the host immune response in CDI. SLPs are the outermost surface components of the bacterium and are responsible for gut colonization and adhesion to the intestinal mucosa. A possible mediation of the SLPs in binding to both the intestinal epithelial cells and some components of their extracellular matrix fibers resulting in further epithelial damage has been proposed. In addition, the pathogenicity of *C. difficile* infection is attributed to the loss of the delicate balance between regulatory and inflammatory cytokines in the immune regulatory cells like monocytes and dendritic cells [38].

Although the *C. difficile* bacteria are noninvasive, their toxins penetrate the mucosal barrier and initiate an immune response in the host [39]. The ability of the host to mount an immune response against toxins is a key factor that accounts for the spectrum of clinical manifestation [29, 40]. Low serum and/or intestinal antibody response to *C. difficile* toxin A is associated with severe, prolonged, and recurrent CDI [41]. Adequate antibody response to toxin A is therefore an important element in clinical recovery from *C. difficile* diarrhea [40]. A genetic polymorphism in the promoter region of interleukin 8 gene has been associated with increased rates of CDI [42] and disease recurrence [43]. Presence of this polymorphism apparently leads to recurrence by prevention of immune response to the toxin(s) of *C. difficile* during a bout of CDI [44]. This genetic marker has not been studied in CDI in patients with transplantation.

Host Immune Response to *C. difficile* Colonization and Infection in Transplant Patients

The therapeutic prescription in transplant recipients includes a delicate balance between immunosuppression to protect the patient from graft-versus-host disease (GVHD)/organ rejection and simultaneous protection from life-threatening bacterial, viral, and fungal infection. With the advent of newer molecules and newer immunosuppressive regimens, the augmented immunosuppression confers protection against GVHD but inhibits the ability to mount a microbial specific cytotoxic T-lymphocyte response [45].

Immunosuppression deactivates immune competence in the transplant recipient through multiple pathways including suppression of anti-inflammatory cytokines and suppression of antibody-mediated response to toxins by immunosuppressive agents, frequent use of antibiotics, and longer and more frequent hospital admissions. These immunosuppressive pathways reduce their ability to mount an aggressive humoral response to the *C. difficile* toxin soon after the infection. Intensified immunosuppressive therapy and pulse steroid therapy that prevent transplant rejection are also major contributors of posttransplant hypogammaglobulinemia (HGG) that is observed in 69.6% of transplant patients [46]. This inhibits immunoglobulin production primarily through an indirect pathway by altering lymphokine production by the T cells which in turn alters the B-cell function. A few newer immunosuppressive agents affect B-cell function through a direct pathway too [47, 48]. Hence these patients are unable to initiate a

specific immune response against *C. difficile*'s toxin A and SLP [41, 49]. Besides, HGG is associated with increased incidence of opportunistic infection. Consequently, broad-spectrum antibiotics are used extensively as a prophylactic as well as therapeutic measure resulting in destruction of the normal intestinal flora. In addition, multiple antibiotics are administered to transplant recipients as perioperative prophylaxis or postoperative therapy. These antibiotics alter the intestinal microecology and reduce the resistance to colonization of the bowel by *C. difficile*. This ultimately results in increased incidence of antibiotic-associated diarrhea and CDI [50]. Iatrogenic immunosuppression in transplant recipients thus offsets the fine balance and makes the patient more vulnerable to CDI.

Emergence of a Hypervirulent Strain

A hypervirulent or BI/027/NAP1 toxinotype III strain of *C. difficile* has emerged during the past decade. This strain of bacteria possesses a binary toxin, with an 18-bp deletion in the tcdC gene that demonstrates in vitro resistance to fluoroquinolones [34, 51, 52]. The BI/027 strain produces 3 to 13 times more toxins and sporulates at a higher degree than historical strains [53]. In the US and UK isolates, the NAP1/027 strain produced 16 times more of toxin A and 23 times more of toxin B concentrations than other strains [54]. These factors contribute to hypervirulence, increased severity of the disease, and widespread emergence of this epidemic strain all too often resulting in the development of toxic megacolon requiring colectomy, leukemoid reaction, shock, and death [34]. The importance of this organism in transplantation medicine has not been established.

CDI in BMT Patients

BMT patients appear to be at increased risk of developing infectious gastroenteritis [55] most probably related to prolonged hospitalizations with enhanced exposure to infectious spores, treatment with numerous prophylactic broad-spectrum antibiotics, myeloablative chemotherapy, and altered integrity of the intestinal mucosa [14, 15, 56]. Cytopenias are frequently seen in these patients in spite of submyeloablative doses of chemotherapy. Prolonged neutropenia and placement of indwelling catheters prior to mobilization process predispose them to infections. Prophylactic antibiotics are given due to high risk of infection following intense chemotherapy to enhance stem cell yield. All these factors predispose this population to increased risk of CDI [57]. However, the duration of immunosuppression is shorter in BMT patients than in SOT patients. Nevertheless, neutropenia seldom occurs in patients following SOT, whereas in HSCT recipients severe neutropenia is routinely seen during the pre-engraftment period. CDI accounts for 1.3–20.4% of all diarrheal diseases in BMT patients [58]. The incidence of CDI is 5–7% in autologous transplant patients [15, 55], while Yolken et al. reported 15%, and Chakrabarti et al. reported CDI 13% in allogeneic BMT patients [17, 59]. This may be due to shorter duration of neutropenia in patients undergoing autologous BMT because of increased use of hematopoietic growth factors [14, 60]. In allogeneic BMT patients, donor effector T cell may cause GVHD, and diarrhea is the common clinical presentation of intestinal tract GVHD [16]. High-dose steroids and antibiotics given to suppress the host anti-inflammatory response in patients with GVHD could have attributed to higher incidence of CDI in allogeneic BMT patients [16].

The average time to onset of CDI after autologous BMT is less than a week [16, 61] and after allogeneic BMT is 33–38 days [16, 17]. Mobilization of stem cells is done by administration of cytokines like filgrastim alone, chemotherapy alone, or both. However, the stem cell yield is greater for those patients receiving a combination of cytokines and chemotherapy. This frequently results in prolonged periods of cytopenias including neutropenia [62]. Moreover, these conditioning regimens, which are indispensable for stem cell mobilization, damage the integrity of mucosal barriers [55]. In addition, the placement of indwelling catheters prior to mobilization of stem cells and prophylactic use of antibiotics destroys the ecologic balance of the normal intestinal flora and promotes colonization of the gut by pathogenic organisms such as *C. difficile* in BMT patients [13, 57]. All these factors along with intense immunosuppressive therapy to prevent GVHD in allogeneic hematopoietic graft recipients may predispose BMT patients to earlier onset of CDI [57] than SOT patients. In a study of patients with CDI having previously undergone HSCT, the 1-year incidence of recurrent CDI was 31% with most recurrences seen in within 6 months of the initial infection [63].

CDI in SOT Patients

It was determined in one study that CDI was five times more common in sold organ transplant recipients than among general medicine inpatients and that CDI was associated with increased 30-day readmission for transplanted patients [64]. Reported incidence of CDI in SOT patients ranges from 1% to 31%: 3–7% in liver, 1–16% in kidney, 8–15% in heart, and 7–31% in lung transplant patients [46, 50, 65–67]. In one study the median time from transplantation until development of CDI was 51 days (14–249 days range) with liver recipients having the shortest time to infection, median 36 days, and lung recipients a longer time to infection, median 136 days [68]. Hospitalized children with solid organ transplant recipients are at increased rates of CDI [69].

Poor pretransplant conditions such as end-stage organ failure and long waiting times, longer and more frequent hospital

admissions, and prolonged/protracted immune suppression over a period of 12 months in SOT patients increase the risk of CDI [65, 67]. These prolonged periods of immune suppression predispose SOT patients to repeated infections, which exposes them to repeated courses of broad-spectrum antibiotics. The use of antibiotics in this group of patients alters the intestinal flora favoring the colonization of gut by *C. difficile* [50]. Suppression of anti-inflammatory and antibody-mediated immune response reduces their ability to mount an effective humoral response to the *C. difficile* toxin after the infection. In addition, immunosuppressive and steroid therapy in the post-transplant period given to prevent transplant rejection is a major contributor of HGG in a vast majority of transplant patients [46]. This inhibits immunoglobulin production primarily through an indirect pathway by altering lymphokine production by the T cells, which in turn alters the B-cell function. A few newer immunosuppressive agents affect B-cell function through a direct pathway too [47, 48]. Hence, these patients are unable to initiate a specific immune response against *C. difficile*'s toxin A and SLP. Besides, HGG is associated with increased risk of opportunistic infection [46]. Another common risk factor in SOT patients is gastric acid suppression by proton pump inhibitors. Hospitalized patients receiving proton pump inhibitors are two times more likely to develop CDI [70]. Though gastric acid does not have any action on the spores, it destroys the vegetative forms and reduces the ability of the spores to germinate. Proton pump inhibitors also alter the gastrointestinal flora, facilitating colonization of the colon by *C. difficile* [71]. In a study by Dallal et al. [18], it was observed that the risk of developing CDI was 46 times higher in lung transplant recipients and they were 8 times more likely to have severe forms of CDI than all other patients with CDI. This may be due to more intense immunosuppression to prevent rejection and frequent use of antibiotics to treat recurrent pulmonary infection as lung transplant recipients are the only SOT patients in whom the allograft is directly exposed to the environment [18]. Poor pretransplantation condition associated with end-stage liver failure, longer waiting times, operative stress, and the required immune suppression impair the normal defense mechanism and predispose liver transplant recipients to higher incidence of infections. Administration of frequent, more diverse, and prolonged use of antimicrobials favor increased incidence of CDI in liver transplant patients than kidney transplant patients. Further, certain newer immunosuppressive agents may cause severe mucosal damage and increase the incidence of CDI in this population [65, 67]. The incidence of CDI in kidney transplant recipients may be low because of underreporting [72]. Further, induction of immunosuppressive treatment and recent use of antibiotics are risk factors that favor CDI in this population [73]. CDI in adult kidney recipients appeared to represent a different pattern by their presentation at a later age invariably associated with use of antibiotics [72]. HGG has been reported in kidney, lung, heart, and liver transplant patients. Severe HGG was observed in approximately 10% of heart transplant patients, which increases the risk of CDI in this subset of transplant patients [48, 74, 75].

CDI occurs more frequently in the first 3 months after transplantation mostly due to enhanced immunosuppression, increased exposure to healthcare settings due to prolonged hospital stay, frequent use of antibiotics, and debilitated condition prior to transplant [50, 65, 66]. Late-onset CDI correlate with the onset of HGG due to exposure to antimicrobials or intensified immunosuppression to treat graft rejection [66, 72, 76, 77]. The outcome of CDI in recipients of solid organ transplants is good with recurrence the major complication as seen in non-transplant patients [78].

Clinical Features

Depending on the immune response to toxin A of *C. difficile*, infected patients exhibit a wide spectrum of clinical manifestations. Patients with a high titer of IgG to toxin A may remain as asymptomatic carriers of *C. difficile* [29]. Approximately 2–3% of healthy adults are asymptomatic carriers of *C. difficile* [79]. Symptomatic patients present with watery diarrhea, cramping, fever, dehydration, and leukocytosis. Some of the complications of CDI include fulminant colitis, hypoalbuminemia, pseudomembranous colitis, toxic megacolon, and perforation of the colon [37, 80]. Recurrent CDI occurs in 10–25% of CDI and is more often due to relapse than reinfection. Some of the risk factors associated with relapse include age greater than 65 years, prolonged hospitalization, prolonged antibiotic use, diverticulosis, and comorbidities [81]. An increased secretion of IgG to toxin A is associated with decreased risk of recurrence [41].

Diagnosis

Though there is no gold standard test to confirm the diagnosis of CDI, the commonly used tests are enzyme immunoassay (EIA) for toxin A/B, glutamate dehydrogenase (GDH), nucleic acid amplification tests (NAATs), toxigenic culture (TC), and cytotoxin neutralization (CTN) test [82, 83]. Diagnosis of CDI is made following detection of *C. difficile* toxin in stool samples in a patient with new onset diarrhea, often associated with antibiotic use. Stool toxin test is the most specific diagnostic test for CDI with sensitivity of 67–100% depending upon the method of toxin testing employed. EIAs are done to detect toxin A and/or toxin B, but they have low sensitivity. In some institutions, a two-step process is being used to detect CDI [84]. Initially, a cost-effective screening test is done to detect the presence of GDH

in stools. As the presence of GDH does not differentiate between toxigenic and non-toxigenic strains of *C. difficile*, patients with stool specimen positive for GDH are subject to further evaluation by assays to confirm the presence of toxigenic *C. difficile*. Stool culture followed by testing the isolate for toxin production is a highly sensitive method (89–100%) with high specificity (84–99%). NAATs such as real-time polymerase chain reaction (RT-PCR) are as sensitive as culture for diagnosing CDI. A stool sample to be tested should be sent to the laboratory as soon as possible as the toxins secreted by *C. difficile* strains undergo degradation within hours [81]. Computed tomography imaging is a useful test that shows colonic thickening, and colonoscopy is also very sensitive showing characteristic white yellow mucosal plaques or pseudomembrane formation [85–87]. False-positive tests commonly occur regardless of test because of *C. difficile* carriage making it difficult to determine if CDI was the diagnosis or diarrhea due to another cause. In a logistic regression model, allogeneic HSCT was identified as a significant risk factor (OR 18.6, $p < 0.01$) compared with other patients for colonization by *C. difficile* [88].

In the absence of above mentioned confirmatory laboratory findings, the following factors may be suggestive of CDI: (1) marked leukocytosis (WBC >15 × 10^9/L), (2) hypoalbuminemia (<30 g/L), and (3) rise in serum creatinine level (133 μM or 1.5 times the premorbid level) [89].

Treatment

General management includes discontinuing of offending antibiotic if possible together with fluid and electrolyte replacement, anti-*C. difficile* antimicrobial therapy and institution of infection control measures. Specific anti-*C. difficile* treatment [85] includes administration of oral vancomycin, oral or intravenous metronidazole, or oral fidaxomicin for 10–14 days [90–92] (Table 16.1). Vancomycin and fidaxomicin are the two FDA-approved drugs for CDI. Response rate to treatment is 86–100%. Oral vancomycin and fidaxomicin are the preferred treatments of CDI [92]. IV metronidazole is helpful for the management of patients with CDI who cannot take oral medications when combined with vancomycin enemas [93]. Though fidaxomicin is associated with lower frequency of recurrence than vancomycin, recurrences are not eliminated, and the drug is much more expensive. See Table 16.1 for summary of treatment options for CDI. Recurrence rate of CDI after appropriate therapy averages 25% [94]. Because of the importance of anti-*C. difficile* antibody development in CDI to ultimate recovery, anti-*C. difficile* toxin vaccines and antibody preparations are in development. A humanized anti-toxin A and B monoclonal antibody preparation reduced the occurrence of CDI recurrence in patients treated with standard anti-CDI therapy [95]. Pooled human immunoglobulin has been used with variable success in treating recurrent CDI [96].

Table 16.1 Specific anti-*C. difficile* treatment

Therapeutic agent	Dose	Comments
Metronidazole	500 mg 3–4 times a day for 10–14 days PO or IV	Not as effective as other drugs when given orally due to high gut absorption; can be given IV if oral route unavailable; give orally when can
Oral vancomycin	125 mg four times a day for 10–14 days	Standard therapy for moderately ill or severely ill patients
Fidaxomicin	200 mg every 12 h for 10 days	Lower recurrence rate than vancomycin but remains the most expensive option

Other drugs with potential value: ramoplanin, rifalazil, rifaximin, tinidazole, nitazoxanide, teicoplanin, and fusidic acid

First recurrent CDI can be managed with a repeat course of the initial antibiotic. Recurrent cases beyond the first recurrence can be treated with pulsed or tapered dose of oral vancomycin over a month or longer [97]. Patients with fulminant CDI may require colectomy for cure [98]. Fecal microbiota transplant (FMT), a process by which feces from a healthy donor is directly transplanted into the duodenum or lower gastrointestinal tract or is administered as frozen FMT capsules to restore normal ecology, has been used increasingly for severe cases of post-antibiotic colitis and more frequently for refractory and recurrent cases of CDI [82, 99–102], the most successful treatment in immunocompetent hosts. However, recommended guidelines suggested avoidance of FMT in SOT recipients due to risk of infection from the organisms in the fecal material [84]. Nevertheless, in a retrospective study of 80 immunocompromised patients, including 19 SOT recipients, who had received FMT for refractory/recurrent/severe CDI, an overall cure rate of 89% was reported [103]. Though there were few severe adverse effects or related adverse effects, infections definitely related to FMT were not reported in this study which fits with another study of FMT for recurrent CDI in HSCT recipients [104]. Though seemingly not appealing, FMT is emerging as an inexpensive, safe, and efficient treatment of refractory and recurrent CDI [105–108]. There are limited centers for this option but the outcome is excellent. More research is needed to understand the positive elements of donor feces studied by metagenomic analyses in the therapy of severe or recurrent CDI.

Recommended Prevention and Control Measures

Preventive measures that effectively reduce the incidence of *C. difficile* infections and cross-infection in hospital settings include a precise and early diagnosis, early initiation of spe-

cific treatment, adopting enteric precautions for symptomatic patients, promoting hand hygiene using soap and water, and adopting barrier precautions. Combination of hand hygiene and contact precaution can result in 60–80% reduction in spread of CDI [109, 110]. As a primary preventive step, environmental disinfection with 10% sodium hypochlorite should be routinely employed in hospital rooms confining or having confined patients with CDI [111]. The use of broad-spectrum antibiotics should be limited by adhering to antibiotic policy of the hospital which should be reviewed periodically [112]. *C. difficile* should be systematically investigated in patients with more serious forms of nosocomial diarrhea. Educational programs for clinical and ancillary clinical staff can help prevent transmission of *C. difficile* from patient to patient. Strict antiseptic measures including use of disposable gloves, mask, and gown, frequent washing of hands with soap and water, and use of disposable thermometers and enhanced environmental cleaning must be enforced. Isolation methods such as private rooms or cohorting of infected patients have been effective in reducing the rate of CDI. Surveillance should be instituted in order to detect hospital and community outbreaks [81, 85].

Patients with CDI continue to excrete the organism for long periods. There is no established treatment for the frequent patient in the hospital who becomes colonized by *C. difficile*. It is therefore essential that patients' rooms be thoroughly sanitized to reduce the potential for reinfection of patients, as this is one of the commonest causes for recurrence of symptoms.

Other Gastrointestinal Infections

Other non-*C. difficile* causes of diarrhea may be seen in the first 6 months after transplantation. Though the infections seen in BMT and SOT patients are similar, there is significant difference in the duration and degree of immunosuppression. Infections that occur in the first month following SOT include endogenous pathogens infecting the patient pretransplant such as herpes viruses, those transmitted from the donor as, for example, hepatitis virus, and those related to the procedure itself such as gram-negative sepsis. Opportunistic infections that occur from 1 to 6 months following SOT include viral, fungal, and parasitic infections. Beyond the first 6 months, SOT patients are at a higher risk for community-acquired infections and lymphoproliferative diseases like B- and T-cell lymphoma due to continued intense immunosuppression [2].

Mucositis is common following BMT [113] and mucosal ulcerations which may be due to cytomegalovirus (CMV), herpes simplex virus, fungal agents, or *Entamoeba histolytica* [114, 115]. Diarrhea due to *E. histolytica*, *Giardia lamblia*, *Cryptosporidium* spp., *Strongyloides stercoralis*, CMV, and noroviruses are known to occur during the period of immunosuppression in BMT patients [116]. Abscess in the perianal region mostly due to bacteria is known to occur during neutropenic episodes [117]. Hepatitis B and hepatitis C may be transmitted from the donor, or reactivation of the virus in an infected recipient may occur in the posttransplant period [118, 119]. Fatal fulminant hepatitis B has been reported in hepatitis B-infected recipients in the absence of viral prophylaxis [120]. Fungal infections are less common in BMT patients due to antifungal prophylaxis [121, 122].

CMV infection is the most common infection that occurs within the first year of SOT, with a peak incidence at 4–6 months after transplant [45, 123]. Lung transplant and heart transplant patients are at a higher risk of developing CMV infection than other SOT patients. CMV hepatitis is more severe in orthoptic liver transplant patients than in any other SOT recipients [124]. Kidney and kidney-pancreas transplant patients are at a lower risk of developing CMV infection as the latent viral load is low in the allograft [123]. This is more likely to occur in those patients who receive antilymphocyte antibody in addition to conventional immunosuppression or mycophenolate mofetil (MMF) for maintenance [124–126].

Herpes simplex virus infection is the second most commonly occurring viral infection in SOT patients. It has great predilection for the squamous epithelium of the esophagus; however, it can involve the intestine and liver in the absence of appropriate prophylaxis. It is mostly due to reactivation of latent virus and hence manifests within the first 4 weeks of transplantation [127]. Other herpes virus infections are less common. However, the risk of dissemination of varicella-zoster virus increases with use of MMF immunotherapy.

Fungal infections usually develop after the first month of SOT especially in patients who have discontinued fungal prophylaxis [127]. Liver transplant patients are at a higher risk to develop invasive fungal infection in general and *Candida albicans* in particular than other SOT patients; while infection by *Aspergillus* spp. is highly prevalent in lung transplant and heart-lung transplant patients [128].

Conclusions

The incidence of CDI in the immunosuppressed population is greater than in the general population and is dependent on receipt of antibiotics and other drugs and exposure to *C. difficile*. Recovery from CDI depends upon the patient's ability to mount a quantitative immune response and presence of comorbidities. Disruption of the delicate balance between iatrogenic immunosuppression to prevent organ rejection and the ability to mount an immune response against pathogenic agents results in life-threatening or recurrent infections by *C. difficile* and other pathogens.

Prompt diagnosis and early treatment of CDI, effective infection control measures, and prudent use of antibiotics may help reduce morbidity and mortality due to CDI. Understanding the gravity of the disease and strict implementation of hand hygiene and antiviral and antifungal prophylaxis may help prevent other gastrointestinal infections following transplantation.

Hepatobiliary Tract Infections

17

Jonathan Merola, Robert M. Mocharla, Alexander Z. Jow, Samuel H. Sigal, and Amar Safdar

Introduction

Patients undergoing solid-organ and hematopoietic stem cell transplantation are at risk for numerous infections involving the hepatobiliary tract. Hepatobiliary tract infections contribute significantly to increased morbidity and mortality among recipients of solid-organ allografts, particularly in patients undergoing liver transplantation. Bacteria and less frequently yeast within the gastrointestinal tract may colonize a dysfunctional biliary system resulting in increased susceptibility for ascending cholangitis. Additionally, opportunistic viral infections such as varicella zoster virus, cytomegalovirus, and Epstein-Barr virus may trigger life-threatening acute illnesses or perpetuate malignancies during the posttransplant period. Fungal and protozoal infections may also find refuge within the biliary tract of immunosuppressed host and requiring multifaceted treatment approach. A thoughtful balance between utilization and adjustment of immunosuppressive medications, which are essential for graft preservation, while limiting the risk for opportunistic bacterial, fungal, viral, and parasitic disease, is pivotal in developing a fastidious approch towards patients undergoing allograft transplantation.

Strategies for infection prevention play an important role in mitigating the risk for infections during the posttransplant period. A thorough pretransplant assessment includes (1) surveillance of active and latent infections, (2) early institution of appropriate antimicrobial drug prophylaxis, and (3) appropriate active and passive immunization. A high level of suspicion for biliary tract and infections involving the liver along with improved new-generation diagnostic tests for early diagnosis, and prompt initiation of effective antimicrobial therapy, as expected, are deemed critical in improved patient outcomes. Lowering drug-induced immune suppression, when possible, remains pivotal in addressing management of infections in this high-risk group. Here were present a comprehensive review of important infections in transplant population involving the hepatobiliary tract.

Bacterial Infections

Pretransplant Cholangitis

Acute cholangitis is a common bacterial infection affecting patients undergoing liver transplantation with advanced liver and/or biliary tract disease. The disease process typically involves an ascending bacterial infection originating in the duodenum that migrates into the lower biliary tract. If untreated, the disease can progress resulting in life-threatening systemic dissemination such as bloodstream invasion, sepsis, severe sepsis, multiorgan dysfunction and death. In the pretransplant setting, cholangitis can develop as a complication of cirrhosis due to any etiology as well as be the first manifestation of chronic liver disease. Cirrhotic patients are prone to cholangitis due to altered biliary motility and anatomic aberrancy involving the biliary tract. In patients with chronic liver disease being considered for liver

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_17

transplantation, underlying biliary disease increases the risk for cholangitis; these include patients with primary or secondary cholangitis and less commonly, other causes of primary biliary tract disease. Following transplantation, such infections may result from technical complications arising from vascular insufficiency and/or compromised biliary duct anastomoses.

In the normally functioning biliary system, the sphincter of Oddi and the constant forward flow of bile prevents retrograde spread of bacteria from the duodenum into the biliary tract. With the frequent clearing of bacteriostatic bile salts, bacterial multiplication is kept in check. These protective systems, however, are less effective in patients with chronic liver and/or biliary tract disease. Inflammatory damage to the hepatocyte and epithelial cells in the bile ducts distort the normal hepatic architecture and bile flow, predisposing to biliary stasis and gallstone formation. The presence of gallstones in turn serves as a nidus that promotes the risk for ascending cholangitis. Bile aspirated from individuals without gallstone disease is usually sterile. However, nearly 32% of bile cultures taken from cancer patients with gallstones demonstrate bacterial colonization [1].

Primary sclerosing cholangitis (PSC) is characterized by chronic inflammatory damage of the intrahepatic and extrahepatic bile ducts, the resulting fibrosis leads to strictures throughout the biliary tract. Although the precise etiology of this disease is not known, due its co-occurrence with inflammatory bowel disease, especially ulcerative colitis, autoimmune damage is presently the favored hypothesis for this progressive and devastating illness. Chronic inflammation impedes normal excretion of bile due to stricture formation and anatomic distortion of bile duct system, resulting in frequent episodes of cholangitis. Patients with PSC are also at a higher risk for gallstone formation. Endoscopic treatment to dilate or place stents in the region of severe bile duct narrowing is often undertaken to alleviate bile stasis and to reduce the risk for recurrent infections.

Secondary sclerosing cholangitis (SSC) is radiographically and clinically similar to PSC. Recurring injury to the bile ducts seen in patients with chronic gallstone disease, recurrent pancreatitis, surgical trauma to the biliary system, treatment with antineoplastic drugs, eosinophilic cholangitis, recurrent bacterial cholangitis, and HIV cholangiopathy are some of the common causes [2]. Injury to the bile duct results in anatomic damage and aberration in bile excretion predisposing to ascending bacterial colonization and infections. Finally, cholangitis may be associated with congenital diseases such Caroli disease and Caroli syndrome. Caroli disease involves the cystic dilation of intrahepatic bile ducts, and Caroli syndrome involves bile duct dilatation as well as congenital hepatic fibrosis [3]. These patients are prone to recurrent acute cholangitis, which manifest as the presenting sign in nearly two-thirds of the patients [4]. The true incidence of cholangitis is likely underestimated, as biliary strictures likely lead to frequent, and conceivably transient bacterial infection.

Acute cholangitis characteristically presents with jaundice, fever, and right upper quadrant abdominal pain. Because patients with chronic liver or biliary tract disease may be chronically jaundiced and have abdominal pain and fever from other causes such as spontaneous bacterial peritonitis, the diagnosis may not be readily perceived. In addition, intrahepatic fibrosis may prevent the development of intrahepatic biliary dilatation [5]. Among patients with hepatic cirrhosis, the diagnostic approach with ultrasound, CT scan, MRCP, and ERCP is the same as for the non-cirrhotic patient. However, ERCP carries significant risk for complications in patients with cirrhosis due to (1) the adverse effects of sedation in preexisting hepatic encephalopathy, (2) risk of uncontrolled bleeding due to coagulopathy, and (3) procedure-associated pancreatitis. ERCP-associated pancreatitis is a serious complication, especially in patients with end-stage liver disease. However, diagnosis and relief from bile duct obstruction is crucial in preventing future infections and other complications.

The causative organisms of acute cholangitis are of intestinal origin and similar to those associated with cholecystitis. Aerobic Gram-negative bacteria (GNB) such as *Escherichia coli*, *Klebsiella* spp. and *Enterobacter* spp.; occasionally, Gram-positive bacteria (GPB) such as *Enterococcus* spp. are isolated. Anaerobes such as *Bacteroides fragilis* or *Clostridium perfringens* are uncommon pathogens [6]. In patients with PSC, *Candida* species are increasingly isolated from the bile cultures [7]. Concurrent yeast and bacterial polymicrobial infection may result in a more severe form of cholangitis. Systemic antifungals should be considered early in the course of therapy for acute cholangitis, especially in patients with known biliary tract yeast colonization, in whom initial empiric antibacterial therapy has failed.

Effective treatment consists of a multifaceted approach including systemic antimicrobials, biliary tract drainage, and supportive care. Current recommendations are to cover broadly for aerobic GNB, GPB, and anaerobes. More than 50% of cases respond well to conservative antimicrobial treatment alone, given for 7–10 days [8]. If patients' clinical status declines or infection fails to improve within the first 24 h after treatment with antibiotics has commenced, emergent drainage of the biliary tract is recommended. Patient with cirrhosis experience high frequency of complications following ERCP and sphincterotomy. Approximately 3–8% of cirrhotic patients will experience bleeding, and 4–5% may develop acute pancreatitis following sphincterotomy [9, 10]. Other complications such as secondary cholangitis, cholecystitis, stent occlusion, stent migration, and bile leak are also more frequent in patients with cirrhosis of liver [10]. Cholangitis in patients with PSC commonly requires dilation and/or stenting of bile duct strictures. Placement of a foreign object act as an additional nidus, that

increases the risk for future infections; recurrent cholangitis was more common after stent placement compared with PSC patients, in whom only balloon dilation was performed [10]. Finally, percutaneous transhepatic cholangiography (PTC) can be employed in cases in which ERCP is not possible due to prior surgery; however, PTC carries an increased risk for bacteremia, hemorrhage, hemobilia, and creation of vascular-biliary fistula. This technique cannot be employed in patients with significant ascites as the ascitic fluid prevents maturation of the cutaneobiliary tract [11].

For patients with frequent, recurrent cholangitis associated with surgical alterations of the biliary tract such as hepaticojejunostomy and sphincteroplasty, the use of long-term antibiotic prophylaxis with rotating antibiotic regimens including amoxicillin-clavulanic acid, trimethoprim-sulfamethoxazole, or ciprofloxacin are proposed to reduce recurrences of cholangitis episodes [12, 13]. As with all long-term antibiotic prophylaxis, colonization and infection due to drug-resistant organisms remain a serious concern.

Finally, potential liver transplant recipients with PSC, during the episodes of recurrent cholangitis, have an increased risk of death; however, it is considerably lower during the intervals without such infection episodes. To account for this additional risk of death, patients who have two or more serious episodes of cholangitis requiring hospitalization and intravenous antibiotic therapy within a 6-month period are eligible to receive MELD exception points to prioritize their prospect for hepatic allograft transplantation [14].

Posttransplantation Cholangitis

Cholangitis that occurs after transplantation procedure can be classified into conditions associated with anatomic alterations in liver transplant recipients and those associated with anti-rejection drug regimen-induced immune suppression. With the first category, bacterial pathogens are most common. In the subsequent category, polymicrobial infections associated with high level of drug-induced, cumulative immune suppression become more prominent. Temporal-relationship, and other associated features such as source of the hepatic allograft, transplantation procedure, and the underlying etiology of end-stage liver disease are important features in assessing patients with cholangitis after transplantation.

Bacterial Cholangitis

Acute cholangitis is the most common infectious complication in liver transplant recipients and may arise at any time after undergoing transplantation. Alterations in the normal biliary anatomy predisposes to infections resulting from choledochojejunostomy anastomosis. Most surgical complications involve the biliary system; 15–30% of transplant recipients will experience a complication involving the biliary tract [15]. Surgical complications such as bile leakage, wound dehiscence, and bile duct strictures are commonly associated with the risk of cholangitis. Recurrence of primary disease in patients with PSC is a well-known risk for acute cholangitis. Finally, viral infections may involve the liver and confer a greater risk of cholangitis by promoting bile stasis.

The causes and risks associated with the infection can roughly be grouped according to two main time periods: within 30 days and after 1st month following transplantation [16]. The incidence of acute cholangitis begins to decrease after the 1st year following transplantation. This is presumably due to a decline in the risk factors for cholangitis that usually manifest early after transplant surgery.

During the first several weeks immediately following liver transplantation, surgical complications are the main cause of acute cholangitis. Acute cholangitis in the first 30 days following transplant is commonly related to biliary anastomotic leaks. Bile leaks usually manifest within the first 30 days after transplant surgery, with a mean time for presentation being 17 days [17]. Subsequently, acute cholangitis as a direct result of surgical complication becomes much less common. Placement of biliary T-tube in the duct-o-duct anastomosis increases the overall risk for complications, including the risk for cholangitis [18].

After the first month, strictures in the biliary tract become the leading cause of cholangitis. Strictures can be classified as either anastomotic or non-anastomotic strictures and typically present around 6 months after transplantation [19]. Anastomotic strictures are short, limited to the surgical anastomosis site, resulting from fibrotic scar tissue formation. Non-anastomotic strictures are typically multiple, long, and proximal to the site of anastomosis involving within the transplanted hepatic allograft. They are divided into three main groups based on causative etiology: macroangiopathic, microangiopathic, and immunogenic. Macroangiopathic strictures are related to vascular events, the most common being hepatic artery thrombosis and hepatic artery stenosis, with an incidence of 1–3% [20]. Non-anastomotic strictures due to microangiopathic complications are related to ischemic events that occur during perioperative period involving donor liver or surgical and postsurgical complications in the recipients such as inadequate tissue perfusion or the need for systemic vasopressor support. Bile duct complications are more frequent in patients undergoing living donor transplantation (LDT) due to the complex biliary and vascular grafting techniques; bile leaks and strictures may occur in up to 12.6 and 5.8% of LDT cases, respectively [21]. Finally, recurrence of primary sclerosing cholangitis can cause immunogenic strictures. Of all the causes of biliary strictures, immunogenic strictures present furthest from the transplant procedure.

The most such complications will present within the first 18 months after transplant; however, they may be encountered years after transplantation [22, 23]. Approximately 10–20% of patients undergoing transplantation for PSC will develop disease recurrence with a median presentation time of 68 months [23, 24]. These cases are associated with HLA subtype, presence of acute cellular rejection, and necessity for chronic systemic corticosteroid therapy for ulcerative colitis [24].

Transplant recipients may or may not present with typical symptoms suggestive of acute cholangitis, and comparable clinical presentation of other conditions may initially obscure the diagnosis. Abdominal pain is not uncommon after liver transplant surgery. Liver biochemistries may be abnormal due for a variety of reasons. As a result, it is often difficult to diagnose an acute episode of cholangitis based on classic physical and laboratory findings. In addition, biliary dilatation is frequently absent in patients with cholangitis due to local edema, blood clots, and sludge in the bile ducts that obscure accurate visualization of the biliary tract. Abdominal ultrasound has low diagnostic sensitivity of 38–68% [25]. As a result, diagnostic MRCP is recommended in all appropriate clinical settings.

Treatment of acute cholangitis in the transplant population is similar to treatment approach for patients with acute cholangitis during pretransplant period; prompt initiation of empiric antibiotic coverage for GNB and GPB is recommended. Concomitant fungal infection may be present in 1–12% among such infections, typically *Candida* spp., rarely *Aspergillus* spp., and it is exceedingly rare to find extrapulmonary *Pneumocystis* as a concurrent fungal pathogen [16, 26]. Antifungal coverage should also be considered in patients receiving intensified antirejection regimen. Invasive fungal disease of the biliary tract is often rapidly fatal unless effective systemic treatment is given empirically and high level of suspicion plays an important role in such decision making [27]. Finally, ERCP-assisted biliary decompression with drainage and placement of stents may be needed.

Cholangitis Associated with Immunosuppression

Immunosuppression used to prevent or treat liver graft rejection predisposes the patients to infection with a variety of viruses and fungi which are normally harmless in individuals with intact immune function. In patients with CMV hepatitis, viral infection may extend to involve the biliary tract; fungal infections primarily *Candida* spp. and less commonly *Aspergillus* spp. may occur, especially in highly susceptible population with (1) documented fungal infection prior to transplantation; (2) advanced renal disease; (3) patients after prolonged transplant operative time; and (4) those with a choledochojejunostomy.

Cholecystitis

Cholelithiasis and cholecystitis are prevalent in the general population, nearly 500,000 cholecystectomies are performed annually in the United States [28]. Detection and treatment of the disease among otherwise healthy individuals is generally successful without significant morbidity and mortality. However, gallbladder disease and surgery in the cirrhotic patient carries significant risk. Development of gallstones and progression to cholecystitis is common in patients with hepatic cirrhosis, this is ascribed to high levels of estrogen, unconjugated bilirubin, and increased risk for hemolysis. In patients with cirrhosis of liver, gallstones may develop at a frequency of 38% higher compared with general population [29, 30]. The prevalence of gallstones increases with disease severity, and recent studies have suggested chronic hepatitis C viral infection as an independent risk factor for gallstone disease in patients with cirrhosis [31, 32].

Clinical presentation of cholecystitis in patients with cirrhosis may be similar to that observed in the general population; however, presence of abdominal distension and abdominal pain from ascites, preexisting liver test abnormalities may obscure the diagnosis. The bacteriology of acute cholecystitis in cirrhosis is similar to that of cholecystitis in otherwise healthy patient, namely, the normal intestinal flora. Gram-negative bacilli such as *E.coli*, *Klebsiella pneumoniae*, *Klebsiella oxytoca*, and *Enterobacter* spp. and anaerobes such as *Bacteroides* and *Fusobacterium* spp. are frequently isolated. Due to higher frequency of exposure to the healcare environment including hospitalization and frequent antibiotic use including antimicrobials given for prevention of spontaneous bacterial peritonitis in patients with end-stage cirrhosis; the probability of infections due to multidrug-resistant organisms (MDROs) is a concern. Colonization of the gastrointestinal tract with MDROs and unusual pathogens resulting from altered hosts' microbiota is regarded as an important contributor in the changing spectrum of the causative agents for acute cholecystitis [33, 34]. Additionally, cirrhotic patients are at increased risk for renal failure due to impairments in normal renal circulation [35]. Predictive factors for renal failure in this population include, higher baseline MELD score of greater than 27 and severity of infection; therefore, administration of albumin with antibiotics has been proposed to improve outcomes in high-risk individuals [36].

Curative therapy for cholecystitis involves surgical removal of the gallbladder, however, patients with cirrhosis are poor surgical candidates. Derangements in fluid dynamics due to portal hypertension, dysregulation in coagulation cascade, and overall poor functional performance status in patients with end-stage liver disease are some of the salient factors contributing to the significant risk associated with surgery. Cirrhosis follows cardiovascular disease such as congestive heart failure in predicting complications during and after surgery. Prior to the

advent of laparoscopic cholecystectomy, advanced cirrhosis was considered as a contraindication for cholecystectomy due to high mortality rates approaching 25–83%. Such patients were managed conservatively with systemic antibiotics and supportive care [37, 38]. Surgical complications included intra-abdominal hemorrhage, variceal bleed, development or worsening of ascites, superimposed infection(s), and cardiovascular compromise. With laparoscopy advanced cholecystectomy techniques, favorable outcomes have improved substantially [39] and should be attempted as the initial approach for a select group of patients [40]. Laparoscopic surgery is associated with shorter hospital stay, earlier resumption of enteral feeding, earlier ambulation, less blood loss, and reduced pain during the postoperative period [41]. Additionally, postoperative ascites is less common after laparoscopic procedure; probably a reflection on reduced disruption of hepatic and biliary lymphatic circulation and lower risk of bleeding in the peritoneal cavity [42]. In cases where laparoscopic total cholecystectomy is not possible due to extensive fibrosis and/or severe local inflammation, subtotal cholecystectomy procedure that leaves the posterior wall of the gallbladder intact along the liver allows symptomatic relief and clinical resolution of the infection, while mitigating the aforementioned risk of complications associated with a more invasive surgical dissection needed during total cholecystectomy procedure [42–44].

Operation risk was initially assessed with Child-Turcotte-Pugh classification. Individuals with Child-Pugh A or B score were considered safe to undergo surgical procedure, whereas those with Child-Pugh C were managed with conservative therapy alone [45, 46]. More recently, the MELD (model for end-stage liver disease) scoring system, which also includes serum bilirubin, INR, and serum creatinine levels, has shown to be a more accurate predictor of postoperative survival. In a retrospective study between 1995 and 2009, complications following surgery significantly increased in patients with MELD scores greater than 13 [47]. Postoperative complications including hemorrhage, abdominal fluid collection, wound infection, and pulmonary infection increased from 11.6% in those with a MELD score of <13 to as high as 45.8% in patients with a MELD score higher than 13 [48, 49]. Many of the surgical complications were a result of portal hypertension, which increases the risk for hemorrhage, formation of ascites, and renal failure during and after surgery. Placement of transjugular intrahepatic portosystemic shunt (TIPS) is now routinely used to lower portal circulation pressure in patients with end-stage liver disease with refractory ascites and/or recurrent, or severe varecieal bleed. This procedure has made liver and intra-abdominal surgery possible in patients, in whom such procedures otherwise would have been differed [50–53]. Patients with advanced cirrhosis are still considered high-risk candidates for laparoscopic cholecystectomy, despite best medical optimization efforts. For appropriate patients, liver transplantation is the only feasible approach. As a provisional measure for patients in urgent need for biliary tract decompression, percutaneous drainage via transhepatic route by placement of cholecystostomy tube or immediate gallbladder aspiration may be considered. Numerous studies have examined this technique versus laparoscopic cholecystectomy among high-risk patients such as elderly and those with multiple comorbidities; favorable results accompanied by reduced complication rates make this as a first-line approach for a select group of high-risk individuals. Treatment success rates approach 83–85% with 30-day mortality rates between 12 and 15% among otherwise inoperable patients [54, 55]. Similar studies involving patients with severe cirrhosis have shown similar favorable outcomes [56]. Finally, placement of stents in the cystic duct during ERCP has also been evaluated. A case series involving 13 nonsurgical candidates with advanced cirrhosis and symptomatic gallbladder disease reported successful stent placement from gallbladder into the duodenum with complete resolution of symptoms and absence of major complications with the procedure [57].

Hepatic Abscess

Hepatic abscesses are a rare, albeit a life-threatening complication in patients undergoing allograft transplantation [58]. As with other serious infections, a high index of suspicion, prompt diagnosis, and institution of appropriate therapy are the essential components for better outcome [58]. Risk factors include diabetes mellitus, hepatic artery thrombosis, and strictures involving the bile duct anastomosis site. Most liver abscesses develop within the first 3 months following transplantation surgery; liver ultrasonography remains the quickest and safest diagnostic test [58, 59]. Enteric Gram-negative bacilli are common causative organisms, including enteric organims with hyperproduction of capsular polysaccharide or those exhibiting hypermucoviscosity, such monomicrobial infections can lead to large, multiloculated intrahepatic collections. Polymicrobial infections, mixed aerobic, ananerobic bacteria and less frequently *Candida* spp. infection may occur. Treatment involves surgical or intervention radiology-assisted abscess drainage, and broad-spectrum intravenous antibiotics.

Viral Infections

Cytomegalovirus

Cytomegalovirus (CMV) is a member of the β-herpesvirus group and is endemic around the world with seroprevalence rates ranging from 45 to 100% [60, 61]. In immunocompetent hosts, primary CMV infection most commonly presents without symptoms or as a self-limiting mononucleosis-like

syndrome. Infected individuals harbor the virus for life in a latent phase. However, reaction of the virus in immunocompromised individuals following allograft transplantation is common and associated with significant morbidity and death [62].

Primary CMV infection in the general popultion presents as asymptomatic infection, and in 10% as mild self-limiting illness; whereas, life-threatening viral disease may rarely lead to severe cholestatic hepatitis and fulminant hepatic failure (FHH) [63–67]. CMV may involve any internal organ; in abdominal organ transplant recipients, gastrointestinal viral disease is most frequently encountered. In one report, FHH due to CMV infection was successfully treated with an emergency living-donor liver transplantation and ganciclovir therapy continued during the posttransplant period. Following liver transplantation, CMV is the most common viral pathogen that affects the overall outcome after transplantation. The clinical impact of CMV infection can be categorized as direct or an indirect viral effect. Direct effects of CMV can manifest as either CMV syndrome with fever, viral myelosuppression, or tissue-invasive end-organ viral disease [68]. CMV may involve any organ resulting in hepatitis, esophagitis, gastritis, enteritis, colitis, meningioencephalitis, retinitis, and pneumonitis to name a few. Transplanted liver allografts are more susceptible to tissue-invasive CMV disease compared with the risk of viral disease involviong the native organ. Reactivation of latent CMV infection in CMV seropositive recipient or allograft-transmitted primary CMV infection in CMV naive liver transplant recipient are well-established risk factor for poor allograft function and patient survival [62, 69, 70]. CMV has the ability to upregulate alloantigen presentation thereby promoting the risk of both, acute and chronic allograft rejection; CMV-induced immune dysregulation included stunted hosts' cellular immune response increases the risk for infection due to other opportunistic pathogens; and its adverse impact on accelerated HCV recurrence after liver transplantation are all important issues [71]. CMV infection has been linked to the vanishing bile duct syndrome, chronic rejection noticeable by ductopenia, and extrahepatic bile duct strictures resulting in chronic cholestasis and eventual allograft failure [72–74].

Epstein-Barr Virus Infection

Epstein-Barr virus (EBV), a member of the herpes virus family, is a nearly ubiquitous infection in humans. According to the World Health Organization (WHO), nearly 95% of the world's population by the age of 35–40 years has latent EBV infection [75]. The virus is transmitted via oropharyngeal secretions and consists of a linear DNA genome, nucleocapsid, and viral envelope. Infection is usually transmitted in early adolescence, and most primary infections are asymptomatic with only 30% presenting as acute viral illness [75]. Primary clinical EBV infection, known as infectious mononucleosis, causes a flu-like illness, patients may have fever, pharyngitis, generalized lymphadenopathy, splenomegaly, atypical lymphocytosis, and elevations in transaminase levels. Acute infection is usually a self-limiting illness and managed with supportive care; most infections resolve in 4–6 weeks. Less than 5% of patients present with jaundice [76]. In very rare instances, acute EBV infection leads to fulminant hepatic failure with jaundice, aminotransferase levels elevated to 10,000–20,000 international units; hepatic encephalopathy, coagulopathy, and thrombocytopenia are other common features. In some, an alarming progression of disease may result in nearly 90% mortality [77]. Although fulminant hepatic failure is more common in immunocompromised patients [78], this has been reported in individuals with competent immune function, both adults and children are at risk for this rare complication [79, 80]. Serologic testing confirms acute EBV primary infection; blood EBV quantitative PCR is better to assess severity of infection. Low levels of free EBV DNA are usually present in acute infection, whereas high viral DNA levels are noted in severe life-threatening cases; patients with fatal EBV infection tend to have 100× higher EBV DNA level in blood [81]. Liver transplantation is the only curative treatment once disease has progressed to fulminant hepatic failure. Although there is no expert consensus or ongoing trials to assess pharmacotherapy, high-dose steroids, antiviral agents; plasmapheresis is recommended while awaiting liver transplantation. Finally, there is limited information regarding the risk for EBV recurrence after transplantation in patients with EBV-induced liver failure. A single case report noted prevention of EBV recurrence up to 2 years after hepatic allograft transplantation with a regimen of acyclovir, low-dose antirejection immune suppression, and anti-EBV gamma globulin therapy; however, this has not been replicated in other reports [77]. In the posttransplant period, acute EBV infection can either be the result of a primary infection or more commonly reactivation of remotely acquired latent viral infection. EBV has been implicated in a number of diseases that may occur in this population, such as posttransplant lymphoproliferative disorder, lymphoma, nasopharyngeal carcinoma, Burkett's lymphoma, and Hodgkin's disease and are discussed in detail elsewhere [82–86].

Herpes Simplex

Herpes simplex virus (HSV) is a common, double-stranded DNA virus with two subtypes HSV-1 and HSV-2; in the developed world prevalence of HSV-1 is around 80% and HSV-2 nearly 30% [87, 88]. Primary and recurrent HSV

infection may rarely result in a disseminated infection that may result in fulminant hepatitis. Less than 1% of acute liver failure and 2% of viral-induced acute liver failure are caused by HSV [87, 89]. HSV hepatitis most commonly affects infants who acquire the virus via vertical transmission and adults with impaired cellular immunity due to malignancy, HIV/AIDS, and treatment with immunosuppressive anti-rejection or anti-GVHD drugs [90–92]. Though commonly associated with immune deficiency, 25% of patients with HSV hepatitis are seen in patients with apparently competent immune function [87]. The development of HSV hepatitis can occur as a result of large inoculums at the time of initial infection that overwhelm natural immune defenses or secondary to dissemination from recrudescent herpetic lesion in the absence of an effective hosts' immune response. Virulence through reactivation of latent virus with superimposed infection due to a new viral strain and infection due to hepatotropic viral strain promote risk for HSV hepatitis [92–94].

Patients with HSV hepatitis most commonly present with fever (98%), coagulopathy (84%), encephalopathy (80%), and leukopenia (71%) [87]. A rise in transaminase levels in the absence of jaundice is a characteristic feature of severe HSV hepatitis [90]. The presence of a herpetic rash can be observed in 40–60% of cases [87, 92]. Diagnosis of HSV hepatitis is challenging, as most cases are diagnosed during postmortem examination [87]. Pelvic examination may be helpful as women may less evident vaginal or cervical herpetic lesions while sparing the vulva or perineum [87, 95]. Tzanck smear, or direct fluorescent antibody staining of skin lesions aid in diagnosis [87, 96]. Serologic testing has limited clinical use [87]. Detection of HSV DNA in blood by PCR and/or demonstration/isolation of the virus in liver biopsy samples is needed for establishing diagnosis [87, 97]. Gross pathologic specimens of HSV hepatitis are characterized by a mottled appearance with multiple red-yellow necrotic lesions. Histologic examination often reveals centrilobular hemorrhagic necrosis, scattered acidophilic bodies, and intranuclear ground-glass inclusions with margination of chromatin. The inflammatory response in these tissue specimens is often minimal [90, 98, 99].

Clinical suspicion alone should prompt initiation of high-dose intravenous acyclovir given as 10 mg/kg dose every 8 h adjusted to renal dysfunction, when present [94, 100]. In a review of 134 patients with HSV hepatitis, 49 were treated with acyclovir within 4 days of the symptoms onset; 51% deaths and progression to liver transplant vs. 81% in the untreated group was a significant difference in outcome [87]. Risk factors for death and liver transplantation include age > 40, male gender, coagulopathy, immunosuppression, encephalopathy, ALT >5000, platelets <75,000 U, and the absence of treatment with acyclovir. A delay in institution of antiviral therapy of 4.7 vs. 3.5 days from the onset of symptoms was significantly related with the risk for death or need for urgent liver transplantation. Three of seven patients who underwent orthotopic liver transplantation for HSV acute liver failure survived [87]. Children have a significantly better 5-year survival (74%) compare with long-term survival of 27% seen in adult liver transplant recipients with fulminant HSV hepatitis [92].

Acyclovir prophylaxis is recommended for all patients undergoing liver transplantation for HSV liver failure [98, 100]. However, several recent reports have noted recurrence of infection due to acyclovir-resistant HSV strains following transplantation, close monitoring is recommneded for possible recurrent infection due to a mutant viral strains [97, 98]. Foscarnet therapy followed by liver retransplantation in such cases demonstrated a 43% survival rate, though the degree of immune suppression in patients with severe sepsis-like syndrome should be deemed carefully [101–103].

Fungal Infections

Aspergillosis

Aspergillus is a ubiquitous, saprophytic fungus that is widely distributed in the natural environment and the second most common cause of invasive fungal disease (IFD) in patients undergoing liver transplantation [104, 105]. Nearly one quarter of all IFD is due to *Aspergillus* spp. and account for 1–8% of infections in the post-liver transplant period [106]. Risk factors of invasive aspergillosis include renal insufficiency, retransplantation, CMV infection, thrombocytopenia, leukocytopenia, recurrent bacterial infections, allograft dysfunction, fulminant hepatic failure, high requirement for blood and blood products, and treatment with anti-CD3 monoclonal antibodies [106–113]. Invasive aspergillosis historically manifest within 3 weeks after liver transplantation. However, several recent studies have noted that most cases of invasive aspergillosis are seen 100 days after transplant surgery [108, 114–116]. This late occurrence coincides with CMV infection and prophylaxis with fluconazole, when used does not provide adequate protection against filamentous molds such as *Aspergillus* spp. [106]. Hepatic *Aspergillus* spp. abscesses were described in liver and in renal transplant recipients, especially during treatment with high-dose corticosteroid therapy for acute allograft rejection [117, 118].

Invasive aspergillosis (IA) typically manifest as a sinopulmonary disease in patients undergoing allogeneic hematopoietic stem cell transplantation, and due to neurotropism, fungal brain involvement may also occur, although fungal brain abscesses are not common complications in allograft transplant patients with IA. Given its ability to invade blood vessels, fungus may be disseminated widely and patients may have clinically diverse presentations, including

involvement of the eyes, liver, spleen, heart, kidneys, bone, and brain [119]. In patients with seldom seen aspergillosis of the liver, fungal abscesses and mycotic aneurysms are notible presentations [117, 120–123]. Posttransplant mycotic abscesses carry a significant mortality of nearly 60%; it is important to note that ruptured mycotic aneurysm may be the initial presentation of IA in patients undergoing liver allograft transplants [117, 120–123]. Early diagnosis continues to pose a challenge and thought to contribute toward high mortality seen with these infections [124–126]. All liver abscesses require guided aspiration to establish correct diagnosis and early institution of appropriate therapy [117, 120–122]. Fungal stains and culture of fine-needle aspirates samples from intra- or extrahepatic collections should be performed routinely; however, to establish diagnosis of proven IFD, it is important to demonstrate tissue invasion by molds; and tissue biopsy should be pursued when possible in patients suspected for invasive aspergillosis [117, 120–122]. The role of ancillary fungal antigen assays such as beta D glucan and galactomannan for diagnosis of IA involving hepatic allograft remain uncertain.

Amphotericin was effective in the treatment of hepatic mycotic pseudoaneurysms [127]. Mortality rate associated with aspergillus abscesses in allograft transplant recipients was unacceptably high, despite treatment with amphotericin B [117, 120–122]. The addition of broad-spectrum triazole-based drugs such as voriconazole, posaconazole and the recent addition of isavuconazonium sulfate in the current antifungal armamentarium provided a less toxic and more effective treatment option for these life-threatening opportunistic pathogens. Similarly, echinocandins including caspofungin, micafungin, and anidulafungin also considered safe treatment option and with significantly less potential for drug-drug interaction compared with the triazole drugs. Reduced intragenic, drug-induced immune suppression is important in solid allograft transplant patients with an active invasive fungal disease, an option that is not available for patients with IFD following allogeneic HSCT. Surgical drainage, excision of necrotic tissue, or resection of the infected devitalized organ is considered as important as treatment with effective antifungal drugs [117, 119, 121, 128, 129]. However, due to various reasons, patients with IFD during posttransplant period may not be suitable candidate for surgical resection or debridement.

Candidiasis

Candida is a commensal yeast normally found on skin and mucus membranes of upper respiratory, orointestinal, and genitourinary tracts [119]. Particular disease-causing species of *Candida* may lead to tissue invasive infection with a potential for widespread hematogenous systemic dissemination. Yeast colonization involving multiple body-sites, yeast overgrowth in patients with impaired milieu inflicting alterations in hosts' protective microbiota, presences of indwelling foreign devices such as intravascular catheters, and surgical drains increases the risk for invasive candidiasis in severely immunosuppressed patients undergoing transplantation. Individuals treated with extended and often multiple courses of broad-spectrum antibiotics and prolonged exposure to healthcare that includes doctors office visit, repeat hospitalizations among others, are vulnerable to these complications.

Candida infection plays a particularly prominent role in the development of cholangitis. In a recent retrospective study of 171 patients with PSC that were followed for 20 years, the presence of *Candida* in biliary cultures was associated with a significantly poor transplant-free survival compared to patients with sterile bile cultures [130]. Infection with *Candida* and *Enterococcus* is responsible for sclerosing cholangitis in critically ill patients, this entity represents severe biliary disease, which may rapidly progress to liver cirrhosis; distinguished from PSC by a more rapid clinical course and absence of a prior history of liver disease or injury responsible for bile duct obstruction [131].

Early diagnosis of invasive candidiasis presents a challenge as clinical features are not specific and *Candida* colonization is particularly common in such hospitalized patients; furthermore, lack of sensitivity of routine blood cultures makes diagnosis of fungemia difficult. The fungal antigen assasys like beta-D-glucan assay, which detects fungal cell wall complex sugar in blood and bronchoscopy samples, common to most clinically relevant fungi, are increasingly used to diagnose *Candida* spp. invasive disease. Several studies in renal transplant recipients have noted a diagnostic specificity of 80% and a sensitivity of 50% with this assay [132–134]. Dialysis with cellulose membranes, concomitant use of certain antibiotics, perhaps infection due to *S. pneumoniae*, use of albumin products, coagulation factors, and human plasma-derived albumin and globulin may occasionally result in false-positive detection of beta-D-glucan in sterile body fluid samples [135]. Recently, flow cytometry has been used to identify yeast colonization in patients undergoing living-donor liver transplantation [136].

Empiric antifungal therapy is recommended in organ transplant patients with persistent fever, despite treatement with broad-spectrum antibiotics [119]. Historically, amphotericin B was considered the drug of choice at a dose of 0.5–0.7 mg/kg/day [119]. Echinocandins, such as caspofungin, micafungin, or anidulafungin, have shown high degree of efficacy and excellent safety profile compared with amphotericin B in patients undergoing solid-organ and hematopoietic stem cell transplantation [137–141]. A recent case report by Goicoechea et al. has documented biliary excretion of caspofungin at levels above the MIC_{50} for *C. albicans* [142].

Transient elevation of serum transaminases was observed in patients receiving caspofungin 70 mg daily along with cyclosporine; FDA has cautioned against such combination therapy [143, 144]. Fluconazole remains an alternative agent for *C. albicans* infections, although increasing resistance among the *C. glabrata* clinical isolates warrants fluconazole use as first-line agent, especially in transplant patients with invasive candidiasis, which may include anastomosis site abscesses, fungal cholangitis, with or without evidence of fungemia [145–147].

Protozoal Infections

Cryptosporidium

Cryptosporidium is a genus of protozoan parasites that causes an acute, self-limited diarrheal illness in the normal host, whereas in patients with severe immune suppression, *Cryptosporidium* may be responsible for debilitating chronic diarrheal illness. The most common species affecting humans is *Cryptosporidium parvum*, which is ubiquitous in natural water source around the world; transmission occurs via ingestion of water or food contaminated with mature oocysts. Cryptosporidiosis is an uncommon illness among transplant recipients in the United States and Europe; however, such infections are more visible in the immunosuppressed patients residing or visiting *Cryptospridium* endemic regions in the Middle East, India, South America, or Africa.

Extraintestinal manifestations are rare; biliary tract involvement has been noted in patients with advanced HIV/AIDS, those with congenital immunodeficiencies, and in patients undergoing organ allograft transplantation [148–154]. Biliary manifestations observed in patients with AIDS include acalculous cholecystitis, sclerosing cholangitis, and pancreatitis [148, 149]. Diagnosis of cryptosporidiosis is based on microscopic examination of stool with findings of oocysts similar to size and shape of yeasts [154]. Immunofluorescent assays that employ monoclonal antibodies against *Cryptosporidium* oocysts and antigen-detection assays by ELISA and immunochromatographic formats are also available and have higher sensitivity compared with stool studies using acid-fast staine. Initial management should focus on replacement of fluids and electrolytes. Treatment includes reducing the degree of drug-induced immunosuppression; antiparasitic agents active against *C. parvum* are nitazoxanide, paromomycin, or macrolide antibiotics [154]. To date, only five cases of *C. parvum*-associated sclerosing cholangitis have been reported in the transplant population [150–152]. One case was reported in an adult renal transplant recipient with a reversal of cholangiopathy secondary to *C. parvum* after reduction in immunosuppression [152]. Three other cases were in children in a series of 461 pediatric liver transplant recipients who developed diarrhea with a diffuse cholangitis while on immunosuppression with tacrolimus and prednisone [151]. Bile duct anastomosis was revised in all three children, and one required retransplantation procedure. The fifth case was in an adult liver transplant recipient in whom the diagnosis of *C. parvum*-associated sclerosing cholangitis was made after percutaneous core biopsy of the liver showed *C. parvum* lining the bile duct epithelium [150]. In this patient, diarrhea and liver abnormalities resolved after treatment with azithromycin plus paromomycin, and follow-up liver biopsy was negative for the parasite.

Entamoeba Histolytica

Entamoeba histolytica is transmitted via oral-fecal contamination; such infections are common in the developing countries and areas of poor water sanitation. Disease initially involves the intestinal mucosa, the amoeba subsequently penetrates hepatic tissue forming multiple cysts or liver abscesses throughout the organ, although most patients present with a single prominent liver lesion and other smaller cysts scattered throughtout the organ. Patients present with vague abdominal discomfort or pain and a history of prolonged diarrheal illness. Laboratory evaluation may reveal leukocytosis, but liver tests are usually unremarkable. Diagnosis includes a high index of suspicion along with fecal antigen and/or serum antigen tests. Radiographic imaging show multiple cysts in the liver. Paromomycin is recommended for treatment due to limited cyst penetration by metronidazole. Surgical drainage is generally not required.

There is no clear consensus as to increased risk for amebic liver disease in patients with hepatic cirrhosis. A report in the 1980s suggested a reduced prevalence of hepatic amebiasis in patients with cirrhosis; which was hypothesized to reflect reduced number of viable hepatocytes susceptible to amoebic invasion and severely altered hepatic architecture [155]. More recent reports, however, suggest contrary to be the case. A decade-long review of liver abscesses among cirrhotic patients in a high-incidence region of Thailand reported that 36% were due to amoebiasis [156].

Treatment is usually effective against protozoal infections; however, in nearly 7% of successfully treated individuals, residual hepatic lesions may persist on ultrasound; these are vestiges of previously treated infection and do not require further antiparasitic therapy [157]. For unclear reasons, the residual lesions can persist for years at the site of prior infection, and as long as patients are not symptomatic, this does not warrant further therapy. This holds true for individuals being considered for organ transplantation. A recent report described a patient who had residual abscess cavity after receiving treatment for amoebic liver disease; patient

underwent successful renal transplantation without infection recurrence during posttransplant follow up [158].

Mycobacterial Infection

Tuberculosis is the most common mycobacterial infection worldwide. In the developed world, incidence of active tuberculosis infection after allograft transplantation is less than 1%. Whereas, in the developing world, active tuberculosis may be encountered in as high as 15% of transplant recipients [159, 160]. Predisposing factors for acute tuberculosis include coinfection with HCV and/or HIV and severe drug-induced cellular immune suppression [161–163]. Most cases are reactivation of latent tuberculosis rather than newly acquired, primary infection. In 63%, infection is confined to the lungs. Extrapulmonary foci of infection may be seen in 12% of the cases with active tuberculosis infection. Disseminated tuberculosis may occur in upto 25% of transplant patients and involves various extrapulmonary sites. Gastrointestinal tract is the most common non-pulmonary infection site; nearly half of such patients (48%) will demonstrate tuberculous hepatitis.

Following transplantation, diagnosis of tuberculous hepatitis may be challenging as common presenting symptoms are non-specific, which may include recurring fever, along with other constitutional symptoms, and a vague right upper quadrant discomfort. Most patients with active tuberculosis will present within first year after transplantation [160, 164]. Common laboratory findings are elevated liver enzymes, including high alkaline phosphatase levels and coagulation abnormalities. Elevated alkaline phosphatase is the most common finding seen in 75–87% of patients, whereas elevated serum transaminase levels are noted in 35–75% of patients [165, 166]. Isolated cases of tuberculous hepatitis may occur, although it is rare to see tuberculosis confined to the liver as most patients will have concurrent pulmonary disease [166, 167].

Demonstration of acid-fast bacilli and/or a positive *M. tuberculosis* cultures in liver biopsy samples confirms the diagnosis of active tuberculosis infection. In contrast to the general population, presence of granuloma in the hepatic parenchyma in itself is not diagnostic for active tuberculosis infection, especially in allograft transplant recipients as granulomas may occur with other conditions such as acute cellular allograft rejection, recurrence of PBC, infections due to nontuberculous mycobacteria; hepatosplenic candidiasis, nocardiosis, and endemic mycoses among others. In a retrospective analysis, in patients after liver transplantation, less than 3% of granulomas were attributed to active *M. tuberculous* infection [168].

The common nontuberculous mycobacterial infections in patients undergoing allogeneic HSCT or SOT, are as follows: *Mycobacterium avium complex*, *Mycobacterium haemophilum*, *Mycobacterium kansasii*, *Mycobacterium abscessus*, and *Mycobacterium chelonae*. These insidious infections may present months to years after transplantation; a variety of organ systems may be involved [169]. It is not uncommon for hepatic *M. kansasii* infection to present with a protracted febrile illness accompanied by abdominal pain; multiple liver abscesses may be seen on imaging [170]. Granulomatous liver disease due to MAC may present as portal hypertension and ascites [171]. Elevated alkaline phosphatase serum levels may be the only finding, transaminase and bilirubin levels are often within the normal range. Treatment of mycobacterial infection is presented in Chapter 56.

Schistosomiasis

Schistosoma is an infection of trematode fluke that affect nearly 200 million people in the endemic regions worldwide [172]. Transmission occurs through infectious cercariae that emerge and released from freshwater snails into the local water reservoirs such as lakes, ponds, and rivers. The cercariae penetrate human skin and transform into immature worms [173]. Worms mature over 6 weeks and hone to target vessels in the mesentery and bladder, producing eggs that erode into the walls of the intestine and urinary bladder [173]. Three major *Schistosoma* species are known to cause disease. *Schistosoma mansoni* is prominent in Africa and South America, whereas *Schistosoma japonicum* intestinal and hepatic schistosomiasis is prevalent in Asia. Hepatic schistosomiasis results from entrapment of eggs lodged in the portal venules, initiating an inflammatory cascade that ultimately leads to portal fibrosis and venous congestion [173]. *Schistosoma haematobium* is associated with urinary bladder infestation; post-obstructive nephropathy is the consequence of chronic bladder and ureteral inflammation among patients in Africa and the Middle East [174, 175].

Acute schistosomiasis infection is asymptomatic although patients may experience fever, headache, myalgia, abdominal pain, or a systemic serum sickness-like reaction known as Katayama fever, which results from immune responses to parasitic invasion and migration [173]. Liver abscesses may occur in persons with early schistosome infections due to the sequestration of encapsulated bacteria in the integument of the adult worms [176]. Chronic schistosomiasis may occur in 60% of infected individuals, leading to extensive liver disease in 4–8% of cases [172, 177]. Patients with hepatic schistosomiasis may present with variceal bleeding and splenomegaly due to portal congestion; synthetic liver function indices are often normal, and histologically, tissue infiltration with inflammatory cells is routinely noted. Advanced fibrosis in patients with long-standing schistosomal infection

Table 17.1 A summary of hepatobiliary tract infections in patients undergoing liver trnasplantation, along with clinical features, diagnosis and treatment

Infection	Pathogens	Clinical features	Diagnosis	Treatment
Cholangitis	*E.coli*, *Klebsiella*, *Enterobacter*, *Enterococcus* (plus fungal following transplantation)	Jaundice, fever, RUQ pain	Ultrasound, CT, MRCP (avoid ERCP in cirrhotics)	7–10 days antimicrobials, emergent drainage if no response within 24 h
Cholecystitis	*E.coli*, *Klebsiella*, *Enterobacter*, *Bacteroides*	RUQ pain	Ultrasound	Cholecystectomy, percutaneous drainage with abx if surgery contraindicated
Viral	CMV	Hepatitis, biliary stasis	Serum PCR, viral ctx, liver biopsy	Ganciclovir, transplant for FHH
	EBV	Jaundice, FHH	Serum PCR	Transplant for FHH (bridge w/ steroids, antivirals, plasmapheresis)
	HSV	Fever, coagulopathy, encephalopathy, leukopenia	Serum PCR, liver biopsy	IV acyclovir
Fungal	*Aspergillus*	Variable, usually always pulmonary involvement	Abscess drainage with culture	Itraconazole, voriconazole, or caspofungin, consider surgical drainage
	Candida	Primarily involves biliary tract (cholangitis), usually within 1st 30d of transplant	Difficult dx; can try beta-D-glucan or flow cytometry if suspicious	Amphotericin B
Protozoal	*Cryptococcus*	Diarrhea with cholangitis and/or cholecystitis	Stool oocysts or antibody oocyst testing	Nitazoxanide, paromomycin, or macrolides
	E. histolytica	Vague abdominal pain with diarrhea	Fecal or serum antigen, radiographic cysts	Paromomycin
Mycobacterial	*M. tuberculosis*	Sweats, weight loss, almost always pulmonary involvement	Biopsy with AFB stain or positive culture	Extrapulmonary TB regimen with close LFT monitoring
Trematode	*Schistosome*	Fever, myalgia, abdominal pain (Katayama fever – serum sickness)	Eggs in stool or on mucosal biopsy	Praziquantel (oxamniquine if *S. mansoni*)

resembles clay pipestems histologically and known as Symmers pipestem fibrosis [178].

Diagnosis is established by demonstrating schistosome eggs in the stool sample. The extent of fecal egg output correlates with the burden of mature worms and the extent of disease in infections due to *S. mansoni* and *S. japonicum* [173]. ELISA assays are useful for population screening, however, a + ELISA test result does not predict the activity of parasite in an individual [173]. Identification of *Schistosoma* eggs on mucosal biopsy remains the most sensitive method of diagnosis, although there are no widely accepted screening guidelines for patients undergoing allograft transplantation. It has been suggested that individuals from endemic areas, particularly the Middle East, Africa, South America, and Asia, should undergo serological and stool screening for ova and parasites during the pretransplant assessment [173, 179–181].

Effective treatment of schistosomiasis is achieved with three doses of 20 mg/kg praziquantel or oxamniquine given every 8 h for *S. mansoni* infection. Early treatment can result in total resolution of fibrosis, particularly in patients with early and mild disease [182]. Response to treatment may be followed by serial stool analysis. Epidemiological studies have demonstrated that high levels of IgE correlate with long-term resistance to schistosomal reinfection in individuals residing in the endemic regions [183].

Schistosoma-HCV coinfection is a leading indication for transplantation in Egypt and Saudi Arabia [184–186]. Mass treatment programs for schistosomiasis prior to 1980 utilized non-disposable syringes and needles, which significantly worsened the spread of HCV and regarded as largely responsible for the high HCV prevalence and transmission rates in the North African countries [187]. Clinical studies have demonstrated that *Schistosoma*-HCV coinfection accelerates liver injury compared with HCV-positive patients without schistosomiasis; co-infection has as been known to increases the risk for hepatocellular carcinoma [184, 187–189]. It has been suggested that TH1 response, critical for containment and resolution of acute HCV infection, is downregulated by a prominent TH2 cellular immune response garnered to tackle the invading parasites [190–192].

Recent evidence has demonstrated that patients with schistosomiasis in the absence of detectable organ damage may be viable liver and kidney donors. A study compared schistosoma-positive 20 living kidney donors with 20 uninfected donors; the investigators found no significant difference in graft survival over an average of 3.5-year follow-up [193]. Several case reports have demonstrated similar findings in recipients of liver allograft from schistosoma-seropositive donors [194–196]. Moreover, a large trial by Mahmoud et al. demonstrated no significant difference in

renal allograft function; incidence and frequency of acute vs. chronic graft rejection between patients with schistosoma infection vs. no evidence of schistosoma infection [197]. In this trial, however, immunosuppression in schistosoma-positive patients was challenging due to higher doses of cyclosporine needed to achieve target blood level, which probably reflected poor intestinal drug absorption in the presence of parasitic infestation [198].

Recurrence of schistosomiasis after liver transplant is rare, with only few case reports described in the literature, and all of such cases were successfully treated with praziquantel [179, 186]. Transplant recipients are at increased risk for reinfection particularly in endemic areas where re-exposure to parasite remains high. A study in Egypt by Sobh et al. demonstrated that 23% of allograft recipients were diagnosed with reinfection during posttransplant follow-up [199]. End-stage kidney or end-stage liver disease may be present for many decades after the initial exposure to the parasites, and it is recommended that previously infected patients be treated prophylactically before undergoing allogeneic transplantation, as adult worms can survive for several years after the initial exposure [179, 194]. Table 17.1 provides a summary of hepatobiliary tract infections in patients undergoing liver transplantation.

Introduction

Transplant patients may develop infections in any part of the eye and ocular adnexa. The most common site of ocular infection is in the posterior segment of the eye, which includes the vitreous, retina, choroid, and optic nerve. Posterior segment infections occur most often from either hematogenous spread of systemic infection like endophthalmitis or reactivation of latent infections such as viral retinitis, and ocular toxoplasmosis. The anterior segment of the eye includes the conjunctiva, sclera, cornea, aqueous, iris, and ciliary body. These structures can be infected either through direct inoculation in cases of keratitis or corneal infection or via hematogenous spread resulting in endophthalmitis. Various terms are used to define the location and structures of the eye involved in infectious and inflammatory processes. Endophthalmitis refers to a bacterial or fungal infection involving the vitreous and/or aqueous humors. Uveitis refers to an inflammatory or infectious process involving the uvea, which is comprised of the iris, ciliary body, and choroid. The uvea is highly vascular, so the choroid may be the first structure involved if a bacteremia or fungemia seeds the eye. Retinitis is considered a type of uveitis, even though the retina is not part of the uvea. In many cases of infection involving the retina, there is also underlying choroidal involvement, hence the term chorioretinitis. In treating intraocular infections, the blood-eye barrier must be considered. This is similar to the blood-brain barrier and prevents some antibiotics from achieving therapeutic intraocular levels.

Ocular Complications in Transplant Patients

The most common ocular complications in transplant patients are noninfectious. Cataract is the most common complication in several studies and usually occurs as a complication of corticosteroid therapy or, in allogeneic

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_18

hematopoietic stem cell transplant (HSCT) recipients, total body irradiation. In a study of 71 pediatric renal transplant recipients with a mean follow-up of 5.6 years, cataract was the most common ocular complication and occurred in 8% [1]. Similarly, in a study of 46 lung transplant recipients who underwent eye examination, cataract was the most common finding, occurring in 28% of patients [2]. In a prospective study of 115 heart, lung, or heart-lung transplant recipients, cataracts were again the most common finding, occurring in 17%, followed by hypertensive changes (8%), chorioretinal scarring (5%), and diabetic retinopathy (3%) [3]. In bone marrow transplant recipients, a major ocular complication is dry eyes related to chronic graft versus host disease (GVHD). In a prospective study of 101 consecutive patients who received allogenic stem cell transplants between 2004 and 2007, ocular GVHD developed in 54% and consisted mainly of dry eyes and conjunctivitis [4].

The incidence of ocular infections after solid organ or HSCT is low, with studies from around the world reporting an incidence of approximately 2%. In a study of 1198 solid organ or bone marrow transplant recipients examined at an eye clinic in Korea between 1995 and 2005, 33 had retinal complications, including 21 (1.8%) with infectious etiologies (15 viral, 5 fungal, 1 *Toxoplasma*) [5]. Over 80% of these eye infections occurred within the first year posttransplant. Of the viral infections, cytomegalovirus (CMV) retinitis was the most common (11 cases), while acute retinal necrosis (ARN) occurred in 3 and progressive outer retinal necrosis (PORN) in 1. A review of 860 patients who had received heart, lung, or liver transplants in Sydney, Australia, between 1984 and 1997 identified 19 (2%) who had non-cataract ocular complications [6]. Of these, ocular infections occurred in 14 patients (1.6%), with viral infections in 11 (5 ARN, 3 CMV retinitis, 2 herpes simplex virus keratitis, 1 herpes zoster ophthalmicus), fungal chorioretinitis in 2, and bacterial dacryocystitis in 1. These infections occurred from 5 months to 4 years posttransplantation. A study of heart, lung, and heart-lung recipients in London found only 1 of 115 (0.8%) developed an ocular infection (*Aspergillus* endophthalmitis) [3]. A study of 620 patients who underwent allogeneic stem cell transplant from 1997 to 2007 in Riyadh, Saudi Arabia, found ocular infections in 16 (2.6%), with keratitis in 11 patients (bacterial 10, viral 1), CMV retinitis in 4 patients, and mold endophthalmitis in 1 patient [7]. A study of 313 patients who received heart transplants at the Mayo Clinic in Rochester, Minnesota, between 1988 and 2006 found 6 patients (1.9%) with potentially serious eye infections (1 CMV retinitis, 1 *Aspergillus* endophthalmitis, 3 herpes zoster ophthalmicus, 1 preseptal cellulitis), while 2 others had minor infections (conjunctivitis, blepharitis) [8].

Common Eye Infections in Transplant Patients

Viral Retinitis

Acute Retinal Necrosis

The acute retinal necrosis syndrome (ARN) is a rapidly progressive viral retinitis that was first described in 1971 [9]. Although ARN is mainly reported in immunocompetent patients, it is still one of the most common infections seen in transplant patients. The onset of ARN occurred 7 months to 7 years posttransplant in several studies, with the average onset greater than 1 year posttransplant [5, 6, 10]. Most cases have been described in solid organ transplant patients rather than HSCT recipients. ARN is caused by varicella zoster virus (VZV), herpes simplex virus (HSV) types 1 and 2, and less commonly CMV. In non-transplant patients, VZV is the most common etiology, causing 60% of cases, while HSV causes 30–40% and CMV less than 10% of cases [11, 12]. The relative frequency of these etiologies in transplant patients has not been described. In transplant patients, the herpes viruses may be more likely than other infections to present solely in the eye without concomitant extraocular infection or graft rejection [5]. In immunocompetent patients, there is an age distribution for the different viral etiologies with VZV more likely to be the cause of ARN in older patients and HSV type 2 more likely in younger patients [13]. It is unclear whether this distribution also exists in transplant patients.

ARN usually presents with unilateral eye pain, photophobia, and decreased vision. The eye pain may be mild or absent. In up to 30% of cases, ARN occurs in both eyes, although usually one eye is affected before the onset of symptoms in the other. The American Uveitis Society has established the following clinical criteria for diagnosis of ARN: (1) focal well-demarcated areas of retinal necrosis located in the retinal periphery, (2) rapid circumferential progression of necrosis, (3) occlusive vasculopathy, and (4) prominent inflammation (white blood cells) in the vitreous and aqueous [14]. Clinical exam is significant for a panuveitis (which produces symptoms of pain and blurred vision) and peripheral retinal whitening/retinitis (Fig. 18.1a, b).

The differential diagnosis of ARN includes CMV retinitis, *Toxoplasma* chorioretinitis, ocular syphilis, and infectious endophthalmitis. The ocular findings in CMV retinitis differ from CMV-ARN and are discussed below; one major difference is that CMV-ARN has marked intraocular inflammation, while this is not a feature of CMV retinitis. Nearly all patients develop ARN as reactivation of latent infection due to VZV, HSV, or CMV, although rare cases have been described after recent acquisition of virus. Although ARN is primarily a clinical diagnosis, other diag-

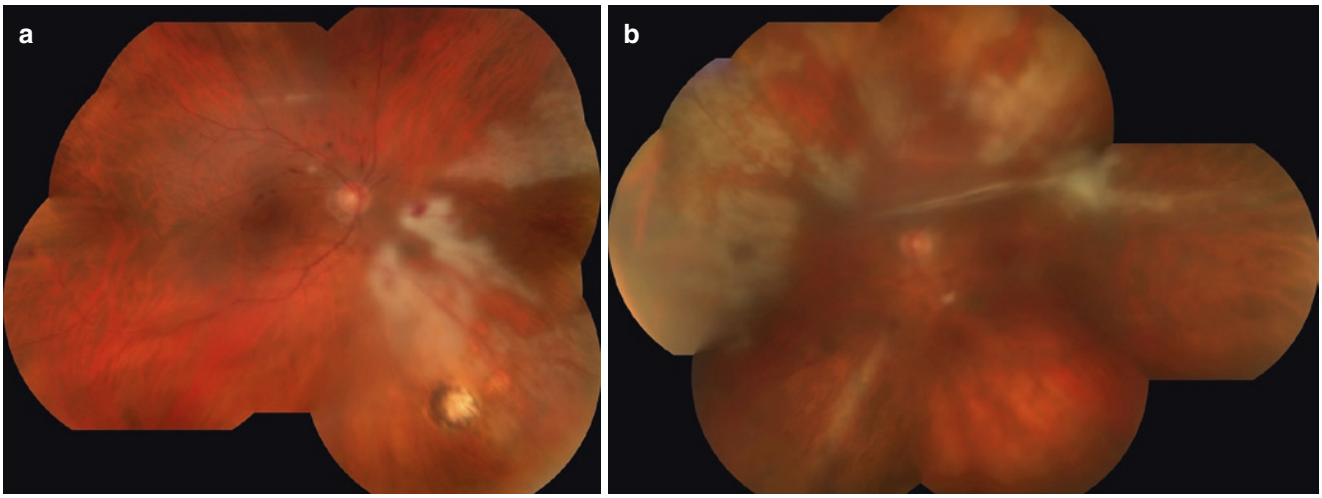

Fig. 18.1 (**a**, **b**) Acute retinal necrosis (ARN): fundus photographs of each eye demonstrating peripheral retinal whitening with hemorrhages and vitritis. Vitreous PCR was positive for CMV. The patient had been CMV seronegative when he received a kidney 14 months earlier from a CMV-seropositive donor. He developed bilateral ARN 2 months after completing a year of valganciclovir prophylaxis

nostic tests may be helpful in distinguishing specific viral etiology and in tailoring treatment. Serum antibody titers are generally not helpful in diagnosis, given the high baseline level of seropositivity in the general population. However, negative serology (IgM and IgG) for a particular virus (e.g., HSV or CMV) usually excludes that pathogen as an etiology of ARN. Molecular diagnostic testing with polymerase chain reaction (PCR) from ocular fluid samples provides a more specific test for identifying viral pathogens in ARN [13]. Aqueous fluid sampling is a relatively safe office procedure and can be used even in cases of primarily posterior segment disease including necrotizing retinitis even though the quantitative yield can be low [15, 16]. A vitreous aspirate has a higher yield and can also be obtained in the office but has more potential for complications, including infection and retinal detachment. A diagnostic vitrectomy can be performed in the operating room to obtain a larger sample of fluid for testing, especially in cases of minimal anterior segment inflammation. Clinicians should have a low threshold for performing molecular diagnostic testing in transplant patients with ARN in whom the viral etiology is unclear. Aqueous and/or vitreous sampling for viral PCR is especially important if initial empiric antiviral therapy does not halt progression of retinitis by funduscopic examination. Quantitative PCR can also be used to monitor response to therapy; if there is no significant decline in viral load from vitreous aspirate signifying potential antiviral resistance, a change in antiviral therapy can be implemented [17, 18]. However, the results of such quantitative PCR testing may not be available in a timely fashion, and decisions must be made day by day based on the ophthalmologist's examination of the eye. Progression of ARN in one eye or new involvement of the other eye while on intravenous antiviral therapy should prompt immediate change in therapy in order to save vision in this potentially blinding infection.

Treatment of ARN in transplant patients always includes intravenous antiviral therapy initially and may also include intravitreal injections of antiviral agents. Intravenous acyclovir is the standard initial therapy for ARN in immunocompetent patients, in whom CMV-ARN is very uncommon [19]. Intravenous acyclovir has also been used successfully in treating transplant patients with VZV and HSV ARN [10]. Valacyclovir has been used in treatment of early ARN in immunocompetent patients, but we do not recommend this, especially in immunosuppressed patients as retinitis may progress rapidly. One question in treating ARN is whether intravenous ganciclovir, rather than intravenous acyclovir, should be used initially in transplant patients and other severely immunosuppressed patients, given the increased likelihood of CMV-ARN in immunosuppressed patients. This question has not been answered. Successful treatment of ARN requires daily communication between the infectious disease specialist and the retina specialist, with the goal of halting retinitis progression as quickly as possible. Failure of intravenous acyclovir to halt progression of retinitis may signify either CMV-ARN or acyclovir-resistant HSV or VZV (e.g., due to thymidine kinase mutation). CMV-ARN requires intravenous ganciclovir (acyclovir is ineffective), but progression despite ganciclovir may occur and may signify ganciclovir-resistant CMV. Such patients would be given intravenous foscarnet or, failing that, intravenous cidofovir, plus intravitreal foscarnet injections. Transplant patients on chronic acyclovir prophylaxis are at increased risk for acyclovir-resistant HSV and VZV, and gan-

ciclovir will not be effective for such patients: intravenous foscarnet should be given. Cidofovir may be necessary in cases that continue to progress despite foscarnet. Intravitreal injections of foscarnet may be used to supplement systemic therapy. Intravitreal injection of ganciclovir (for acyclovir-sensitive HSV or VZV and ganciclovir-sensitive CMV) or foscarnet within 48 h of initiation of systemic therapy may prevent rapid progression of retinitis and improve visual prognosis [11]. Multiple intravitreal antiviral injections may be given to halt the progression of retinal necrosis.

Systemic intravenous antiviral therapy should be given for a minimum of 1–2 weeks and can then be transitioned to an oral antiviral (valacyclovir or valganciclovir, if patients responded to intravenous acyclovir or ganciclovir, respectively). Valacyclovir or valganciclovir is usually given for several months in immunocompetent patients, although the optimal duration of this therapy is unknown. Dosing may then be reduced to provide long-term prophylaxis, which may be necessary indefinitely in the transplant patient. In patients who require intravenous foscarnet for acyclovir-resistant HSV or VZV or for ganciclovir-resistant CMV, an oral equivalent is not currently available, so long-term prophylactic therapy becomes more difficult.

A late complication of ARN is retinal detachment, which occurs 4 weeks to 6 months after the acute infection [20]. Barrier retinal laser photocoagulation can be performed at the edges of retinal necrosis early in the course in an attempt to prevent subsequent retinal detachment, but many patients with extensive necrosis may still develop retinal detachment [21, 22]. The severity of vitreous inflammation in the acute phase of infection may prevent adequate visualization of the retina for laser therapy. Vitrectomy with or without silicone oil tamponade can be performed to repair retinal detachments associated with ARN.

Visual prognosis in ARN is guarded, and more than 50% of patients develop retinal detachment [21]. One retrospective study of 58 patients with unilateral ARN diagnosed between 1981 and 2008 and who had at least 6 months of follow-up reported that significant vision loss (≤20/200) in the affected eye occurred in 50% of patients by 3 months and 75% by 5 years [20]. Patients with worse initial visual acuity or who developed a retinal detachment had worse outcomes in this study. This study found that 19% of ARN patients were immunocompromised, but did not note whether any were transplant recipients. The rate of significant visual loss from ARN is unknown in the transplant population. One study that included three patients treated with intravenous acyclovir found that all three had excellent outcomes [6], while another study of four patients (five eyes infected) found that final visual acuity was <20/200 in 40% [5]. Viral etiology also affects prognosis, and VZV has been associated with worse visual prognosis and more rapid necrosis compared to HSV [11].

Progressive Outer Retinal Necrosis

Progressive outer retinal necrosis (PORN) is a variant of a herpetic necrotizing retinitis that primarily involves the "outer" (deeper) layers of the retina. This rapidly progressive infection is characterized by lack of inflammation and retinal vasculitis. PORN initially was described only in severely immunosuppressed AIDS patients [23, 24]. This syndrome has also been noted in several cases of hematopoietic stem cell transplant (HSCT) and kidney transplant patients [5, 25, 26]. VZV is the most common etiology for PORN, and the majority of transplant patients have an antecedent history of disseminated or localized herpes zoster infection prior to the development of necrotizing outer retinal necrosis. Several reported cases of PORN in HSCT patients occurred in the setting of significant immunosuppression for graft versus host disease [26, 27].

Rather than a blurred vision, patients often present with complaints of painless dimming of vision or constriction of their visual field. Visual complaints may be out of proportion to what is seen on clinical examination in early stages of disease. Clinical exam reveals multifocal circumscribed creamy deep retinal lesions in the periphery of the retina although the central macula can also be involved. These lesions rapidly progress to become confluent areas of retinal whitening with perivascular sparing (Fig. 18.2). Progression to near total vision loss is often very rapid in PORN, and timely and aggressive antiviral therapy is essential. Unlike cases of ARN, there is no inflammation in the anterior chamber or vitreous and no occlusive vasculitis in PORN. The optic nerve can be involved with profound visual loss. Many

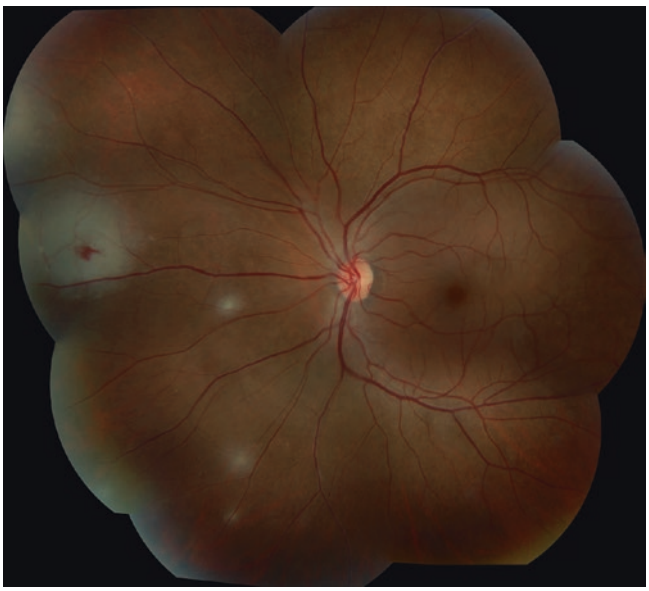

Fig. 18.2 Progressive outer retinal necrosis (PORN): fundus photograph demonstrating areas of retinal whitening and minimal vitritis. The risk factor in this patient was AIDS

patients present with retinal detachments which often occur early in the course of the disease [28].

The differential diagnosis for PORN includes ARN, atypical toxoplasmosis, CMV retinitis, and ocular syphilis. Diagnosis is primarily clinical, but in cases of uncertainty, ocular fluid sampling for PCR can be performed. There have been rare cases of PCR positive for CMV and HSV from vitreous samples of patients with PORN [29].

Treatment for PORN also differs from ARN in that intravenous acyclovir has been found to be ineffective in many cases of PORN. Because many immunosuppressed patients have already been treated with prophylactic acyclovir or valacyclovir, there is concern that acyclovir resistance may be highly prevalent in patients who subsequently develop PORN [24]. Intravenous ganciclovir and foscarnet are the systemic therapies of choice due to the aggressive and rapid course of this disease. Induction doses of ganciclovir can be given for 3 weeks and foscarnet for 2 weeks followed by maintenance therapy until the retinitis has completely regressed [28]. Early treatment with intravitreal antiviral therapy, either foscarnet or ganciclovir, is also recommended; intravitreal therapy can be given as frequently as three injections per week at the outset of disease followed by weekly injections until the retinitis has stabilized. Barrier laser photocoagulation can be performed at the borders of areas of retinal necrosis, although even when performed, many patients still may develop retinal detachments. The absence of vitreous inflammation makes laser treatment more feasible in PORN compared with many cases of ARN.

PORN has the worst visual prognosis of all types of viral retinitis, with reports of greater than 60% of patients losing vision to the level of no light perception [23]. Macula and optic nerve involvement can cause profound vision loss, and 70% of patients develop retinal detachments [28]. The aggressive use of intravenous and intravitreal antiviral therapies has improved visual outcomes, but early diagnosis and treatment are paramount. Transplant patients with history of herpes zoster should be referred immediately for evaluation if they develop any new visual complaints.

CMV Retinitis

CMV retinitis (CMVR) is an opportunistic infection most commonly seen in AIDS patients prior to the era of highly active antiretroviral therapy (HAART). While the overall incidence of CMVR has declined in AIDS patients in association with HAART therapy, this disease process has been reported in both the solid organ transplant and hematopoietic stem cell transplant (HSCT) populations. The incidence of CMVR after solid organ transplantation is reportedly between 2% and 15% compared to 0.19–2.2% for HSCT populations [6, 29–31], but there is some variation by study. A review of 101 studies from 1987 to 2007 involving 12,653 liver transplant patients found CMV retinitis in only 0.1% [32]. The incidence of CMVR may be increasing due to the earlier recognition and treatment of CMV reactivation and decreased likelihood of lethal systemic CMV disease early in the posttransplant course [33]. The source of CMV infection can either be a CMV-antibody-positive donor, reactivation of latent CMV, or primary infection with CMV in the setting of transfusion or immunosuppression [5]. Characteristics associated with the development of CMVR in transplant patients include severe immunosuppression and/or lymphopenia, graft versus host disease, and other systemic infections [5, 33]. Viral retinitis has been reported more commonly in heart transplant patients likely due to the high level of immunosuppression required [5, 6]. In HSCT, risk factors for CMVR include unrelated donors, delayed lymphocyte engraftment, and increased CMV reactivation in the CMV-seropositive graft recipients [31].

Clinical Presentation

Patients often present with complaints of floaters and blurred vision, but many patients may be asymptomatic if lesions are in the peripheral retina. Bilateral involvement is common, occurring in 40% of HSCT patients in one study [29] and 60% of solid organ transplant patients in another [34]. There are two characteristic fundus lesions seen on clinical examination: (1) a wedge-shaped area of hypopigmented retinal infiltrate along a vascular arcade often with associated intraretinal hemorrhages and (2) a peripheral yellow granular retinal lesion with a scarred center and an active border that slowly expands. Other associated clinical signs include satellite lesions adjacent to the main lesion, retinal vascular sheathing, and rarely extensive exudation along retinal blood vessels referred to as "frosted branch angiitis." In contrast to other ocular infections, such as ARN and toxoplasmosis, CMVR has minimal anterior segment and vitreous inflammation.

The differential diagnosis for CMVR includes HSV or VZV retinitis, atypical ocular toxoplasmosis, fungal or bacterial endophthalmitis, and ocular syphilis. CMVR can generally be diagnosed based on clinical examination. In atypical cases, molecular diagnostic tests such as PCR can be performed from aqueous or vitreous fluid samples. In most cases of CMVR, transplant patients may already have known systemic CMV disease and positive CMV antigenemia.

The immune reconstitution syndrome (IRS) (also called immune recovery uveitis) has also been reported in transplant patients who have been treated for CMVR. IRS is thought to be an immune reaction to CMV antigens in patients with active or inactive disease but is more common with larger-sized lesions [35]. This syndrome presents in the eye with vitritis, optic nerve edema, macular edema, and epiretinal membrane formation which can decrease visual acuity.

Treatment

The treatment of CMVR involves systemic induction therapy as well as local intravitreal therapy with ganciclovir or foscarnet. Intravitreal therapy serves as an important adjunct therapy for CMVR, especially in patients who cannot tolerate high-dose systemic therapy due to neutropenia [33]. In severe cases with rapid progression of retinitis, a ganciclovir sustained release implant can be inserted [36]. There have been cases of transplant patients who develop CMVR in spite of CMV prophylaxis with valganciclovir or ganciclovir, with one series reporting that 7 of 11 transplant patients were on ganciclovir for CMV antigenemia prior to the development of CMVR [5]. In patients where retinitis continues to progress despite standard therapy with ganciclovir or valganciclovir, ganciclovir resistance should be suspected, and alternative therapy with foscarnet (intravenous and/or intravitreal) or cidofovir is imperative [32]. Such patients should have samples of plasma tested for ganciclovir resistance (e.g., UL97 and UL54 gene sequencing). Duration of maintenance therapy varies for CMVR in transplant patients and depends on the level of cumulative immune suppression, systemic disease and adverse effects. Treatment of ocular IRS usually includes systemic or periocular corticosteroids in addition to ongoing antiviral therapy.

Prognosis

Visual prognosis for transplant patients with CMVR is guarded. In one large series of CMVR in patients without HIV, the majority of patients had decreased visual acuity within 1 year following diagnosis [35]. Causes of ocular morbidity and limited visual prognosis include retinal scarring and retinal detachment. Retinal necrosis leads to the development of retinal tears and subsequent detachment. Transplant patients with CMVR have a lower likelihood of developing retinal detachment compared to AIDS patients regardless of HAART therapy [35].

Endophthalmitis

Endophthalmitis means bacterial or fungal infection involving the vitreous and/or aqueous. Endophthalmitis may be either exogenous, introduced from outside in, such as after eye surgery or eye trauma, or endogenous, due to hematogenous seeding of bacteria or fungi. The most common type of endophthalmitis in the general population is exogenous and bacterial, while the most common type in the transplant population is endogenous and fungal.

Cataract surgery is the most common type of ocular surgery, with over two million surgeries performed annually in the United States alone. Endophthalmitis develops postoperatively in approximately 0.1% of cases, and 75% of patients develop symptoms (decreased vision, eye discomfort, redness) within the first week after eye surgery. Bacteria cause nearly all cases in western countries, with coagulase-negative staphylococci accounting for 70% of cases. Cataracts (opacities of the lens) are common in the transplant population, occurring in at least 15% of patients as noted above. Both corticosteroid therapy and total body irradiation are risk factors in the transplant population. Many of these patients will eventually require cataract surgery, so post-cataract endophthalmitis is a risk in this population. However, this infection has not been specifically mentioned in reviews of ocular infections in transplant patients, so the incidence may be the same as in the general population.

Endogenous fungal endophthalmitis is the most common type of endophthalmitis in transplant patients and is often associated with disseminated fungal infection or fungal infection at another site. Blood cultures may be negative, however, as fungemia may be transient. It is worth noting a nomenclature issue: in the literature, fungal chorioretinitis (i.e., without significant vitritis) is sometimes distinguished from fungal "endophthalmitis," a term that implies significant vitritis. However, most of the transplant literature does not make this distinction, and we will only note the degree of vitritis here, when relevant.

Fungal endophthalmitis accounts for 20–25% of posterior segment infections in transplant patients, second only to viral retinitis [5–7]. Overall, 0.1–0.4% of transplant patients develop fungal endophthalmitis [5–7]. The onset is within 1 year of transplant in nearly all cases. Because infections are endogenous, the "back" of the eye is usually seeded first – often the highly vascular choroid. This infection may be clinically silent at first, but then the patient develops decrease in vision with or without eye pain. On examination, fluffy white lesions may be seen in the posterior pole with minimal vitritis – this is termed chorioretinitis and is typical of early endogenous *Candida* infections. Patients with more severe eye infection usually have significant vitritis (white blood cells in the vitreous), often coalesced as "fluff balls" or a "string of pearls," as well as inflammation in the aqueous (Fig. 18.3). At this stage, there may be eye pain and a "red eye." On examination, a hypopyon (layer of white blood cells in the aqueous) may be present. There may be so much intraocular inflammation that the view of the retina is obscured. In some cases of mold endophthalmitis in transplant patients, the primary appearance is of a subretinal abscess.

Both yeasts and molds have been described as causes of fungal endophthalmitis in transplant patients. Patients with *Candida* endophthalmitis may have concurrent or antecedent candidemia. *Aspergillus* endophthalmitis is the most common type of mold endophthalmitis in transplant patients and accounts for over half of cases [37]. There is often another

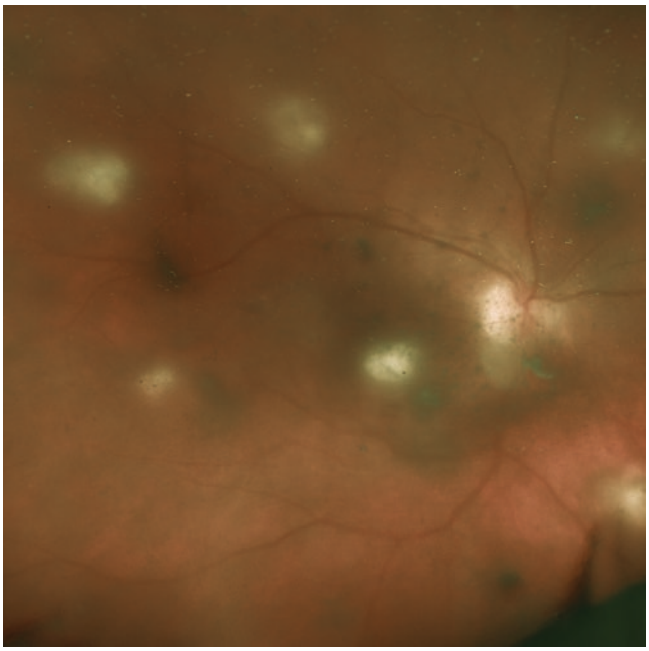

Fig. 18.3 Fungal endophthalmitis: fundus photograph demonstrating several vitreous "fluff balls" typical of fungal endophthalmitis. Gram stain and fungal stain of aqueous humor samples demonstrated yeast, but cultures of the aqueous, vitreous, and blood were negative. The risk factor in this patient was intravenous drug abuse

organ infected concurrently, such as *Aspergillus* endocarditis [8] and pulmonary aspergillosis [6]. Endogenous *Aspergillus* endophthalmitis may be unrecognized during life, especially if patients are too ill to complain of eye symptoms. In an autopsy series of 85 liver transplant patients, 6 patients were found to have *Aspergillus* endophthalmitis, but only 1 was diagnosed before death [38]. The eye was the second most common site of infection, after the lungs.

Scedosporium apiospermum (the asexual form of *Pseudallescheria boydii*) is another common cause of fungal endophthalmitis in transplant patients [39]. It is often associated with disseminated infection, and mortality is at least 50% in transplant patients and nearly 100% in lung transplant recipients. This fungus is resistant to amphotericin but usually responds to voriconazole. Successful treatment using long-term voriconazole has been described in two lung transplant patients with disseminated infection including endophthalmitis [40]. *Fusarium* endophthalmitis is the second most common cause of mold endophthalmitis worldwide, after *Aspergillus*, but in non-immunocompromised patients, this infection usually arises exogenously – either as an extension of *Fusarium* keratitis (corneal infection), after eye trauma, or as a nosocomial complication of eye surgery in tropical countries. In transplant patients, *Fusarium* is usually associated with disseminated infection, as in the case of a HSCT patient with bilateral endophthalmitis who died despite maximal therapy [41].

Bacterial endophthalmitis is rare in transplant patients and nearly always occurs from bacteremic seeding, although blood cultures may be negative at the time of presentation with eye findings. Case reports have described other bacterial etiologies, including a case of bilateral *Pseudomonas* endophthalmitis in a cystic fibrosis patient after lung transplantation [42], *Listeria* endophthalmitis in a renal transplant patient [43], and *Nocardia* endophthalmitis in a cardiac transplant patient [44].

Treatment of fungal endophthalmitis requires systemic antifungal therapy optimized for the fungus involved. In cases of *Candida* chorioretinitis without vitritis, or with minimal vitritis, systemic therapy alone may be sufficient to also treat the eye infection. However, if significant vitritis is present or in cases of mold endophthalmitis, intravitreal injections of antifungal agents must also be given. These are either amphotericin or voriconazole injections and may be repeated more than once. Vitrectomy, if the patient is well enough to undergo eye surgery, is often essential to control intraocular mold infections; in these cases, an injection of antifungal (amphotericin or voriconazole) is given at the end of the case.

The prognosis for endogenous fungal endophthalmitis in transplant patients has been poor, and many die of the systemic fungal disease. However, successful therapy is increasingly common in the era of the new antifungal agents.

Rare Eye Infections in Transplant Patients

Infectious Uveitis

Ocular Toxoplasmosis

Ocular toxoplasmosis is the most common infectious cause of posterior uveitis in the world. In transplant patients, toxoplasmosis can present as encephalitis, pneumonitis, or myocarditis, but it has been reported infrequently in the eye. In one series of 102 non-AIDS immunocompromised patients, 6% of patients developed chorioretinitis, and 70% of these patients had concomitant encephalitis [45]. The overall incidence of reactivation of toxoplasmosis in HSCT patients who have known *Toxoplasma* IgG seropositivity is 2% [46]. The majority of cases of toxoplasmosis in HSCT develop within 6 months after transplant [47]. Ocular toxoplasmosis in transplant patients is most often reactivation of latent disease, although reports of acquired infection from transplantation have been described, particularly in cardiac and liver transplants [48]. Immunocompromised patients with positive antibodies to *Toxoplasma* prior to transplantation may be more likely to have reactivation of disease. Other risk factors for ocular toxoplasmosis in the transplant patient include prior episodes of ocular toxoplasmosis and severe GVHD.

Fig. 18.4 Toxoplasma chorioretinitis: fundus photograph demonstrating pigmented chorioretinal scar with adjacent active area of hypopigmented chorioretinitis

Clinical Presentation

Patients may present with complaints of blurred vision, floaters, eye pain, and scotomata. Clinical examination reveals a mild cellular reaction in the anterior and posterior chambers with areas of white-yellow chorioretinal lesions which may be adjacent to an area of pigmented chorioretinal scarring (Fig. 18.4). These lesions are generally more bright white and have borders with smooth contours compared to CMV retinitis lesions. There can be associated retinal vasculitis. Patients may have multiple lesions and bilateral involvement. In contrast with ocular toxoplasmosis in immunocompetent patients, which is often associated with significant vitritis, transplant patients may have mild inflammation and more extensive chorioretinal necrosis, making it difficult to distinguish from viral retinitis [49].

Diagnostic Tests

Most cases of ocular toxoplasmosis are diagnosed clinically. Serologic testing for *Toxoplasma* antibodies (IgM and IgG) can be helpful, particularly if patients were seronegative prior to transplantation. Molecular diagnostic testing with PCR may be performed on ocular fluid samples in cases of atypical toxoplasmosis, Goldmann-Witmer coefficient testing comparing antibodies in ocular fluids and serum may be inconclusive in severely immunosuppressed patients who may not be able to mount a sufficient antibody response for detection. One case of ocular toxoplasmosis was diagnosed in a HSCT patient based on fine needle aspiration biopsy of the chorioretinal lesion demonstrating *Toxoplasma gondii* tachyzoites and intracytoplasmic cysts; this approach can be reserved for atypical cases where it is unclear if the retinal process is infectious or a recurrence of leukemia [50]. Because of the potential for systemic *Toxoplasma* infection including encephalitis, neuroimaging should be performed in immunocompromised patients with ocular toxoplasmosis.

Treatment

The treatment for ocular toxoplasmosis in the immunocompromised patient is sulfadiazine, plus pyrimethamine, with folinic acid rescue; clindamycin may also be added for "triple therapy." Patients must be monitored closely for adverse effects of medications including additional bone marrow suppression with pyrimethamine and renal failure with sulfadiazine. Trimethoprim-sulfamethoxazole has been used to treat immunocompetent patients. Prophylactic treatment with either trimethoprim-sulfamethoxazole 160 mg/800 mg or combination of pyrimethamine/sulfadiazine has been recommended in transplant patients with known prior episodes of *Toxoplasma* chorioretinitis [47]. This prophylactic therapy is continued for months to years or even lifelong, with the duration depending on factors such as the degree and duration of immune suppression, type of transplantation procedure, and the presence of GVHD or allograft rejection.

Prognosis

The visual prognosis for ocular toxoplasmosis is dependent on the location of chorioretinal lesions. Once treated, lesions involving the macula or adjacent to the optic nerve become fibrotic scars with associated poor visual acuity. Patients with peripheral lesions generally have a good visual prognosis, with full recovery to baseline visual acuity with treatment. Potential complications which may also affect visual prognosis include retinal detachment and reactivation of infection.

Ocular Tuberculosis

Ocular involvement of tuberculosis (TB) is rare. In a large series of patients from the United States during the era of TB sanatoria, only 1.4% of patients with pulmonary TB had ocular involvement [51]. The incidence of TB in solid organ transplant populations was reported to be 25–50 times higher than the general population, according to one recent series from a single center in the United States [52]. The majority of transplant patients present with pulmonary or disseminated TB within the first year after transplantation when the level of immunosuppression is highest. Ocular TB in transplant patients is rare and has been reported in a handful of cases, mainly in renal transplant patients with disseminated or pulmonary involvement [53, 54]. Ocular TB occurs following hematogenous spread from pulmonary or disseminated infection.

Patients may present with complaints of blurred vision, floaters, or eye pain, depending on the location of the ocular involvement. One of the most common manifestations of ocular TB is a choroidal granuloma ("tubercle") which appears as a gray or yellow mass deep to the retina with or without inflammation. Choroidal tubercles can be found in both eyes, range in size from one-fourth to several disc diameters, and are histopathologically similar to tubercles found in other parts of the body, with caseating granulomas containing acid-fast bacilli [55]. Untreated, choroidal granulomas can grow in size and become subretinal abscesses as the choroid is replaced with necrotic tissue. Other types of ocular involvement include multifocal chorioretinitis which can coalesce to form serpiginous choroiditis, retinal vasculitis (mainly periphlebitis), vitritis, panuveitis, granulomatous anterior uveitis, and scleritis. The differential diagnosis of ocular TB includes ocular syphilis, ocular toxoplasmosis, viral retinitis, and noninfectious etiologies such as sarcoidosis and ocular Behcet's disease.

Diagnosis of ocular TB in the absence of pulmonary or disseminated TB can be challenging. Immunosuppressed patients are more likely to have a negative tuberculin skin test even in the presence of active TB. Interferon gamma release assays (IGRA), may be more sensitive in detecting TB in immunosuppressed patients and in patients with prior BCG vaccination [56]. Culture of ocular fluids rarely produces positive results. Ocular fluid sampling can be performed for molecular diagnostic testing, but the sensitivity and diagnostic yield of TB PCR in ocular fluids are low. [57]. Because transplant patients with ocular TB most likely have systemic involvement, it is important to perform a thorough workup for evidence of disseminated TB.

Treatment of ocular TB consists of standard multidrug TB therapy as used for systemic infections. A quinolone antibiotic is sometimes substituted for ethambutol given concern for ethambutol-associated optic neuropathy. In patients with severe intraocular inflammation, where the inflammation alone may be harmful to the retina, local or systemic corticosteroids may be used. However, systemic corticosteroids should be used with caution in transplant patients with disseminated disease.

Visual prognosis depends on the extent and location of ocular involvement. Patients with large choroidal granulomas or subretinal abscesses who present with more advanced disease are at risk for significant vision loss. Early recognition of eye involvement and treatment with antitubercular therapy is important for preventing severe vision loss and for treating systemic infection.

Infectious Keratitis: Herpes Zoster Ophthalmicus, Herpes Simplex

Reactivation of VZV is a common complication in solid organ transplant and HSCT patients. VZV in the distribution of the first branch of the trigeminal nerve, also known as herpes zoster ophthalmicus (HZO), can cause significant morbidity. The incidence of HZO in one series of HSCT in children was 1.2% [58]. Patients present with the vesicular rash in a dermatomal distribution. Herpes simplex keratitis can also occur in transplant patients and can be distinguished from VZV by the absence of the dermatomal rash. There have also been rare instances of bilateral HSV keratitis in patients with graft versus host disease following SCT [59].

Patients often complain of eye pain, redness, tearing, and blurred vision, although there may be eye involvement in the absence of significant symptoms. Clinical examination may reveal a corneal pseudodendrite in HZO (similar to the dermatologic vesicular lesion in zoster) or a corneal epithelial dendrite in HSV. Both HZO and HSV may also present with stromal keratitis, anterior uveitis, scleritis, and conjunctivitis. HZO can cause an optic neuropathy or extraocular muscle palsy. Both entities can cause elevated eye pressure on presentation. Systemic antiviral therapy should be instituted within 72 h of the development of the rash in HZO to decrease disease duration and potential morbidity, including postherpetic neuralgia. Transplant patients are often treated with intravenous acyclovir for HZO, likely due to concerns for more aggressive disease process or risk of disseminated disease in immunosuppressed patients. There have also been cases of severe HSV keratitis in transplant patients requiring the use of intravenous acyclovir [60]. However, there is concern for acyclovir resistance especially in immunocompromised patients with VZV who may have been on antiviral prophylaxis. There was a case of HZO in a HSCT patient that persisted in spite of intravenous acyclovir therapy [61]. Transplant patients should be maintained on oral antiviral prophylaxis with acyclovir, valacyclovir, or famciclovir to prevent recurrence of inflammation, particularly stromal keratitis and anterior uveitis [62]. Topical and local corticosteroids are used for the treatment of associated corneal stromal disease and intraocular inflammation. Visual prognosis is dependent on the location and severity of eye involvement. A small corneal dendrite in HSV may heal with minimal scarring and preservation of visual acuity. Recurrent inflammation, involvement of the corneal stroma with the development of neovascularization and opacification, and any involvement of the optic nerve can significantly limit visual prognosis.

Orbital and Adnexal Infections

Transplant patients are susceptible to common and uncommon bacterial and fungal infections of the orbit and adnexa. As with immunocompetent patients, orbital infections in transplant patients often develop as an extension of sinus disease. The most common orbital infection in transplant patients is orbital zygomycosis (or mucormycosis). Zygomycosis is an invasive fungal infection with a

high rate of morbidity and mortality, particularly in the transplant population. Ubiquitous fungi from the genera *Mucor*, *Absidia*, and *Rhizopus* invade the oral and sinus mucosa of immunocompromised patients and can extend into the orbit and intracranial tissues (rhino-orbital-cerebral mucormycosis). In one large series of patients with zygomycosis, 19.5% of patients developed orbital involvement [63]. In one series of solid organ transplant patients with zygomycosis, the average time to infection after transplant was between 60 and 120 days; risk factors included diabetes or hyperglycemia, acidosis, and renal failure [64]. Patients present with complaints of unilateral headache, eye pain, periorbital swelling, double vision, and vision loss. Signs on exam include periorbital edema with erythema, conjunctival edema (chemosis), ophthalmoplegia, proptosis, and diminished visual acuity. There is often hypesthesia of the first and/or second divisions of cranial nerve 5. In late stages of the disease, examination of the nasal mucosa reveals a black eschar which results from tissue necrosis and infarction due to fungal invasion of blood vessels. Neuroimaging is important to ascertain the extent of invasion; solid organ transplant patients are more likely than diabetic patients to have central nervous system involvement [65]. A high index of suspicion is essential, as the clinical findings often precede any radiologic evidence of infection. An intranasal or sinus "black eschar" may not be present, and biopsy of nasal and sinus mucosa should be performed early. Biopsy of normal mucosa may demonstrate the invasive hyphae. Treatment of zygomycosis includes intravenous amphotericin B and surgical debridement of involved tissues. The liposomal formulation of amphotericin B has been associated with better outcomes than amphotericin B deoxycholate or other antifungal therapies [63, 65]. Posaconazole has been used in rare cases of medication toxicity or treatment failure with amphotericin B, but is not recommended as first-line therapy [63, 66]. There have been reports of breakthrough zygomycosis in patients who are on posaconazole prophylaxis, leading to the concern for potential drug resistance [67]. Isavuconazole is a new antifungal agent that may have similar efficacy as amphotericin against mucormycosis, based on results of a single-arm non-randomized trial [68], although it is currently not recommended as first-line treatment. Exenteration may be necessary in some patients with mucormycosis involving the orbit in order to prevent intracranial extension of disease. Overall prognosis is poor, and mortality rates of rhino-orbital-cerebral zygomycosis in transplant patients have been reported between 52% and 100% [64, 65]. CNS invasion is associated with higher mortality [65].

Intracranial, Spinal, and Paraspinal Infections in the Transplant Recipient

19

Matthew W. McCarthy, Axel Rosengart, and Thomas J. Walsh

Introduction

Intracranial, spinal, and paraspinal infections contribute significantly to morbidity and mortality in patients receiving solid organ and stem cell transplants [1, 2] and should be considered a medical emergency [3]. The incidence of CNS involvement varies but is estimated to occur in 5–10% of transplant recipients [4] and is influenced by multiple factors, including the organ transplanted [5], the type and degree of immunosuppression, post-transplant adverse events [1], as well as donor characteristics, e.g., autologous vs. allogeneic [6].

Fungal, viral, bacterial, and parasitic infections of the central nervous system are well-documented in transplant recipients [7]. Because post-transplantation immunosuppressive regimens may modify the clinical presentation of CNS infections, special attention should be given to even minor neurologic symptoms and noninfectious causes such as the toxic effects of calcineurin inhibitors, and lymphoma should be included in the differential diagnosis [3]. Here we review the most common intracranial, spinal, and paraspinal infections in the post-transplant patient.

Part 1: Intracranial Infection in the Transplant Recipient

Some of the more common organisms responsible for intracranial infection in the transplant recipient include species of *Aspergillus*, *Toxoplasma*, *Candida*, *Klebsiella*, *Cryptococcus*, *Coccidioides*, *Listeria*, and *Mucor*. In the late 1980s, three organisms – *Listeria monocytogenes*, *Aspergillus fumigatus*, and *Cryptococcus neoformans* – accounted for the great majority of these infections in transplant recipients [8]. When presenting as meningoencephalitis or abscesses, these lesions were often multiple and deep-seated and were frequently associated with pulmonary or disseminated infection [9]. However, with the development of new immunosuppressive agents, antimicrobial prophylaxis, shifts in nosocomial flora, and improved diagnostic methods, it is now recognized that a broad array of pathogens cause intracranial infection and tend to occur at discrete time points in the post-transplant patient [10, 11].

These infections can be divided into the early post-transplantation period, intermediate period, and late post-transplantation period and are influenced by epidemiologic exposures, net state of immunosuppression, antimicrobial prophylaxis, and the type of transplantation [3, 12]. Below is a review of intracranial infections at each time point.

Early Time Period Intracranial Infection

The early post-transplant period is generally defined as the first month after transplantation. Because the major effects of exogenous immunosuppression are not yet apparent, the causes of intracranial infection in this time period are those derived from either the donor or recipient and infectious complications of the transplant and hospitalization [13].

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_19

Recipient-Derived Infections

An important component of the pretransplant evaluation is to identify and treat any infection in the donor and recipient. Cytomegalovirus, Epstein-Barr virus, *Mycobacterium tuberculosis*, and *Toxoplasma gondii* are examples of pathogens that may exist in a latent state in the recipient and may be reactivated after transplantation, causing intracranial lesions. For this reason, they are routinely screened for prior to transplant [14]. Pretransplant vaccination has also become recognized as an important measure to protect patients from reactivation of latent pathogens. Many inactive and conjugate vaccines have been approved for use in the pretransplant patient. Recommendations for vaccinations of adult transplant recipients including special considerations for household contacts have been published [15].

Donor-Derived Infections

Transmission of donor-derived pathogens has been well-documented in the transplant recipient [16]. In 2010, a case was reported in which a 24-year-old patient developed invasive *Aspergillosis* of the brain 9 days after heart transplantation [17]. Five organs from this patient were subsequently used for transplantation into five recipients. Of the five recipients – two kidney, one liver, one islet cell, and one lung recipient – one lost the kidney graft because of invasive *Aspergillosis* of the transplanted organ. The lung recipient died due to primary non-function unrelated to infection. In the remaining recipients, prompt initiation of therapy prevented the outbreak of symptomatic *Aspergillosis*. Severe malaria, including cerebral malaria, has been reported following organ transplantation, but it is not clear that the incidence of cerebral malaria is elevated in this population [4]. Transplant-transmitted viral encephalitis from West Nile virus and Rabies virus has also been reported within 30 days of transplantation [18, 19].

Infectious Complications Related to Surgery

The organisms responsible for postoperative intracranial infections are often the bacteria and fungi that have colonized the recipient or donor prior to transplant. These include antimicrobial-resistant organisms, such as fluconazole-resistant *Candida* species, methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant *Enterococcus*, *Clostridium difficile*, and resistant Gram-negative bacteria [20–26].

Because recipients are immunosuppressed, they are at risk for developing neurologic sequelae from bacteremia, and the risk is further increased with the use of indwelling vascular access catheters, urinary catheters, and surgical drains. Organ transplantation from donors with fever or viral syndromes is controversial. In cases in which the need for transplantation is not critical, we recommend avoiding the use of organs from donors with unexplained fever, encephalitis, or untreated infectious syndromes [3].

Intermediate Time Period Intracranial Infections (1–6 Months After Transplant)

In the period 1–6 months after transplantation, the composition of intracranial pathogens changes. Opportunistic infections prevail although there is geographic variation given the inter-institution variation in immunosuppressive and antimicrobial prophylaxis strategies. Local epidemiology also plays a role, as endemic fungi, e.g., *Histoplasma capsulatum*, *Coccidioides* spp., and *Cryptococcus gattii*, as well as *Mycobacterium tuberculosis* and nontuberculous mycobacteria have been observed to cause infection [27–29].

Although the incidence has decreased with routine use of antimicrobial prophylaxis, transplant recipients are at increased risk for acquiring infection with *Toxoplasma gondii* and *Pneumocystis jirovecii*, although intracranial infection remains rare. In a multicenter, matched case-control study in a 1:2 ratio, 22 cases of toxoplasmosis were identified among 15,800 solid organ transplant recipients performed in 11 Spanish hospitals between 2000 and 2009 [30]. With respect to central nervous system involvement, five manifested as brain abscesses and one had meningitis.

Antiviral prophylaxis with has decreased the incidence of intracranial viral infections, but the disease has not been eliminated. Herpesviruses have frequently been implicated in interim period intracranial infection [31]. A 2011 analysis of 2628 patients after allogeneic stem cell transplantation found that viral encephalitis occurred in 32 patients [32]. Detected viruses included human herpesvirus 6, Epstein-Barr virus, herpes simplex virus, JC virus, varicella zoster virus, cytomegalovirus, and adenovirus. More than one virus was identified in 16% of patients with viral encephalitis. The median onset time was 106 days after allogeneic stem cell transplantation for the total group of 32 patients, but onset times were shortest in those with HHV-6 encephalitis and longest in those with JC virus-associated progressive multifocal leukoencephalopathy [32].

Progressive multifocal leukoencephalopathy (PML) is a rapidly progressive demyelinating disorder of the central nervous system almost exclusively encountered in immunocompromised individuals and is caused by reactivation of the John Cunningham virus (JCV) [32]. In January, 2011, a 59-year-old woman underwent umbilical cord stem cell transplantation for follicular non-Hodgkin lymphoma [33]. On day 35, the patient developed grade 2 acute GVHD reaction of the skin without other organ dysfunction, and 2 mg/kg methylprednisolone was started. On day 51, the patient developed CMV reactivation in the peripheral blood (detected by PCR = 1359 copies); and an antiviral treatment with ganciclovir (Cymevan) 2.5 mg/kg/day was administrated. On day 68, she developed confusion and short-term memory dysfunction, with abnormal Babinski reflexes on the left. Brain MRI (FLAIR sequence) revealed hyper-intensity

lesions in the white matter of the frontal lobes. On day 84, the patient's mental status was stable, and a lumbar cerebrospinal fluid (CSF) examination revealed a white blood cell (WBC) count of 1 cells/L, a normal glucose level of 3.89 mmol/L, and a normal protein level of 389 mg/L. Gram staining and culture were negative. A specimen was sent for polymerase chain reaction (PCR) analysis for JC virus was positive in the CSF and the serum which was negative for CMV, VZV, HHV-6, EBV, and herpes simplex virus by PCR. A treatment with 5 mg/kg/week of cidofovir was initiated on day 86 associated with mefloquine and mirtazapine. However, the patient's neurologic condition continued to deteriorate, and she expired on day 110 after umbilical cord blood transplant; post-mortem neuropathologic examination was not performed secondary to the wishes of the family.

Transplant recipients are also at increased risk for acquiring *Mycobacterium tuberculosis*. Solid organ transplant recipients are 20–74 times more likely to acquire *Mycobacterium tuberculosis* than the general population and more frequently presents with extrapulmonary tuberculosis [34]. After solid organ transplant, the median time to development of tuberculosis is 183 days, and intracranial tuberculosis infection appears to follow that pattern [35]. The most common symptoms of intracranial tuberculosis infection are fever, headache, vomiting, and altered level of consciousness. The basilar meninges and cistern are frequently affected and cause cranial nerve dysfunction, especially of the sixth (abducens or abducent) and seventh (facial) cranial nerves [36, 37]. Tuberculous meningitis may have an insidious onset, so physicians should have a high clinical suspicion in transplant recipients with altered level of consciousness in tuberculosis-endemic areas.

Microsporidia are spore-forming, obligate, intracellular parasites that are ubiquitous and infect invertebrates as well as all classes of vertebrates. At least one case of parasitic involvement of the brain parenchyma in the intermediate time period post-transplantation has been reported [38].

Late Time Period Intracranial Infection (More than 6 Months After Transplant)

More than 6 months after transplantation, most patients with good graft function receive stable and reduced levels of immunosuppression while continuing on some form of antimicrobial prophylaxis. The pathogens that cause intracranial infection tend to more closely resemble the community-acquired pathogens responsible for these infections in immunocompetent hosts.

In contrast, patients with concern for rejection or impaired graft function generally require more significant immunosuppressive therapy and remain at highest risk for opportunistic infections. In addition to the opportunistic pathogens mentioned in prior sections, these patients are at risk for developing intracranial nocardiosis [39], which has a special tropism for neural tissue [40]. Central nervous system nocardiosis is a formation of a parenchymal abscess that can occur in any region of the brain. A matched case-control study of 5126 organ transplant recipients between January 1995 and December 2005 revealed 35 cases of *Nocardia* infection [41]. Of the 35 cases, 7 had disseminated disease, including 3 with CNS involvement, all in the form of brain abscess as 1 presented with a solitary abscess and 1 presented with multiple abscesses.

An emerging pathogen in the immunocompromised host, *Rhodococcus equi*, is a Gram-positive coccobacillus that is a well-documented pathogen in veterinary literature causing pneumonia and sepsis in farm animals, especially in horses and cattle. It is an unusual cause of infection in humans but has recently been described as a cause of intracranial infection in the post-transplant patient. In one case report, a 42-year-old woman developed end-stage renal failure because of hemolytic uremic syndrome and malignant hypertension in 2001 and subsequently underwent kidney transplantation in 2003 [42]. Five years later, while on maintenance of immunosuppressive therapy with mycophenolate mofetil 500 mg BID, tacrolimus 1 mg BID, and prednisolone 7.5 mg once a day, she presented with a deep subcutaneous abscess in her right hip. The abscess was treated with surgical drainage and antibiotic therapy, and *R. equi* was identified in cultures from drained material from the subcutaneous abscess. Five weeks after this episode, she presented again with an abscess in her right hip, for which she again underwent surgical drainage. During her stay at the hospital, she developed epileptic seizures, and imaging revealed two brain abscesses that were not accessible to surgery. She subsequently died 14 days after admission from transtentorial brain herniation.

Conclusions

The nature of intracranial infections after solid organ transplantation continues to evolve, and with improved diagnostic tools, new pathogens have been identified in this subset of patients, including many with significant antimicrobial resistance [43]. An emerging issue is that of donor-derived infection, including West Nile virus, rabies, and lymphocytic choriomeningitis virus [44]. As of 2012, four clusters of organ transplant-associated lymphocytic choriomeningitis virus (LCMV) transmissions have been identified in the United States [45]. In immunocompetent patients, the disease can cause a non-specific febrile illness and, in some cases, aseptic meningitis [46]. In the transplant recipient, LCMV may cause multi-organ failure and often death. Of 15 confirmed cases of transplant-associated LCMV in the United States, 12 patients died of complications from the virus [45].

Part 2: Spinal Infection in the Transplant Recipient

Although rare, spinal infection in the post-transplant patient has been documented [47, 48] and has potentially devastating consequences if not identified and treated appropriately. For most patients, the primary route of infection is via hematogenous spread secondary to bacteremia. Septic emboli lodge at the vertebral end plate as it is supplied by end-arterial circulation. This leads to local infarction, and the avascular vertebrae become involved in the infective process [49]. These infections can be classified by the anatomical location involved: the vertebral column, the intervertebral disk space, and the spinal canal as well as by the time frame in which they occur after organ transplantation (i.e., early, intermediate, and late). Infection in adjacent soft tissues will be discussed later in the chapter.

Because of blunted host immune response, signs and symptoms of spinal infection may vary. The overriding symptom, however, is back pain. Radiculopathy, myelopathy, and sensory loss may accompany focal tenderness. CT scan, magnetic resonance, and bone scan play a vital role in the diagnosis of these infections [50]. The cornerstone of treatment is the identification of the responsible pathogen, appropriate medical therapy including possible surgical debridement, immobilization of the affected segment of the spine, and physical therapy to combat physical deconditioning [50].

Early Time Period Spinal Infection

Spinal infection in the first month after organ transplantation is rare, and incidence remains on the level of the case report [51]. As with intracranial infection, spinal infections in this period are usually attributed to nosocomial factors (surgery and hospitalization) or infection derived from the host or donor that spreads to the spine.

Intermediate Time Period Spinal Infection

Between 1 and 6 months after organ transplantation, bacterial and fungal pathogens predominate and tend to occur as a result of hematogenous seeding to the spine. However, viral complications such as progressive multifocal leukoencephalopathy caused by the reactivation of the JC virus have been reported [33]. The incidence of pyogenic spinal infection continues to occur, but its incidence has been decreased by the routine use of antimicrobial prophylaxis. And as result of improvements in transplant surgical methods, the prevalence of invasive fungal infections – primarily *Candida* and *Aspergillus* species, respectively – has declined as a whole over the past two decades [52]. However, a reduction in the number of spinal infections caused by *Candida* species has been accompanied by a rise in infections caused by *Aspergillus*. A 2010 review of *Aspergillus* spinal infection in solid organ transplant recipients identified 15 cases of spondylodiscitis [48]. Most cases (80%) were afebrile on presentation. All patients presented with progressive pain, showing radiographic evidence of lumbar osteomyelitis and discitis. In liver transplant recipients, the median time to onset was 2.125 months; for heart transplant recipients, it was 5.4 months. *Aspergillus fumigatus* and *Aspergillus flavus* were the most common pathogens, occurring in 84.62% and 15.38% of isolates, respectively. In all of the cases reviewed, heart transplant recipients were more inclined to have spinal *Aspergillosis* than renal or liver graft recipients There has been some success treating these patients with surgical debridement and voriconazole although the data is limited [53].

Late Spinal Infection

The majority of spinal infections reported in the literature occur after 6 months. These patients are often on reduced levels of immunosuppression, and the role of lifetime trimethoprim-sulfamethoxazole or antifungal prophylaxis remains controversial. Such long-term prophylaxis carries some risk of the development of microbial resistance to the prophylactic agents and possible future drug interactions [3]. *Staphylococcus aureus* is frequently implicated in cases of vertebral osteomyelitis in immunocompetent hosts and has similarly been reported in cases of post-transplantation vertebral osteomyelitis [49]. In one case of an orthotropic heart transplantation, the patient presented 14 months post-transplantation, with fever, nausea, vomiting, and severe epigastric pain that was unrelated to food but aggravated by movement and lying supine. Examination revealed bilateral tenderness over the lumbar region with localized tenderness over the lower thoracic and lumbar spine. Blood cultures revealed methicillin-sensitive *Staphylococcus* aureus, and MRI revealed findings consistent with infective diskitis and T-10 vertebral body osteomyelitis. The patient was successfully treated with intravenous and oral antibiotics, and the authors speculate that spinal infection may have resulted from hematogenous spread to areas of previously diseased osteoporotic vertebrae or damaged vertebral facet joints from analgesic injections.

Vertebral osteomyelitis by *Aspergillus* remains rare, although vertebrae are the most common site of *Aspergillus* infection in the bone [54]. In 2003, a case of a 46-year-old man with a 30-year history of type I diabetes, complicated by end-stage renal disease, who underwent simultaneous pancreas/kidney transplantation was reported [55]. One year after his transplant, the patient presented with fever, progressive low back pain, and paravertebral tenderness in the lum-

bar region. The patient was noted to be neutropenic with a white blood cell count of 1600 cells/mL, and imaging revealed L2–L3 osteopenia and diskitis, without compression, fracture, or abscess. Computed tomography (CT)-guided biopsy of L3 vertebra showed hyphae on mycological smears, and culture revealed *Aspergillus fumigatus*. The patient was treated with amphotericin B 1 mg/kg/day and underwent diskectomy, with debridement and drainage.

Some evidence suggests CMV disease or being a CMV-seronegative recipient of a CMV-seropositive donor organ is a predictor for invasive fungal disease following solid organ transplantation [56] and is now routinely included in the pre-transplantation assessment of both donor and recipient.

Conclusions

Spinal infection in the transplant recipient is an uncommon but aggressive disease that may cause spinal instability, neurological insult, and possibly death. Because the host's immune system is often suppressed, the clinical must retain a high level of suspicion to ensure prompt diagnosis and treatment. Aggressive surgical treatment with concurrent pharmacotherapy can successfully treat these infections and prevent neurological injury.

Part 3: Paraspinal Myositis and Other Paraspinal Infections in the Transplant Recipient

Paraspinal infection in the post-transplant patient is a rare event and includes paraspinal myositis and psoas muscle abscesses. It may be caused by a broad range of bacterial, fungal, parasitic, and viral agents and remains uncommon due to the relative resistance of musculature to infection [57]. Modes of transmission include transcutaneous infection of the deep tissue by needles or catheters, surgery, blunt trauma, and hematogenous seeding from remote sites. Signs and symptoms of paraspinal infection include back or flank pain, fever, inguinal mass, limp, anorexia, and weight loss [58]. In cases of psoas abscess formation, CT is the imaging modality of choice. Management consists of drainage and prompt initiation of antibiotics.

Bacterial causes are categorized by organism and anatomic location (i.e., *Staphylococcus aureus* myositis, group A streptococcal necrotizing myositis, group B streptococcal myositis, clostridial gas gangrene, and nonclostridial myositis). In the transplant recipient, however, atypical pathogens have also been implicated in paraspinal infection. In 2004, a case report detailed the course of a 35-year-old man who underwent combined kidney and pancreas transplantation in 2000 [59]. Two years after undergoing transplantation, the patient developed septic arthritis affecting the right knee and sternoclavicular joints and pain in the left iliac fossa. Radiological investigations demonstrated abnormal gallium uptake in these areas and an associated left psoas abscess. Purulent fluid was aspirated from the psoas abscess; however, no microorganisms were noted by microscopic evaluation or culture. Amplification of 16S rRNA gene was performed on psoas abscess material and demonstrated sequence homologies of 99–100% with *Mycoplasma pneumoniae.* Treatment with oral doxycycline 100 mg BID was then introduced, resulting in a rapid and complete clinical improvement within 3 weeks.

Fungal myositis is rare; *Histoplasma capsulatum* necrotizing myofascitis has been identified in a renal transplant patient, but the infection was of the upper extremity, not the paraspinal muscles [60]. Similarly, severe *Coccidioides immitis* myositis of the lower extremity has been seen in an orthotopic cardiac transplant recipient. For this reason, a careful travel history should be obtained in any transplant recipient with an unexplained febrile illness [61]. Parasitic myositis in the immunocompetent host is most commonly a result of trichinosis or cysticercosis, but other protozoa or helminths may be involved and are often suggested by peripheral eosinophilia and/or travel history [57]. To our knowledge, a parasitic cause of paraspinal infection in the transplant recipient has not been reported. Viruses known to cause myositis in the immunocompetent host include influenza virus and coxsackievirus B. Interestingly, one case of influenza vaccine-induced proximal muscle rhabdomyolysis has been described in a renal transplant patient [62]. The diagnosis of paraspinal infection in the transplant recipient may be subtle and is ultimately determined by the clinical presentation, radiologic imaging, and microbiologic or serologic testing. Therapy is based on the clinical presentation and the underlying pathogen.

Summary

Immunosuppression following organ transplantation increases susceptibility to central nervous system infections [4]. Despite ever-improving surgical techniques, diagnostic modalities, and prophylactic and therapeutic antibiotic regimens, intracranial, spinal, and paraspinal infections remain an important source of morbidity and mortality among transplant recipients. Because signs and symptoms may be subtle, the clinician must retain a high index of suspicion with any patient presenting with fever or neurologic symptoms. These infections should be considered a medical emergency, and treatment should be prompt to minimize the risk of neurologic sequelae and death. Table 19.1 shows a summary of antimicrobial therapy for common pathogens causing infection of the central nervous system in transplant recipients.

Table 19.1 Summary of antimicrobial therapy for common pathogens causing infection of the central nervous system in transplant recipients

Organism	First-line therapy	Second-line therapy/comments
Fungi		
Aspergillus spp.	Voriconazole	ABLC (5 mg/kg/day IV)
	Loading dose: 6 mg/kg IV q12hr	Caspofungin
	Maintenance dose: 4 mg/kg IV q12h	*Loading dose*: 70 mg day IV
	L-AMB (5–7.5 mg/kg/day IV)	*Maintenance dose*: 50 mg/day IV thereafter
		Posaconazole (200 mg QID initially and then 400 mg PO BID)
		Itraconazole (dosage depends upon formulation)
Mucorales	L-AMB (3–5 mg/kg/day IV)	Posaconazole (200 mg QID initially and then 400 mg PO BID)
	ABLC (5 mg/kg/day IV)	
Cryptococcus	*Induction therapy*: liposomal AmB (3–4 mg/kg per day) *or* ABLC (5 mg/kg per day) PLUS flucytosine (100 mg/kg per day)	*Induction therapy*: liposomal AmB (6 mg/kg per day) *or* ABLC (5 mg/kg per day)
	For 2 weeks	
	Consolidation therapy: fluconazole (400–800 mg per day)	
	For 8 weeks	
	Maintenance therapy: fluconazole (200–400 mg per day)	
	For 6–12 months	
Candida spp.	L-AMB (5–7.5 mg/kg/day IV)	Fluconazole (400–800 mg per day)
		Micafungin 100 mg IV q12hr
		Caspofungin
		Loading dose: 70 mg day IV
		Maintenance dose: 50 mg/day IV thereafter
Protozoa		
Toxoplasma	Pyrimethamine (100 mg loading dose PO followed by 25–50 mg daily) plus sulfadiazine (2–4 g/day PO q6hrs)	Pyrimethamine (100 mg loading dose PO followed by 25–50 mg daily) plus azithromycin (500 mg daily) or atovaquone 750 mg Po q12hr
Bacteria		
Listeria monocytogenes	Ampicillin 2 g IV q4hr × 21 days	Trimethoprim-sulfamethoxazole (5 mg/kg [based on the trimethoprim component) IV or PO every 6–12 h
		Meropenem 1 g IV q8hr
Streptococcus pneumoniae	In patients with isolates that are susceptible to penicillin (MIC ≤0.06 mcg/mL), penicillin (4 million units IV every 4 h) can be used	Ceftriaxone 2 g IV q12hr in patients with penicillin (MIC ≤0.06 mcg/mL)
Methicillin-resistant Staphylococcus aureus	Vancomycin 15–20 mg/kg IV every 8–12 h (not to exceed 2 g per dose or a total daily dose of 60 mg/kg); adjust dose to achieve serum trough concentrations of 15–20 mcg/mL)	Daptomycin 8 mg IV q24hr
Viral		
CMV	Valganciclovir	Ganciclovir 5 mg/kg IV every 12 h
	Induction therapy: 900 mg PO q12hr 14–21 days	
	Maintenance therapy: valganciclovir 900 mg PO q12hr	
VZV	Valacyclovir (1000 mg PO q8hr) for 7 days	Famciclovir (500 mg PO q8hr)
EBV	Supportive care	
HSV	Acyclovir (10 mg/kg IV every 8 h) for 14–21 days	
WNV	Supportive care	The use of alfa interferon is based upon evidence of efficacy against WNV in vitro and in animal models
		Hyperimmune globulin on protocol

*Surgical resection may be appropriate for focal lesions
**Dosages are written for adults

Respiratory Tract Infections: Sinusitis, Bronchitis, and Pneumonia

20

Benjamin A. Miko, Marcus R. Pereira, and Amar Safdar

Introduction

Upper and lower respiratory tract infections are among the most common infectious processes among solid organ and hematopoietic stem cell transplant (HSCT) recipients [1]. As with most infectious syndromes outlined in this text, the increased risk of respiratory tract disease encountered in transplant recipients relates in part to defects in innate and adaptive immunity. Within this population, however, the incidence and microbiological etiology of respiratory infections are quite variable. This is due in part to the use of heterogeneous immunosuppressive regimens and differing prophylactic antibiotic strategies. In addition to diminished host immunity, anatomic breaches in upper and lower respiratory tract defenses may increase the susceptibility of immunocompromised hosts to a variety of common and opportunistic pathogens. Such anatomical considerations are especially important in patients who have undergone thoracic surgery for lung and heart transplantation and individuals who have required prolonged mechanical ventilation. Medical devices such as nasogastric and endotracheal tubes hinder coordinated glottic movement and mucociliary function and act as conduits for the introduction of pathogenic organisms to the respiratory tract [2].

Several immune deficits can affect transplant recipients and consequently increase the risk of upper and lower respiratory tract infections. These include:

1. *Neutropenia*: Commonly associated with medication toxicities, chemotherapy, hematological malignancies, and viral infections, deficits in neutrophil count and function can increase the risk of infection with staphylococci, streptococci, Gram-negative bacilli (GNB), and fungi [3, 4].
2. *T lymphocyte deficiency*: Caused by many transplant immunosuppressive medications that include calcineurin inhibitors, mTOR inhibitors, glucocorticoids. T lymphocyte deficiency is also encountered in the setting of HIV infection, lymphoma, leukemia, and infection/reactivation of various herpesviruses, especially *Cytomegalovirus* (CMV). Patients with cellular immune dysfunction are at increased risk of respiratory infection due to intracellular organisms such as *Listeria monocytogenes*, *Salmonella* spp., *Legionella* spp., and *Toxoplasma gondii*, mycobacteria, fungi-like *Cryptococcus* spp., *Histoplasma capsulatum*, and *Pneumocystis jirovecii*, as well as CMV, *Human herpesvirus 6* (HHV-6), varicella-zoster virus (VZV), and respiratory viruses [5–7].
3. *B lymphocyte deficiency*: Associated with various transplant/oncology medications like azathioprine, mycophenolate, rituximab, and glucocorticoids and hematological malignancies such as leukemia, multiple myeloma, and other causes of humoral immune defects increases the risk of infection with encapsulated bacteria including *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*.
4. *Asplenia and hypocomplementemia*: Similarly increase the risk of infection with encapsulated bacteria as well as *Capnocytophaga*.

Because such immune defects are often mixed, careful attention to clinical and radiographic features as well as recognition of nosocomial versus community sources of infection are critical to making a correct diagnosis and initiating empiric antimicrobial therapy [1]. In both solid organ transplant and HSCT recipients, delays in appropriate antimicrobial therapy may increase the risk of secondary complications and infection-associated deaths, especially in those with

severe immunosuppression. Therefore, it is common practice to initiate empiric or preemptive antimicrobial therapy in patients for whom the suspicion of infection is high.

This chapter reviews the common respiratory tract infections affecting transplant recipients including sinusitis, bronchitis, tracheobronchitis, and pneumonia. Particular attention is directed to epidemiological risk factors including healthcare exposure, clinical presentation, diagnosis, and common microbiological etiologies. Unique causes of opportunistic pneumonias are reviewed in the final section of this chapter.

Sinusitis

Sinus infections are a common occurrence in transplant recipients, affecting between 4% and 31% of HSCT recipients [8, 9] and probably a similar percent of solid organ transplant recipients [10]. Of note, transplant patients with underlying cystic fibrosis (CF) are at extremely high risk for sinusitis with between 90% and 100% of individuals with CF showing pan-sinusitis on imaging by 8 months of age [11]. In HSCT recipients, risk factors for developing severe rhinosinusitis include graft-versus-host disease (GVHD) [12, 13]. The determinants of sinusitis in solid organ transplant recipients are less clearly defined, possibly due to the heterogeneous disease processes prompting transplantation. Unlike non-immunosuppressed individuals, no studies have linked tobacco, allergy, asthma, and low IgG levels to sinusitis in transplant recipients [13].

In general, sinusitis can be classified temporally as acute (<4 weeks), subacute (4–12 weeks), or chronic (>12 weeks) and in terms of severity as invasive or noninvasive. Typical signs and symptoms include nasal congestion, focal sinus pressure or pain, nasal discharge, and reduced sense of smell although, as is generally the case, transplant recipients can often have a muted clinical picture. Among HSCT recipients, nasal congestion and cough are the most common symptoms of acute sinusitis (80% and 61%, respectively) [8]. The nonspecific nature of these symptoms may ultimately lead to delays in diagnosis resulting in poorer clinical outcomes of invasive infections.

The diagnosis of acute sinusitis is often based entirely on clinical presentation in the immunocompetent patients, whereas in transplant recipients, a high degree of suspision due to dampened clinical signs and symptoms should be accompanied by an appropriate diagnostic investigation that often includes CT or MRI scan of the face and paranasal sinuses. In most cases, cultures of nasal discharge are not helpful; a nasal wash for bacterial cultures and a PCR panel that assesses a number of common and uncommon respiratory viruses may considerably improve diagnostic yeild. When imaging is obtained, fluid levels are found in 86% of cases [6]. Although a wide variety of organisms can cause acute sinusitis, the vast majority of infections are due to viral pathogens. These include rhinovirus, respiratory syncytial virus (RSV), adenovirus, coronavirus, influenza, parainfluenza, and even CMV [14–16]. Viral infections can be short-lived but viral shedding can be prolonged among immunocompromised patients. Bacterial sinus infections are much less common and rarely occur with less than 7 days of symptoms [17]. Common bacterial causes of acute bacterial sinusitis include *S. pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, *S. aureus*, and anaerobes. *Pseudomonas* can be a prominent sinus pathogen in cystic fibrosis patients both before and after lung transplantation [18, 19]. While most cases of acute bacterial sinusitis are caused by one predominant organism, up to one quarter have two distinct pathogens present in high concentration [20]. It is important to note, however, that in routine clinical practice, the majority of patients with acute sinusitis do not have a bacterial pathogen isolated.

In the immunocompetent patients treatment of acute sinusitis is usually supportive except in cases where symptoms persist for greater than 7 days, at which point empiric antimicrobial therapy may be warranted. In severely immunocompormised transplant patients with or without neutropenia, approach has been to start treatment early when bacterial sinus infection is suspected. Complications of acute sinusitis include facial cellulitis, preseptal periorbital cellulitis, brain abscess, cavernous sinus thrombosis, and orbital invasion that may result in sight and life threatening orbital (post-septal) cellulitis [21]. Intracraneal extension should be suspected if mental status changes occur or if there are focal neurological signs [22]. CT imaging or MRI scan should be urgently obtained, and otolaryngology evaluation with endoscopy should be sought for both diagnosis (cultures and histology) and therapeutic drainage. Empiric antimicrobials should be initiated while this diagnostic evaluation is pending. In lung transplant recipients with underlying cystic fibrosis, sinus surgery can decrease recurrence of *Pseudomonas*-related sinus infections [18].

Invasive fungal sinus infections are associated with increased morbidity and mortality that may range from 50% and may beupto as high as 90% in patients undergoing solid organ allograft and allogenic hematopoietic stem cell transplantation [23]. Bony erosions can be a sign of invasive disease. There is a correlation with chronicity and invasiveness. Invasive sinus disease is often fungal although bacterial causes such as *Pseudomonas* and *S. aureus* are not uncommon. In transplant recipients, *Candida* and *Aspergillus* species remain the most common fungal organisms to cause sinusitis, resulting in invasive and noninvasive sinus disease [24]. *Rhizopus* is also an important organism associated with rapidly progressive infection with high mortality rate [21]. Even rarer fungal etiologies include *Scopulariopsis* [25], *Fusarium* [26, 27], *Trichoderma* [28], *Scedosporium* [29], and *Pseudallescheria* [30]. *Acanthamoeba* is a rare but well-described parasitic cause of invasive rhinosinusitis in immunosuppressed patients with a strong predilection for intracraneal involvement, in such patients brain infection carries high fatality [31, 32].

Bronchitis and Tracheobronchitis

The terms tracheobronchitis and acute bronchitis are frequently used interchangeably, with acute bronchitis having a preferential use in the literature with the exception of aspergillosis and ventilator-associated tracheobronchial infections [33–35]. As such, both are generally defined as a self-limited inflammation of the large airways of the lung, or bronchi, due to an infection. As opposed to pneumonia, the lower airways are not involved, and chest imaging is generally normal. Patients typically present with a cough lasting more than 5 days, an important factor distinguishing it from mild upper respiratory infection (URI) [36]. Symptoms usually persist for 10–20 days but may extend for more than 4 weeks. Most patients report purulent sputum, indicating sloughing of tracheobronchial epithelium and inflammation. As opposed to bronchiolitis, acute bronchitis does not usually present with progressive cough, wheezing, tachypnea, respiratory distress, and hypoxemia. Chronic bronchitis, on the other hand, entails continuing symptoms on most days of the month for at least 3 months of the year during two consecutive years.

Many studies have shown that community-acquired viruses are by far the most common cause of acute bronchitis [37–40]. These include influenza A and B, adenovirus, rhinovirus, coronavirus, parainfluenza, RSV, and human metapneumovirus [37–40]. Bacteria, particularly atypical organisms, can also cause acute bronchitis; commonly implicated pathogens include *Bordetella pertussis*, *Chlamydophila pneumoniae*, and *Mycoplasma pneumonia*. Among immunocompromised patients, the causative agents of acute bronchitis are largely similar to the general population [41–43]. Opportunistic pathogens can also cause tracheobronchial infections, particularly among lung transplant and allogeneic HSCT recipients. The most important of these include invasive fungal infections, especially *Aspergillus* [35, 44, 45].

Acute bronchitis affects about 5% of adults annually, with the majority of infections occurring during the fall and winter [46]. The incidence of upper respiratory tract infections among solid organ transplant and HSCT recipients appears to be similar to that of the general population [43, 47–49]. Despite similar epidemiology, immunocompromised patients often suffer from prolonged periods viral shedding and progress to pneumonia more frequently [50]. Higher rates of airflow obstruction and increased mortality are also key differences [50, 51]. Respiratory viral infections immediately prior to bone marrow transplant are associated with decreased survival [52]. Among lung transplant recipients, respiratory viral infection, particularly RSV, can be associated with progression of chronic rejection and bronchiolitis obliterans syndrome (BOS) on histopathologic examination [41, 47, 48, 53]. Patients undergoing allogeneic hematopietic stem cell transplantation similarly are at risk for BOS that potentially may have been triggered after an episode of respiratory viral infection [54].

The major procedures employed for diagnosis of upper respiratory tract infections include multiplex PCR platforms and sputum cultures. When a fungal etiology is suspected, bronchoscopy is often performed to establish microbiological diagnosis. Among lung transplant recipients, examination of the bronchial anastomosis is essential to ascertain its integrity and the presence of necrosis.

Treatment for acute bronchitis depends on the causative infectious agent [51]. For the viral organisms without an established therapy, supportive care and close monitoring is recommended. Please refer to each specific pathogen for further information on treatment.

Pneumonia

Guidelines put forth by the Infectious Diseases Society of American (IDSA) and American Thoracic Society (ATS) suggest that the diagnosis of pneumonia requires a constellation of suggestive clinical features such as fever, purulent sputum, leukocytosis, and decline in oxygen saturation, and a demonstrable infiltrate on chest radiograph or other imaging technique with or without supporting microbiological data [55, 56]. As the common clinical and radiographic manifestations of pneumonia may be absent or attenuated in immunosuppressed patients due to impaired inflammatory responses [1], the diagnosis of pneumonia may be difficult to establish in solid allograft transplant and both autologous and allogeneic HSCT recipients. Adding to this diagnostic challenge is the frequent colonization of the upper airway with microorganisms that do not contribute to lung disease, rendering the microbiological diagnosis of pneumonia by conventional culture techniques difficult. Conversely, sterile respiratory tract cultures do not exclude an infectious etiology, particularly in the setting of recent exposure to broad-spectrum antibiotics. The common use of prophylactic antimicrobials in transplant recipients may contribute to suppression of culture results while increasing the risk of infections that are resistant to commonly used antimicrobial agents given for infection prophylaxis such as fluoroquinolones, trimethoprim-sulfamethoxazole, triazole-based antifungals, and valacyclovir or valganciclovir [57–59].

As in the general population, pneumonias occurring in transplant recipients are traditionally defined based on the setting in which they are acquired, i.e., community-acquired vs. hospital-acquired. Until 2016, the IDSA and ATS designated a third category, healthcare-associated pneumonia (HCAP), to delineate patients with significant exposure to nursing homes, dialysis centers, and outpatient clinics. While this was intended to highlight this group's increased risk of multi-drug resistant pathogens, several studies have shown HCAP to be caused by organisms similar to those causing community-acquired pneumonia (CAP) [60–62]. Given that, the HCAP designation was removed from the most-recent IDSA/ATS guidelines for

the management of hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP) [56].

Community-Acquired Pneumonia

CAP, as defined by IDSA and ATS, refers to the radiographic and clinical development of pneumonia in the community setting, distinguishing it from HAP, as outlined below [55, 56]. The distinction of CAP from nosocomial pneumonia remains important as it allows for prediction of likely pathogens and permits prognostic estimations based on epidemiologic descriptions of the underlying cause. Consequently, this distinction provides a framework for decisions regarding the appropriate diagnostic evaluation and empiric antimicrobial therapy.

The etiologic spectrum of bacterial pathogens causing CAP among transplant recipients with mild-to-moderate immunosuppression is similar to that of patients without a history of transplantation. However, a clinically insignificant microbial inoculum in the general population may cause severe infection among patients with underlying immunosuppression. *S. pneumoniae* remains the most commonly identified pathogen and the most frequent cause of lethal CAP [63]. *S. aureus*, nontypeable *Haemophilus influenzae*, *Pseudomonas* spp., and other GNB may also cause life-threatening CAP. Recently, other non-lactose fermenting (NF)-GNB such as *Stenotrophomonas*, *Burkholderia*, *Chryseobacterium*, *Achromobacter*, and *Alcaligenes* species have been increasingly recognized as etiologic agents in both CAP and nosocomial infections [64]. *S. pyogenes*, *Neisseria meningitidis*, and *Moraxella catarrhalis* also cause CAP less frequently. The incidence of CAP associated with the atypical pathogens such as *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella* spp. varies widely with patient age, seasonal variation, and geographic location. Viral pneumonias, most commonly caused by influenza, parainfluenza, and adenovirus, are also sources of CAP, which may be severe in the setting of transplantation. It is important to note that lower respiratory tract infections may be due to a mixed population of viruses, bacteria, and fungi in solid organ transplant and HSCT recipients [65–70].

The microbiological diagnosis of CAP is based upon recovery of a likely pathogen from an otherwise sterile source like blood, urine, pleural fluid, isolation of a noncommensal organism in respiratory secretions, or positive results of selected serological tests. Although the utility of Gram staining and culture of expectorated sputum in the diagnosis of pneumonia has been debated for years, carefully procured sputum specimens with cytologic confirmation of a lower respiratory source appear to be diagnostically useful, particularly if they are obtained before the initiation of antimicrobial therapy. Timely establishment of an accurate diagnosis contributes to a successful outcome, although treatment should not be withheld while diagnostic interventions are underway. Antimicrobial selection should be based upon the probable infecting organism(s), the severity of the patient's pneumonia, the patient's underlying immune status, and the presence or absence of comorbid conditions [71, 72].

Hospital-Acquired Pneumonia

Lower respiratory tract infections that occur more than 48 h after hospital admission in patients without antecedent clinical symptoms or radiographic findings suggestive of pneumonia are referred to as HAP. The etiological spectrum of microbial pathogens causing HAP among low-risk transplant recipients with no recent antibiotic exposure is similar as that seen in the general population. *H. influenzae*, *S. pneumoniae*, *S. aureus*, and *Enterobacteriaceae* are frequently encountered. Methicillin-resistant *S. aureus* (MRSA) may cause severe HAP, especially among patients with prior MRSA colonization, antibiotic exposure, advanced age, and/or prolonged ventilatory support [73]. Protracted mechanical ventilation and recent antibiotic administration are also associated with increased rates of HAP caused by *P. aeruginosa*, *Acinetobacter baumannii* complex, *Enterobacter* spp., and emerging strains of MDR NF-GNB such as *S. maltophilia*, *Burkholderia cepacia* complex, and *Alcaligenes* (*Achromobacter*) species, which may be difficult to treat. Mortality rates associated with HAP due to MRSA or *P. aeruginosa* are disproportionately higher than those caused by other nosocomial bacterial pathogens [74].

Polymicrobial isolates and MDR pathogens are more common among patients with HAP, particularly when it occurs as a late complication during hospitalization. Because of the frequency with which multiple organisms are identified on a single respiratory sample, recent evidence-based guidelines advocate the use of quantitative or semiquantitative lower respiratory tract cultures obtained either bronchoscopically or noninvasively as part of the initial evaluation of the patients with suspected HAP or VAP [75].

Empiric antibiotic selections for HAP that develop within 7 days of admission should target *S. pneumoniae*, *S. aureus* including MRSA, *Streptococcus* spp., *H. influenzae*, and Enterobacteriaceae. Patients with late HAP occurring >1 week after hospitalization should receive empiric antimicrobial therapy that includes coverage for MDR-GNB. The scope of alternative antimicrobial choices in patients with refractory or slow-to-respond HAP or VAP should be based on institution-dependent susceptibility profiles. If an institution's incidence of MRSA pneumonia is low and respiratory cultures are unavailable or unrevealing, screening for MRSA nasal colonization may be useful in guiding therapy [76]. As the absence of MRSA nasal colonization has a high negative predictive value for MRSA pneumonia, coverage for that organism can often be discontinued early in the treatment course if screening swabs are negative [76].

Pneumonias Caused by Aspiration and Bronchial Obstruction

Aspiration of orogastric contents and mechanical obstruction of the airways may create a favorable milieu for pneumonia caused by microaerophilic or anaerobic bacteria like *Peptostreptococcus* spp. A variety of factors, such as abnormal swallow function, altered cough reflex, impaired mucociliary clearance, altered mental status, the use of sedating medications, chemotherapy-induced mucositis, supine positioning, gastroparesis, mechanical ventilation, and nasogastric tube feeding, all contribute to the increased predilection for aspiration in patients with histories of transplantation or malignancy [77–79]. Pneumonia associated with large-volume aspiration of gastric contents typically occurs as a late finding. The acidic gastric contents act as a poor medium for bacterial growth. Thus, the initial clinical syndrome following aspiration of gastric contents arises from the direct caustic effect of the acidic aspirate on the cells of the alveolar-capillary interface, i.e., chemical pneumonitis. A true bacterial pneumonia, if it occurs, is consequently a superimposed process. Aspiration of oral contents, by contrast, results from inhalation of nonsterile oropharyngeal material. The clinical presentation is often insidious, and the diagnosis is commonly inferred based on a compatible patient risk profile coupled with radiographic evidence of pneumonia.

Chest radiographs may show focal abnormalities that correlate with the patient's position at the time of aspiration. For example, aspiration that occurs while the patient is in the upright position typically localizes to the basilar segments of the lower lobes, whereas the superior segments of the lower lobes and posterior segments of the upper lobes are more frequently affected following aspiration that occurs in the supine position. The major pathogens underlying nosocomial versus community-acquired aspiration pneumonias differ although a microbiologic diagnosis may not be established due to the limited yield of conventional anaerobic cultures [78, 80–82]. If necessary, such cultures may be best obtained bronchoscopically using a protected strategy.

The management of patients with significant lung injury associated with the aspiration of gastric contents includes aggressive supportive care. Upper airway suctioning, pulmonary toilet, and, if necessary, positive pressure ventilation comprise the mainstays of therapy. There is no clearly established role for corticosteroids in this setting, though the practice of prescribing moderate- to high-dose prednisolone is not uncommon. Early and aggressive antimicrobial therapy is recommended for patients with pneumonia secondary to aspiration of oropharyngeal contents. Antimicrobial selections should be tailored to the immune status of the patient and setting in which the aspiration occurred, i.e., community vs. healthcare environment but in general should be broad in spectrum and target Gram-negative organisms and oral anaerobes. Anaerobic coverage may be particularly important in patients with periodontal disease, putrid sputum, or evidence of necrotizing pneumonia [78].

Other Sources of Pneumonia

Transplant recipients with altered pulmonary anatomy specifically lung transplant recipients with bronchial anastomotic strictures may be at risk for obstruction of the airways, atelectasis, and postobstructive pneumonia. The associated pneumonias tend to be polymicrobial in nature including GNB, staphylococci, and anaerobes and may require relief of the obstruction to achieve adequate antimicrobial effects, even if appropriate antibiotics are selected. This is often most rapidly achieved through interventional bronchoscopic techniques such as bronchial dilation with or without stent placement.

The lungs may also become infected via septic emboli arising from suppurative endovascular bacterial and, less commonly, fungal infections. Infected intravascular septic deep venous thrombi are increasingly recognized as a potential source of infection in immunosuppressed patients. The radiographic pattern in these patients is distinctive and includes multicentric, pleomorphic lung nodules with asymmetric, relatively small, thick-walled cavities.

Specific Pathogens

Opportunistic organisms commonly implicated in transplant-related respiratory tract infections are outlined below.

Nocardia and Actinomycosis

Over 30 species of *Nocardia* have been associated with human disease [83]. *Nocardia asteroides* complex, including *N. asteroides* sensu stricto and *N. farcinica*, accounts for nearly 90% of *Nocardia* infections, both in cancer patients and the general population. Risk factors for *Nocardia* pneumonia include profound deficiencies in cellular immunity, prolonged use of high-dose systemic corticosteroids, especially in the treatment of chronic lung diseases [84], and the presence of GVHD. Solid organ transplant recipients are also at particular risk for *Nocardia* infections although this varies based upon the organ transplanted. One review demonstrated infection rates of 3.5%, 2.5%, 1.3%, 0.2%, and 0.1% among recipients of the lungs, hearts, intestines, livers, and kidneys, respectively [85]. *Nocardia* infections commonly occur within the 1st year of transplantation although early (<1 month) and late (>2 years) infections have also been reported [85–87]. Infection with the organism should be considered if nodular pulmonary infiltrates are seen, although reticulonodular or diffuse infiltrates are occasionally described. Solitary nodules associated with irregular, thick-walled cavities that mimic invasive pulmonary aspergillosis, histoplasmosis, necrotizing cancer, or chronic bacterial lung abscess have also been associated with *Nocardia* infection.

Indolent *Nocardia* pneumonia may be clinically indistinguishable from other actinomycetes infections and from pneumonias caused by pulmonary eumycetes. Severely immunosuppressed cancer patients with refractory leukemia or prior allogenic HSCT may present with rapidly progressive multifocal nocardiosis. Spontaneous pneumothorax and hemoptysis are also recognized presentations of *Nocardia* infection among immunocompromised patients. Concomitant brain involvement is not uncommon, and preemptive evaluation is recommended to diagnose asymptomatic brain abscess in patients with pulmonary *Nocardia* infection. Trimethoprim-sulfamethoxazole (10–12 mg/kg daily) is effective against many *Nocardia* species. Retrospective studies suggest that clinical outcomes are improved when appropriate therapy is given for an extended period of time (6–12 months) [88]. Despite aggressive antimicrobial therapy, pulmonary nocardiosis carries a high mortality in immunosuppressed individuals [84]. Pulmonary actinomycosis typically presents in a very similar manner to nocardiosis, although it is classically associated with invasion across tissue plans. As such, pulmonary infection may involve the adjoining pleura and subsequently erode through the chest wall. Isolation of Actinomycetes from the respiratory tract should be evaluated critically as their presence may represent oropharyngeal contamination.

Tuberculosis

Mycobacterium tuberculosis is a rare cause of pulmonary infections in the developed world but is important to consider in severely immunosuppressed patients, especially foreign-born individuals or patients undergoing allograft solid organ or stem cell translantation in the developing countries where tuberculosis is regarded as an endemic disease [89]. Solid organ transplant recipients are estimated to have 20–74 times higher incidence of active tuberculosis than that of the general population [90]. Frequency of disease varies based upon the organ transplanted and the time from transplantation, with two-thirds of cases occurring within 1 year of transplantation [91].

A broad range of clinical manifestations may be possible with tuberculosis infection. Pulmonary tuberculosis may present as an insidious pneumonia that is difficult to distinguish from Actinomycetes and eumycetes infection. Patients with impaired T-cell response may develop rapidly progressive tuberculosis that follows the course of a virulent bacterial infection. Systemic corticosteroid therapy is an independent predictor of both tuberculosis reactivation and suboptimal response to combination antimicrobial therapy. Hence, once the diagnosis of tuberculosis is established, every effort should be made to discontinue steroid therapy if not indicated for a specific syndrome [89]. Just as HIV-infected patients may develop clinical worsening of tuberculosis pneumonia when initiating antiretroviral therapy such as immune reconstitution inflammatory syndrome, tuberculosis-related lung disease in solid organ transplant or HSCT recipients may infrequently worsen as immune function recovers following temporary discontinuation or partial withdrawal of antirejection or anti-GVHD therapy. Nonetheless, minimizing immunosuppression may be helpful in clearing such infections.

Nontuberculous Mycobacteria

Nontuberculous mycobacteria (NTM) are ubiquitous in the environment and generally cause infection only in hosts with specific anatomical or immunological defects [92]. Transplant recipients are at particular risk due to their impaired cell-mediated immunity. Among patients with structural lung disease particularly those before and after lung transplantation, this risk is further compounded by anatomical abnormalities. Epidemiological data are somewhat lacking for these pathogens as NTM infections are not reportable infections [92]. Incidence rates for NTM pulmonary infections are estimated at 0.24–2.8% among heart transplant recipients and 0.46–8.0% among lung transplant recipients [93–95].

Pulmonary NTM infections are classically caused by *M. avium-intracellulare* complex and other slow-growing mycobacteria. These opportunistic pathogens are most frequently associated with chronic, indolent pneumonias. In the United States, the rapidly growing mycobacteria particularly *M. abscessus* and *M. fortuitum* have emerged as another important, albeit less frequent cause of NTM lung disease. The diagnosis of pulmonary NTM infections remains a challenge as identification of these organisms in respiratory cultures may result from colonization of the respiratory tract or environmental contamination. Causality is suggested by identification of NTM in sterile lower respiratory tract specimens coupled with corresponding clinical manifestations such as chronic nonproductive cough and exertional dyspnea and a NTM lung disease compatible radiographic presentation. Fever, night sweats, weight loss, pleuritic chest pain, and pleural effusions are also possible but less frequent in the absence of systemic disseminated infection.

Radiographic features of NTM infection include upper lobe predominant nonspecific nodular lesions and small, thin-walled cavities. Chest CT findings demonstrating the characteristic “tree-in-bud” appearance may also be seen in patients with other chronic infections. The so-called Lady Windermere syndrome, characterized by relapsing or refractory pulmonary NTM infection due to slow-growing mycobacteria, may be seen in patients with defects in endogenous interferon-gamma cellular immune response [96]. NTM pulmonary infections are usually insidious, although rapidly progressive disease has been seen in patients with profound defects in helper T-cells. Treatment should include at least two antimicrobial agents to which the *Mycobacterium* is susceptible.

Pneumocystis jirovecii

Similar to NTM, *P. jirovecii* previously known as *P. carinii* is thought to be ubiquitous in the environment and only causes infection in the setting of impaired immunity. Classically described in HIV-positive individuals with pronounced CD4 lymphocytopenia, *Pneumocystis* is an important pathogen in solid organ transplant recipients [97]. In most immunosuppressed patients, *Pneumocystis* pneumonia presents as a slowly progressive infection accompanied by nonproductive cough, exertional dyspnea, and hypoxemia, although an acute, rapidly progressive form has been described. CT evidence of perihilar infiltrates may be mistaken for pneumonitis caused by common acquired viral infections such as RSV, influenza, parainfluenza, or CMV during the early phase of the infection. Bronchoalveolar lavage typically has a high diagnostic yield either through silver staining or through PCR amplification. High-dose trimethoprim-sulfamethoxazole (15–20 mg/kg daily) given for 21 days is the treatment of choice. Adjuvant systemic corticosteroids should be administered to most patients with severe hypoxemia. Oral atovaquone, primaquine plus clindamycin, and parenteral pentamidine may be given to patients who are intolerant of sulfa-containing regimens.

Invasive Fungal Pneumonia

Invasive pulmonary aspergillosis (IPA) is a relatively common cause of pneumonia in patients undergoing allogeneic HSCT and severely immunosuppressed patients following high-risk solid organ allograft transplantation [98]. Among cancer patients, risk factors for invasive pulmonary aspergillosis include prolonged (>1 week) and severe (<100 cells/μL) neutropenia, refractory leukemia, allogeneic HSCT, GVHD, immunosuppressive therapy, and treatment with high-dose systemic corticosteroids [99, 100]. Among solid organ transplant recipients, risk factors vary based upon the organ transplanted but often include renal failure, reoperation/retransplantation, and CMV infection [101]. *Aspergillus fumigatus* is most commonly encountered, although non-*fumigatus Aspergillus* species are increasingly recognized. Similarly, a marked increase in pulmonary invasive fungal infections due to non-*Aspergillus* molds including *Fusarium*, *Pseudallescheria boydii*, and *Scedosporium* spp. and the dematiaceous (black) molds has also been noted, making the selection of an effective empiric regimen more challenging. The increased incidence of pulmonary mucormycosis may be related to changes in antifungal utilization with a shift away from amphotericin B compounds in favor of mold-active triazole drugs like voriconazole [102]. The effects of newer triazole agents like posaconazole and isavuconazonium on the overall feasibility, efficacy and safety in magagement of fungal pneumonia in transplant recipients is evolving and appears encouraging.

While the clinical symptoms of fungal pneumonia may be similar to those seen in bacterial pneumonia, CT imaging may reveal a highly suggestive "halo sign" during the early course of infection and/or less often observed "crescent sign" that becomes apparent during the later course of IPA. Despite this, in most cases of pulmonary mycosis, the only radiographic findings at the time of presentation are peripheral, pleural-based lung nodules, sometimes with thick-walled regular or irregular cavities [103]. The definitive diagnosis of pulmonary invasive fungal infection requires demonstration of fungal hyphae within the involved lung tissue. Therefore, the clinical diagnosis is often made by inference as high prevalence of thrombocytopenia and coagulopathies in transplant recipients render lung biopsies unsafe. It is important to note that isolation of fungi in respiratory samples may misrepresent the etiology of underlying pulmonary infiltrates as they may reflect environmental contamination or respiratory tract colonization.

The measurement of fungal antigens such as serum galactomannan, bronchoalveolar lavage galactomannan, and serum beta-D-glucan can aid in the detection of invasive pulmonary mycosis. Newer assays, including sequence-based nucleic acid amplification techniques, may further alter the diagnostic strategies used for invasive fungal infection in the future. Therapeutic strategies for these infections are discussed elsewhere.

Viruses

As previously noted, respiratory viruses including RSV, influenza A and B, parainfluenza, and adenovirus are common causes of upper respiratory tract infections that may have lower respiratory tract manifestations in immunosuppressed patients. Human metapneumovirus (hMPV) is also recognized as a serious pulmonary pathogen in this population. The spectrum of hMPV disease may range from mild upper respiratory tract infection to serious disseminated infection leading to respiratory failure and encephalitis. Herpesviruses, particularly CMV, are also important causes of pneumonitis in transplant recipients. As invasive CMV disease often affects the transplanted allograft, lung transplant recipients are at particularly high risk of CMV pneumonitis [104]. The virus itself is immunomodulatory in nature, and CMV has been associated with bacterial and fungal superinfections as well as lymphoproliferative disorders [105, 106].

Fever and nonproductive cough are prominent but nonspecific features of viral respiratory tract infection. In patients with extensive lung involvement, dyspnea may appear early in the course of infection. Viral nucleic acids in nasal washes, tracheal aspirates, and bronchial specimens are most frequently used in diagnosing viral respiratory infections through multiplex PCR platforms. Despite that,

the isolation of CMV especially by PCR amplification from lower respiratory tract secretions may not necessarily indicate CMV lung infection as even in transplant recipients with severe cellular immune defects; intermittent low-level viral replication and shed virus without developing viral lung disease has been well established. Hosts' risk assessment and CMV disease susceptibility evaluation along with radiographic imaging such as non-iv-contrast chest CT scan prove helpful in discerning active viral lung disease versus non-disease associated CMV respiratory tract viral shedding. Of note, chest CT scans may show ground glass opacities even when conventional chest radiographs are unremarkable, improving the sensitivity of diagnosis. Ganciclovir or foscarnet are commonly prescribed for systemic CMV infections. In transplant recipients with CMV pneumonitis, IVIG immune modulation along with effective antiviral drug if recommended. A detailed discussion is provided regarding specific pathogens and approach towards therapeutic management of lung infections in chapters throughout this book.

Respiratory Tract Diseases That May Be Mistaken for Infection

21

Robert M. Kotloff, Burton F. Dickey, and Nicholas Vander Els

Introduction

The prevention, diagnosis, and treatment of pneumonia are critical to outcomes among transplantation patients. The diagnosis of pneumonia is usually considered when a new radiographic infiltrate is identified. Rarely, pneumonia may present initially without infiltrates in an immunocompromised host. However, even in severely immunosuppressed patients, infectious microbes cause inflammation through innate immune mechanisms that lead to tissue edema which is evident radiographically. The occurrence of pneumonia that is not apparent when a CT scan is included in the assessment is sufficiently rare that it will not be further considered here. Instead, we begin with an abnormal imaging study of the lungs, which is typically obtained during the workup of a symptom or sign such as cough, fever, or chills. The differential diagnosis of a lung infiltrate in a transplantation patient includes several common non-infectious causes. Failure to accurately diagnose non-infectious causes of lung infiltrates can lead to unnecessary treatment with antibiotics, and more importantly to failure to address the underlying pathophysiologic process. This chapter is focused on clinical presentations of pulmonary disorders that mimic infectious pneumonia.

Hematopoietic Stem Cell Transplantation (HSCT)

Despite advances in treatment regimens and supportive care, pulmonary complications still occur in up to 60% of HSCT recipients [1]. These complications are mostly due to toxicities from conditioning regimens, delayed bone marrow recovery, prolonged immunosuppressive therapy, and graft-versus-host disease (GVHD). As the incidence of infectious pulmonary complications has diminished, largely due to effective prophylactic therapy, non-infectious pulmonary complications have emerged as a major cause of morbidity and mortality [2]. Pulmonary complications have been divided into those that occur "early" (during the first 100 days after transplantation) and those that occur "late," but this is not a rigid division. In particular, some "late" complications such as cryptogenic organizing pneumonia and constrictive bronchiolitis occur with substantial frequency during the first 100 days.

Pulmonary Edema

Cardiogenic (hydrostatic) pulmonary edema occurs with regularity in transplant patients due to the large volumes of fluid administered with chemotherapy and antibiotics, chemotherapy-induced cardiotoxicity, and co-morbidities (e.g., renal insufficiency) [3]. The classic presentation of cardiogenic pulmonary edema, consisting of acute, bilateral, symmetrical, perihilar infiltrates with interstitial thickening, an enlarged heart, and pleural effusions in a patient with pre-existing heart disease and associated findings of peripheral edema and bibasilar rales, is easy to recognize. However, cardiogenic pulmonary edema may also be the cause of asymmetrical infiltrates in a patient with underlying lung disease, such as bullous emphysema, that precludes alveolar filling in localized regions (see Fig. 21.1). An enlarged heart may not be present on the radiograph if cardiac dysfunction is not longstanding, so that the heart has not had time to

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_21

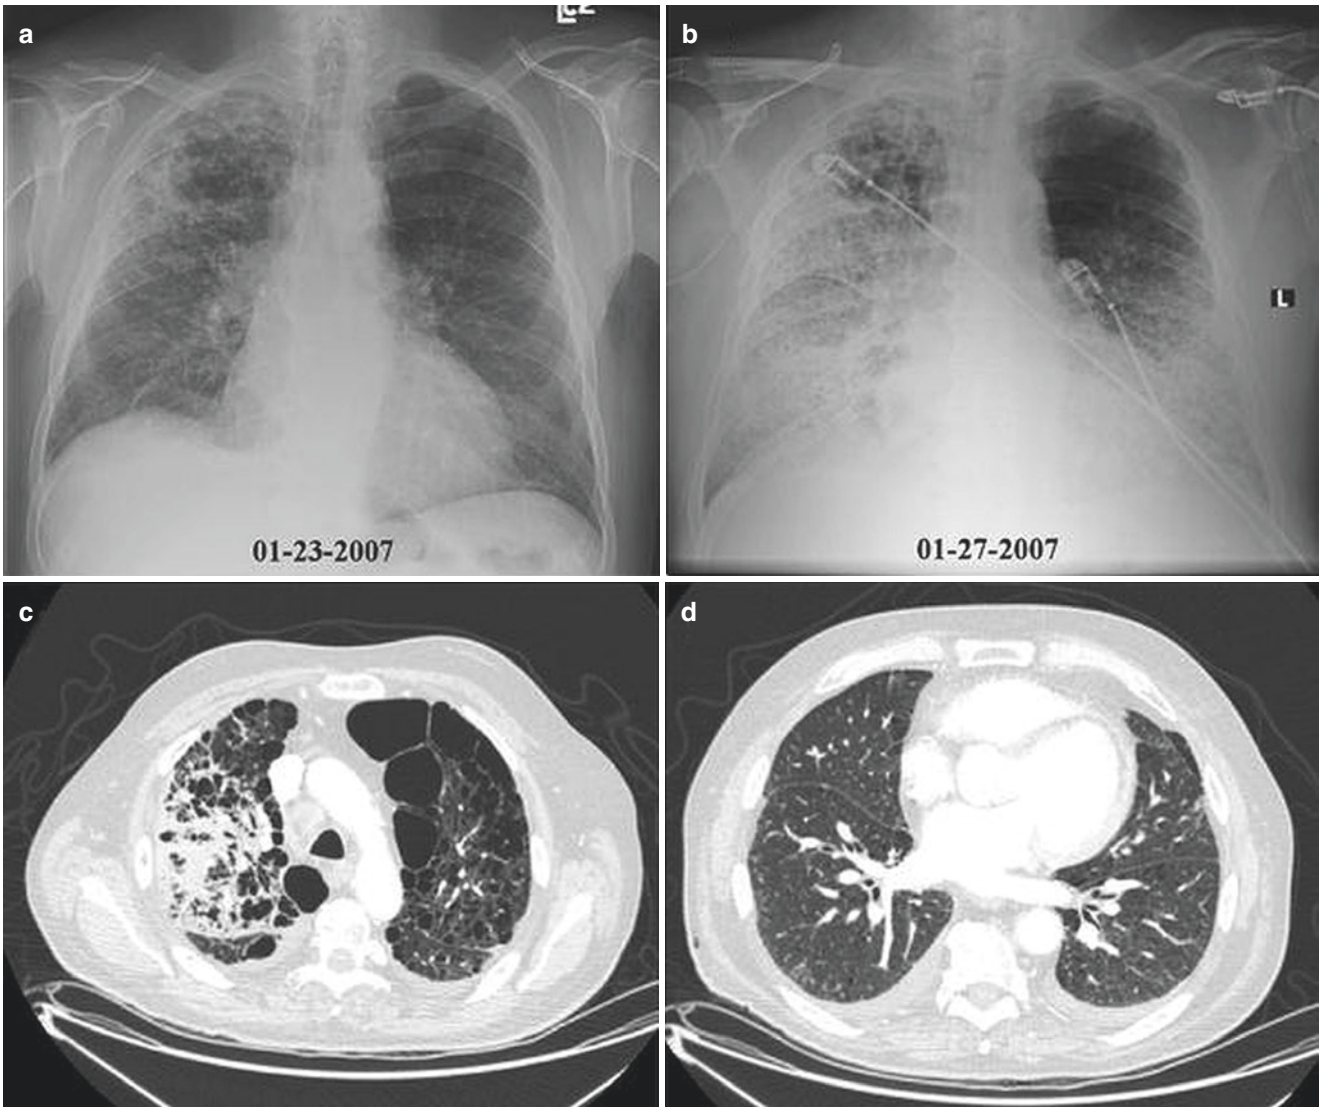

Fig. 21.1 Atypical presentation of congestive heart failure. A 68-year-old male was receiving radiation therapy to a squamous cell carcinoma of the upper lobe of the right lung. He had received 19 of 37 planned fractions, when he was admitted because of increasing dyspnea and cough, presumed to be pneumonia. (**a**) The PA radiograph in the left upper corner shows the right upper lobe with associated radiation pneumonitis. (**b**) The AP radiograph in the right upper corner taken 4 days later shows lung infiltrates that spare the left upper lobe. (**c**) However, the CT angiogram on the lower panel performed on the day of admission 01-24-2007 shows that the left upper chest is mostly occupied by emphysematous bullae, accounting for the sparing of the left upper lung field when pulmonary edema developed. (**d**) The remainder of the lung fields contain ground-glass opacities suggestive of *congestive heart failure*. The diagnosis of congestive heart failure was supported by the patient's history of prior episodes of pulmonary edema, bilateral ankle edema, a depressed left ventricular ejection fraction of 30–35%, moderate mitral regurgitation, elevated BNP of 1043, transudative pleural effusion, and improvement with diuresis [8]. (Reprinted from Kaplan et al. [8], with permission of Springer)

remodel (e.g., acute volume overload or diastolic dysfunction secondary to acute ischemia). In these cases, additional studies can be very helpful in establishing the diagnosis [4–6]. CT of the chest may show the diffuse nature of alveolar infiltrates and pleural effusions that are less apparent on plain films, and may additionally reveal interstitial edema and cardiac chamber enlargement. Review of serial radiographs may show infiltrates that wax and wane in association with variations in patient weight, peripheral edema, or fluid administration. Echocardiography is very supportive when it reveals systolic dysfunction, but it is important to recognize that diastolic dysfunction is an equally prevalent cause of heart failure [7], potentially exacerbated by rhythm disturbances such as atrial fibrillation, valvular dysfunction, or transient ventricular wall stiffening due to ischemia. Brain natriuretic peptide (BNP) levels are quite specific and sensitive but are less elevated in diastolic than in systolic dysfunction [7].

Non-cardiogenic pulmonary edema due to increased permeability of the alveolocapillary membrane (acute lung injury and adult respiratory distress syndrome (ARDS)) can occur as a result of a wide variety of causes in transplant patients. Sepsis is the most common cause of permeability edema of the lungs in general [6, 9, 10] and can cause radiographic infiltrates in transplant patients. In addition, transplant patients are susceptible to lung injury from causes unique to this population, such as from chemotherapy or the effects of acute GVHD. Transplant patients are also frequently exposed to treatments associated with lung injury in the general hospital population, such as transfusion. Transfusion-related acute lung injury (TRALI) is the leading cause of mortality from transfusions [11] and has been associated with all plasma-containing blood products, including immunoglobulins. The incidence of TRALI is not known, but has been estimated at 0.02% per unit transfused and 0.16% per patient transfused [12]. Patients with TRALI commonly present with dyspnea, cough, fever, acute hypoxemia hypotension, and bilateral pulmonary infiltrates within 1–6 h after the transfusion. Transient leukopenia, due to pulmonary sequestration of the circulating pool of leukocytes, may be observed. The mainstay of treatment for TRALI is to discontinue the transfusion, followed by supportive care. Although there has never been a randomized controlled trial of glucocorticoid therapy, they have no effect on the 5–8% mortality. With supportive treatment, infiltrates usually resolve, within 96 h, and survivors have no long-term sequelae [13].

Engraftment Syndrome (ES)

ES is characterized by a constellation of symptoms and signs including fever, erythrodermatous skin rash, diarrhea, and non-cardiogenic pulmonary edema with bilateral pulmonary infiltrates, which generally occur within 5 days of neutrophil engraftment following HSCT. In more severe cases, systemic involvement, i.e., renal failure, hepatic failure, encephalopathy, or seizures, may be observed. Seen most often following autologous HSCT, ES has also been described in those individuals who have undergone allogeneic HSCT with a nonmyeloablative preparative therapy. Although the pathophysiology of ES is not well understood, it is thought to result from a combination of endothelial injury due to preconditioning chemotherapy and the production and release of cytokines and products of neutrophil degranulation and oxidative metabolism, leading to capillary leak, with either local injury in the lung or systemic tissue injury [14]. Bronchoalveolar lavage (BAL) may show a neutrophilic alveolitis. Surgical lung biopsies, when obtained, often reveal diffuse alveolar damage. Treatment entails observation and supportive care (i.e., antibiotics, intravenous fluids) in mild cases. High-dose corticosteroid therapy is very effective, often resulting in rapid clinical improvement in those with progressive or symptomatic ES. Respiratory failure requiring mechanical ventilation has been observed, however, in up to one-third of patients [15].

Idiopathic Pneumonia Syndrome (IPS)

In 1993, a panel convened by the NIH proposed a broad working definition of IPS as widespread non-lobar radiographic infiltrates in the absence of congestive heart failure or evidence of lower respiratory tract infection [16]. IPS occurs in 10% of HSCT recipients, usually 14–90 days following transplantation. Mortality rates range from 50% to 70% [17]. Possible etiologies of IPS include direct toxic effects of the chemoradiation conditioning regimen, occult infection, and/or the release of inflammatory cytokines secondary to some as yet unknown inciting stimuli. The association of IPS with the presence of acute GVHD after allogeneic HSCT suggests that alloreactive T cells may be at least one of these stimuli [17, 18].

The clinical presentation is non-specific, with symptoms of dyspnea, cough, and fever associated with diffuse infiltrates on chest radiograph. The diagnosis of IPS largely relies on the exclusion of infection on lower respiratory samples obtained from a diagnostic procedure, e.g., BAL or lung biopsy. Common pathologic findings of non-specific interstitial pneumonitis (NSIP) and/or diffuse alveolar damage (DAD) may be seen. Although no randomized controlled trials of treatment for IPS are available, current standards include high-dose intravenous corticosteroids and supportive care, such as supplemental oxygen and broad-spectrum antibiotics. Recent preclinical and clinical data suggest a potential role for tumor necrosis factor-α (TNF-α) in the pathogenesis of IPS [19–21], and a randomized trial using etanercept, a TNF receptor fusion protein, is being conducted by the Blood and Marrow Transplant Clinical Trials Network.

This same Network has included diffuse alveolar hemorrhage (DAH) within the definition of IPS, and we know of no reason to separate the two. Post-transplantation DAH was initially described in autologous HSCT recipients as widespread lung injury manifested by diffuse radiographic infiltrates that occurred in the absence of identifiable infection. DAH is now known to occur in both allogeneic and autologous transplant recipients and is seen in approximately 5% of all HSCT [22]. The etiology is unclear, but is not clearly related to any specific coagulopathy or to thrombocytopenia [23]. Pre-transplant high-dose chemotherapy, thoracic and/or total body irradiation, and undocumented infections are putative factors which may cause the initial injury, priming the lung for subsequent development of DAH. It can coincide with stem cell engraftment, but late onset (after the first 30 days) has been observed and is associated with a worse prognosis. Hemoptysis occurs in less than 20% of patients.

Bronchoscopic diagnostic criteria include progressively bloodier returns on BAL or the presence of 20% or more hemosiderin-laden macrophages on cytologic inspection of BAL fluid. However, these bronchoscopic criteria may be seen in association with diffuse lung injury from a wide variety of causes, including infections, congestive heart failure, and malignancy. There are no prospective randomized trials addressing the treatment of DAH. Earlier retrospective studies demonstrated reduced need for mechanical ventilation and mortality in a cohort of patients receiving high-dose corticosteroids, but more recent observational studies found no survival benefit [24, 25].

Drug-Induced Lung Injury (DILI)

DILI may present with dyspnea, fever, and pulmonary infiltrates, clinically indistinguishable from a pneumonia [26]. DILI may present at the time of transplantation as a consequence of chemotherapy administered for treatment of an underlying cancer or after transplantation as a consequence of chemotherapy administered as part of the conditioning regimen, or given as prophylaxis of GVHD. Agents of concern are listed in Table 21.1. Symptoms vary with the severity of injury; fever can be absent, and patients may have only dyspnea on exertion or be asymptomatic. In such patients, diffuse infiltrates seen on radiographs or abnormalities on pulmonary function testing may be the only signs of lung injury. There is no pathognomonic finding unique for DILI, and the diagnosis is one of exclusion [27]. Given the severe immune compromise of HSCT patients, bronchoscopy to exclude infection is indicated for most patients with new diffuse infiltrates.

Lung injury may occur either from a drug's cytotoxic mechanism or from its presence as an antigen. The histologic and radiographic patterns produced vary and include Usual Interstitial Pneumonitis (UIP)/fibrosis, hypersensitivity pneumonitis, and acute lung injury (ALI)/ARDS. Bleomycin produces lung injury both by cytotoxic action and as an antigen. It is used primarily to treat Hodgkin's disease and forms a moiety with ferrous ions that induces oxidative injury to tumor cells [28]. Human lungs and skin lack an enzyme, bleomycin hydrolase, which limits injury to other tissues. A UIP/fibrosis pathology is produced, with peripheral and basal infiltrates [29]. (See Fig. 21.2.) Exposure to supplemental oxygen can exacerbate this form of toxicity, by potentiating oxidative injury. As an antibiotic, bleomycin can cause hypersensitivity pneumonitis, with high fevers and acute infiltrates. This presentation tends to be responsive to steroid therapy [28–30]. Methotrexate also produces hypersensitivity pneumonitis. It is used both for the treatment of lymphoma and for prophylaxis against GVHD after HSCT. In contrast to bleomycin, the hypersensitivity from methotrexate can be accompanied by peripheral eosinophilia and thoracic adenopathy [31, 32]. Granulomas are seen on biopsy, and the toxicity is responsive to steroid therapy [31]. The substituted nucleoside fludarabine may also produce granulomatous disease, as well as eosinophilic pneumonia [33, 34]. Etoposide is rarely toxic but can produce a severe hypersensitivity reaction with symptoms of angioedema or ARDS [35, 36]. Etoposide use is common in HSCT, as a component of the ICE

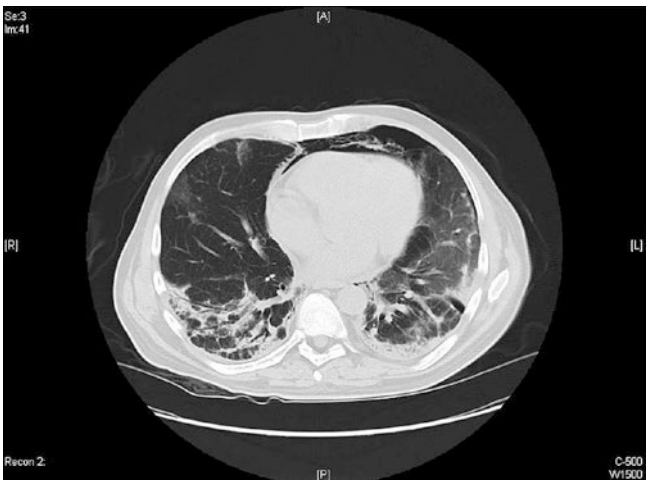

Fig. 21.2 Severe bleomycin toxicity, UIP presentation. Note peripheral and basal pattern of infiltration, as well as spontaneous pneumothorax seen anteriorly

Table 21.1 Chemotherapeutic agents characterized by class, indication, and pulmonary toxicity

Agent	Class	Indication	Pulmonary toxicity
Anti-thymocyte globulin	Monoclonal antibody	Induction agent	ALI/ARDS
Bleomycin	Antibiotic	Lymphoma	IP/H/OP
Busulfan	Alkylating agent	Induction agent	IP/pleural effusion
Carmustine/BCNU	Nitrosourea	Induction agent	IP/fibrosis
Cyclophosphamide	Alkylating agent	Induction/lymphoma	IP/pleuritis
Cytarabine	Substituted nucleoside	AML	Capillary leak
Etoposide	Anti-podophyllotoxin	Induction agent/lymphoma	ALI/ARDS
Fludarabine	Substituted nucleoside	CLL/induction	EP/H
Melphalan	Alkylating agent	Induction agent	IP
Methotrexate	Antimetabolite	Induction/GVHD	H/pleuritis/adenopathy
Sirolimus	mTOR inhibitor	GVHD	IP

Abbreviations: ALI acute lung injury, *EP* eosinophilic pneumonia, *H* hypersensitivity, *IP* interstitial pneumonitis, *OP* organizing pneumonia

(ifosfamide, cisplatin, and etoposide) regimen, as a "salvage" regimen for lymphoma, and also as an induction agent [37, 38]. Cytarabine, commonly used to treat acute myeloid leukemia (AML), may cause non-cardiogenic pulmonary edema. This is usually responsive to steroid therapy and is resolved prior to transplant [39]. Dasatinib is a tyrosine kinase inhibitor useful in the treatment of CML. In addition to producing pleural effusions, ground-glass opacities can be seen as well as alveolar septal thickening [40].

HSCT patients receive high-dose chemotherapy as an induction regimen to eliminate marrow cells and prevent rejection of the graft. Following transplantation, immunosuppressive agents to prevent GVHD are prescribed for patients who received allogeneic grafts. Anti-thymocyte globulin is an antibody derived from rabbit or equine serum that can produce interstitial infiltrates and progress to ARDS [41, 42]. The mechanism of lung injury is not clear. As ATG is an anti-leukocyte antibody, the pathogenesis may be similar to that of transfusion-related lung injury (TRALI), or it may stem from its presence as a foreign protein [41, 42]. BCNU may produce DILI within 6 weeks of administration or as late as 20 years after administration to treat pediatric cancers [43, 44]. It presents with diffuse infiltrates and dyspnea, generally without fever, and is irregularly responsive to steroid therapy. The alkylating agents busulfan, melphalan, and cyclophosphamide can all produce a UIP/fibrosing pattern of injury [27]. Busulfan was the first cytotoxic agent described to produce lung injury more than 50 years ago [45]. In one series, the incidence of toxicity was 46% [46]. Today, it is only used as an induction agent for HSCT. Melphalan is well-tolerated at standard doses but given at the high doses used for induction can produce a DIP-like presentation [47]. Cyclophosphamide, used to treat lymphoma and for induction, can produce an early-onset pneumonitis, within 1–6 months of administration, which may be responsive to cessation of the drug or steroid therapy [48]. It can also produce fibrosis and pleural thickening that can chronically progress despite cessation. Rituximab, which is a B-cell-depleting monoclonal antibody, is used to treat lymphomas and rheumatologic ailments. It can be used for induction as well. Symptoms may appear as early as 30 days or as late as 5 months. It rarely causes interstitial lung disease, with only 121 cases reported to date; however, 15% of the cases were fatal [49]. Sirolimus, temsirolimus, and everolimus are mTOR inhibitors used for prevention of GVHD and for treatment of renal and other cancers [50, 51]. The mTOR inhibitors can all cause pneumonitis and are discussed in the subsequent section on solid organ transplantation.

Radiation-Induced Lung Injury

As with DILI, lung injury can be a consequence of radiation administered for control of a tumor prior to transplantation or for radiation administered as part of an induction regimen for HSCT. The symptoms and radiographic findings are a consequence of both radiation injury per se to pulmonary parenchyma and the host immunologic response to the injury. Bilateral lymphocytic alveolitis is seen after radiation is administered to only one lung [52, 53]. Roberts et al. performed bilateral BAL on 17 patients receiving radiation therapy for breast cancer, and bilateral lymphocytic alveolitis was seen even in the 15 asymptomatic patients [52]. This type presentation can be appreciated as part of the natural course of radiation-induced lung injury in the young patient shown in Fig. 21.3. Three months earlier, he had received a hilar "boost" of radiation therapy prior to an HSCT for Hodgkin's disease. Low-grade fevers and increased interstitial markings (Fig. 21.3a, b) evolved over weeks into the dramatic infiltrate seen in Fig. 21.3c. By the time of the final radiograph, fevers had resolved and no steroids were prescribed. In general, radiation lung injury may be treated as a self-limited process, with steroid therapy reserved for patients who are febrile or hypoxic.

Total body irradiation (TBI) administered for induction is associated with acute pulmonary toxicity. Among 101 patients undergoing HSCT with TBI at Duke, one-third developed severe pulmonary toxicity, though the only independent factor correlated with the development of pulmonary toxicity was the number of chemotherapy regimens prior to transplant [54]. Gopal et al. found a similar rate of severe pulmonary toxicity among patients receiving 12 cGy of TBI in 4 once-daily fractions (6 of 24 patients, 25%) [55]. There was a lower incidence of severe toxicity among patients treated with 10.2 cGy in 6 twice-daily fractions (7 of 57, 12%); however, the difference was not significant (*P*-0.19). TBI has also been associated with alveolar hemorrhage in patients undergoing autologous transplantation [23].

Pulmonary Alveolar Proteinosis (PAP)

PAP is a rare complication that may occur within the first 100 days after HSCT [56, 57]. Patients typically present with slowly progressive dyspnea and a non-productive cough. Bilateral diffuse alveolar densities and diffuse ground-glass attenuation with superimposed interlobular septal thickening and intralobular lines in a "crazy-paving" pattern on chest CT are non-specific, but supportive radiographic findings (see Fig. 21.4a). Bronchoscopic examination demonstrates copious, milky BAL effluent, which on cytologic examination contains foamy macrophages engorged with periodic acid-Schiff-positive intracellular inclusions and granular, acellular eosinophilic proteinaceous material (see Fig. 21.4b). Concentrically laminated phospholipid lamellar bodies may be seen on electron microscopy, which is occasionally necessary to confirm the diagnosis. Spontaneous reversal of PAP

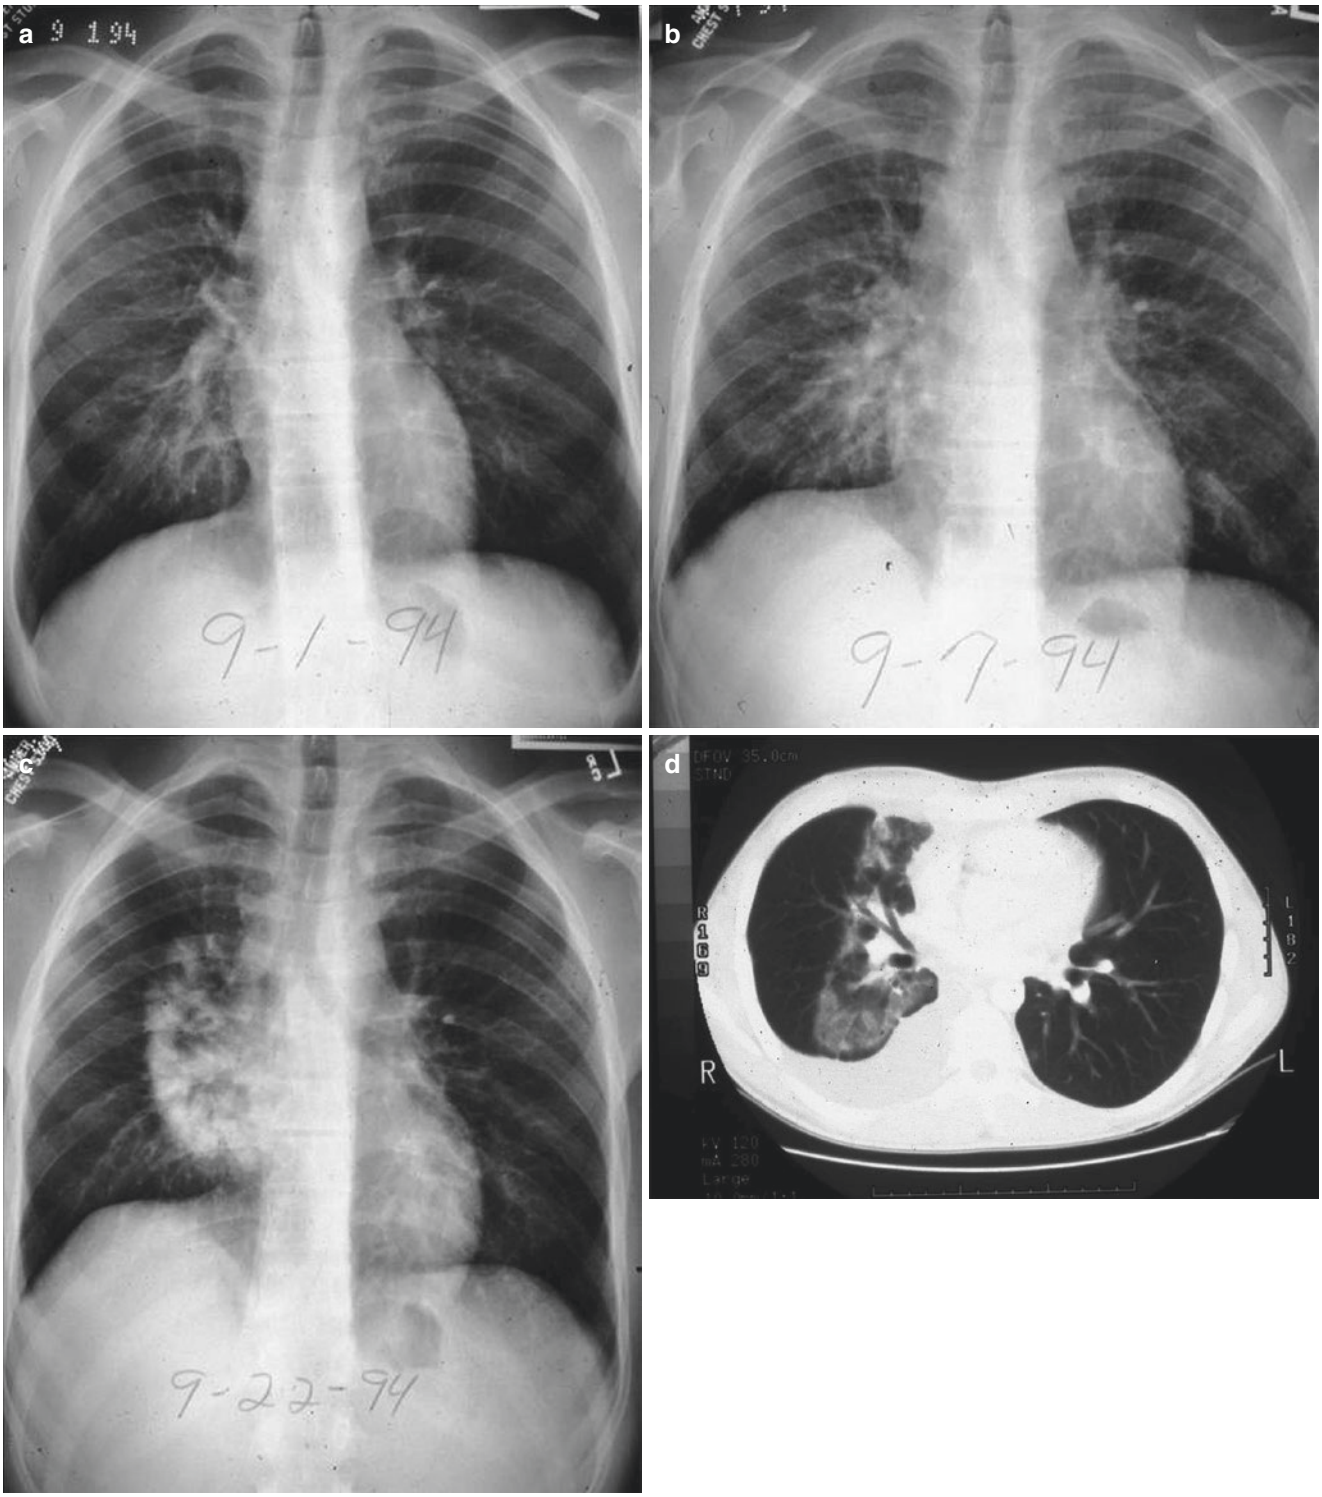

Fig. 21.3 Natural progression of radiation pneumonitis, 3 months after treatment. A young man underwent autologous HSCT for Hodgkin's disease in June of 1994 after receiving a right hilar "boost" to an enlarged lymph node. (**a**) A PA chest radiograph from 09-01-1994 showed increased interstitial markings on the right. (**b**) A PA chest radiograph on 09-07-1994 during a febrile episode attributed to an infected catheter showed an increase in the interstitial infiltrates. (**c**) The pulmonary service was consulted to evaluate this PA chest radiograph on 09-22-1994; however, the patient was asymptomatic. (**d**) A chest CT confirmed the linear border of the infiltrate and revealed an unsuspected small effusion. No treatment was prescribed

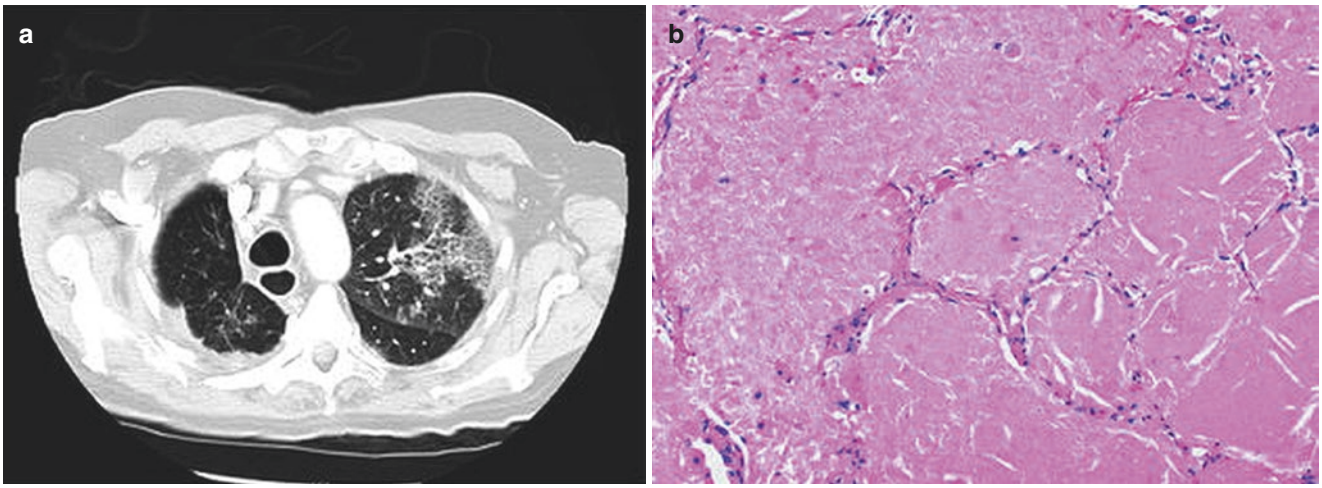

Fig. 21.4 Pulmonary alveolar proteinosis (PAP) in a patient with chronic myeloid leukemia. (**a**) CT chest demonstrates a "crazy-paving" pattern, with a network of smoothly thickened reticular (i.e., septal) lines superimposed on ground-glass opacities. (**b**) Histopathologic findings in PAP include the filling of alveolar spaces with eosinophilic proteinaceous material, which may stain periodic acid-Schiff-positive [8]. (From Kaplan et al. [8], with permission of Springer)

has been described after the resolution of neutropenia or an associated infection. In patients with severe dyspnea and/or significant hypoxemia, whole lung lavage or GM-CSF administered either subcutaneously or via nebulization have been effective in patients with PAP not associated with HSCT [58, 59]. Steroids are not recommended, since they may increase mortality.

Cryptogenic Organizing Pneumonitis (COP)

COP [formerly, Bronchiolitis Obliterans with Organizing Pneumonia (BOOP)] occurs mostly in allogeneic HSCT recipients with GVHD or following CMV pneumonitis [60], with an onset between 1 and 13 months after transplantation. It is less common than post-transplantation constrictive bronchiolitis (PTCB) and should not be confused with it since PTCB is not associated with radiographic infiltrates. Cough and fever are the most common symptoms of COP on presentation; dyspnea, if present, is mild, and, in some cases, patients are asymptomatic [61]. COP usually presents with patchy bilateral alveolar opacities which can be migratory on chest radiograph. The opacities have a lower lobe predominance and are peripheral in location. They may appear as ground-glass opacities or consolidation with air bronchograms on high-resolution CT scans (see Fig. 21.5a). Occasionally, COP can present radiographically as a solitary nodule or mass mimicking a neoplasm or chronic nonresolving pneumonia. In 1 retrospective study of 43 cancer patients, 81% of patients with solid organ tumors had nodular or mass-like radiographic abnormalities, and 19% presented with diffuse infiltrates [62]. In the same study, diffuse infiltrates were seen in the majority of patients with hematologic malignancies, including HSCT, and mimicked infection and drug-induced toxicity.

Pathologically, COP is characterized by the presence of granulation tissue within the lumen of the distal air spaces with or without bronchoalveolar involvement (see Fig. 21.5b). This pathologic picture can be seen with multiple other accompanying diagnoses, such as congestive heart failure, infections, and drug-induced toxicity; hence, in the HSCT recipient, other diagnoses should be excluded before a diagnosis of COP is made. COP is highly responsive to corticosteroids. The minimal effective dose and duration of therapy are unknown; however, a prolonged steroid course with a slow taper is usually necessary due to high relapse rates. Macrolides have been used with success in some cases and might be considered in those individuals who are intolerant to steroid therapy or in whom relapse occurs [63]. Although the specific mechanism of action is not known, macrolides are thought to exert their beneficial effects through anti-inflammatory rather than anti-microbial activities.

Post-transplantation Lymphoproliferative Disorder (PTLD)

PTLD occurs in approximately 1% of HSCT patients, usually within the first 4–12 months after transplantation [1, 64]. The clinical constellation may include fever, lymphadenopathy,

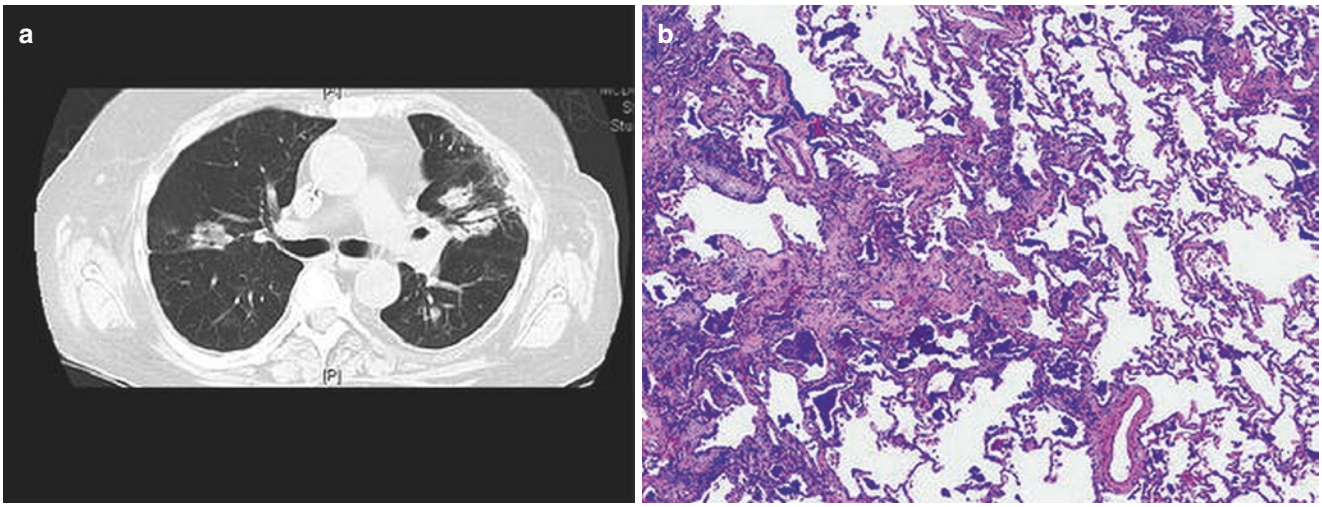

Fig. 21.5 Organizing pneumonia in a patient with a history of chronically waxing and waning pulmonary infiltrates. (**a**) Patchy airspace consolidation with air bronchograms, often in a subpleural location, is a characteristic radiographic presentation for organizing pneumonia. (**b**) On histopathologic examination, granulation tissue can be seen within the lumen of the distal air spaces, swirling into alveoli, associated with chronic inflammation in the surrounding alveoli [8]. (From Kaplan et al. [8], with permission of Springer)

pharyngitis, hepatosplenomegaly, and neurologic symptoms. There appears to be a greater incidence of fulminant, disseminated PTLD in HSCT recipients as compared to solid organ transplant recipients, possibly accounting for the increased mortality associated with PTLD in this population [65]. The lung is involved only 20% of the time, usually as a component of disseminated disease, most commonly with ill-defined nodular infiltrates. It can also present as well-defined nodules, surrounded by a rim of ground-glass density (halo sign), mimicking the features of invasive aspergillosis. Hilar and mediastinal adenopathy and pleural effusions may also be seen. The pathogenesis of PTLD and its treatment are addressed below under Solid Organ Transplantation.

Solid Organ Transplantation

A number of non-infectious pulmonary complications affecting solid organ transplant recipients present with clinical and radiographic features that may mimic infection. These are described in the following sections; complications limited to specific organ recipient populations are noted in the subheadings.

Primary Graft Dysfunction (Lung Transplantation)

Primary graft dysfunction (PGD) represents a form of acute lung injury associated with the development of non-cardiogenic pulmonary edema within the first 72 h following lung transplantation [66]. It is presumed to result from ischemia-reperfusion injury to the allograft(s), but inflammatory events triggered by brain death in the donor prior to implantation, as well as surgical trauma and lymphatic disruption, may be contributing factors. In most cases, the process is mild and transient, with fleeting pulmonary infiltrates on chest x-ray. In approximately 10% of cases, however, the presentation and course are similar to the acute respiratory distress syndrome (ARDS) with severe hypoxemia, widespread airspace opacities on chest x-ray, and the need for mechanical ventilator support. In common with ARDS, lung biopsies performed in patients with PGD demonstrate a prevailing pattern of diffuse alveolar damage.

A multitude of factors have been identified as associated with an increased risk of developing PGD, though the causal nature and mechanisms underlying these associations have not been established. Donor-related risk factors include female gender, African-American race, older age, and low donor PaO_2/FiO_2 ratio [67–69]. An elevated level of interleukin-8 in bronchoalveolar lavage fluid recovered from the donor has been associated with the development of severe PGD, supporting the notion that inflammatory events preceding organ harvest may play a role. Recipient risk factors include an underlying diagnosis of idiopathic pulmonary arterial hypertension as well as the presence of elevated pulmonary artery pressures independent of diagnosis. An association between graft ischemic time and PGD has not been consistently demonstrated. A possible explanation for the conflicting data is that ischemic time may become a factor only when it exceeds a certain threshold, suggested by one study as occurring beyond 6 h [70].

PGD should be considered when pulmonary infiltrates appear in the allograft(s) (sparing the native lung in cases

of single lung transplantation) within the initial 3 days after lung transplantation. The diagnosis is one of exclusion. Other entities to be considered include volume overload, hyperacute rejection, aspiration pneumonitis, and pulmonary venous outflow obstruction. Pneumonia, transmitted from the donor via the allograft or acquired de novo post-transplantation, is an additional consideration. Evaluation should include assessment of hemodynamics (especially pulmonary capillary wedge pressure if a right heart catheter is in place), bronchoscopy to assess for purulent secretions and to obtain cultures, transesophageal echocardiography to visualize the pulmonary veins, and immunological testing for the presence of donor-specific anti-HLA antibodies.

As with ARDS due to other causes, treatment of severe PGD is supportive. Mechanical ventilation, employing a "low stretch" protocol, is the mainstay of care. Adjunct measures considered when oxygenation is tenuous include use of inhaled nitric oxide or prostacyclin and extracorporeal life support. Results of emergent retransplantation in this setting have been poor [71]. Severe PGD is associated with a mortality rate in the range of 30–40% and represents a leading cause of perioperative death among lung transplant recipients. Recovery among survivors is often protracted, but achievement of normal graft function is possible. Survivors do appear to be at increased risk of developing bronchiolitis obliterans syndrome [72].

Allograft Rejection (Lung Transplantation)

Hyperacute rejection is a rare cause of widespread pulmonary infiltrates in the immediate postoperative period following lung transplantation [73]. This form of rejection is mediated by preformed donor-specific anti-HLA antibodies present in the recipient at the time of transplantation. These antibodies target the pulmonary microvasculature, leading to complement- and neutrophil-mediated damage and widespread deposition of platelet/fibrin thrombi. Hyperacute rejection becomes clinically manifest within minutes to hours of establishing perfusion to the freshly implanted allograft. Intraoperatively, the allograft often appears dusky, mottled, and grossly edematous. Profound hypoxemia, hemodynamic instability, and dense opacification of the allograft(s) on chest x-ray are accompanying features. Four of five patients with this complication reported in the literature died; the one survivor was treated with a combination of plasmapheresis, anti-thymocyte globulin, and cyclophosphamide [74, 75]. Routine screening of all lung transplant candidates for preformed anti-HLA antibodies and either avoidance of donors with the targeted antigens or prospective cross-matching prior to transplantation have proven to be highly effective in minimizing the risk of hyperacute rejection.

Acute cellular rejection is a common alloimmune phenomenon, occurring in up to 75% of lung transplant recipients during the first post-transplant year but diminishing markedly in frequency beyond this time point [76]. It may be clinically and radiographically silent in up to 40% of cases, detected only by surveillance transbronchial lung biopsies. When clinically overt, symptoms include malaise, low-grade fever, dyspnea, and cough. Radiographic features are varied and include consolidation, ground-glass opacities, interstitial opacities, and pleural effusions (Fig. 21.6). A decline in oxygenation and/or spirometry values is often seen. Notably, similar clinical, radiographic, and physiologic features accompany bouts of infection; reliance on these features to make a diagnosis of acute rejection runs the risk of misdiagnosis and needless augmentation of immunosuppression. Rather, transbronchial lung biopsies should be obtained in all suspected cases, unless contraindicated by severe hypoxemia or marginal lung function. The reported sensitivity of transbronchial biopsies in the diagnosis of acute cellular rejection is 61–94% and the specificity exceeds 90% [77]. Diagnosis requires demonstration of perivascular lymphocytic infiltrates that in more severe cases spill over into the adjacent interstitium and alveolar spaces. Lymphocytic bronchiolitis may accompany the parenchymal involvement or may be an independent feature. Standard treatment for acute cellular rejection consists of a 3-day pulse of intravenous methylprednisolone, typically at a dose of 15 mg/kg. In most cases, this leads to clinical and radiographic improvement within several days. Anti-thymocyte globulin is employed in refractory cases.

Antibody-mediated rejection is a more recently recognized but still ill-defined form of acute rejection in lung transplant recipients [78]. In contrast to hyperacute rejection, in which donor-specific anti-HLA alloantibodies are present in the recipient at the time of transplantation, this process is mediated by antibodies that develop de novo after transplantation,

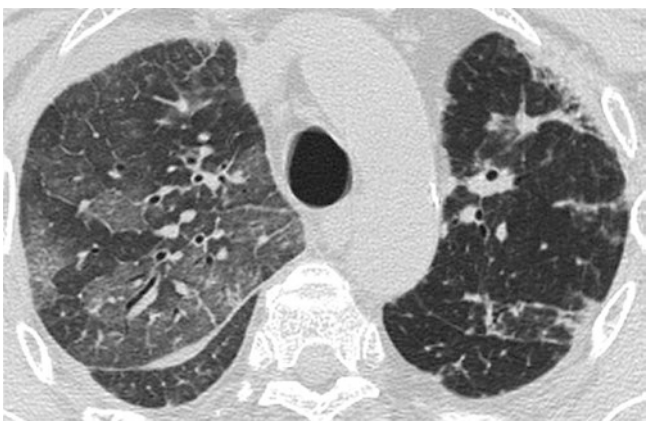

Fig. 21.6 Chest CT demonstrating ground-glass opacities and interlobular septal thickening in the right lung allograft of a single lung transplant recipient. Transbronchial biopsies demonstrated acute cellular rejection

and it is therefore delayed in onset. The clinical presentation can be indistinguishable from acute cellular rejection or infection, with dyspnea, hypoxemia, and diffuse radiographic opacities. Hemoptysis, reflecting the presence of capillaritis, is an important clue but occurs in only 25% of cases [79]. Proposed diagnostic criteria for acute antibody-mediated rejection are (1) presence of circulating donor-specific anti-HLA antibodies, (2) histopathological evidence of capillaritis, and (3) detection of endothelial cell C4d deposition. Treatment with high-dose corticosteroids is effective in less than half of patients; the addition of plasmapheresis is beneficial in the majority of steroid-refractory cases [79]. Intravenous immunoglobulin and anti-CD20 monoclonal antibodies have also been used as adjunctive therapy.

Post-transplantation Lymphoproliferative Disorder (PTLD)

PTLD encompasses a spectrum of abnormal proliferative responses involving B cells in the majority of cases and ranging from benign hyperplasia to frank lymphomas. Epstein-Barr virus is responsible for driving B-cell proliferation in approximately 90% of cases. Proliferation occurs in an unregulated fashion due to absence of the normal cytotoxic T-cell response in the immunosuppressed patient. The proliferating B cells are of recipient origin in most cases. In contrast to B-cell-derived PTLD, the less commonly encountered T-cell neoplasms are predominantly EBV-negative.

The prevalence of PTLD varies considerably among the different solid organ transplant populations. The prevalence is lowest in kidney recipients (1%); intermediate in liver (2–5%), heart (2–5%), and lung (2–8%) transplant recipients; and highest in bowel transplant recipients (up to 30%) [80, 81]. Across all organ types, EBV-naïve recipients who receive organs from EBV-positive donors are at greatest risk for developing PTLD [82]. The net state of immunosuppression and, in particular, the use of anti-lymphocyte antibodies, has also been implicated as a risk factor. A recent study of lung transplant recipients documented a decline in the incidence of PTLD at one large center in recent years; the authors speculate that this may relate to the shift from anti-lymphocyte antibodies to the less immunosuppressive interleukin-2 antagonists for induction [83].

The risk of PTLD is greatest in the first post-transplantation year. The development of this complication may be heralded by constitutional symptoms of fever, malaise, sweats, and weight loss. The particular pattern of organ involvement varies among the different solid organ transplant populations and includes lung, intestine, central nervous system, liver, kidney, and lymph nodes. Intrathoracic involvement occurs in the majority of cases of PTLD in lung and heart-lung transplant recipients. It occurs less commonly in other recipient populations, with reported frequencies of 16–32% in heart transplant recipients, 4.2–24% in liver recipients, and 4.4–15% in kidney recipients [81, 84]. Lung involvement typically manifests as one or multiple nodules or masses (Fig. 21.7). Occasionally, these opacities may have a surrounding halo, mimicking the radiographic appearance of invasive aspergillosis (Fig. 21.8). Airspace consolidation is a less common radiographic

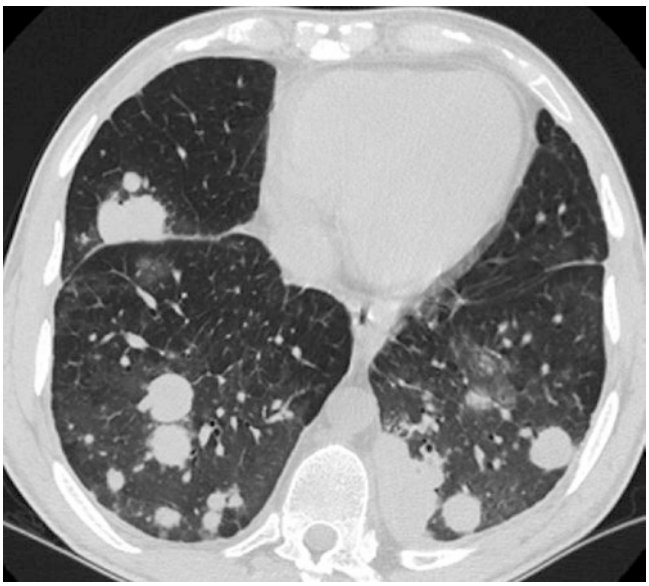

Fig. 21.7 Multiple lung nodules and masses due to PTLD in a bilateral lung transplant recipient

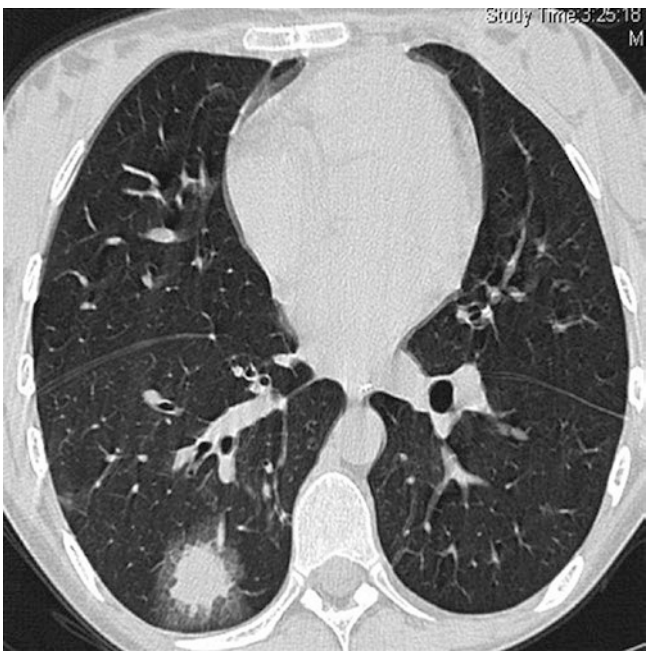

Fig. 21.8 Halo sign (lung nodule with surrounding rim of ground glass) associated with PTLD. This finding is more commonly associated with invasive aspergillosis and invasive lung disease due to other opportunistic mold infections

manifestation, but one that similarly creates diagnostic confusion with infection. Intrathoracic lymphadenopathy may accompany parenchymal abnormalities or may occur in isolation. Pleural effusions are uncommon.

Definitive diagnosis of PTLD requires tissue biopsy; fine needle aspiration rarely yields sufficient material to establish a diagnosis with confidence. Pathological analysis should include flow cytometry to determine clonality, in situ hybridization or immunohistochemical staining to assess for the presence of EBV, and determination of CD-20 expression to assist in planning treatment. Determination of EBV viral load by quantitative polymerase chain reaction assays has been touted as an ancillary diagnostic tool. However, this technique is limited by a lack of consensus on the appropriate specimen source (serum, whole blood, or peripheral mononuclear cells) and by varying threshold value definitions of a positive result. As a consequence of this, performance characteristics of EBV viral load testing in the diagnosis of PTLD vary considerably in the published literature [85, 86].

The initial treatment of PTLD involves reduction in the magnitude of immunosuppression to allow partial reconstitution of host T cellular immunity against EBV. Regression of tumor ensues in up to three-quarters of patients, typically within 2–4 weeks [87]. While often successful, reduction in immunosuppression carries the attendant risk of precipitating acute or chronic allograft rejection, documented in 39% of patients in one series [87]. Factors predictive of failure to respond to reduced immunosuppression include elevated serum lactate dehydrogenase level, severe organ dysfunction (need for hemodialysis, mechanical ventilation, vasopressors (bilirubin >4 mg/dL), and multiple visceral sites of involvement [87].

For patients with CD-20-positive PTLD who fail to respond to reduced immunosuppression alone or have more aggressive tumors, administration of anti-CD20 monoclonal antibodies (rituximab) has emerged as the treatment of choice. This agent is generally well-tolerated and has been associated with remission rates of up to 60% and improved survival [88, 89]. Standard chemotherapy is reserved for patients with CD-20-negative PTLD, for rituximab failures, and for aggressive, life-threatening disease. While effective, chemotherapy is often poorly tolerated and associated with a significant risk of lethal infectious complications [89]. Antiviral therapy is not effective in the treatment of established PTLD, but prophylactic use of antiviral agents for other purposes has been associated with a reduced risk of subsequent development of PTLD.

Lung Cancer (Heart and Lung Transplantation)

The reported incidence of lung cancer is 1.6–4.1% in heart transplant recipients and 2–4% in lung transplant recipients [90]. These rates are considerably higher than that reported in other solid organ recipient populations and in the general population. It is not clear, however, that these rates truly represent increased risk or simply reflect expected occurrence rates in populations with similar risk factors. Among lung transplant patients, the vast majority of reported cases involve the native lung of single lung transplant recipients with underlying chronic obstructive pulmonary disease or pulmonary fibrosis (Fig. 21.9), the majority of whom were former smokers. In one study that specifically examined the incidence by transplant type, lung cancer developed in 6.9% of single lung transplant recipients compared to none of the bilateral lung recipients [91]. Risk factors other than transplant type that were identified in this study were increasing age and >60 pack-year history of cigarette smoking. Rarely, lung cancer of donor origin has been transmitted to recipients via the allograft. Lung cancer in the transplant recipient often progresses at a rapid pace, potentially leading to initial confusion with an infectious process. Overall prognosis is poor but should not preclude attempts at curative resection in the minority of cases in which early stage disease is encountered.

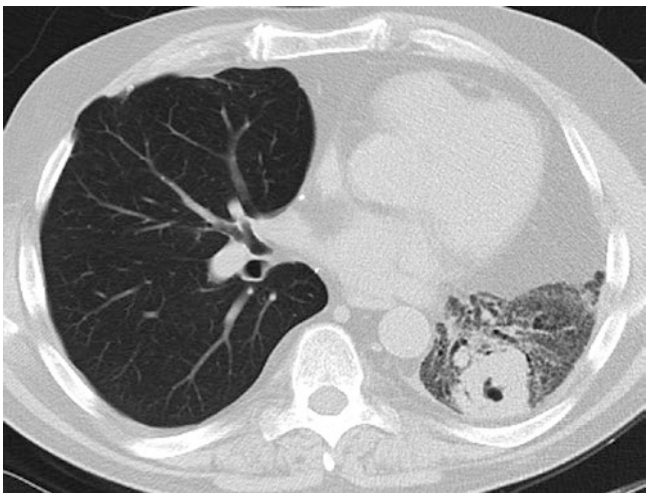

Fig. 21.9 Cavitary squamous cell carcinoma in the fibrotic native lung of a single lung transplant recipient

Sirolimus (mTOR Inhibitor) Pneumonitis

Sirolimus, also known as rapamycin, is used with varying frequency in different solid organ transplant populations as a component of the maintenance immunosuppressive regimen. Since its introduction into clinical practice, there have been numerous reports of interstitial pneumonitis developing in association with sirolimus [92–94]. The incidence of this complication remains poorly defined. Initial reports suggested that interstitial pneumonitis was largely a

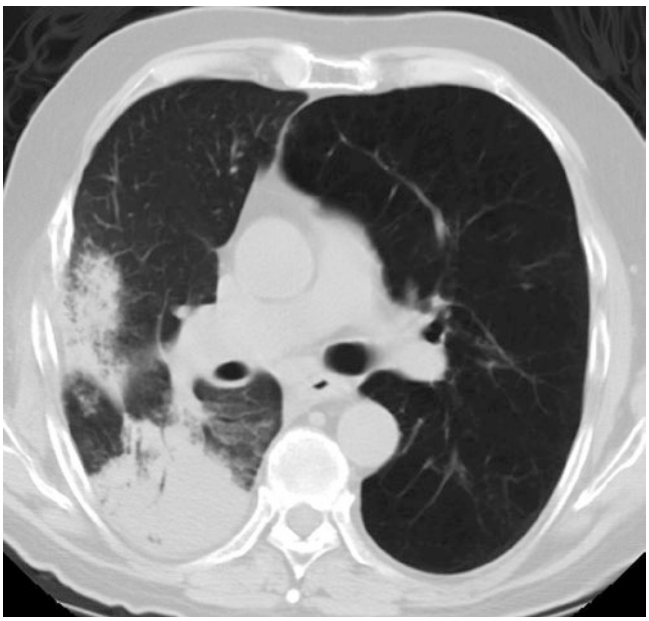

Fig. 21.10 Areas of dense consolidation due to sirolimus pneumonitis in the right lung allograft of a single lung transplant recipient

complication of excessive sirolimus blood concentrations, but more recent reports have documented cases in the setting of therapeutic drug levels. Approximately 50% of cases develop within the first 6 months after initiation of the drug. Onset is usually insidious, but acute and fulminant presentations have been described [95]. Common presenting symptoms include dyspnea, non-productive cough, and fever; hemoptysis is occasionally present. Radiographic abnormalities include bilateral interstitial infiltrates, alveolar consolidation, ground-glass opacities, and nodules (Fig. 21.10). Bronchoalveolar lavage reveals evidence of a lymphocytic alveolitis and, less commonly, of alveolar hemorrhage. Histological findings are diverse and include bronchiolitis obliterans with organizing pneumonia, interstitial lymphocytic infiltrates, alveolar hemorrhage, and non-necrotizing granulomas. Discontinuation of the drug typically leads to prompt clinical improvement while radiographic abnormalities may take several months to fully resolve. In more severe cases, high doses of corticosteroids have been administered, but the true efficacy of these agents remains uncertain.

Conclusion

Multiple common disorders in transplantation patients are associated with radiographic lung infiltrates that can be confused with infectious pneumonia. While pneumonia is a serious complication in transplantation patients, leading to an appropriately high index of suspicion, accurate diagnosis of both infectious and non-infectious etiologies of lung infiltrates is essential to optimal treatment. The identification of non-infectious etiologies of lung infiltrates can usually be made on the basis of clinical findings and imaging studies, but invasive studies are sometimes necessary.

Skin and Soft Tissue Infection in Transplant Recipients

22

Robert G. Micheletti and Carrie L. Kovarik

Introduction

Transplant patients are vulnerable to a vast array of infectious and noninfectious cutaneous complications related to immunosuppression, chemotherapy and antibiotic exposure, and immunologic interactions between host and donor tissue. The diagnosis and treatment of cutaneous infections are especially challenging due to the vast array of infections—both common and rare—which may occur and the marked variability of appearance, both typical and atypical, with which they may present.

Yet, with this great challenge, comes great opportunity. The skin and mucous membranes form the host's most basic barrier against infection. Visible to the naked eye, their surfaces provide warning of invaders from the outside and, more ominously, dissemination of infections from the inside. Accessible to examination and easily sampled for pathology and culture, the skin can provide a wealth of information on the health of the patient.

In the following chapter, we review common, serious, or otherwise important cutaneous infections and their presentations in the immunocompromised transplant patient. Where possible, we discuss both typical and atypical presentations of these diseases and provide strategies for diagnosis and treatment. In all cases, the clinician must stay alert; maintain appropriate diagnostic suspicion; be aware of relevant history, timing, and systemic symptoms; carry out thorough examinations; and not hesitate to perform appropriate diagnostic studies. Systematic attention to these tenets and the cutaneous exam itself may be lifesaving.

Gram-Positive Bacteria

Staphylococcus

Staphylococci colonize the skin of immunologically intact hosts and are a frequent cause of superficial skin infections. Transplant patients and other immunocompromised patients are no different in this regard. While unusual infections and atypical presentations are seen, common things remain common, and staphylococci often cause skin and soft tissue infections in the transplant population.

Staphylococcal skin colonization is increased in certain populations of patients, including those with pre-existing skin diseases such as atopic dermatitis and cutaneous T-cell lymphoma, as well as those with various types of immunosuppression, such as diabetes, chronic granulomatous disease, hyper IgE syndrome, acquired immunodeficiency syndrome (AIDS), leukopenia, and cancer (particularly hematologic malignancies) [1–3].

Superficial cutaneous staphylococcal infections are common in such patients and increase in incidence with more significant immunodeficiency. Impetigo, with its honey-colored crust, is common in periorificial areas, at sites of injury, or where the normal skin barrier function is otherwise compromised (Fig. 22.1). It may involve weeping skin in a patient with profound lower extremity edema or anasarca, and it can superinfect lesions of herpes simplex or herpes zoster. Patients who develop cutaneous toxicities from chemotherapy or immunotherapy may also develop superinfection of the affected areas. A large number (38%) of those with rash secondary to one of the epidermal growth factor (EGF) receptor inhibitors develop bacterial superinfection of the lesions, most often with *S. aureus* [4].

Folliculitis or furunculosis of hair-bearing areas typically presents with follicular erythematous papules and pustules. It may become quite extensive, causing fever and systemic illness in some patients, but can also be subtle in neutropenic patients whose ability to mount an inflammatory response is

A. Safdar (ed.), *Principles and Practice of Transplant Infectious Diseases*, https://doi.org/10.1007/978-1-4939-9034-4_22

Fig. 22.1 A patient with relapsed cutaneous T-cell lymphoma following stem cell transplantation developed *S. aureus* impetigo superinfection

impaired. Ecthyma typically presents as a shallow ulceration and is most commonly due to staphylococcal or streptococcal species.

Cellulitis in transplant patients generally presents as it does in the general population, with swelling, warmth, and erythema. Special attention to the skin around indwelling lines, which may be covered from view by tape or bulky dressings, is essential to avoid a delay in diagnosis. Irritation or allergy to adhesives or topical cleansers, such as chlorhexidine, may cause some irritation which can be mistaken for cellulitis; clues to a contact dermatitis include linear, geometric, or sharply defined shape, itching, and weeping or scaling of the skin. It is also important to note that atypical presentations of fungal, viral, or other bacterial infections may mimic Gram-positive cellulitis. A high index of suspicion for atypical infections is especially appropriate in cases which do not respond to antibiotic therapy for the usual staphylococcal or streptococcal species.

Staphylococcal scalded skin syndrome (SSSS) is characterized by toxin-mediated generalized erythema and superficial exfoliation caused by local cutaneous infection with *S. aureus* type 71, phage group 2. This bacterium elutes exfoliating toxins A and B, which circulate and cleave the desmosomal protein desmoglein 1 in the superficial epidermis, resulting in widespread peeling. This syndrome is most commonly observed in young children, in whom the prognosis is quite good. Risk factors for adult infection include impaired renal function, which decreases clearance of the toxin, as well as immunosuppression due to systemic steroids, malignancy, or organ transplantation [5]. In adults with these comorbid diseases, the incidence of positive blood cultures and the mortality rate are increased [6].

Unusual presentations of *S. aureus* infection in immunosuppressed patients include blastomycosis-like verrucous plaques with multiple pustules, violaceous plaque-like lesions of folliculitis, monomorphic vesicles or bullae, and chronic suppurative infections with bacterial granules (botryomycosis) [3]. Blistering distal dactylitis, characterized by tender, tense bullae on the fingertips, may also be caused by staphylococcal species [7].

Streptococcus

Like *Staphylococcus*, cutaneous streptococcal infections are quite common. Streptococcal species are responsible for the majority of cellulitis and erysipelas and also cause impetigo and ecthyma.

In immunocompromised patients, all of these more typical manifestations may be seen, but streptococcal infections may be unusually extensive or may appear clinically atypical. *Streptococcus pyogenes* (group A β-hemolytic strep) may cause extensive ecthyma or facial erysipelas that can result in bacteremia [8, 9]. *Streptococcus agalactiae* (group B strep) most commonly causes invasive infection in pregnant women and neonates but is also increased in immunocompromised patients [10]. In addition to erysipelas, cellulitis, and ecthyma, group B strep can cause myositis, necrotizing fasciitis, and toxic shock syndrome, as well as an acute cellulitis-adenitis condition with rapidly enlarging lymph nodes and fever [11].

Streptococcus pneumoniae uncommonly causes skin or soft tissue infection but may result in a facial and neck cellulitis in patients with hematologic malignancies [12]. Pneumococcal cellulitis commonly appears brown or dusky with bulla formation [13]. Necrotizing fasciitis and purpura fulminans/disseminated intravascular coagulation (DIC) are rare but deadly complications of *S. pneumoniae* infection. Transplant patients are at increased risk of such complications as are others who are immunosuppressed, particularly those with functional or anatomical asplenism.

Clostridium

Clostridial myonecrosis (gas gangrene) may be posttraumatic or spontaneous. Underlying immunosuppression, such as that caused by hematologic malignancy or neutrophil dysfunction, increases the risk of spontaneous infection. *Clostridium perfringens* (60%) and *Clostridium septicum* (30%) are the most common isolates from these infections [14], resulting in a 32% and 79% mortality, respectively [15].

Clostridial myonecrosis is characterized by a relatively sudden onset of severe pain in the involved site, rapid extension of infection, and systemic toxicity. The skin may appear pallid or mottled, then a dusky brownish purple. Finally, tense hemorrhagic bullae develop, signaling necrosis of the involved tissue. Crepitus may be detected clinically or on radiographic imaging.

Underlying muscle and soft tissue involvement may be quite extensive, far exceeding what is visible on the skin surface. Rapid progression, sepsis, and death can occur within 1–2 days. Timely diagnosis is essential. Gram staining of the serosanguineous fluid found in the hemorrhagic bullae shows numerous Gram-positive rods. Computed tomography (CT) or other radiographic imaging may help define the extent of infection [15], but surgical debridement and treatment with intravenous antibiotics (high-dose penicillin is the treatment of choice) should not be delayed for imaging studies. Granulocyte colony-stimulating factor (G-CSF) should be considered as adjunctive therapy in neutropenic patients.

Bacillus

Bacillus cereus is best known as a cause of mild food poisoning, but it can also cause life-threatening infection in immunocompromised patients, particularly those with neutropenia following chemotherapy or stem cell transplantation. A single painful vesicle, pustule, or bulla may appear on a digit or extremity at a site of inoculation, followed by necrosis and ulcer or eschar formation, rapidly spreading cellulitis, and high fever [16]. This presentation may mimic that of clostridial myonecrosis, complete with large Gram-positive rods on Gram stain. However, unlike C*lostridium*, *B. cereus* is generally resistant to many beta-lactam antibiotics including most cephalosporins. Vancomycin, aminoglycosides, and carbapenems are acceptable alternatives. Severe infection, with necrotizing fasciitis, endocarditis, and brain abscesses, in immunosuppressed patients has been reported and is frequently fatal [17, 18].

Corynebacterium

Aside from *C. diphtheriae*, corynebacteria are part of the normal skin flora, rarely cause infection, and are susceptible to most antibiotics. *C. jeikeium* most commonly colonizes the perineal, rectal, inguinal, and axillary areas of adult men and postmenopausal women, likely related to increased sebum production, which promotes the growth of lipophilic organisms [19]. Risk factors for colonization are the same as for infection and include indwelling intravenous catheters, neutropenia, prolonged hospitalization, and previous treatment with broad-spectrum antibiotics [20].

Primary cutaneous *C. jeikeium* infection occurs at breaks in the skin barrier due to trauma or nosocomial inoculation, most commonly presenting as a cellulitis. The organism may then enter the bloodstream, leading to septicemia [21]. Secondary skin infection results from hematogenous spread. It may present with nontender subcutaneous nodules, erythematous macules or papules, or nonblanching red papules or pustules with secondary necrosis. *C. jeikeium* is most aggressive in those with hematologic malignancies undergoing chemotherapy or status post stem cell transplantation. This group is most likely to develop *C. jeikeium* sepsis and more commonly develops cutaneous manifestations of the disease. Forty-eight percent of such patients develop skin lesions due to hematogenous spread, making the skin the second most common infected organ [22].

Vancomycin is the agent of choice for the treatment of *C. jeikeium* and should be continued until hematologic recovery. The mortality of *C. jeikeium* sepsis approaches 34% in those with hematologic malignancies but drops to 5% in those with bone marrow recovery [22].

Nocardia

Nocardia is a branching, filamentous aerobic bacteria found in soil and decaying plant matter. It is not part of the normal human flora, so positive cultures should be evaluated carefully [23]. *N. asteroides* is the most common member of the genus to cause human infection. It involves the lungs most frequently, followed by the skin, and the central nervous system (CNS).

Immunocompromised states predispose to nocardial infection. Those with a history of hematologic malignancy, organ transplantation, iatrogenic immunosuppressive therapy, and advanced HIV disease (CD4 < 100) are at greatest risk. *Nocardia* infection is more common following solid organ transplantation than hematopoietic stem cell transplantation. Independent risk factors include high-dose steroid therapy, prior cytomegalovirus infection, and high serum levels of calcineurin inhibitor in the month prior to infection [24].

Cutaneous nocardiosis may be due to primary inoculation or secondary to dissemination. Primary lesions may present with swelling, induration, and purulence of a mycetoma; the beefy red nodules of lymphocutaneous or "sporotrichoid" infection spreading along lymphatics from the site of inoculation; or with the erythema, fluctuance, or ulceration of a more superficial cellulitis, abscess, or crusted nodule (Fig. 22.2) [25–27].

Secondary cutaneous lesions due to hematogenous spread may be indistinguishable from the type of abscesses, nodules, or ulcers seen in primary disease. Therefore, all patients presenting with cutaneous nocardiosis should be screened for systemic involvement with imaging of the lungs and CNS. Cutaneous lesions may be the only sign of otherwise asymptomatic disseminated infection [28]. Dissemination from a primary skin lesion to other organs is rare, but late dissemination from the lungs to the skin or CNS can occur in immunosuppressed patients despite appropriate therapy for pulmonary nocardiosis.

Cutaneous nocardiosis may take on other more atypical forms in immunosuppressed patients. Among the less common presentations described in transplant patients are warm

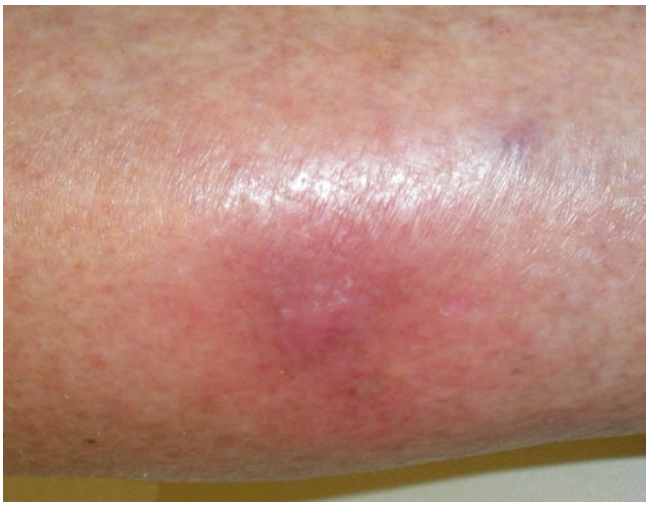

Fig. 22.2 A patient with AML status post stem cell transplantation developed several tender, red, subcutaneous nodules on the legs. Tissue culture grew *Nocardia*

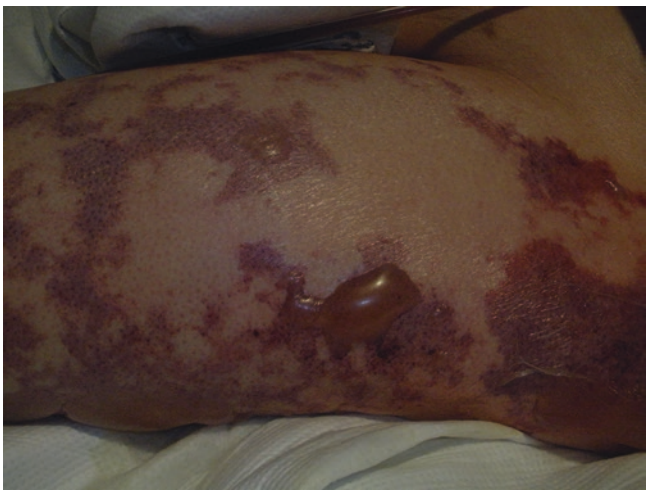

Fig. 22.3 Purpura fulminans and tense bullae in a patient with *E. coli* septicemia. (Image courtesy of Katherine Evans, MD)

and cold subcutaneous nodules [29, 30], pustules, and pyomyositis [31]. Cases of disseminated infection are usually due to *N. asteroides*, but in the organ transplant recipient, *N. nova* is the most frequent cause of disseminated disease.

Cutaneous *Nocardia* can present a diagnostic challenge because lesions may resemble pyogenic bacterial infections. Empiric treatment without culture and failure of the organism to grow in culture before it is thrown away are factors which contribute to treatment failure. *Nocardia* are Gram-positive and variably acid-fast. They are not seen on routine hematoxylin and eosin-stained sections. Gomori methenamine silver (GMS) and Brown-Brenn stains are needed to diagnose the infection histologically. The microbiology laboratory should be alerted if the clinician suspects *Nocardia* so that cultures can be saved for 4 weeks or longer.

A history of inoculation injury, occupational exposure to decaying plant matter, worsening or recurrence of infection despite standard antibiotics, and chronic suppurative infection with negative cultures suggest the possibility of *Nocardia* infection [32]. The coexistence of lung nodules and skin lesions raises the possibility of that diagnosis in an immunocompromised host, as do pleural or pericardial infections [28].

Trimethoprim-sulfamethoxazole is an effective treatment for most *Nocardia*, but *N. farcinica* may be highly resistant to antibiotics.

Gram-Negative Bacteria

Escherichia Coli

Escherichia coli is a Gram-negative aerobic rod which is part of the normal gastrointestinal flora. Cutaneous infection may produce abscesses at sites of inoculation or contaminated surgical wounds. Perirectal phlegmon is seen in neutropenic patients. *E. coli* cellulitis is rare but is more commonly seen in those with neutropenia, corticosteroid treatment, renal or hepatic insufficiency, chronic alcohol use, and diabetes mellitus. Gram-negative cellulitis can be indistinguishable from streptococcal cellulitis, with pain, redness, and fever, though in immunocompromised patients it is frequently described as rapidly progressive. Among transplant patients, hepatic transplant may be a particular risk factor. Spontaneous Gram-negative cellulitis has been well-described in cirrhotic patients due to hypoalbuminemia, edema, and immunosuppression. One reported patient developed spontaneous *E. coli* cellulitis with numerous bullae 8 days after liver transplant for hepatitis C cirrhosis [33].

Ecthyma gangrenosum, classically associated with *Pseudomonas aeruginosa* bacteremia, has been described with many other Gram-negative organisms including *E. coli* [34, 35]. Ecthyma gangrenosum most commonly appears in the gluteal or perineal region (57%) and less frequently on the extremities (30%). For this reason, a thorough skin exam is an indispensable part of the workup of the febrile neutropenic or otherwise immunocompromised patient. Timely diagnosis and treatment are essential; the mortality rate of ecthyma gangrenosum is 10–38% [36].

E. coli septicemia may present with tense serous or hemorrhagic bullae, either on otherwise normal-appearing skin or overlying a cellulitis (Fig. 22.3). These bullae have a predilection for acral sites. Cultures of the bullae, and often of the blood or urine, grow *E. coli* [37, 38].

Malakoplakia is a rare granulomatous skin disease which results from defective killing of bacteria by macrophages. It is most common in immunocompromised patients, particularly those status post renal transplantation. Cutaneous

lesions are typically perianal abscesses, nodules, ulcers, or draining sinuses which may be due to *E. coli, Klebsiella, Enterobacter, S. aureus, Streptococcus,* and *Enterococcus* species [39, 40]. Biopsy reveals large macrophages with intracytoplasmic granules known as Michaelis-Gutmann bodies.

Klebsiella, *Enterobacter*, and *Serratia*

Klebsiella pneumoniae, Enterobacter cloacae, and *Serratia marcescens* are closely related aerobic Gram-negative bacilli that may colonize the gastrointestinal, respiratory, or urinary tracts and are common causes of opportunistic nosocomial infection in debilitated or immunocompromised patients. Like *E. coli*, cutaneous infection with these organisms can cause cellulitis which may progress rapidly to systemic toxicity, hemorrhagic bullae, and necrosis [41]. Cutaneous ulceration, ecthyma gangrenosum, nonclostridial crepitant cellulitis, and necrotizing fasciitis can also occur [42–46]. Like other Gram-negative rods, septicemia with these organisms can cause acral hemorrhagic bullae (Fig. 22.4) [47].

Salmonella

Nontyphoidal *Salmonella* species may rarely cause subcutaneous abscesses, hemorrhagic cellulitis, or necrotizing fasciitis in immunocompromised hosts. One woman developed necrotizing fasciitis due to *Salmonella* while on high-dose immunosuppression status post peripheral blood stem cell transplantation for multiple myeloma [48]. *Salmonella* bacteremia in the absence of gastrointestinal infection is a marker of immunosuppression and portends a poor prognosis [49].

Legionella

Legionella is best known as a pulmonary pathogen in immunocompromised patients but may also rarely be a cause of cellulitis and soft tissue infection in those with dysfunctional immune systems. *Legionella* could be considered in the differential diagnosis for cellulitis, which is refractory to conventional antibiotics for skin and soft tissue infections or relapses after therapy. Gram stain and culture of any purulent material may demonstrate neutrophils but no organisms. *Legionella* skin infection, when present, typically occurs without concurrent *Legionella* pneumonia.

Cellulitis caused by *Legionella* is rapidly spreading and necrotizing. Debridement or amputation may be necessary [50]. Relapse of infection in immunocompromised patients can occur even after prolonged therapy with antimicrobials which should ordinarily be curative.

Fig. 22.4 Hemorrhagic necrotic bullae on the forearm. Blood and wound cultures grew *K. pneumoniae.* (Image reprinted from Grossman et al. [284], Fig. 13.21, p. 261, with kind permission from Springer Nature)

Morganella

Morganella morganii is a Gram-negative rod found in soil, water, and human fecal flora. *Morganella* infection is unusual, but hematologic malignancy, neutropenia, chemotherapy, and systemic steroids, among other things, increase the risk [51]. In reported cases, cellulitis with hemorrhagic bullae is described most often. Gas gangrene with tissue crepitus may occur secondary to fermentation of glucose with production of gas by *Morganella*. As with other Gram-negative organisms, *Morganella* may also present as ecthyma gangrenosum [52].

Helicobacter

Helicobacter cinaedi is a fastidious Gram-negative bacillus which is an unusual pathogen usually affecting only severely immunocompromised patients. Clinical symptoms include fever, rash, arthritis, and leg pain [53]. Common cutaneous manifestations of *H. cinaedi* bacteremia are large, multifocal

cellulitic plaques on the extremities with large joint arthritis adjacent to areas of cellulitis [54]. Lesions resembling superficial thrombophlebitis may also occur [55]. By nature, *H. cinaedi* bacteremia is a relapsing condition with recurrent bouts of multifocal cellulitis, which requires prolonged or repeated courses of antibiotics. Growth of the organism in culture can be difficult.

Citrobacter

Citrobacter freundii and *C. koseri* comprise the majority of *Citrobacter* infections, with increased incidence in immunosuppressed patients. Typical cellulitis and "bilateral inflammatory erysipelas" on the legs have been described in patients following organ transplantation or receiving treatment for hematologic malignancy. *Citrobacter* is another bacterium which may cause ecthyma gangrenosum-like ulcers or hemorrhagic bullae [34, 56, 57].

Pseudomonas

P. aeruginosa is a common nosocomial pathogen encountered in patients' immunosuppressed due to organ transplantation or other causes. Dermatologic manifestations of *Pseudomonas* bacteremia include hemorrhagic bullae, gangrenous or bullous cellulitis, and ecthyma gangrenosum, which presents with erythematous or purpuric macules that progress rapidly to become violaceous or "gun metal" gray necrotic plaques or bullae with a red halo [58]. These lesions have a predilection for the anogenital area so may not be readily visible. Pathologically, the violaceous color and necrosis that occur in this condition signal compromise of the underlying cutaneous blood vessels due to invading bacteria.

Though ecthyma gangrenosum is classically due to pseudomonal bacteremia, it has been described in association with many other Gram-negative bacterial, fungal, and viral infections in immunocompromised patients. Furthermore, ecthyma gangrenosum can occur in the absence of bacteremia as a primary and localized infection due to inoculation injury, in which case the prognosis is better [59].

Pseudomonas also causes a necrotizing cellulitis in neutropenic patients which progresses from tense, tender erythema to purpuric, cyanotic, bullous, and ultimately black, necrotic tissue associated with systemic toxicity. The course of this entity is often fulminant and fatal; surgical debridement can be lifesaving but is often performed too late [60, 61].

Subcutaneous nodules and hemorrhagic bullae are other manifestations of *Pseudomonas* bacteremia, which may be solitary or distributed widely over the skin. Some nodules resolve with appropriate antibiotic therapy, but surgical drainage is indicated when nodules or signs of systemic toxicity persist despite antibiotics [62, 63].

Stenotrophomonas

A denizen of moist environs like *Pseudomonas*, and formally a member of that genus, *Stenotrophomonas maltophilia* is an exceedingly resistant nosocomial Gram-negative rod with high mortality rates in immunocompromised patients. Malignancy, neutropenia, chemotherapy, radiation, graft-versus-host disease, antibiotic exposure, central venous catheter, and prolonged hospitalization are risk factors for *Stenotrophomonas* infection [64].

Typical cellulitis, necrotizing cellulitis, ecthyma gangrenosum, metastatic nodules, and multifocal cellulitic plaques are all cutaneous manifestations [65]. These lesions typically manifest with red or violaceous erythema and tenderness and often eventuate in necrosis and ulceration [66–68].

Aeromonas

Aeromonas is another water-loving Gram-negative rod which can cause nosocomial infection in immunosuppressed patients. A rapidly progressive cellulitis can follow trauma with freshwater exposure. Suppuration and necrosis can occur, necessitating debridement of necrotic tissue. Severe infections such as fasciitis, myonecrosis, and ecthyma gangrenosum can result. Septicemia in immunocompromised patients can result in multiple hemorrhagic bullae, followed by extensive necrotizing fasciitis and septic shock [69, 70].

Vibrio

Vibrio vulnificus is the most common member of this genus causing opportunistic wound infection or septicemia in immunocompromised patients. Though classically associated with cirrhosis and chronic iron overload, hematologic malignancy, organ transplantation, and the use of immunosuppressive medications are also risk factors for infection [71, 72]. Infection can occur via primary inoculation injury in a marine environment or through dissemination from the gastrointestinal tract following consumption of raw or inadequately cooked seafood.

Local infection can progress rapidly from edema and cellulitis to hemorrhagic bullae with fever, chills, hypotension, and necrotizing fasciitis. *Vibrio* bacteremia is characterized by fever, chills, hypotension, and shock with rapidly progressive erythematous or ecchymotic plaques and large hemorrhagic bullae on the extremities or trunk. Necrotic ulcers may result in fasciitis and gangrene. Such infections

can be rapidly fatal with a mortality >50%. Early diagnosis and aggressive treatment, including surgical debridement, if warranted, are paramount [73–76].

Bartonella

Bartonella species are responsible for cat scratch disease, Oroya fever/verruga peruana, and trench fever as well as bacillary angiomatosis. Though most commonly seen in AIDS patients with CD4 count <100 cells/mm^3, bacillary angiomatosis due to *B. henselae* and *B. quintana* also occurs in patients immunocompromised for other reasons, including solid organ and bone marrow transplant recipients [77], as well as those undergoing chemotherapy for hematologic malignancy. Bacillary angiomatosis typically manifests with nonspecific constitutional symptoms. It can affect multiple organs including the liver, lymphoreticular system, brain, bone marrow, conjunctiva, gastrointestinal, respiratory, oral mucosae, and the skin. Of these, skin lesions are the most common clinical manifestation [78, 79]. Characteristically, single or multiple asymptomatic, firm, red-purple papules are found on the skin. These lesions may be innumerable and disseminated over the entire body surface. They may appear smooth, pedunculated, or verrucous. They resemble pyogenic granuloma and Kaposi sarcoma but do not ulcerate or bleed. Less commonly, bacillary angiomatosis may also present with flesh-colored, subcutaneous nodules. Erythromycin is the therapy of choice.

Mycobacteria

Mycobacterium tuberculosis

M. tuberculosis infection of the skin can occur via inoculation injury, contiguous spread from other infected sites, or hematogenous dissemination. Cutaneous manifestations are on a spectrum from primary cutaneous tuberculosis (tuberculous chancre) to tuberculosis verrucosa cutis, tuberculosis cutis orificialis, scrofuloderma, lupus vulgaris, and miliary cutaneous tuberculosis. Further immunologically driven manifestations include the tuberculids erythema induratum, papulonecrotic tuberculid, lichen scrofulosorum, and nodular tuberculid [80].

Tuberculosis is a serious cause of opportunistic infection among solid organ transplant recipients. It may occur through primary infection or reactivation of latent disease, or it may be acquired through the transplanted organ. Acute miliary tuberculosis can present with a widespread eruption of erythematous or brown macules and papules which evolve into vesiculopustules and can become crusted or necrotic [81]. Signs of systemic infection, including fever, cough, and generalized wasting, may be present. Other reported manifestations of disseminated tuberculosis in immunosuppressed transplant patients include subcutaneous nodules, erythema and edema mimicking cellulitis, and multiple ulcerating nodules [82–84]. Biopsy of such lesions is generally floridly positive with caseating granulomas and numerous acid-fast bacilli.

Nontuberculous Mycobacteria

Nontuberculous or atypical mycobacteria are ubiquitous in the environment [85]. Presentations of cutaneous disease vary markedly between immunocompetent and immunoincompetent patients. In those with normal immune systems, inoculation injury may lead in several weeks to a verrucous nodule or abscess, usually on an extremity, followed in some cases by "sporotrichoid" spread up the regional lymphatics as is seen in the "fish tank" granuloma of *Mycobacterium marinum*. In immunosuppressed patients, a history of trauma may or may not be elicited. Infection may more often lead to multiple localized violaceous subcutaneous nodules with sporotrichoid spread [86, 87] or to widespread disease in the form of nodules, sinus tracts, ulcers, abscesses, or cellulitis (Fig. 22.5) [86, 88–90].

The most common presentations of atypical mycobacterial infection in solid organ transplant patients are cutaneous lesions on the extremities, tenosynovitis, and arthritis, often with skin lesions overlying affected joints [91, 92]. Chronic indwelling central venous catheters are a common cause of atypical mycobacterial infection in solid organ or bone marrow transplant patients [93]. Diagnosis can be difficult since many of these organisms are difficult to grow in culture and hard to demonstrate on histologic sections. Notifying the microbiology lab of suspected pathogens will alert them to use proper plating media and incubate at the correct temperatures. Polymerase chain reaction (PCR) can be performed to aid in diagnosis when suspicion is high. Speciation is essential to guide therapy, as susceptibility profiles differ among the organisms in question.

Viruses

Herpes Simplex

Herpes simplex virus (HSV) infection is exceedingly common among both immunocompetent and immunocompromised hosts. In normal hosts, primary and secondary, or recurrent, infections are self-limited. Typically, 1–2 mm pruritic or painful vesicles arise in the orolabial or anogenital areas, progress to crusted erosions, and resolve over the course of several days. In immunocompromised hosts, HSV

Fig. 22.5 A heart transplant patient presented with a 3-month history of left arm cellulitis. A tender erythematous plaque involved the left arm. Skin biopsy demonstrated sarcoidal granulomas with numerous acid-fast bacilli. Tissue cultures grew *M. haemophilum* after 12 weeks. (Image reprinted from Grossman et al. [285], Fig. 5.23, p. 126, with kind permission from Springer Nature)

Fig. 22.6 Herpes simplex virus infection manifesting in a heart transplant patient as a chronic, nontender, crusted plaque with scalloped borders extending from the left naris onto the upper lip

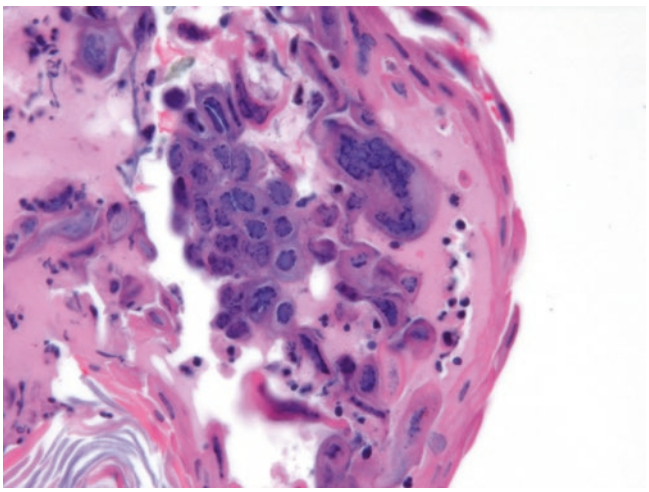

Fig. 22.7 Biopsy of the plaque demonstrated viral cytopathic changes including multinucleation, nuclear molding, and nuclear margination of keratinocytes consistent with herpes simplex virus infection; viral culture confirmed the diagnosis

infections may be chronic and atypical in appearance, belying the diagnosis and leading to therapeutic delay.

In unusual cases of HSV, it is useful to think about the appearance and normal progression of the individual herpetic lesion. The initial 1–2 mm vesicle may become pustular or hemorrhagic; when unroofed, it becomes a wet or weeping 1–2 mm round erosion; then, ultimately, a crust or scab forms. When multiple lesions are present, vesicles or erosions may coalesce to form large areas of open, weeping skin. A scalloped border created by the joining of multiple individual round erosions is a morphologic clue to the origin of such lesions as typical herpetic vesicles. When chronic HSV infection occurs in an area which is moist or macerated, such as the intergluteal cleft, weeping erosions or deeper ulcerations persist. In areas which are drier, such as the cutaneous lips or nose, serous or sanguineous exudate from the erosions dries out and becomes a crusted and heaped-up plaque which may appear exophytic and verrucous (Fig. 22.6). Upon close examination, helpful clues such as a scalloped, friable, eroded, or minute vesicular border may be visible.

Given these myriad presentations, any periorificial ulcer or crust in an immunocompromised host should be considered herpes simplex until proven otherwise. Prompt diagnosis using Tzanck smear, direct immunofluorescence, PCR, culture, or skin biopsy should be used to guide management (Fig. 22.7). Correct technique for performing such tests is important to avoid false-negative results. Vesicles and crusts must be unroofed, and the raw area beneath scraped or swabbed.

Other atypical manifestations of cutaneous HSV infection in immunocompromised patients include intra-oral involvement, an unusual finding among those with intact immune systems. Intra-oral HSV appears as single or multiple erosions or ulcers on the gingiva, palate, tongue, or buccal mucosa with the characteristic scalloped or polycyclic border. Such lesions may occur without herpes labialis, making diagnosis more difficult. In transplant patients, lesions generally develop in the first 4 weeks after transplantation, often following a serious infection or rejection episode [94].

Involvement of the tongue with HSV may result in tender ulcers or linear fissures on the dorsum known as herpetic geometric glossitis [95, 96]. These ulcers may be confused with radiation or chemotherapy-induced mucositis, aphthous stomatitis, erythema multiforme, and other infectious causes. Extension of the infection into the esophagus or respiratory tract may also occur.

Chronic perianal or buttock HSV may be confused with pressure ulcers but tend to be more superficial, have scalloped borders, and involve body fold areas which are not subject to decubitus pressure. Heaped-up granulation tissue may in some cases result in exophytic papules or plaques which mimic condyloma or squamous cell carcinoma. This hypertrophic HSV, also called herpes vegetans, can occur rarely in organ transplant recipients as well as patients with AIDS [97, 98]. Superinfection with bacteria and/or yeast may further complicate the presentation of anogenital HSV and should be considered when ulcers fail to heal with antiviral therapy. Chronic herpetic ulcers in the inguinal or gluteal creases may develop so-called "kissing" lesions on the opposing side of the skin fold, another clue to the diagnosis. Deep linear fissures due to chronic HSV infection can occur in intertriginous areas like the inguinal crease or inframammary or infra-abdominal folds. Termed the "knife-cut sign," this atypical presentation of HSV in immunosuppressed patients should not be confused with other more common types of intertrigo [99].

Digital HSV infection (herpetic whitlow) occurs in immunocompetent patients, often as an occupational hazard of dentists or dental hygienists. In immunosuppressed patients, including transplant patients, digital herpes can produce paronychial inflammation and chronic fingertip ulceration [100]. Such lesions are quite painful and destructive and are frequently incorrectly diagnosed as bacterial infection or paronychia.

Disseminated HSV infection is rare following solid organ transplantation compared with bone marrow transplantation [101]. Dissemination may occur from primary HSV infection, including from the donor organ, as well as through reactivation of donor or recipient virus. Hematogenous dissemination of HSV can result in pneumonitis, hepatitis, pancreatitis, esophagitis, retinitis, encephalitis, and adrenal necrosis [102]. HSV hepatitis should be suspected in an immunocompromised patient presenting with abdominal pain, anicteric transaminitis, fever, and compatible skin lesions [103, 104].

Disseminated cutaneous HSV, also known as Kaposi's varicelliform eruption or eczema herpeticum, presents with widespread 1–2 mm vesicles or punched-out erosions. This eruption can affect immunosuppressed patients and is most likely to occur in those with preexisting skin diseases which result in dysfunctional skin barriers, such as atopic dermatitis or cutaneous T-cell lymphoma [105]. The eruption is associated with fever and malaise and increases the risk of bacterial superinfection with impetigo, cellulitis, or even sepsis. Ocular involvement may be a consequence of widespread facial HSV in this condition.

Acyclovir-resistant HSV is increasingly common among immunocompromised patients with chronic HSV [106]. The degree of immunosuppression and prolonged use of acyclovir are two important factors in the development of drug resistance, as well as erratic or suboptimal dosing or lack of compliance. In patients with profound immunodeficiency, however, lack of response to an antiviral agent does not necessarily correlate with in vitro drug resistance [107]. Acyclovir resistance should be considered when lesions do not decrease in size or when new satellite lesions develop after several days of therapy (Fig. 22.8) [108].

Varicella Zoster

Varicella zoster virus (VZV) is a common cause of vesicular rash in immunocompromised patients. VZV may be dermatomal, disseminated, or chronic. Its incidence increases with advancing age and immunodeficiency, as immunity to the virus wanes and reactivated infection occurs. The condition is increased in both solid organ and particularly bone marrow transplant recipients.

Dermatomal VZV is the most common presentation. Typical presentations are easily recognized by the unilateral distribution of vesicles over patchy erythema in a dermatomal distribution with sharp midline cutoff. One or two contiguous dermatomes may be involved, and few scattered vesicles may occur outside the affected dermatomes. As with HSV, vesicles progress over time and may become pustular, hemorrhagic, or crusted (Fig. 22.9). Pain may be severe but need not be present. Periocular lesions in the distribution of cranial nerve V1, particularly when there are vesicles at the tip of the nose (Hutchinson's sign), are worrisome for ocular involvement. Interestingly, herpes zoster may occur in areas of local immunosuppression such as sites of radiation or surgery or overlying tumors or nodal metastasis. Finally, pain may occur even if skin lesions do not develop (zoster sine herpete).

Fig. 22.8 A patient with cutaneous T-cell lymphoma status post stem cell transplant developed chronic herpes simplex virus infection on the face and hands characterized by scalloped borders, scattered intact vesicles, and hemorrhagic and yellow crusts consistent with secondary impetiginization. Refractory to several weeks of intravenous acyclovir therapy, cultures ultimately demonstrated both acyclovir-resistant herpes simplex virus and methicillin-resistant *Staphylococcus aureus*

Fig. 22.9 Varicella zoster virus manifesting as coalescing hemorrhagic vesicles in a dermatomal distribution in a patient with severe thrombocytopenia as a complication of chemotherapy

Disseminated zoster is defined as cutaneous VZV in more than three contiguous dermatomes, more than 20 lesions outside the involved dermatome (s), or evidence of systemic involvement. Dissemination to visceral organs usually occurs after the onset of the rash; pneumonitis, meningoencephalitis, and hepatitis due to VZV can be fatal. Rarely, disseminated VZV can present with severe abdominal pain and hyponatremia from the syndrome of inappropriate antidiuretic hormone secretion (SIADH) [109, 110]. Visceral zoster in bone marrow transplant patients can cause abdominal pain and progressive pancreatitis, hepatitis, and paralytic ileus which precede the onset of skin lesions and carry a mortality of 50% despite antiviral therapy [111]. Testing for VZV in the blood by PCR in the appropriate clinical setting may facilitate earlier treatment for disseminated VZV with acyclovir even if vesicles are not seen.

Another form of disseminated VZV seen in immunocompromised patients is referred to as recurrent primary varicella. This presentation is similar to primary varicella (chicken pox) with widespread vesicles on an erythematous base; however, the total number of lesions is far fewer and the course more attenuated than in primary varicella. In the setting of waning, though partial, VZV immunity, endogenous reactivation or exogenous reinfection may explain this presentation [112, 113].

Chronic herpes zoster, characterized by hyperkeratotic thickly crusted plaques, ecthymatous punched-out ulcerations or eschars, or prolonged widespread disseminated vesicles, is defined as active VZV infection that persists longer than 1 month. This presentation is most common in patients with AIDS but may rarely occur in transplant patients or those otherwise immunosuppressed [114, 115]. Many of the reported cases have demonstrated acyclovir resistance.

Cytomegalovirus

Cytomegalovirus (CMV) disease in an immunocompromised host can result from primary infection of a seronegative patient, reactivation of latent virus, or reinfection with a new virus subtype. Most is due to reactivation of latent virus. In cases of iatrogenic immunosuppression, as is seen in organ transplantation, the onset of CMV disease may be rapid. The pattern of organ involvement varies from group to group; in solid organ transplant patients, gastrointestinal ulceration and hepatitis are more common, whereas interstitial pneumonitis and myelosuppression are more common in bone marrow transplant recipients [116]. Cutaneous manifestations of CMV infection are rare in any circumstance.

Lesions of cutaneous CMV are not sufficiently distinctive to allow the diagnosis to be made on clinical grounds alone.

The most common manifestation of CMV skin infection is chronic ulceration of the anogenital area. These ulcers may be single or multiple, small or large, with sharply marginated borders. Because such ulcers can be clinically indistinguishable from those caused by chronic HSV infection, correct diagnosis relies upon culture, PCR, or histopathology. HSV and CMV co-infection in such ulcers may further complicate diagnosis and management.

Chronic ulcers due to CMV may occur elsewhere on the skin and mucous membranes. They may become quite large with purulent exudate or thick black eschar [117, 118]. Oral manifestations include painful erosions or ulcers of the lip, tongue, or buccal mucosa (Fig. 22.10).

Widespread exanthematous morbilliform eruptions due to CMV have also been described in transplant patients [119]. These eruptions, unlike other nonspecific morbilliform eruptions, demonstrate characteristic large intranuclear inclusions with a surrounding halo, the "owl's eye" nuclei of CMV, in dermal vessel endothelial cells, which may be confirmed with an immunoperoxidase stain [120]. This endothelial cell infection may evolve into capillaritis or vasculitis with consequent purpuric appearance or infarction [121–123].

Human Herpes Virus 6

Human herpes virus 6 (HHV-6), along with HSV, VZV, CMV, and EBV, is a member of the *Herpesviridae* family which is the causative agent of exanthema subitum (roseola infantum) in infancy. As with other herpes viruses, HHV-6 can establish latency after primary infection and reactivate in the setting of immunocompromise. Most such reactivations occur 2–4 weeks after transplantation [124]. The use of muromonab-CD3, alemtuzumab, and antithymocyte globulin for prevention of rejection increases the risk of HHV-6 reactivation in solid organ transplant recipients [125]. Symptoms of HHV-6 reactivation include fever, rash, pneumonitis, bone marrow suppression, and encephalitis. Typically, the rash is an erythematous morbilliform eruption not unlike acute GVHD. Because HHV-6 reactivation has been associated with the development of severe acute GVHD, and because the clinical and histologic findings are nonspecific, it is difficult to distinguish between the two entities [126].

Human Papillomavirus

Human papillomavirus (HPV) infection is common in both immunocompetent and immunoincompetent patients. In those with dysfunctional immune systems, lesions of HPV can be extensive, numerous, exuberant, and recalcitrant in addition to exceedingly common. Eighty percent of organ transplant recipients may develop warts [127].

Lesions of HPV classically are exophytic, verrucous papules or plaques which may be flat, sessile or pedunculated, brown, gray, or flesh colored (Fig. 22.11). They are commonly found in the genital region, where they may become large and confluent, locally destructive cauliflower-like masses in immunosuppressed patients. Facial, oral, and digital warts, as well as more widespread papules on the extremities and trunk, may be seen.

Fig. 22.10 A heart transplant patient presented with an ulcer on the lower lip. Biopsyzrevealed multinucleate giant cells with inclusion bodies and immunoperoxidase staining for cytomegalovirus. (Image reprinted from Grossman et al. [286], Fig. 6.65, p. 168, with kind permission from Springer Nature)

Fig. 22.11 Verrucous perianal papules and plaques of human papilloma virus infection

Molluscum Contagiosum

Typical lesions of molluscum contagiosum are 3–5 mm white or flesh-colored dome-shaped papules with central umbilication (Fig. 22.12). The presence of molluscum, especially widespread or giant molluscum, in an adult patient is a marker of immunosuppression. Such presentations are most common with advanced HIV disease but are also seen in transplant patients and those immunosuppressed for other reasons [128].

Giant molluscum may present as large verrucous or lobulated nodules. Molluscum may also cause a viral folliculitis with multiple reddish papules on the chin and cheeks mimicking tinea barbae [129]. Disseminated cryptococcosis and histoplasmosis can appear molluscoid and should be suspected in the proper clinical setting, particularly when the lesions are atypical and there are signs of systemic illness. In contrast with normal hosts, in whom molluscum is self-limited, molluscum in immunosuppressed patients can be highly recalcitrant, chronic, and resistant to therapy.

Subcutaneous and Deep Mycoses

Aspergillus

Invasive aspergillosis is the most common opportunistic fungal infection following hematopoietic stem cell transplantation [130]. Infection with this ubiquitous mold occurs in the setting of severe or prolonged neutropenia, high-dose corticosteroid therapy for graft-versus-host disease (GVHD), and other states of profound immunosuppression. Following stem cell transplant, invasive aspergillosis is now more commonly seen in the post-engraftment phase due to iatrogenic immunosuppression for GVHD than in the neutropenic period [131]. It is less common, but not infrequently seen, in solid organ transplant recipients.

Cutaneous *Aspergillus* infection can result from primary inoculation injury, in which case *A. flavus* and *A. niger* are the most common causes, or secondary dissemination, most often due to *A. fumigatus* [132]. Primary cutaneous infection generally occurs at sites of iatrogenic trauma or contamination, under arm boards or tape or where intravenous cannulas puncture the skin. Such sites are frequently hidden from view under dressings and are difficult to examine but should be visualized as part of a thorough assessment.

Lesions of cutaneous aspergillosis begin as tender erythematous or purpuric macules or papules that progress to violaceous, edematous plaques with necrotic black or purple centers and a bright purpuric rim. Lesions may become hemorrhagic bullae as the necrotic skin sloughs or ultimately black eschars (Fig. 22.13). Less common presentations include

Fig. 22.13 A hemorrhagic bulla on the forearm of a child with ALL. Potassium hydroxide (KOH) preparation, biopsy, and culture all demonstrated *Aspergillus fumigatus*. (Image reprinted from Grossman et al. [287], Fig. 1.5, p. 4, with kind permission from Springer Nature)

erythematous to violaceous plaques studded with pustules, subcutaneous purplish nodules, and cellulitic plaques, among others [133–138].

When such a lesion is noted, it should prompt a thorough examination of the remainder of the skin and mucous membranes to determine whether other lesions are present. Potassium hydroxide (KOH) prep of the blister roof can reveal characteristic broad, regularly septate hyphae dichotomously branching at acute angles, providing an immediate presumptive diagnosis [139]. Otherwise, prompt diagnosis of invasive disease through frozen section biopsy or "rushed" preparation of a fixed specimen, as well as tissue culture, is essential for proper management. Histologic findings may include intravascular thrombosis with masses of angioinvasive hyphae, hemorrhage, necrosis, and inflammatory infiltrate.

While only 10% of cases of disseminated aspergillosis have skin manifestations, cutaneous lesions may be the presenting sign of systemic disease [140]. Thus, in addition to a thorough skin exam, patients with suggestive lesions should undergo further workup, such as CT scans of the chest, abdomen, pelvis, and brain, to determine whether there is evidence of dissemination. Determination of whether a single lesion—or multiple lesions—is present is critical for guiding treatment and predicting outcome.

Single primary lesions have a more favorable prognosis than secondary or disseminated disease. In addition to systemic antifungal therapy with voriconazole, amphotericin B, itraconazole, posaconazole, or caspofungin, surgical excision and debridement may play a critical role. Because *Aspergillus* may secondarily disseminate from primary skin lesions, local control of the infection may be critical to cure. Conversely, if there is more than one cutaneous lesion or radiographic evidence of disseminated disease, there is no role for debridement, and antifungal therapy alone is used. In such cases, mortality is high, particularly without resolution of underlying immunosuppression.

Fusarium

Fusarium is a ubiquitous soil mold which can cause infection in immunocompromised patients which is clinically and histologically similar to that of *Aspergillus*. Major risk factors for *Fusarium* infection include prolonged neutropenia and corticosteroid use as commonly occurring in those with hematologic malignancies who receive stem cell transplantation and require treatment for graft-versus-host disease [141–144].

Primary, locally invasive disease presents at sites of trauma such as that which occurs with intravenous cannula placement or accidental injury to a digit or extremity. Skin lesions evolve rapidly from a painful red macule or papule into a violaceous, necrotic pustule, bulla, ulcer, or eschar with a rim of erythema [145–148].

Disseminated infection occurs almost exclusively in those who are neutropenic or status post bone marrow transplantation. Skin lesions evolve as they do in primary infection. Compared with disseminated *Aspergillus*, cutaneous lesions of *Fusarium* are more common (75–90% versus only 10%) and more numerous and widespread [3]. They appear clinically similar to lesions of other angioinvasive fungi, including *Aspergillus* and *Mucor* species, but they tend to be smaller. Associated sinopulmonary disease is common, as is fungemia.

Disseminated fusariosis is almost uniformly fatal, especially without white blood cell recovery [149]. Compared to neutropenic patients, infection which occurs in the setting of solid organ transplantation is more likely to be localized and has a better prognosis.

Scedosporium and *Pseudallescheria*

Infection with this soil saprophyte (*Scedosporium* is the asexual and *Pseudallescheria* the sexual state of the organism) is typically acquired through inhalation or inoculation. Infection is most commonly associated with hematopoietic stem cell transplants, organ transplants, hematologic malignancies, and HIV. A significant cause of disease, it is responsible for approximately 25% of non-*Aspergillus* mold infections in organ transplant recipients [150]. When infection occurs in this group, it most often does so within 6 months of transplant and with devastating consequences; more than half of patients present with disseminated disease, and around 60% die [150].

One-third of patients with *Scedosporium* infection have cutaneous lesions [151]. Localized lesions may follow trauma, whereas disseminated lesions are secondary to hematogenous spread [151, 152]. *Scedosporium* and *Pseudallescheria* may present with ulcerated dusky nodules, tender pustules, necrotic bullae, or subcutaneous suppurative nodules with spread along cutaneous lymphatics that resembles that of sporotrichosis [153–159].

Scedosporium, *Aspergillus*, and *Fusarium* can be indistinguishable in histologic section; tissue culture is required to differentiate these organisms. Blood cultures may also be positive in 75–80%, in contrast with many other disseminated fungal infections [160, 161]. Itraconazole and voriconazole, as well as surgical debridement, may be effective in some cases of *S. apiospermum* infection, but *S. prolificans* is resistant to almost all antifungals and has a mortality approaching 100% [161].

Mucormycosis/Zygomycosis

Mucormycosis, or zygomycosis, is a term used to describe invasive infection with molds of the genera *Rhizopus*,

Absidia, *Rhizomucor*, and *Mucor*. The organisms in these genera are morphologically identical and cause the same clinical disease.

These fungi are ubiquitous in the environment. In susceptible patients, they can cause rhinocerebral, pulmonary, cutaneous, gastrointestinal, central nervous system, and disseminated infections [162]. Infections most commonly present in the nose and paranasal sinuses or on the palate, from which they spread rapidly to the central nervous system through the orbit and cribriform plate.

Cutaneous mucormycosis most commonly affects patients with significant immunocompromise, including those receiving immunosuppressants following solid organ or stem cell transplantation, as well as those with prolonged neutropenia, and those receiving systemic corticosteroids and other agents for severe graft-versus-host disease [162–165]. An additional risk factor is voriconazole use for fungal prophylaxis after transplantation. Since this agent does not cover zygomycetes, its use may select for zygomycotic infection [166, 167].

Primary inoculation of mucormycosis into the skin most commonly develops at the sites of intravenous catheters, injections, burn injuries, or surgical wounds or in the setting of contaminated tape, dressings, or arm boards. An erythematous papule or plaque initially develops and then becomes purpuric, pustular, hemorrhagic, or ulcerated, ultimately developing into a necrotic eschar [168]. Infection may spread rapidly along tissue planes such that the involved area may far exceed that which is visible clinically. As with *Aspergillus* and other angioinvasive fungi, identification of a single primary cutaneous lesion is critical, as surgical debridement may be curative and systemic dissemination from a primary lesion can occur [169–171].

Secondary cutaneous mucormycosis occurs as a consequence of disseminated infection, most often originating in the lungs or sinuses in the setting of hematologic malignancy, bone marrow transplantation, and prolonged neutropenia. Lesions are most often violaceous and necrotic-appearing plaques with concentric shades of black, yellow, and purple with a thin purpuric red rim, the so-called "bull's-eye infarct" of cutaneous zygomycosis (Fig. 22.14) [172]. Histologically, this clinical appearance corresponds to hyphal invasion and thrombosis of dermal blood vessels with consequent necrosis of surrounding tissue (Fig. 22.15).

Rhinocerebral mucormycosis is the most common presentation of systemic infection. One of the earliest signs is nasal discharge. The nasal mucosa may appear black and necrotic. Invasion into the mouth may cause infarction of the palate, producing a black eschar or ulcer. Necrotic facial lesions suggest aggressive and advanced angioinvasive infection. Extension of infection through the nasal turbinates into the sinuses may result in orbital cellulitis, extraocular muscle paresis, proptosis, chemosis, and eyelid edema.

Fig. 22.14 Disseminated mucormycosis manifesting as a rapidly expanding violaceous and necrotic-appearing plaque on the neck with concentric shades of black, yellow, and purple and a peripheral rim of erythema

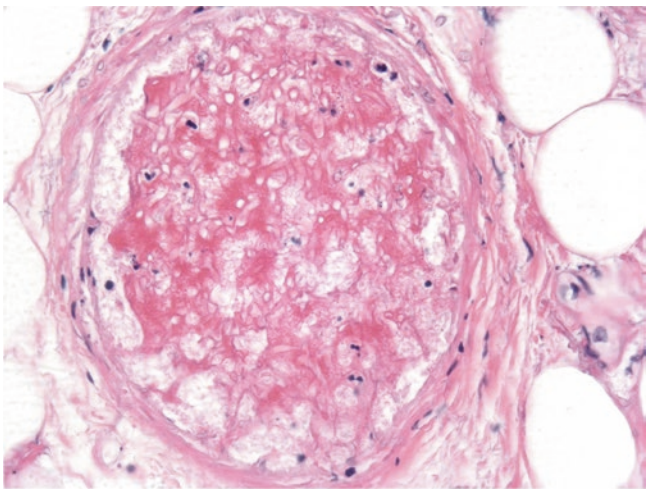

Fig. 22.15 Frozen section and permanent section biopsy demonstrated thick, translucent, ribbon-like, nonseptate hyphae with right-angle branching filling a vessel in the subcutis; findings consistent with mucormycosis. The patient had two other cutaneous lesions and multiple infarcts in the lungs, kidneys, brain, and other organs discovered on computed tomography scan and at autopsy

Diagnosis of cutaneous mucormycosis relies on histologic demonstration of tissue invasion. A touch preparation of a skin biopsy specimen to a glass slide may allow rapid confirmation of infection. Otherwise, frozen section biopsy or "rushed" permanent section processing is vitally important to dictate management [173]. Zygomycetes in tissue appear as wide, ribbon-like, nonseptate hyphae with right-angle branching. Such an appearance is suggestive, if present, but zygomycetes cannot reliably be differentiated from *Aspergillus* on the basis of histologic features alone [174]. Culture is required to identify the particular fungal organism.

The mortality rate of invasive mucormycosis is exceedingly high, on the order of 80–100% [166], particularly in the absence of hematologic recovery or resolution of the underlying immunodeficiency. Prompt initiation of amphotericin B is the therapy of choice, particularly in those already on prophylactic voriconazole. Surgical debridement can play an important role if infection is localized and not widely disseminated. Long-term or even lifelong therapy with posaconazole may be required in those who survive the acute phase of infection.

Hyalohyphomycoses

Together with *Fusarium*, this group of hyaline (nonpigmented) septate molds includes *Paecilomyces*, *Acremonium*, *Trichoderma, Scopulariopsis*, and *Trichosporon*. Though less common, these organisms are nonetheless medically important pathogens in the transplant population.

The majority of reported *Paecilomyces* infections involve those with solid organ or bone marrow transplant, chronic steroid use, or lymphoma. *Paecilomyces* enters where there has been a breakdown of the skin barrier, such as occurs with tinea pedis or onychomycosis. Lower extremity involvement is therefore common [175]. Indwelling catheters may provide another portal of entry [176]. Lesions appear as erythematous macules, vesicles, pustules, painful red nodules or furuncles, or cellulitis [177–181]. Culture and histology are necessary for diagnosis, and species identification is important to guide management. Most cases of *Paecilomyces* in immunocompromised patients are localized to the skin and achieve cure with antifungal therapy +/− surgical debridement, but *P. lilacinus* is intrinsically resistant to conventional antifungals such as amphotericin, flucytosine, and fluconazole.

Like *Paecilomyces*, *Acremonium* and *Trichoderma* are increasingly recognized opportunistic pathogens which cause a variety of presentations in immunocompromised patients with hematologic malignancies, prolonged neutropenia, chronic steroid use, or organ transplantation [182]. *Acremonium* may present with widespread painful and necrotic cutaneous papules or nodules in the setting of refractory febrile neutropenia and myalgias [183–185], frequently associated with positive blood cultures [186]. Mycetoma of the extremities with tumefaction and draining sinuses has also been reported as a manifestation of *Acremonium* in transplant patients [187, 188]. *Trichoderma* may present with necrotic, ulcerated plaques at intravenous cannula sites in immunosuppressed transplant or neutropenic patients; from there, the fungus may lead to fatal dissemination to the lungs, liver, and brain [189–192].

Cutaneous manifestations of *Scopulariopsis* infection reported in immunosuppressed transplant patients include a solitary necrotic black eschar at an intravenous cannula site, red-purple, ulcerative, subcutaneous nodules on the extremities, and onychomycosis with necrotic periungual cellulitis [193–196]. Most *Scopulariopsis* species are resistant to amphotericin B, itraconazole, and many other conventional antifungals. Surgical debridement may play an important role in eliminating localized infection.

Trichosporon is a rare but emerging opportunistic pathogen. Invasive infection most commonly affects neutropenic leukemic patients. It presents similarly to candidiasis, with fever, myalgia, endophthalmitis, and multiple necrotizing purpuric papules and nodules in one third of patients [197–201]. However, fungemia, visceral involvement, and death are more common in *Trichosporon* infection. Skin biopsy and tissue culture have high diagnostic yield. Cryptococcal antigen and *Aspergillus* galactomannan may be cross-reactive and falsely positive [202]. Case fatality approaches 80% in disseminated disease despite antifungal treatment unless hematologic recovery occurs [203].

Phaeohyphomycosis

Infection by one of these pigmented fungi, which include such organisms as *Phialophora, Fonseca, Cladosporium, Exophiala, Alternaria, and Scedosporium*, usually results from accidental inoculation of the skin with plant matter, soil, or wood. Lesions may appear up to several years after the event during immunosuppression for transplantation or other causes. A subcutaneous phaeomycotic nodule or abscess may develop, often without pain or other signs of local or systemic inflammation. Suppuration, sinus tract formation, and ulceration may occur less often, or the lesion may become scaly and verrucous [160, 204–208] (Fig. 22.16).

Disseminated phaeohyphomycosis usually occurs in immunosuppressed patients [160]. It is more common for infection to disseminate from the lungs or other viscera to the blood and skin, but secondary dissemination from the skin has also been reported [209]. Disseminated cutaneous lesions may be tender subcutaneous nodules, ulcerated papules, pustules, or nonhealing ulcers (Fig. 22.17) [210].

Surgical debridement is the treatment of choice, if possible, for primary cutaneous phaeohyphomycosis. Amphotericin B, itraconazole, ketoconazole, voriconazole, and terbinafine are antifungal agents which may be useful.

Candidiasis

Behind *Aspergillus*, *Candida* is the second most common invasive fungal infection in patients following hematopoietic stem cell transplantation. Among solid organ transplant recipients, it is the most common cause of invasive fungal

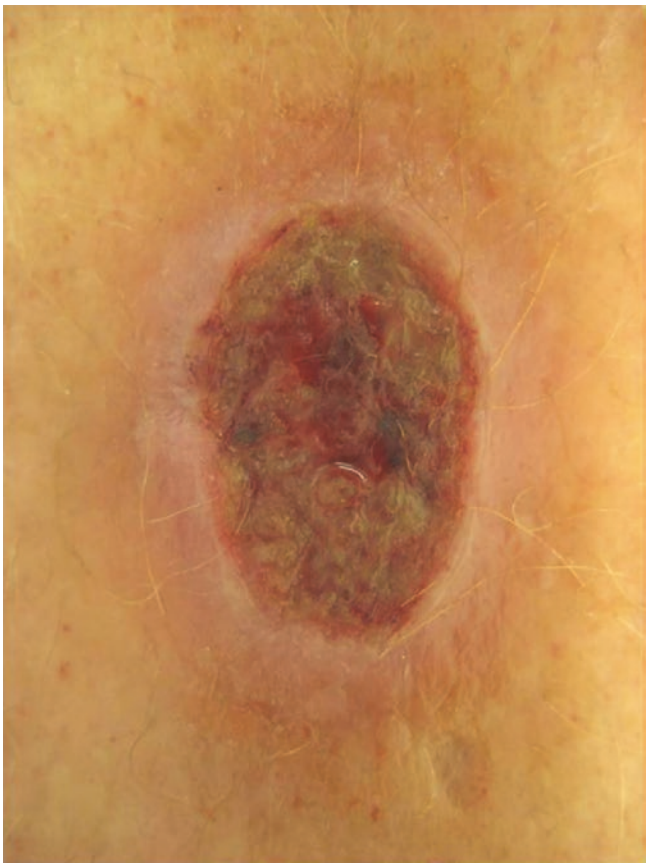

Fig. 22.16 A patient with a history of bilateral lung transplant for α-1 antitrypsin deficiency developed an indurated ulcer and two erythematous nodules on the right lower leg 11 years after transplantation. Pathology and DNA sequencing confirmed the diagnosis of phaeohyphomycosis due to *Exophiala spinifera*

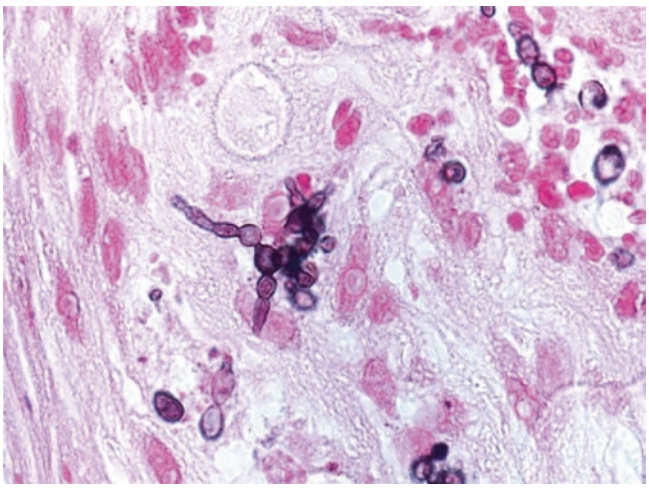

Fig. 22.17 Biopsy of the phaeohyphomycotic ulcer edge demonstrated pigmented yeast-like and pseudohyphal elements highlighted by Fontana Masson stain

infection [211]. The spectrum of infection ranges from thrush to widespread dissemination. Iatrogenic immunosuppression, chemotherapy, hematologic malignancies, neutropenia, and prolonged broad-spectrum antibiotics predispose to disseminated candidiasis. The gastrointestinal tract, indwelling lines, and even a transplanted organ may be the source of dissemination [212].

Candida albicans causes approximately half of disseminated candidiasis—*C. glabrata*, *C. tropicalis*, *C. krusei*, and *C. parapsilosis* account for most of the rest of infections. About 10–13% of the time, disseminated candidiasis is associated with skin lesions [213]. Of these cases, *C. albicans* causes only about 10%, whereas *C. tropicalis* and *C. krusei* make up the majority [131, 214, 215].

Diagnostic delay is a significant contributing factor for the high mortality associated with disseminated candidiasis. Nonspecific symptoms and a frequent lack of positive blood cultures make diagnosis difficult. The presence of cutaneous lesions, however, provides an opportunity for earlier diagnosis and treatment.

Skin lesions may be single or multiple, localized or diffuse, most often involving the trunk and proximal extremities. Morphologically, they are typically erythematous 0.5–1.0 cm papules may be purpuric and can have pale, necrotic, or pustular centers. (Fig. 22.18). Subcutaneous nodules, folliculitis, and cellulitis-like plaques may also occur. Patients are often ill-appearing with fever and clinical deterioration despite therapy with broad-spectrum antibiotics.

Disseminated candidiasis can also cause endophthalmitis with blurred vision and eye pain, as well as muscle abscesses with fever and severe myalgias. Hepatosplenic infection is also characteristic.
