Fig. 25.5 The canonical Wnt signaling pathway. (**a**) Off state. The Wnt signaling pathway is in the off state either when Wnt is not present or when Wnt binding to its membrane-bound receptors, including Frizzled (Frz) proteins and co-receptors low-density lipoprotein receptor-related protein (LRP), is prevented by Wnt binding to other factors, including CER1, WIF1, and SFRP. In the cytoplasm, a complex composed of APC, Axin, casein kinase 1 (CK1), and glycogen synthase kinase 3β (GSK3β), aptly named the destruction complex, phosphorylates β-catenin and targets it for destruction. In the destruction complex, GSK3β and CK1 act to phosporylate β-catenin, while Axin and APC function as scaffold proteins that assemble substrate (β-catenin) and enzymes (GSK3β and CK1). β-Transducin repeat-containing protein (βTrCP) shuttles phosphorylated β-catenin to the proteosome for degradation. In the nucleus, Wnt target genes are silenced by a repressor known as Groucho that interacts with DNA-bound T-cell factor (TCF). In addition, the inhibitor of β-catenin (ICAT) and Chibby further suppress β-catenin nuclear activity. (**b**) On state. In the on state, Wnt binding to Frz and LRP results in phosphorylation of the LRP cytoplasmic tail by CK1 and GSK3β as well as recruitment of axin to phosphorylated LRP by dishevelled (Dsh) to inactivate the destruction complex. In the nucleus, Wnt target genes can be transcribed by displacement of Groucho, TCF interaction with β-catenin and recruitment of B cell lymphoma 9 (Bcl9), Pygopus, mixed-lineage leukemia (MLL) methyltransferases, APC, C-terminal-binding protein (CtBP), and βTrCP. Several target genes known to be regulated by β-catenin and Wnt signaling have been identified including *c-myc, cyclin D1, CDH1, Tcf-1, c-jun, Fra-1, PPARd, Gastrin, uPAR, MMP7, Survivan, Axin2/Conductin, CD44, Id2,* among others. Figure used by permission from Schneikert and Behrens [96].

20 amino acid repeats. The truncations result in removal of an interaction site with AXIN and consequent dysregulation of β-catenin degradation. In addition, the truncated APC protein lacks nuclear export sequences (NESs), which appears to be important in normal shuttling of β-catenin from the nucleus to the cytoplasm [97].

While APC has been primarily characterized as a scaffold protein in Wnt signaling as discussed above, there is emerging evidence of its role in Wnt pathway-independent activities which may contribute to carcinogenesis. There are data that APC is involved in apical-basal and front-rear polarity, migration, differentiation, DNA replication, mitosis, DNA repair, and apoptosis. Appreciation of APC's Wnt-independent activities has important implications especially as Wnt inhibitors are being investigated as cancer therapeutics. For a comprehensive discussion of APC and Wnt-independent pathways, readers are directed to a review by Prosperi and Goss [98].

25.5.3.3 Wnt Pathway Inhibitors

Given evidence of dysregulated Wnt signaling in CRC as well as other tumor types, there has been interest in developing agents that can inhibit the pathway and prevent nuclear transcriptional functions of β-catenin. There are two classes of Wnt pathway inhibitors: small-molecule and biological inhibitors [99]. Small-molecule inhibitors of the Wnt pathway include agents such as nonsteroidal anti-inflammatory drugs (NSAIDs), vitamins (such as A and D), and polyphenols (such as curcumin and resveratrol). NSAIDs, such as aspirin, sulindac, and cyclooxygenase (COX) inhibitors,

have been studied for prevention of adenomas in FAP and in patients with CRC. Their mechanism of action might be through inhibition of Wnt signaling via prostaglandin suppression of β-catenin degradation [100]. Additional small-molecule inhibitors have been identified through high-throughput screening studies and are classified into four groups: β-catenin/TCF antagonists, transcriptional co-activator modulators, PDZ domain of Dvl binders and alternative mechanism-based inhibitors. These agents are largely still in discovery or preclinical development; though, in 2010, a transcriptional co-activator modulator targeting CBP is in phase I testing. Biological inhibitors include monoclonal antibodies and small interfering RNA (siRNA) against Wnt-1 and/or Wnt-2 have shown promise as possible therapeutic agents and are currently in preclinical development. While Wnt pathway inhibitors hold promise as therapeutic agents, there are concerns about specificity given the role of Wnt signaling in normal cell homeostasis, in particular, stem cell homeostasis. The future of Wnt pathway inhibitors as therapeutic agents depends on specifically targeting tumor cells with aberrant Wnt signaling. The role of newer Wnt pathway inhibitors in FAP remains to be determined.

25.6 Muir-Torre and Turcot Syndrome

Muir-Torre and Turcot syndrome are rare variants of hereditary CRC syndromes. Individuals with Muir-Torre present with uncommon sebaceous skin tumors and internal malignancies. Most patients have mutations in *MSH2* though there have been reports of mutations in *MLH1* as well. Interestingly, some of *MSH2* mutations in this variant are the same as those in classic Lynch syndrome perhaps due to underreporting of personal or family histories of skin conditions. A review paper provides additional detail on Muir-Torre syndrome [101].

Turcot syndrome (TS) describes patients with hereditary CRC associated with CNS tumors. The molecular basis of TS can result from germline defects in *APC* or MMR genes. TS due to mutations in MMR genes results in CRC and gliomas in both children and adults. In contrast, TS associated with *APC* mutations leads to CRC and childhood cerebellar medulloblastoma. Reported mutations in MMR genes associated with TS include *MSH2, MLH1,* and rarely, *PMS2.*

25.6.1 MYH-Associated Polyposis (MAP) Syndrome

Since 2002, a distinct hereditary polyposis syndrome associated with mutations in the gene *MUTYH*, which is the human ortholog of the base-excision repair gene *MutY* of *Escherichia coli*. MUTYH is a DNA glycosylase that initiates the base-excision repair of specific lesions in oxidized DNA; consequently, mutations in *MUTYH* lead to accumulation of mutations due to oxidative DNA damage. The 8-oxo-guanine (GO) lesion is the major oxidative lesion in DNA, which results in a GO:C mismatch in the DNA [102]. The mismatch is repaired by the product of the *OGG1* gene and the base-excision repair pathway (Fig. 25.6). However, if the GO base is not repaired prior to DNA replication, a GO:A base pair will arise after DNA replication. The mismatched A base pair is specifically excised by MUTYH. Following excision of the A base pair, a C base is inserted opposite the GO base and the GO:C mismatch is subsequently resolved to a G:C base pair by *OGG1* and the base-excision repair pathway.

The initial discovery of *MUTYH* in cancer susceptibility came through a study of a family of three sibs with *APC* mutation-negative FAP [103]. By sequencing the *APC* gene in the colonic adenomas, investigators discovered a skew in the types of somatic mutations that had arisen in the *APC* gene. The skew in mutation types was consistent with a defect in the base-excision repair of oxidative damage. All three siblings were genetic compounds for the *MUTYH* mutations Y165C and G382D, whereas unaffected family members were either homozygous for the normal allele or heterozygous suggesting autosomal recessive inheritance. These *MUTYH* mutations greatly reduced the activity of the protein when experimentally introduced at the orthologous position in the *E. coli* MutY protein. Further genetic epidemiologic studies have confirmed that Y165C and G382D are disease-causing mutations associated with MAP. These mutations account for the majority of Caucasian cases of MAP [104, 105]. Biallelic *MUTYH* mutations have been detected in approximately 0.5 % of consecutive CRC cases. This frequency is approximately 50–100 times greater than the expected frequency of biallelic *MUTYH* mutations carriers in the general population. In addition, 36 % of the CRCs arising in biallelic *MUTYH* mutation carriers occur in the absence of detectable polyp development. There is evidence for a small increase in CRC risk in carriers of mono-allelic *MUTYH* mutations [106].

Clinically, MAP may be difficult to distinguish from FAP or AFAP in that numbers of adenomas can range from none to hundreds. Furthermore, polyp histology appears to be heterogeneous in MAP with hyperplastic and sessile serrated adenomas being common [107]. This finding suggests that aberrant base-excision repair targets both *KRAS* as well as *APC* in MAP. In contrast to FAP, MAP presents at a later age with a mean age of CRC diagnosis at age 50 and there is rarely a significant family history of CRC. Genetic testing

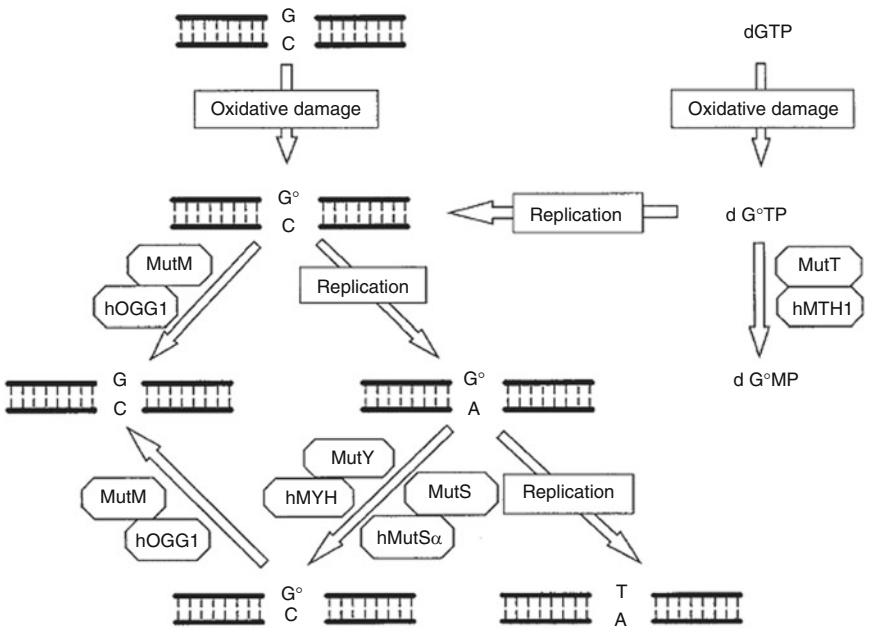

Fig. 25.6 Base-excision repair. In *E.coli,* MutT, MutM, MutY, and MutS and their respective homologues in humans, hMTH1, hOGG1, hMYH, and hMutSα repair oxidative DNA damage. Specifically, this mechanism protects against the mutagenic effects of 8-oxo-guanine (G°). MutT (hMTH1) prevents 8-oxo-dGMP incorporation into DNA. MutM (hOGG1) is a DNA glycosylase that removes the oxidized base. MutY (hMYH) is also a DNA glycosylase that excises the A residue that is misincorporated opposite the 8-oxoG residue during replication. MutS (hMutSα) is an alternative pathway for this excision step. Cells defective in base-excision repair accumulate G:C to T:A transversions. In MYH-polyposis, patients have defective hMYH function due to biallelic mutations. Used by permission from Lu [117].

for MAP is done when a patient with polyposis tests negative for *APC* mutations. Currently, affected individuals should undergo regular colonoscopy and probably also upper endoscopy to screen for duodenal polyposis. Unfortunately, due to its recessive inheritance, MAP patients may not be diagnosed until multiple polyps and/or CRC is already present.

25.6.2 Hamartomatous Polyposis Syndromes

A distinct group of hereditary polyp conditions result in formation of hamartomas, which are an overgrowth of mesenchymal, stromal, endodermal, and ectodermal tissues. Together, these conditions represent <1 % of all CRC. However, given the substantial risk of cancer in affected individuals and the possibility of genetic testing/counseling in family members, understanding these syndromes is important. A number of syndromes fall into the hamartomatous polyposis group, including familial juvenile polyposis, Cowden's disease, Peutz-Jeghers, Bannayan-Riley-Ruvalcaba syndrome, Basal nevus syndrome, Neurofibromatosis I, MEN2B, and mixed polyposis. A summary of clinical, genetic, and pathophysiologic characteristics is presented in Table 25.5. An in-depth discussion of hamartomatous syndrome can be found in a comprehensive review article [108]. Here, we briefly discuss familial juvenile polyposis, Cowden's disease, and Peutz-Jeghers.

25.6.3 Familial Juvenile Polyposis

Familial juvenile polyposis is estimated to have an incidence of 1:100,000 live births and is the most common of the hamartomatous syndromes. It is inherited in an autosomal dominant fashion. It is characterized by multiple hamartomas in the colon and rectum. The syndrome can co-occur with Osler-Weber-Rendu syndrome. Risks of colon, gastric, small intestinal, and pancreatic cancer are increased. By age 60, the risk of CRC is estimated at 68 % and of gastric cancer at 20 %. Screening with colonoscopy and upper endoscopy is important with referral for colectomy in cases of diffuse polyposis. The genes involved include SMAD4, on chromosome 18q21.1, which encodes a protein involved in signal transduction in response to TGF-β, and *BMPR1A*, on 10q22.3, which encodes a receptor for BMP1.

Table 25.5 Hamartomatous syndromes

Syndrome	Gene (location)	Cancers	Select clinical features
Juvenile polyposis	*SMAD4*(18q21.1) *BMPR1A*(10q22.3)	Colon Gastric small intestine Pancreatic	Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu) especially with *SMAD4* mutations
Peutz-Jeghers	*STK11*(18p13.3)	Thyroid Ovarian Lung Pancreatic Breast	Predominantly small intestinal hamartomas that may obstruct or bleed; hyperpigmented macules mouth, eyes, nostrils, perianal, buccal mucosa
Cowden's	*PTEN*(10q23.31)	Thyroid Breast Endometrial Brain Renal cell Colon	Mucocutaneous features (present in up to 80 %) Macrocephaly Mixed colonic polyposis

Adapted from Schreibman *Am J Gastroenterol* 2005 [108]

25.6.4 Peutz-Jeghers Syndrome

PJS is a hamartomatous polyposis associated with mucocutaneous hyperpigmentation. The incidence is similar to Cowden's syndrome at 1:200,000 live births. It is inherited in an autosomal dominant fashion. There is variable penetrance with some affected family members developing polyps and oral hyperpigmentation and some only with skin changes. In contrast to familial juvenile polyposis and Cowden's syndrome, polyps are more often seen in the small intestine, although they do occur in the colon and stomach. Polyps usually form in early adolescence. Besides oral mucosal hyperpigmentation, PJS can be associated with genitourinary tumors. There is a risk of malignant transformation in the intestinal polyps as well as in breast, ovarian, and pancreatic tissue. One gene associated with PJS is *STK11*, a serine-threonine protein kinase 11 (*LKB1*), located on 19p13.3. This gene product is a tumor suppressor gene. A quarter of PJS mutations are thought to be de novo or result from low-penetrance variants. Aggressive screening is recommended given the possibility of multiple cancers.

25.6.5 Cowden's Syndrome

Cowden's syndrome has an incidence estimated at 1:200,000 live births. It also has an autosomal dominant inheritance pattern. Mutations in the phosphatase and tensin homolog gene (*PTEN)* on chromosome 10q23 have been associated with individuals with Cowden's syndrome. Cowden's syndrome may involve the skin, breast, and thyroid. Lifetime risk of breast cancer is estimated at 36 % and of thyroid cancer at 10 %. The risk of CRC is controversial, though screening with colonoscopy is advocated. A study of 127 *PTEN* mutation carriers undergoing routine colonoscopic screening showed that mixed polyposis especially hyperplastic polyps was common and that the risk of early-onset colorectal cancer was greatly elevated compared to controls [109].

25.7 Conclusion

Mendelian CRC hereditary syndromes reviewed in this chapter have provided great insight into molecular mechanisms of colorectal cancer overall. Moreover, timely identification of mutation carriers and at-risk family members allows for implementation of surveillance programs and surgical treatments that save lives. While there are clearly unanswered questions remaining in hereditary CRC syndromes, great progress has been made in this field since Warthin's original description of cancer-prone families in the early 1900s.

Returning to the question posed in this chapter's introduction "…*what is hereditary CRC?*...," there is clearly more to CRC heritability than the Mendelian syndromes reviewed here. A few notable examples of developments in the field warrant comment. Recent work has identified a likely new rare CRC susceptibility gene *GALNT12* which is involved in O-glycosylation leading to aberrant glycosylation [110]. A study using familial CRC kindreds identified a linkage peak at chromosome 9q22-31 [111], which has been validated in multiple, independent studies [112, 113]. Further fine-mapping localized this linkage signal to a five SNP haplotype at 98.15 Mb on chromosome 9q which harbors a number of candidate genes [114]. Another study has identified germline structural variants in the tumor suppressor gene *PTPRJ* in early-onset CRC that leads to hypermethylation and gene inactivation [115].

Finally, much effort has been invested in identifying novel genetic variants that increase susceptibility to CRC using genome-wide technologies. Genome-wide association studies have identified common genetic variants (with minor allele frequencies over 5 %) using familial and/or early-onset cases [116]. These studies have yielded important results. In particular, they have highlighted the TGFβ/SMAD signaling pathway in CRC susceptibility and many novel associations have opened new avenues in genetic risk factor research. More work is needed to identify likely causal variants in these genes/chromosomal regions and test their functional consequences. With the advent of next-generation sequencing,

the field is moving toward whole-exome and whole-genome sequencing to discover common as well as rare susceptibility variants. While these approaches have substantial bioinformatics challenges, the future is bright in our efforts to further elucidate molecular mechanisms of CRC.

Hereditary Breast and Ovarian Cancer

26

Michael P. Lux, Mayada R. Bani, Peter A. Fasching, and Matthias W. Beckmann

BRCA1/BRCA2-associated BC has special pathological characteristics. The lesions have an increased mitotic rate greater pleomorphism, higher proliferation rates, a lower grade of differentiation, and are more often grade III. *BRCA1*-associated carcinoma is more frequently estrogen-receptor-negative and progesterone-receptor-negative. Hereditary and sporadic OC show similar pathological characteristics, but the affected women have a longer relapse-free interval after initial chemotherapy and a longer overall survival.

Clinical options require information regarding the risks of the disease and its mutation status. Chemoprevention is currently a controversial topic. The use of oral contraceptives can be regarded as reducing the risk of OC. Prophylactic mastectomy and bilateral ovariectomy are the only options that lead to a demonstrable reduction in risk but they do of course affect the patient's physical integrity. It is not currently known whether intensified early cancer detection is individually beneficial, but this is currently the option that is least invasive and least burdensome to the patient. Although hereditary BC has different pathological characteristics and the *BRCA* mutation is an independent negative prognostic factor, there are currently no special treatment guidelines. Without adjuvant hormone therapy or chemotherapy, the overall survival in *BRCA* mutation carriers is reduced. Chemotherapy regimens involving platinum are particularly beneficial in the treatment of hereditary BC.

26.1 Introduction

Breast cancer (BC) is the most frequent form of carcinoma in women. The incidence of BC is still increasing, particularly in women under the age of 50 [1]. Most cases of BC affect older women and have a sporadic pathogenesis. Approximately 10–15 % of all cases of BC and 25–40 % of cases in patients under the age of 35 involve a genetic predisposition. *BRCA1/BRCA2* mutations are responsible for 3–8 % of all cases of BC and 15–20 % of familial cases (but are found in over 80 % of families in which six or more cases occur) [2, 3]. In addition, the familial BC risk is associated with an increased risk for ovarian cancer (OC). Ten percent of all cases of OC involve a predisposition with autosomal-dominant inheritance, particularly with *BRCA1/BRCA2* mutations [4]. The cumulative risk for disease is 39 % in carriers of the *BRCA1* mutation and 11 % in carriers of the *BRCA2* mutation, up to the age of 80 [5]. Most cases of OC are diagnosed at an advanced stage [6]. The prognosis is still poor, despite the enormous efforts that have been made in the field of therapy. It is essential to identify and provide genetic consultation for women who are at high risk, in order to assess the individual disease risk, calculate the probability of mutation carrier status, offer genetic analysis, advise women on the need for intensified early detection of cancer, provide preventive care and prophylactic surgery, and offer psychological support [1, 7, 8].

26.2 Epidemiology

26.2.1 Carcinoma Incidence and Risk for Disease by the Hereditary Breast and Ovarian Cancer Syndrome

The incidence of BC is still increasing. However, current studies suggest that the mortality is declining due to improved diagnostic methods, adequate early cancer detection programs,

and increased awareness regarding BC in the general population [9]. The cumulative risk of developing BC is 2 % up to the age of 50, and it increases to 10 % up to the age of 80 [10]. There are many risk factors for BC (Table 26.1) [3, 11]. In addition, factors such as age, a lack of previous pregnancies, and a family history of BC increase the risk [12, 13]. Nutrition, lack of exercise, environmental factors, use of oral contraceptives, and hormonal therapy can also affect the risk [12].

A family history of BC is an important risk factor. The disease has a hereditary pathogenesis in approximately 5–10 % of all patients with BC and 25–40 % of those under the age of 35. The risk of developing BC increases with the number of affected family members (Table 26.1)—for example, it is doubled when there is a first-degree relative with BC [14].

Mutations in the *BRCA1* and *BRCA2* genes are responsible for 3–8 % of all cases of BC and 40 % of familial cases of BC [2, 3]. The prevalence of germline *BRCA1* or *BRCA2* mutations in the general population is 0.1–0.2 % [15]. The risk of BC up to the age of 70 is 65 % (95 % CI, 44–78) for *BRCA1* mutation carriers and 45 % (95 % CI, 31–56) for *BRCA2* mutation carriers [5]. In addition, mutation carriers have an increased risk of developing a relapse after BC. Haffty et al. [16] reported a relapse rate of 49 % during a follow-up period of 12 years (with a rate of sporadic carcinoma of 21 %).

Women with a familial risk, particularly those with *BRCA1/BRCA2* mutations, develop the disease at a younger age than in sporadic cases. *BRCA1* mutation carriers have an 18 % risk (15 % for *BRCA2* mutation carriers) of developing BC up to the age of 39, and the risk increases to 59 % (34 % for *BRCA2* mutation carriers) in the age group of 40-49 years [17]. Malone et al. [18] detected a *BRCA* mutation in 9.4 % of women with BC under the age of 35 and in 12.0 % of women with BC under the age of 45.

Table 26.1 Risk factors for breast cancer [3, 11]

Risk factor	Relative risk (RR)
Family history	
First-degree relative with BC	2.40
Mother with BC before the age of 50	2.41
Sister with BC before the age of 50	3.18
Two first-degree relatives with BC	2.93
Three or more first-degree relatives with BC	3.90
History of breast biopsy	
Atypical ductal hyperplasia	4.30
Lobular carcinoma in situ	6.90
Reproductive history	
Age at first childbirth 35 years versus 20 years	1.32
Age at menarche 11 years versus 13 years	1.20
Age at menopause 54 years versus 50 years	1.31

BC breast cancer

OC is the sixth most frequent cancer in women, and there has been a noticeable increase in the incidence of the disease over the last century. The highest incidences in the world are found in developed Western countries, although stabilization in the incidence has been noted during the last 30 years. The use of oral contraceptives (reducing ovulation) and the practice of carrying out bilateral ovariectomy in patients undergoing hysterectomy are partly responsible for this trend [1].

The risk of OC rises with increasing age and involves hormonal interactions. Table 26.2 provides an overview of the risk factors for OC [19]. A considerable increase in the risk is observed in patients with a family history of OC. At least 10 % of all epithelial ovarian cancers are hereditary, with mutations in the BRCA genes accounting for approximately 90 % of cases and most of the remaining 10 % being attributable to hereditary nonpolyposis colorectal cancer [20]. Women with a *BRCA1* mutation have a cumulative lifetime risk of 39 % (95 % CI, 18–54) of developing OC, while in those with a *BRCA2* mutation the cumulative lifetime risk is 11 % (95 % CI, 2.4–19) [5]. The risk increases with age. King et al. [21] reported a risk of 3 % (2 % in *BRCA2* mutation carriers) of developing OC under the age of 40. The risk increased to 21 % (2 % in *BRCA2* mutation carriers) up to the age of 50, 40 % (6 % in *BRCA2* mutation carriers) up to the age of 60, and 46 % (12 % in *BRCA2* mutation carriers) up to the age of 70. The lifetime risk was 54 % (23 % in *BRCA2* mutation carriers). Other studies have reported risk levels of 29 % (in *BRCA1* mutation carriers) and 0.9 % (in *BRCA2* mutation carriers) up to the age of 50 [3, 22].

Table 26.2 Risk factors for ovarian cancer [19]

Risk factors	Relative risk (RR)
Family history	
First-degree relative diseased	3.1–3.6
Second-degree relative diseased	2.9
Two or more relatives diseased	4.6
Hereditary syndrome (HBOC/HNPCC)	25–30
Additional risk factors	
History of infertility	2.0–5.0
No pregnancies	2.0–3.0
Early menarche	1.5
Late menopause	1.5–2.0
Women from North America/Europe	2.0–5.0
Caucasian	1.5
Exposure to talc	1.0–2.5
Socially advantaged living standard	1.5–3.0
Older age	3.0
Nutrition (animal fibers, galactose)	1.5–2.0

HBOC hereditary breast-ovarian cancer, *HNPCC* hereditary nonpolyposis colorectal cancer

26.2.2 BRCA1/BRCA2 and Other Hereditary Breast and Ovarian Cancer Syndromes

BRCA mutations are responsible for a large proportion of cases of familial BC with autosomal-dominant inheritance. However, these only represent a small proportion of all cases of hereditary BC. *BRCA1* and *BRCA2* are each responsible for 20 % of cases of familial carcinoma [23]. In recent years, a number of other genes have been identified that are associated with a predisposition to develop BC. *CHEK2* was detected in 1999. *CHEK2* is a tumor-suppressor gene that encodes a protein kinase required for DNA repair and replication [24]. *CHEK2* mutations can be identified in 5 % of patients with familial BC, and are also associated with a disposition to develop sarcoma and brain tumors. The individual lifetime risk of developing BC is less than 20 % [23]. The Li–Fraumeni syndrome is caused by mutations in *TP53*. It is responsible for approximately 1 % of cases of familial BC. The lifetime risk of BC is 90 %. *PTEN* mutations cause a predisposition to develop thyroid carcinoma, BC, and benign hamartoma (Cowden's disease), but are only responsible for a small proportion of familial BC syndromes [23]. The type I Lynch syndrome (hereditary nonpolyposis colorectal cancer, HNPCC) involves the development of colorectal carcinoma at a young age. Type II also involves extra-colorectal carcinoma, particularly in the female reproductive tract [25]. Women in HNPCC families have a tenfold increase in the risk of developing OC [26]. Table 26.3 presents an overview of common hereditary BC and OC syndromes [27].

Fifty-four percent of cases of familial BC are caused by genes that have not yet been identified, with a variable level of associated risk [23]. Identifying these genes is challenging due to their genetic heterogeneity, reduced penetrance, and different frequencies of mutation. Numerous approaches have been tested in the effort to identify other high-penetrance and low-penetrance genes. Case-control studies are used to identify polymorphisms with an associated risk. Candidate genes are selected on the basis of biological plausibility—usually genes involved in cellular processes such as detoxification, DNA repair, immune system control, and steroid hormone metabolism. A large number of genes have already been described [28].

Women with *BRCA* mutations show a high degree of variability in the site of BC and in age at diagnosis. This can be explained by different types or locations of the mutations. On the other hand, exogenic factors or risk-modifying genes might also be responsible for the variation. Another approach has attempted to describe risk modifiers of this type [29]. Hereditary BC and OC syndrome is a complex phenomenon that involves multiple factors, with numerous different approaches needed to understand the genesis.

26.2.3 The Hereditary Breast and Ovarian Cancer Syndrome and Other Associated Carcinomas

Women with two BC and/or OC lesions are at increased risk of developing other types of cancer. Evans and colleagues [30] analyzed the data for 2813 women in England who had at least two carcinomas of the breast and/or ovaries (2274 women with two BCs, follow-up 4.9 years; 25 women with two OCs, follow-up 2.7 years; and 514 women with BC and OC, follow-up 2.7 years). An increased risk was found for four different types of carcinoma. The standard incidence ratio (SIR) was 14.7 (95 % CI, 1.73–51.6) for oropharyngeal carcinoma, 4.68 (95 % CI, 2.02–9.22) for malignant melanoma, 3.07 (95 % CI, 1.72–5.06) for endometrial carcinoma, and 5.04 (95 % CI, 1.8–11.0) for myeloid leukemia. The SIR for colon carcinoma was 1.60, but the figure did not reach statistical significance (95 % CI, 0.93–2.54). These observations are almost identical with the published data for

Table 26.3 Hereditary carcinoma syndromes including BC or OC [27]

Syndrome	Chromosome, gene	Primary carcinoma	Secondary carcinoma
Familial BC/OC syndrome	17 g21 *BRCA1*	BC, OC	Colon carcinoma, prostate carcinoma
Familial BC/OC syndrome	13q12 *BRCA2*	BC, OC	Male BC, endometrial carcinoma, prostate carcinoma, oropharyngeal carcinoma, pancreatic carcinoma
Cowden's disease	10q23 *PTEN*	BC, thyroid carcinoma	Intestinal hamartoma, cutaneous lesions
Li–Fraumeni syndrome	17p13 *TP53*	Sarcoma, BC	Brain tumor, leukemia
HNPCC	2p15 *MSH2, 3, 6* 3p21 *MLH1* 2p32 *PMS1* 2p32 *PMS1* 7p22 *PMS2*	Colorectal carcinoma	Endometrial carcinoma, OC, Muir–Torre syndrome, hepatobiliary carcinoma, genitourinary carcinoma, glioblastoma
Louis–Bar syndrome	11 g22 *ATM*	Lymphoma	Cerebellar ataxia, immune deficiency, glioma, medulloblastoma, BC (heterozygous)
CHEK2	13q21 *CHEK2*	BC, sarcoma, brain tumor	

BC breast cancer, *HNPCC*, hereditary nonpolyposis colorectal cancer, *OC* ovarian cancer

BRCA-linked carcinomas. The Breast Cancer Linkage Consortium [22] detected an increase in the relative risk of developing oropharyngeal cancer (RR 2.26) and malignant melanoma (RR 2.58). In addition, there was an increased risk for gastric cancer (RR 2.59), carcinoma of the gallbladder (RR 4.97), and pancreatic cancer (RR 3.51). *BRCA2* mutation carriers have no increased risk for colorectal carcinoma, but *BRCA1* mutation carriers have a relative risk of 4.11. The risk of prostate carcinoma is also increased (RR 1.82) [31]. Women aged 15–34 whose mother had two BCs were found to be at increased risk in a Swedish study (SIR 2.26; 95 % CI, 1.04–4.34) [32]. Together with the data published by Evans et al. (showing a fivefold increase in the risk) [30], these results underline the hypothesis that the lesions have a similar origin. Evans et al. [30] did not detect a higher risk of developing cervical cancer, but this might be explained by the average age of the group of patients studied (56 years). Thompson et al. [31] reported a relative risk of 3.72 (95 % CI, 2.26–6.10) on the basis of a study including 699 *BRCA1* mutation carriers and 11,847 relatives. The risk of endometrial cancer was also increased (RR 2.65; 95 % CI, 1.69–4.16). The Hereditary Ovarian Cancer Clinical Study Group [33] diagnosed six of 857 women with *BRCA1* or *BRCA2* mutations with endometrial cancer after an average follow-up period of 3.3 years, in comparison with 1.13 cancers expected (SIR 5.3; $P=0.0011$). Four of the six patients had used tamoxifen in the past. The risk among women who had never been exposed to tamoxifen treatment was not significantly elevated (SIR 2.7; $P=0.17$), but among the 226 participants who had used tamoxifen (220 as treatment and six for the primary prevention), the relative risk for endometrial cancer was 11.6 ($P=0.0004$). The main factor contributing to the increased risk for endometrial cancer among *BRCA* carriers is tamoxifen treatment for a previous breast cancer.

26.3 Genetics

Modern molecular–biological techniques have made it possible to obtain new insights into the genetic basis for carcinogenesis. The genes that play a key role in carcinogenesis can be classified into different categories (e.g., oncogenes, tumor-suppressor genes). *BRCA1* and *BRCA2* are tumor-suppressor genes with autosomal-dominant inheritance.

The existence of a familial disposition to develop BC and OC has been recognized for many years, but the genetic basis for this was unclear until 1990. Families with large numbers of individuals who developed BC and OC were recorded for linkage analyses, and a locus was detected on chromosome 17 [34]. Tumors in family members almost always showed a loss of heterozygosity at 17q, suggesting that the associated gene, named *BRCA1*, was a tumor-suppressor gene. Further studies confirmed the location of *BRCA1*, and an 8 cM-long candidate region in men and a 17 cM-long region in women was identified within the following 2 years. Finally, mutations in the *BRCA1* gene were detected in five independent cases [35]. Subsequently, missense mutations were detected throughout the opening reading frame, which suggested that the full-length gene product is a major effector of tumor suppression. At the same time, a further susceptibility gene, *BRCA2*, was described on 13q12 [36].

In 1971, Knudson observed that two consecutive mutations in a single tumor-suppressor gene are necessary to transform a normal cell into a tumor cell [37]. The identification of homozygous tumor cells in heterozygous patients led to the conclusion that one mutation is inherited, while the second mutation—with loss of the remaining functional copy of the tumor-suppressor gene—is acquired during an individual's lifetime [38]. It is assumed that a two-hit mechanism of this type is responsible for many hereditary cancer syndromes involving Mendelian inheritance. Normally, the first inherited mutation is a point mutation, while the second mutation is caused by loss of part of the chromosome by nondisjunction, mitotic recombination, or de novo deletion in familial and also sporadic cases. The mechanism involved in *BRCA1* and *BRCA2* differs from that in Knudson's model, which was originally proposed to explain both familial and sporadic cases of retinoblastoma due to mutation of a single tumor-suppressor gene. Loss of heterozygosity can be seen at the *BRCA1* and *BRCA2* locus in sporadic BC, but the remaining allele almost never mutates [39]. *BRCA*-linked disease is therefore reserved for the hereditary syndrome, and *BRCA*-associated BC must be regarded as a different entity from sporadic BC. This view is supported by differences in the pathology, prognosis, and therapeutic management.

Although little is known regarding the functions of *BRCA1* and *BRCA2*, some similarities between the two genes have been described. It is now clear that the normal protein products of *BRCA1* and *BRCA2* are involved in the fundamental cellular processes of maintaining genomic integrity and transcriptional regulation. Both genes have a comparable length of genomic DNA and are activated in most tissues. *BRCA1* consists of 24 exons, 22 of which encode for the protein [40]. The ATG start codon is on exon 2. Exon 11, which consists of 3427 base pairs, is exceptionally long and covers more than half of the encoding regions of *BRCA1*. The complete sequence is known.

BRCA2 has 27 exons and approximately 80 kb. Like *BRCA1*, *BRCA2* has large encoding exons. Exon 10 consists of 1116 bp and exon 11 of 4933 bp. Both genes encode for large proteins. The *BRCA1* protein is a polypeptide with 3418 amino acids, with a mass of 384 kDa (albumin has a mass of 69 kDa). A list of known mutations is available in the Breast Information Core databases (http://www.nhgri.nih.gov/Intramural_research/Lab_transfer/Bic).

26.3.1 BRCA Expression

It is thought that the expression and regulation of the two genes are similar. Expression can be detected in almost all human tissues. The highest mRNA levels can be found in the thymus [41]. Intensive studies have been carried out in mice. Chodosh's laboratory detected the highest level of expression in tissues with high proliferation rates [42]. *BRCA2* also has an effect on almost all tissues [43, 44]. Both genes are activated in murine breast tissue, and expression increases during pregnancy [43]. The coordinated regulation of *BRCA1* and *BRCA2* suggests that the genes are induced by, and may function in, overlapping regulatory pathways involved in the control of cell proliferation and differentiation. Their levels are highest during the S phase, which suggests a function in DNA replication. The two genes are located in the nucleus of somatic cells, where they coexist in characteristic subnuclear foci that are redistributed after DNA damage [45]. On the basis of the genes' upregulated expression during puberty and pregnancy, it has been suggested that estrogen may stimulate the expression of *BRCA1* and/or *BRCA2* [46].

26.3.2 BRCA Protein Motifs

In many cases, the function of a gene can be understood through comparison with that of similar known genes, but the sequences of *BRCA1* and *BRCA2* have no significant similarities with other genes.

BRCA1 has an N-terminal zinc-binding RING motif, which is defined by a series of precisely positioned cysteine and histidine amino acids and has been described in several genes [47, 48]. The RING motif plays a key role in numerous pathways. Protein–protein interactions show that *BRCA1* and *BARD1* form a heterodimer complex. *BARD1* has a RING motif similar to that in *BRCA1*, and this is responsible for the interaction. Somatic mutations of *BARD1* have been detected in breast, ovarian, and endometrial carcinoma [49].

The carboxyl end of the Brca1 protein carries two tandem-repeat globular domains, termed Brct (standing for *BRCA1* C-terminal) [50]. This domain has been described in several other proteins and is responsible for p53 linkage; p53 is a tumor-suppressor gene that is mutated in numerous cancer entities. In addition, it is thought that Brct binds other proteins such as Rad9, Xrcc1, Rad4, Rap1, and Ect2, which are involved in cell cycle regulation and DNA damage response [51]. Detection of missense mutations in the encoding regions has demonstrated that intact functioning of these domains is necessary for tumor suppression [35]. The Brct and RING motifs have not been detected in *BRCA2*.

In 1996, Chen et al. [52] described a direct interaction between the Brca1 protein and importin, a component of the core membrane. In addition, Brca2 binds directly to Rad51, a human homologue of the *Escherichia coli* RecA gene, which plays an important role in recombination and double-strand break repair [53]. The Brca1 protein interacts indirectly with Rad51.

26.3.3 BRCA as Caretaker of Genomic Integrity

Biochemical, genetic, and cytological studies have revealed multiple functions for the *BRCA1* and *BRCA2* genes. Brca1 and Brca2 interact with Rad51. All three proteins are located in nuclear foci during the S phase after exposure to ionizing radiation [54–58]. It is thought that the Brca1 and Brca2 proteins form a DNA double-strand breakage repair system with Rad51 [59]. Brca proteins appear to be responsible for the maintenance of genomic integrity and control of homologous recombination. If DNA synthesis is arrested due to external agents, Brca1 is rapidly phosphorylated in sites of DNA synthesis together with Brca2, Rad51, and Bard1 [56, 57]. This underlines the function of the corresponding genes for homologous recombination during the S phase. Expression of the three genes is upregulated during development. In addition, the proteins are located in meiotic chromosomes during the formation of synaptinemal complex, a structure that is associated with the regulation of meiotic recombination [39, 55, 56]. These observations indicate that *BRCA1* and *BRCA2* cooperate in a single pathway.

Support for these observations has been obtained from gene-targeting experiments. *BRCA1*+/– mice are normal and fertile and lack tumors at the age of 11 months. Homozygous *BRCA1* mutant mice die before day 7.5 of embryogenesis, and homozygous *BRCA2* mutant mice die at around day 8.5 [55, 60]. In both cases, cells show activation of the p53 pathway and p21, a DNA damage-dependent cell cycle checkpoint effector. Subsequently, fulminant chromosome breakage can be observed [61]. This underlines the major role of Brca protein–Rad51 complexes in recombination during the S phase [39]. In addition, homozygous *BRCA* mutant cells show centrosome amplification mitotic checkpoint defects and defective transcription-coupled repair of oxidative DNA damage [62, 63].

Several different biochemical fractionations of *BRCA1* have been published that potentially implicate *BRCA1* in many processes, including chromatin remodeling [64], transcription regulation [65, 66], mismatch repair, and recombination control [67].

26.3.4 Structure–Function Relationships of Brca Proteins

The RING domain of Brca1 is able to mediate ubiquitin-conjugating enzyme-dependent ubiquitination in vitro. This

is enhanced by Brca1–Bard1 RING–RING heterodimers [68]. If missense mutations arise affecting the RING domain, the in vitro ubiquitination ligase function is lost [68]. Similar mutations failed to reverse hypersensitivity to ionizing radiation and caused increased sensitivity to DNA-damaging agents [69, 70]. This suggests that the ubiquitination ligase function is required for tumor suppression. Brca1 also interacts with Bap1, a ubiquitin hydrolase [71]. There appears to be an intriguing interplay between these proteins with regard to the promotion (Bard1) or prevention (Bap1) of ubiquitin-mediated protein degradation [70].

The C-terminal Brct domains of Brca1 appear to be multifunctional. The Brct region can stimulate transactivation of reporter genes, interact with transcriptional corepressor CtIP, and is necessary for interaction between the full-length Brca1 protein and the RNA polymerase II holoenzyme [39]. These observations suggest that the Brct domain has an important function as regulator of transcription. Mutations affecting the Brct region also affect the function of double-strand breakage repair. This part of the polypeptide therefore has at least a dual function [72].

The functions of many regions of the Brca1 polypeptide are not known, although a large number of protein–protein interaction domains have been identified [73]. It has been shown that a central region of the polypeptide has DNA-binding activity. Deletion of part of this region abrogates the genome integrity maintenance function, and missense mutations affecting this region disrupt the double-strand repair function [72].

Analysis of Brca2 proteins has focused on BRC repeats, which have been shown to mediate the Brca2–Rad51 interaction [74, 75]. It appears that Brca2 may play a more direct role in DNA repair than Brca1. Davies et al. [76] produced synthetic BRC-repeat peptides. Binding of the Brca peptide to Rad51 prevented the formation of a Rad51 DNA nucleoprotein filament. This suggests that Brca2 modifies the DNA-binding activity of Rad51 and prevents the formation of multimeric Rad51 complexes. Rad51 can be kept in an inactivated state by binding to Brca2 to prevent unplanned interactions within the nucleus. Rad51 is thus maintained in a state of readiness for relocation to sites of DNA damage, where activation allows repair by homology-directed gene conversion [76]. These observations are underlined by the fact that human and mouse cells that are deficient in Brca2 fail to develop Rad51 nuclear foci after induction of DNA damage [77].

26.3.5 Models of BRCA-Linked Cancer Predisposition and Tumor Suppression

It is not known why *BRCA*-linked cancer predisposition manifests in particular epithelial tissues such as the breast and ovaries, although several hypotheses have been developed to explain this. *BRCA* mutations may have tissue-specific effects that promote transformation and make breast and ovarian cells more sensitive to local mutagens, such as estrogen metabolites [78].

The recombination functions of *BRCA1* and *BRCA2* may not be their only functions. The function of tumor suppression may involve some multifunctionality. Inactivation of *BRCA1* or *BRCA2* might produce cancer-predisposing defects in multiple biochemical pathways. There is already some evidence that *BRCA1* is essential for ductal morphology in the developing breast [79], and that *BRCA1* and *BRCA2* regulate the growth response to estrogen-receptor signaling [80]. Further studies are needed to reveal the way in which Brca proteins are able to function as tissue-specific tumor suppressors. An alternative hypothesis is that the frequency with which loss of the second *BRCA* allele occurs may effectively be higher in tissues with prolonged proliferation, such as the breast and ovaries [77].

BRCA-linked tumors show differences in the age of cancer onset, the degree of penetrance, and even the type of tumor to which individuals are predisposed. Identifying the genetic and environmental factors that influence phenotypic effects of mutations may provide new insights into the functioning of *BRCA1* and *BRCA2*.

26.4 Pathological Characteristics

BRCA1/BRCA2-linked BC has special clinical and pathological features (Table 26.4) [81–83]. The prevalence of ductal and lobular carcinoma in situ (DCIS/LCIS) is lower than in sporadic cases (DCIS 45 % versus 55 %, LCIS 3 % versus 6 %) [84, 85]. In addition, DCIS can be detected more often

Table 26.4 Clinicopathological features of hereditary breast cancer [81–83]

	Sporadic BC (%)	*BRCA1* (%)	*BRCA2* (%)
Grade 3	35	67	62
DCIS	55	38	53
LCIS	6	2	3
ER-positive	65	10	50
PR-positive	59	21	45
erbB2-positive	15	3	3
p53-positive	80	60	74
Medullary BC	2–4	13	
PFC	7	25	
Mitotic count		+	
Pleomorphism		+	
Lymphoplasmacytic infiltrates		+	
Tubular formations		–	–
Lobular formations		+	

BC breast cancer, *DCIS*, ductal carcinoma in situ, *ER* estrogen receptor, *LCIS* lobular carcinoma in situ, *PFC* proliferative fibrocystic changes, *PR* progesterone receptor, +, higher frequency than sporadic breast cancer; –, lower frequency than sporadic breast cancer

in *BRCA2*-linked BC than in *BRCA1*-linked BC (53 % versus 38 %) [1]. Analysis of the clinical features of the lesions has shown that medullary tumors are more frequent (13 % versus 2–4 % in sporadic cases) and that the prevalence of invasive lobular and tubular carcinomas is reduced in *BRCA1* mutation carriers [81, 82]. These lesions were associated with dense lymphocyte infiltration. *BRCA1*-linked BCs are characterized by high rates of mitosis, increased pleomorphism, high proliferation rates, low differentiation, and an increased prevalence of grade III tumors [81, 82, 84]. This association is not observed in *BRCA2*-linked carcinomas. However, the latter develop tubular formations less often than sporadic carcinoma [81, 82]. In comparison with sporadic carcinoma, *BRCA1*-linked carcinoma shows reduced estrogen-receptor and progesterone-receptor expressions. While only 10 % of *BRCA1*-linked carcinomas are estrogen-receptor-positive (65 % in sporadic carcinomas), *BRCA2*-linked carcinomas have normal estrogen-receptor expression [81, 82]. In addition, estrogen-receptor expression in *BRCA1* mutation carriers shows a clear degree of age dependency. While mutation carriers under the age of 45 only show expression in 19.0 % of cases, among women aged 45–55 the figure is 31.1 % and among women aged 55–65 it is 38.0 % ($P=0.20$) [86, 87]. In carriers of *BRCA2* mutations, the age distribution is homogeneous ($P=0.418$).

Lakhani et al. [82] reported that 21 % of *BRCA1*-associated carcinomas express the progesterone receptor (59 % in control individuals). While 15 % of the control individuals were Her2-positive, only 3 % of *BRCA1/BRCA2*-linked carcinomas showed Her2 expression. Adem et al. [83] found that *BRCA1/BRCA2*-associated carcinomas showed proliferative fibrocystic changes less frequently. These changes were seen in 25 % of the control tumors in patients without a family history and in 7 % of *BRCA1*-linked carcinomas ($P=0.075$). In addition, mutation carriers show increased MIB-1-Ag expression in comparison with patients with sporadic carcinoma. This is associated with an increased proliferation rate. At Garber et al. [86] summed up the typical features of *BRCA* tumors as follows:

- *BRCA1* breast cancers:
  Are ER-negative, PR-negative, and Her2-negative in 80 % of cases.
  Are of the basal-like type on microarray analysis in 80 % of cases.
  Show low expression of cyclin E, p27, and AKT.
  Are often positive for CK5, CK6, CK17 by IHC.
  Show a high frequency of p53 mutations.
  Show frequent amplification of myc and EGFR.
- *BRCA2* breast cancers:
  Do not show a typical phenotype (unlike the features observed with BRCA1-associated cancers).
  Tend to be of higher grade and have less tubule formation in comparison to sporadic cancers.
  Have estrogen and progesterone receptor profiles similar to those of sporadic cancers (most are ER-positive).

A comparison between sporadic and *BRCA*-linked OCs did not reveal any differences in type, grading, or stage [88]. Although most of the clinical and pathological characteristics of familial and sporadic carcinoma are similar, women with *BRCA*-linked carcinoma have a longer relapse-free interval and a longer overall survival after initial chemotherapy [88].

BRCA mutation is an independent prognostic factor [89]. By analyzing Ki-67-positive cell nuclei, Levine et al. [90] showed that familial OCs have a significantly higher proliferation rate than sporadic carcinomas ($P=0.017$). This may explain the better response to chemotherapy. There were no differences between *BRCA1*-linked and *BRCA2*-linked carcinomas. Familial OCs showed a reduced frequency of mucin formations (2 % versus 12 % in sporadic cases) and are more often at an advanced stage at the initial diagnosis [88]. In addition, *BRCA*-linked carcinoma is associated with p53 mutations [91] and peritoneal carcinosis (24 % versus 14 % in sporadic cases) [92].

In ovaries removed from patients undergoing prophylactic ovariectomy for a known family history of ovarian cancer, there are more surface epithelial inclusion cysts and surface micropapillae than in ovaries removed from women lacking such a history [20]. Precursor lesions such as dysplasia and atypical hyperplasia have been reported in fallopian tubes removed prophylactically. Rare cases of unexpected microscopic carcinomas of the ovary and fallopian tube have been discovered [93, 94].

It can be assumed that familial OC has a different pathogenesis and is more aggressive than sporadic cases [95]. Comparison of *BRCA1*-linked and *BRCA2*-linked OCs showed that *BRCA2*-associated carcinomas are more often diploid (13 versus six of 60 carcinomas analyzed) [96].

26.5 Counseling and Risk Calculation

26.5.1 Interdisciplinary Genetic Counseling

Current insights regarding the genetic disposition to develop carcinoma have raised requirements for all physicians. It is not possible for all physicians to keep up with all the changing insights into diagnosis, early cancer detection, DNA analysis, and support for women who have a familial risk. However, all physicians should be encouraged to refer patients who have a family history of BC and/or OC to interdisciplinary genetic care centers. Collaboration between physicians in the fields of gynecology, histopathology, human genetics, psychosomatic medicine, molecular biology, and radiology is the appropriate approach in order to identify women who are at familial risk, to calculate the risk

of the disease and mutation carrier status, to inform affected individuals about early cancer detection, chemoprevention, and prophylactic surgery, and to provide analysis of the *BRCA1/BRCA2* genes [1, 97, 98]. Psychological support can also be offered. A psychological counseling session is a prerequisite for analysis of a patient's *BRCA1* and *BRCA2* genes [97]. The decision on whether to carry out genetic testing is based on inclusion criteria, which can be checked in relation to pedigrees. If the inclusion criteria are met, blood samples can be requested from family members who already have disease. Detection of a mutation is probable if an affected family member is analyzed. If a mutation is detected, the consulter can also be analyzed to confirm or exclude the identified mutation. Analysis of the *BRCA1/BRCA2* genes is carried out by direct sequencing of the gene or denaturing high-performance liquid chromatography analysis of frequent mutations [99, 100]. Actual, also next generation sequencing can be done in validated laboratories. Founder effects can be observed for specific mutations in different regions and countries.

26.5.2 Determining and Calculating Risk

Calculation of the lifetime risk of disease and of the probability of mutation is required by patients and physicians in clinical practice, particularly in the setting of genetic care centers. The certainty with which a known mutation in a defined gene location (e.g., in the *BRCA1* or *BRCA2* genes) can be diagnosed is greater than 97 %. However, as the remaining predisposing genes that are responsible for the other 50 % of hereditary breast carcinomas have not yet been identified, testing is not possible. In concrete terms, this means that it can only be established or excluded with a certainty of 50 % whether a mutation is present in a given individual [101]. If the findings are negative, the test is regarded as being uninformative—i.e., the individual has to be treated as if no testing had been carried out. Risk calculation is extremely important here in order to support clinical decision-making. The threshold values for the risk situation have been set internationally at between 15 % and 30 % [101].

Different calculation models are available. The Gail model is a widely accepted calculation model [102]. Age, age at menarche, number of breast biopsies, age at first childbirth, and number of first-degree relatives with BC are used to calculate the lifetime risk for women without risk factors. A model updated with data from the Surveillance, Epidemiology, and End Results (SEER) study and with death statistics is available online (http://bcra.nci.nih.gov/brc/).

The risk calculation in the Claus model is based on the number of affected first-degree and second-degree relatives and their age at the onset of disease [103]. The original version consisted of tables providing information about the risk in 10-year intervals (from 29 to 79 years of age) relative to age and the age of affected relatives. Various software programs have incorporated this model, such as CancerGene (http://www3.utsouthwestern.edu/cancergene/files/download.htm).

BRCAPRO [104, 105] uses information about male and female relatives, unilateral and bilateral BC, and OC cases in the family. The model also incorporates published gene frequencies and data on the penetrance of *BRCA1* and *BRCA2* [17, 106, 107]. The calculation can be used for different frequencies and penetrance functions. The program can be downloaded free of charge as element of the CancerGene program, or can be purchased in context of a pedigree program (www.cherwell.com).

This program postulates the existence of another gene linked with BC in addition to *BRCA1* and *BRCA2*. The probability of a predisposing mutation and the lifetime risk can be calculated on the basis of family history. Reproductive and hormonal risk factors are incorporated into the model (use of hormone replacement therapy, age at menarche, age at menopause, body mass index, and history of atypical hyperplasia) [107].

In clinical practice, it needs to be taken into account that all of these models are based on different statistical methods and different epidemiological data sets and that they use different patient history parameters. Programs such as CancerGene include several calculation models. The Gail model is the one most widely used in the USA, and it can be used for women with no family history of BC and/or OC. The Claus model and BRCAPRO should be used for patients with a positive family history. The European model (Tyrer–Cuzick) includes family history and the patient's individual medical history and appears to be an adequate model for European women with risk factors [108]. Calculation models can provide support for decision-making regarding genetic testing. Consulters should be informed about the consequences of risk calculation and options should be offered.

26.6 Options

The choice of clinical options requires information regarding the patient's risk of disease and mutation status. The options include primary, secondary, and tertiary prevention.

26.6.1 Early Cancer Detection

26.6.1.1 Breast

Table 26.5 shows the recommended intensified early cancer detection program for women with a high familial risk who are *BRCA1/BRCA2* mutation carriers [1, 97]. It is not currently known whether there is any individual benefit of an

Table 26.5 Intensified early cancer detection program [1, 97, 98]

Age	Examination
	Start at the recommended age, or 5 years before the youngest affected relative
25	Monthly self-palpation of the breast
25	Biannual palpation by gynecologist
25	Biannual ultrasonography of the breast (7.5–13 MHz)
40	Annual ultrasonography of the breast
30	Annual mammography
25	Annual magnetic resonance imaging
25	Biannual vaginal palpation
25	Biannual transvaginal ultrasound

intensified early cancer detection program for *BRCA1/BRCA2* mutation carriers. However, this option is less invasive and less burdensome for the patient in comparison with chemoprevention or prophylactic surgery, and it should be offered to women at risk [98].

Self-palpation of the breast should be started at the age of 25 to ensure regular examinations and an ability to recognize the normal characteristics of breast tissue [109]. Women should carry out palpation every month at the same time (if possible on the second to 6th day of the cycle) in order to assess tissue changes. An analysis of several studies reported a reduction in BC <2 cm in size and in lesions with positive lymph nodes in patients carrying out regular self-palpation of the breast. Engel et al. [110] detected an age-related reduction in mortality of 25 %. Hackshaw and Paul [111] analyzed 20 observational studies and three clinical trials. They did not find a significant reduction in the mortality rate associated with self-palpation (RR 0.90; 95 % CI, 0.72–1.12). Nor did providing teaching and training in palpation lead to any reduction (RR 1.01; 95 % CI, 0.92–1.12). Self-palpation was associated with increased numbers of breast biopsies. However, women with a family history of BC and/or OC might be able to benefit from this method more than the general population. Confidence in the method and the accuracy of the assessment can be improved with practice and medical instruction.

Clinical examination of the breast can detect palpable BCs. In addition, it is capable of detecting tumors that are overlooked at mammography or occur during the screening interval. The estimated sensitivity of the method is reported as 17–89 %, depending on the examiner's experience and the size of the tumor [112]. Clinical examination can be beneficial for young women with a familial risk, in view of the reduced sensitivity of mammography in dense tissue [113].

Mammography should be started with a baseline examination at the age of 30 and if possible, examinations should be conducted in a setting in which images from previous examinations are available. The efficacy of this approach has been demonstrated for women aged 50–69. Mammography can achieve a 30 % reduction in the mortality rate [114]. The provision of screening in patients under the age of 50 is currently a matter of controversy. However, its effectiveness (a 20 % reduction in the mortality rate) can be regarded as proved in women aged 40–49. The U.S. Preventive Services Task Force [115] has stated that the current results do not argue either for or against mammographic screening for young women. The high risk of BC in women with a family history of BC and/or OC suggests that they are able to benefit from this approach, although the currently available data do not clearly prove this. There have only been a few studies analyzing the effectiveness of screening in high-risk women. False-positive results and a potential increase in the risk as a result of early and repeated radiation exposure are often mentioned in relation to mammography. The risk increases when mammographic screening is started early and continues at regular intervals [114]. A higher radiation dosage is needed, as tissue is dense in the young breast. It is estimated that BC cases caused by mammography are low in comparison with the numbers of BCs detected by mammographic screening. The benefits of early cancer detection may predominate, so that an early start is justifiable for women at familial risk. Progression proceeds faster in the premenopausal period, underlining the need for short screening intervals. A 1-year interval should be offered to young women with a familial risk [109, 116].

High-resolution ultrasonography of the breast (7.5–13 MHz) should be carried out biannually and started at the age of 25. In view of the reduced sensitivity of mammography in young women and the potential increase in the risk of hereditary cancer due to mammography, ultrasonography of the breast should be incorporated into early cancer detection programs and women should be encouraged to increase their participation [117, 118].

Warner et al. [119] carried out surveillance of 196 *BRCA* mutation carriers using clinical examinations, ultrasonography, magnetic resonance imaging (MRI), and mammography. Although mammography was able to detect invasive carcinomas in areas of low density, the detection rate was reduced in high-density areas. Ultrasonography of the breast had a sensitivity of 60 % and a specificity of 93 %. Ultrasound may be beneficial in combination with other methods in women with a familial risk [119]. The results presented by Kuhl et al. [120] support the use of a combination of ultrasonography, MRI, and mammography for early cancer detection.

MRI of the breast is the method with the highest sensitivity for detecting local relapses in radiographically dense breast tissue (with a sensitivity of 92 %, in comparison with 86 % for ultrasound and 66 % for mammography). It is therefore an important element of maintenance after breast-preserving surgery [121]. It is possible to detect small carcinomas (>4 mm) if angiogenesis and multicoated BC occur, and to carry out MRI-guided intervention [122]. In a prospective study including 192 asymptomatic women with a family history of BC and/or OC, Kuhl et al. [120] reported

on the efficacy of this method in young women at familial risk. Surveillance was carried out with clinical examinations, ultrasonography, mammography, and MRI. Nine BCs were detected. MRI was the most sensitive and specific method. Several other studies have provided further support for these results [119, 123–126]. MRI was found to be superior to ultrasound and mammography in a study including 235 *BRCA* mutation carriers [127]. The highest efficacy was obtained with a combination of all of the methods. Kriege et al. [128] carried out surveillance in 358 mutation carriers and 1052 women at high risk (with a follow-up period of 2.9 years). Forty-five BCs occurred; 49 % of the cases were capable of being diagnosed by MRI alone; 77 % of the lesions were detected in stage N0, and 46 % were smaller than 1 cm. In two recent studies [126, 129], the sensitivity of MRI was 77–91 %, while mammography only had a sensitivity of 33–40 %. The low sensitivity of mammography is explained by two factors. In addition to the density of the glandular parenchyma in young women, *BRCA*-associated breast carcinomas show atypical characteristics with all imaging methods. They express microcalcifications more rarely. In addition, these carcinomas (not only with medullary differentiation, but also with ductal differentiation) often show morphological characteristics that would really be typical of benign tumors (fibroadenomas) or even cysts — smooth delimitation, apparently expansive growth, a hypoechoic or almost anechoic internal structure, and dorsal signal enhancement [101]. In an update of their surveillance study, Kuhl et al. report that 86 % of stage 0 or stage I carcinomas were detected [129]. This mainly applied to lesions detected using MRI, which were all diagnosed at stage pTis or pT1, N0. With purely mammographic early detection, the rate of interval carcinomas is up to 36–56 % [125]. Using MRI early detection, the rate was 2 % (one of 43) [129]. These results underline the importance and efficacy of the MRI. However, only 5.4 % of women at familial risk use this method for early cancer detection [130, 131]. This can be explained by the high cost of the method, its limited availability, and the limited information about its efficacy. Annual MRI screening examinations can be offered to high-risk women in specialized centers.

26.6.1.2 Ovaries

Early cancer detection is a potential option for *BRCA1/BRCA2* mutation carriers and high-risk women at familial risk. At present, there is no evidence for a reduction in the mortality rate as a result of early cancer detection [113]. There is also a lack of detailed guidelines [113]. The NIH Consensus Statement on Ovarian Cancer recommends transvaginal ultrasonography and CA-125 assessment for screening of *BRCA* mutation carriers every 6–12 months, starting at the age of 35 [132]. The Cancer Genetics Studies Consortium Task Force recommends these methods starting at the age of 25–35 [133]. In interdisciplinary genetic clinics in Germany, biannual transvaginal ultrasonography and pelvic examination is recommended starting at the age of 25 [1, 97].

The recommendation that CA-125 assessment should be carried out is based on the association of OC with elevated CA-125 levels. However, only 50 % of patients with early-stage disease have elevated CA-125 values. In addition, non-malignant conditions (e.g., endometriosis or benign ovarian changes) and nongynecological cancer can also lead to elevated CA-125 values. The low predictive value of the finding and the fact that raised values can be caused by benign conditions exclude the use of this test for general screening and it should be regarded with reservations in the screening of high-risk women [1, 97].

Transvaginal ultrasonography is capable of delineating the size and morphology of a lesion. The method can assess whether a lesion is malignant or benign on the basis of morphological criteria (thickness of the septum, size of cystic findings, papillary structures) [113]. Transvaginal ultrasonography is a low-cost, noninvasive method that is well tolerated by most patients. However, the quality of the examination depends on the examiner's level of experience and the quality of the equipment. Scoring systems using color duplex sonography can objectify the assessment. Sensitivity levels of nearly 100 % and a specificity of 94.9 % can be achieved [134]. Normal physiological changes in advance of ovulation can simulate cancer-linked values in duplex sonography. The examination should therefore not be conducted around the time of ovulation in premenopausal women [135].

The results of ongoing studies are awaited in order to establish the appropriate use and screening intervals with this method. Its efficacy needs to be reexamined in view of recent technological improvements and the higher resolution available with modern equipment. At present, consulters should be informed regarding the lack of evidence available for the efficacy of screening with this technology.

26.6.2 Chemoprevention

26.6.2.1 Breast Cancer

Estrogen may modulate the risk of BC in women with *BRCA* mutations, since premenopausal ovariectomy has a preventive effect, tamoxifen decreases the risk of a second carcinoma and improves overall survival, and two main estrogen tissues (breast and ovarian tissue) are at high risk for carcinoma in *BRCA1* and *BRCA2* mutation carriers. Estrogens increase the probability of mutation due to enhanced proliferation and the direct genotoxic effects of estrogen metabolites. The combined effect of estrogen-promoted cell proliferation and the loss of the *BRCA* DNA repair pathway may increase unwanted events and mutations

that lead to carcinogenesis in breast cells [136]. Chemoprevention focuses on a variety of endocrine, paracrine, and autocrine factors [95, 98]. Aromatase inhibitors, retinoic acid, isoflavonoids, gonadotropin-releasing hormones, low-dose contraceptives, and hormone replacement treatment have been tested.

The concept of using tamoxifen for BC prevention was based on experiments conducted in the early 1970s. A 50 % reduction in the risk of contralateral BC was demonstrated in studies of adjuvant therapy with tamoxifen. Subsequently, the results of four studies (the National Surgical Adjuvant Breast and Bowel Project, the Breast Cancer Prevention Trial, Phase 1 (BCPT-P1), the Royal Marsden Hospital Randomized Chemoprevention Trial, and the Italian Randomized Trial among Hysterectomized Women) were published, which analyzed the administration of tamoxifen in comparison with a placebo for the prevention of BC. The BCPT-P1 study included 13,388 women with a 5-year BC risk of at least 1.7 % (calculated using the Gail model; average risk 3.2 %; 5 years administration of tamoxifen 20 mg/days versus placebo). After a follow-up period of 4 years, the risk of estrogen-receptor-positive BC was reduced by 49 % in patients treated with tamoxifen [117, 137]. By contrast, studies in Europe did not observe a reduced risk with tamoxifen [138, 139]. The differences might be explained by the use of different variables in the different studies (age, compliance, follow-up, additional administration of hormone replacement treatment) and differences in the inclusion criteria and in the way in which risks were estimated and calculated [117]. In the Italian study, the lack of any observed effect of tamoxifen might have been due to the size of the group of patients studied ($n = 5408$), the low risk (48 % with bilateral ovariectomy and no BC risk as a requirement for participation in the study) and limited compliance (149 participants did not complete the 5th year). The patients in the British study were much younger than those in the BCPT-P1 study (62 % versus 39 % of the patients were younger than 50) and had a higher level of familial risk (96 % versus 76 % with an affected first-degree relative). Differences in these factors might have led to a higher risk level in participants in the British study and could explain the observed failure of tamoxifen [140]. The studies show that 6600 women with a low or moderate risk of BC would need to be treated with tamoxifen to prevent 82 early lymph node-negative, estrogen-receptor-positive cases of BC. The use of tamoxifen for prevention is currently a matter of controversy. King et al. [141] analyzed the 288 cases of BC in the BCPT-P1 study; 6.6 % ($n = 19$) of the BC cases were associated with *BRCA1/BRCA2* mutations. The use of tamoxifen reduced the incidence of BC by 62 % in *BRCA2* mutation carriers. There was no influence on the risk in *BRCA1* mutation carriers. The patients has started tamoxifen at the age of 35. Whether an earlier start might reduce the incidence of BC requires further investigation. In addition, the short treatment period might have led to an early therapeutic effect. Narod et al. [142] reported that the use of tamoxifen is capable of reducing the risk of contralateral BC in women who are at familial risk and are *BRCA* mutation carriers. The data from these studies should be discussed with women at risk.

The selective estrogen-receptor modulator raloxifene is currently the subject of ongoing studies. The Multiple Outcomes of Raloxifene Evaluation (MORE) study analyzed the reduction in the numbers of bone fractures associated with the use of raloxifene (120 mg/days versus a placebo) and reported a 60 % reduction in the incidence of BC as a side effect in a group of 7505 postmenopausal women [143, 144]. Further studies have analyzed the effectiveness of aromatase inhibitors such as anastrozole in comparison with a placebo (IBIS II), or exemestane versus a placebo, for the prevention of BC [144, 145]. Regarding the IBIS-II-trial, 1920 women were randomly assigned to receive anastrozole and 1944 to placebo. After a median follow-up of 5·0 years, 40 women in the anastrozole group (2%) and 85 in the placebo group (4%) had developed breast cancer (hazard ratio 0·47, 95% CI 0·32-0·68, p<0·0001). The predicted cumulative incidence of all breast cancers after 7 years was 5.6% in the placebo group and 2.8% in the anastrozole group. The GISS study is analyzing the preventive effect of screening and the use of gonadotropin-releasing hormone (GnRH) analogues and ibandronate in comparison with screening alone in premenopausal women with a high level of familial risk [146–148]. Pilot studies have reported a risk reduction of 50 % with 10 years of goserelin administration and 70 % after 15 years. Administration of the drug is combined with bisphosphonates to avoid reductions in bone density.

26.6.2.2 Ovarian Cancer

The genesis of OC is associated with rapid changes in and repair of epithelial cells after ovulation. The long-term use of oral contraceptives can reduce the risk of OC by approximately 50 % and the mortality rate by approximately 80 % [149–151]. In low-risk women, oral contraceptive use for at least 5 years leads to a reduction in the relative risk to 0.68 (95 % CI, 0.5–0.9) and 10–14 years use is associated with a relative risk of 0.54 [19]. Comparable results have been reported for the mortality rate, with a reduction in the relative risk to 0.2 (95 % CI, 0.0–1.3) with 10 years intake of oral contraceptives [19, 152].

The use of contraceptives, particularly monophase compounds, is an option for the prevention of OC in high-risk women. Narod et al. [153, 154] reported a significant reduction in the risk of OC in two studies with *BRCA1/BRCA2* mutation carriers. The odds ratio was 0.44 (95 % CI, 0.28–0.68), with a risk reduction of 4.4 % per year of intake ($P = 0.056$). However, it should be noted that the risk reduction is not yet evident after 10 years of use.

26.6.3 Prophylactic Surgery

26.6.3.1 Prophylactic Mastectomy

At present, the view that bilateral prophylactic mastectomy and ovariectomy are effective is based on the results of retrospective studies. Detailed guidelines for the indication and technique are lacking. Numerous retrospective studies have been conducted to analyze the efficacy of prophylactic mastectomy. The studies show major differences in the inclusion criteria, the proportion of high-risk women or mutation carriers included, and follow-up periods (Table 26.6) [155–160]. An important study is the retrospective analysis carried out by Hartmann et al. [159]. The incidence of BC was reduced by 90 %. Afterwards, the women were screened for *BRCA1* and *BRCA2* mutations. In 26 identified mutation carriers, no BC developed during a follow-up period of 13.4 years [159]. Seventy-six mutation carriers with prophylactic mastectomy and 63 mutation carriers without prophylactic mastectomy are receiving surveillance in the first prospective study to be conducted [123]. At present, no BC has been observed in the group with prophylactic surgery, while eight cases have been detected in the control group (Table 26.6). These preliminary results support the published data from retrospective studies.

A significant portion of breast tissue remains in the area of the areola after subcutaneous mastectomy. In 11 patients with relapses, three of the relapses were observed in the area of the areola and eight in the conserved tissue lobe [161]. In addition, there is still a need for regular mammography. False-positive results may increase due to scar tissue and postoperative calcifications, which require additional biopsies. Total mastectomy is capable of reducing breast tissue by 90–95 %; only total mastectomy with a thin skin flap provides the maximum prevention [161, 162]. A breast reconstruction (primary or secundary) and a psychological support should be offered to all patients with prophylactic surgery.

26.6.3.2 Prophylactic Ovariectomy

Prophylactic ovariectomy is the most commonly used method of reducing the risk of OC. The benefits of this option decline with increasing age at surgery. The completion of family planning or a minimum age of 35–40 is recommended, due to the young average age of onset in this disease [132].

The efficacy of this option has been confirmed by numerous studies (Table 26.7) [163–167]. Three studies on the topic analyzed a total of 396 high-risk women who underwent prophylactic ovariectomy [163–165]. Seventeen cases of OC were observed. The highest risk appears to be the development of peritoneal carcinosis, which was diagnosed in 11 patients (3 %). These observations might be explained by the presence of an occult OC at the time of surgery, malignant ectopic ovarian tissue, or transformation of the peritoneum, which has the same embryonic origin as the surface epithelium of the ovaries. Two retrospective studies have reported that this method is effective in *BRCA1* and *BRCA2* mutation carriers (Table 26.7). Kauff et al. [167] reported a risk reduction of 85 %. Rebbeck et al. [166] observed a risk reduction of 96 %. These results support the recommendation that this option should be chosen after the completion of family planning, as the median age of onset was 50.8 years in the control group (range 30–73 years). The average age at onset was 50.0 years in *BRCA1* mutation carriers and 55.0 years in *BRCA2* mutation carriers in the German group included in the Hereditary Breast and Ovarian Carcinoma Consortium (*Konsortium hereditäres Mamma- und Ovarialkarzinom*) study [8]. Both of the above studies also reported a reduction in the risk of BC with prophylactic ovariectomy (68 and 53 %). The possibility of reducing the risk of relapses and of contralateral BC was mentioned above.

In a study of *BRCA* mutation carriers and those with a high-risk family pattern, an occult malignancy was identified during prophylactic ovariectomy in 13.3 % (four of 30) [168], with three of the occult carcinomas being found in the area of the fallopian tubes. Deligdisch et al. [169] identified dysplasias in 77.6 % of ovaries removed prophylactically from *BRCA* mutation carriers; dysplasias were only found in 33.3 % of women with negative tests. Due to the high probability of an occult carcinoma and the risk of tubal carcinoma or primary peritoneal carcinoma, a standardized

Table 26.8 Recommendations for conducting prophylactic ovariectomy, in collaboration between the patient, human geneticist, gynecologist, surgeon, and pathologist [170]

1	Bilateral adnexectomy with complete removal of the fallopian tubes (open or laparoscopic)
2	Cytological examination of the peritoneal rinse fluid (procedure: instillation of 50 mL sterile saline into the abdominal cavity and removal of the fluid after 10 min)
3	Multiple peritoneal biopsies
4	Multiple biopsies from the greater omentum
5	Serial sections of the entire fallopian tubes and ovaries at 2-mm intervals and microscopic examination of all sections

procedure should be used in prophylactic ovariectomy, which should include removal of the tubes completely along with the adjacent peritoneum, rinse fluid cytology, and biopsies from the peritoneum and greater omentum (Table 26.8) [8, 20]. Using this protocol, Powell et al. [170] were able to identify seven occult carcinomas in 41 *BRCA* mutation carriers (four tubal carcinomas and three ovarian carcinomas).

Prophylactic ovariectomy can lead to significant psychological stress for patients in relation to their physiological integrity and an increased risk of various diseases may result from the induced menopause. Patients need to be informed about the consequences—e.g., the climacteric syndrome with hot flushes, sweating, palpitations, tachycardia, insomnia and depressive mood, osteoporosis, and cardiac and cerebrovascular diseases [171].

26.6.4 Therapy

Although there are significant differences in the pathological characteristics of hereditary and sporadic BC, no specific guidelines are available on the treatment of patients with hereditary BC. In most cases, there is a lack of adequate risk perception, consultation, and genetic analysis of the *BRCA1/BRCA2* genes at the time of the primary diagnosis. Subsequently, the familial risk and the associated risk of a second BC or OC does not influence treatment decision-making. High-risk women are treated on the basis of general guidelines (www.ago-online.de).

Goffin et al. [172] reported that the overall survival is particularly reduced if *BRCA1* mutation carriers do not receive chemotherapy (278 women with BC, 30 mutation carriers, RR 3.3; 95 % CI, 1.2–8.8; $P=0.01$). There is a statistically significant reduction in the survival in mutation carriers with negative lymph-node status (RR 5.6; $P<0.001$). This could be explained by the reduced frequency of chemotherapy in patients found to have a negative lymph-node status (24 % versus 79 %; $P=0.01$). In view of these results, the possible administration of chemotherapy may be discussed with patients in whom there is no lymph-node involvement who have a positive family history, or in whom a *BRCA* mutation has been identified. Only 10 % of *BRCA1*-linked tumors show estrogen-receptor expression. As endocrine therapy is not possible in this group of patients, survival is significantly impaired (RR 2.3; 95 % CI, 1.2–4.7; $P=0.02$). Narod et al. [142] analyzed the possibility of reducing the risk of contralateral BC with tamoxifen administration in 476 *BRCA1* and 117 *BRCA2* mutation carriers. Thirteen percent ($n=64$) of the *BRCA1* mutation carriers and 33 % ($n=39$) of the *BRCA2* mutation carriers were treated with tamoxifen. The risk was reduced to a statistically significant extent in both groups (OR 0.38; 95 % CI, 0.19–0.74 and OR 0.63; 95 % CI, 0.20–1.59, respectively). The protective effect of tamoxifen administration increased continuously up to 4 years. The authors consider that tamoxifen administration is capable of reducing the risk of contralateral BC by 50 %, and this view is supported by the results of a published meta-analysis. Tamoxifen prevents the development of contralateral carcinoma independently of the hormone-receptor status of the primary BC [173].

A few studies have analyzed the use of different chemotherapeutic agents in patients with hereditary BC. *BRCA*-linked BC lesions have different levels of sensitivity to

chemotherapy regimens. An in vitro analysis reported a reduced sensitivity to taxanes and doxorubicin, while the sensitivity to cisplatin was increased [174]. Although anthracyclines and taxanes are frequently used, their efficacy may be reduced in patients with hereditary BC. Tumors arising in carriers of heterozygous germline mutations in the *BRCA1* or *BRCA2* gene have generally lost the wild-type allele and therefore do not express functional protein. Although a haploinsufficiency phenotype is still a theoretical possibility for *BRCA1* or *BRCA2*, the majority of the evidence suggests that this is not the case, at least for DNA repair functions. This provides an ideal target for treatment [175, 176]. Sensitivity to cisplatin may be increased as a result of DNA damage [174, 177]. To investigate whether the in vitro evidence can translate into improved clinical efficacy, studies randomly assigning patients with metastatic *BRCA1* or *BRCA2* familial breast cancers to either carboplatin or docetaxel chemotherapy have been conducted [176, 178–180]. A clinical trial has presented that patients with a BRCA mutation associated triple negative breast cancer can extremely benefit from combinations with platinum and taxane and achieve a pathologic complete response rate of up to 90 %. This has been confirmed by the phase-III-trial Geparquinto.

Single-strand breaks are usually repaired via the base excision pathway; inhibition of this pathway therefore substantially increases the number of unrepaired single-strand breaks, subsequently leading to collapsed replication forks and double-strand breaks at replication forks. Poly-ADP ribose polymerase (PARP) plays an important role in DNA repair (excision of DNA base pairs) by binding directly to the damaged DNA. Inhibition of this enzyme by RNA interference, or using chemical inhibitors, leads to severe, highly selective toxicity in *BRCA1*-defective and *BRCA2*-defective cells, with a selectivity that is several times higher than that of conventional chemotherapy drugs [181, 182]. The use of PARP inhibitors thus represents a targeted approach to the treatment of *BRCA1/BRCA2*-associated breast carcinomas [86]. The PARP inhibitor olaparib is already approved for patients with a platin-sensitive relapse of ovarian cancer and proven BRCA mutation (germline or tumour). Trials of PARP inhibitors in *BRCA1/BRCA2* mutation carriers with breast cancer are currently ongoing.

With regard to surgical treatment, two important aspects need to be considered. The risk of a contralateral BC is approximately 40 % [142]. Haffty et al. [16] compared the results of surgery in *BRCA1/BRCA2* mutation carriers ($n=22$) and women with sporadic BC ($n=105$). Breast-preserving therapy was carried out in both groups. Relapses and cases of contralateral BC were found to be significantly more frequent in the group of mutation carriers after a follow-up period of 12 years (49 % versus 21 %, $P=0.007$; and 42 % versus 9 %, $P=0.001$, respectively). Although endocrine therapy with tamoxifen and prophylactic ovariectomy are capable of reducing the risk of relapse by 50 and 56 %, respectively [142], bilateral mastectomy needs to be discussed with mutation carriers and high-risk women who have primary disease. In addition, the sensitivity of mammographic surveillance is reduced in mutation carriers. In a study of early cancer detection, Goffin et al. [183] detected six of 13 BCs in *BRCA1* mutation carriers using mammography, while mammography identified 96 of 108 patients with sporadic BC (46 % versus 89 %; $P<0.001$). In the group studied by Meijers-Heijboer et al., 75 % of women with identified *BRCA* mutations and BC opted for bilateral mastectomy with reconstruction [160].

These results support the view that it is necessary to carry out genetic testing when primary disease is diagnosed. Prophylactic ovariectomy needs to be discussed with mutation carriers and women who are at high risk. With regard to the reduction in the risk of contralateral BC associated with prophylactic ovariectomy, Narod et al. [142] reported an odds ratio of 0.31 (95 % CI, 0.15–0.67) on the basis of 185 mutation carriers with BC under the age of 50 who underwent bilateral ovariectomy. The odds ratio was 0.85 (95 % CI, 0.22–2.36) if the age of onset was above 50 years. The risk reduction was persistent. Møller et al. [184] followed up 36 *BRCA1* mutation carriers with BC (21 of whom underwent prophylactic ovariectomy). The 5-year survival rate was 67 % versus 44 %. If mutation carriers with ovariectomy had a negative lymph-node status, the 5-year survival rate was 100 %, compared with 42 % in women who did not undergo ovariectomy ($P=0.009$).

In contrast to hereditary BC, the overall survival is longer in women with hereditary OC in comparison with those with sporadic OC, independently of pathological differences and different stages at the primary diagnosis [88, 92, 185]. *BRCA*-linked tumors show a higher response to platinum-containing chemotherapy agents. Cass et al. [92] analyzed the response, overall survival, and in vitro sensitivity on the basis of 35 mutation carriers (22 with *BRCA1* and 12 with *BRCA2* mutations) and 37 women with sporadic OC. Both groups received a chemotherapy regimen containing platinum. The median survival period was longer in mutation carriers (91 months versus 54 months; $P=0.046$). In addition, in vitro analysis was able to predict the response in the group of mutation carriers ($P=0.0096$). Increased sensitivity to agents containing platinum has been demonstrated in several in vitro studies [186, 187]. This may be explained by the DNA damage induced by platinum and the reduced ability to repair such damage due to loss of function of the *BRCA* gene [92]. On the other hand, the results might also be explained by a higher proliferation rate, with the associated sensitivity to chemotherapy regimens [90].

26.6.5 Follow-Up

Follow-up is becoming increasingly important in patients with hereditary BC and/or OC. General guidelines should be used, owing to the lack of prospective studies [171]. The family history should be analyzed during the first follow-up visit in order to detect the individual risk of contralateral BC, relapse, and OC. Genetic testing should be offered if required. The risk level in the patient's relatives (e.g., daughter, sister, and mother) should also be identified and appropriate options should be offered if needed. The main focus should of course be on early cancer detection in the associated organ—e.g., the ovaries in women with BC. Ovariectomy and prophylactic tamoxifen administration should be discussed. Prophylactic mastectomy must be offered to women with OC. MRI appears to be superior to mammography [119, 120, 123, 124, 127, 128], and the use of MRI should be considered in the context of follow-up examinations.

26.7 Prognosis

Although *BRCA*-linked BC is associated with higher proliferation rates and lower grading, the results of survival analyses are controversial. Only one study was able to detect improved survival among mutation carriers [188]. Further studies reported no differences, or a poorer prognosis. Several studies detected a clearly reduced survival period in comparison with patients with sporadic BC [189, 190]. The authors considered that the poorer survival might be explained by lower grading, more advanced stages at the primary diagnosis, and reduced estrogen-receptor and progesterone-receptor expression. Comparison with sporadic BCs with similar stages and pathological characteristics should show comparable survival rates. Stoppa-Lyonnet et al. [191] identified the *BRCA1* mutation as an independent prognostic factor (Table 26.9). Mutation carriers had a reduced survival period and a shorter metastasis-free interval. *BRCA1* mutation continued to be an independent prognostic factor after adjustment for pathological characteristic (death, RR 3.5, 95 % CI, 1.3–9.7; metastasis, RR 2.6, 95 % CI, 1.0–6.5). Goffin et al. [172] identified the *BRCA1* mutation as an independent prognostic factor in a study including 287 Ashkenazi Jewish women. A univariate analysis of 141 patients with a negative lymph-node status showed that the *BRCA1* mutation status (RR 5.6) was significantly associated with a higher mortality rate ($P > 0.001$). In the multivariate analysis, the mutation status (RR 3.5) was still significant ($P = 0.003$). This might be explained by the absence of chemotherapy for an aggressive tumor.

In contrast to BC, patients with *BRCA*-linked OC have a better survival (Table 26.10). This has been confirmed by several studies. Cass et al. [92] analyzed the survival in 71 Ashkenazi Jewish women with OC, including 22 with *BRCA1* mutations and 12 with *BRCA2* mutations. *BRCA* mutation carriers with advanced disease survived longer (91 months versus 54 months; $P = 0.046$) and had a longer relapse-free interval (49 months versus 19 months; $P = 0.16$). David et al. [192] observed an improved median overall survival period (53.3 months versus 37.8 months) and 3-year survival rate (65.8 % versus 51.9 %), independent of age and the stage at diagnosis of the primary disease (896 patients, 243 mutation carriers).

26.8 Conclusion

Familial risk is an important risk factor in BC. A hereditary origin is present in 5–10 % of patients with BC. Ten percent of all cases of OC are associated with a familial predisposition. Some 15–20 % of all cases of familial BC are linked to *BRCA1* and/or *BRCA2*. In addition, an association with *BRCA1* mutations is found in 80 % of families with familial

OC and an association with *BRCA2* mutations in 15 %. *BRCA* mutations also increase the risk of oropharyngeal carcinoma, malignant melanoma, endometrial carcinoma, cervical cancer, colon cancer, prostate cancer, gastric cancer, cancer of the gallbladder, and pancreatic cancer. Early cancer detection with screening at regular intervals appears to be adequate for the associated carcinomas. *BRCA1*-linked and *BRCA2*-linked carcinomas have special pathological characteristics, which can be relevant for the treatment and prognosis. An increased understanding of the roles played by *BRCA1* and *BRCA2* in DNA repair is beginning to suggest potential therapeutic strategies. Tumors that are deficient in *BRCA1* or *BRCA2* may be highly sensitive to DNA cross-linking agents.

With the growing knowledge available regarding the genetic basis for carcinogenesis and familial disposition, the requirements for all physicians have become more complex. Specialized interdisciplinary genetic cancer clinics are able to identify familial risk, the risk of disease, and the probability of positive mutation status and can provide patients with information regarding the need for intensified early cancer detection, chemoprevention, and genetic testing. Genetic testing can be offered to patients if the inclusion criteria are fulfilled.

It is mainly young women with BC, and women with disease who have numerous affected relatives, who take advantage of the opportunity for genetic testing. Receiving information regarding the level risk in their children and relatives, as well as the risk of relapse, contralateral BC, and OC affects decision-making in women who have already developed the disease.

Risk calculation programs can establish the level of risk without the need for genetic testing and can help patients decide whether to undergo genetic testing of the *BRCA1* and *BRCA2* genes. The available calculation models are based on differing statistical methods, epidemiological data, and different patient history parameters. The Claus model and BRCAPRO should be used if there is a positive family history. The European model (Tyrer–Cuzick) may be the best model for calculating the risk in a European group with several risk factors.

Providing information on the risk of BC and OC and the probability of a *BRCA* mutation is a basic prerequisite for discussing the need for, and availability of, early cancer detection, specific therapy, chemoprevention, and prophylactic surgery with the patients concerned.

The Molecular Basis of Prostate Carcinogenesis

27

Smitha Dutt and Allen C. Gao

27.1 Introduction

This review on prostate cancer is an attempt to update the reader on the current information we have on the disease. There are no definite cures yet for prostate cancer and the exact mechanism of development is far from clear. However, over the years, the information obtained on the disease has increased due to the unceasing flow of research data. In the following pages, you will be briefed on the basic characteristics of prostate cancer, the characterization of the genomic regions affected, the candidate genes involved, the secondary sites of metastases such as bone and the models that have been developed to investigate the disease in detail.

27.2 Epidemiology of Prostate Cancer

Langstaff reported the first case of prostate cancer in 1817 followed by J. Adams, a surgeon in London, who examined the cancer histologically [1, 2]. Prostate cancer is a non-skin cancer that is the cause of the second largest number of male-related deaths in the countries of the West [3]. It is known as the cancer of the elderly as older men over the age of 65 are diagnosed with cancer of the prostate [4]. This is probably why many men die with the cancer rather than due to it [4, 5]. This is observed in the case of asymptomatic sporadic prostate cancer which account for >90 % of the disease [6]. Hereditary and familial prostate cancer, on the other hand, is observed in younger males and is dependent on family history [5]. In 2007, the statistics in CA Cancer Journal for Physicians predict that prostate cancer accounts for ~218,885 new cases and ~27,350 deaths [7, 8].

27.3 Risk Factors for Prostate Cancer

There is no single cause of prostate cancer, but it primarily arises due to aging, discrepancies in sex hormone levels, genetic factors, and environmental agents [4, 9].

27.3.1 Aging

Prostate cancer is known as a cancer of the elderly for the main purpose that tumors arise with increase in age of men [10]. There is a logarithmic increase in malignant potential with increase in age. Prostate cancer has a long natural history and develops very slowly which might account for the delayed appearance of the tumor in the life of an individual. In most cases, carcinoma of the prostate rarely sees the light of day during the lifetime of an individual and is observed during an autopsy. Latent cancers of the prostate and benign prostatic hyperplasia (BPH) are observed more frequently, and differ from the few cancers that develop malignant potential. Surgery is the most common form of treatment to remove BPH [10, 11]. Another hypothesis for the contribution of aging to prostate cancer is the shortening of telomere sequences and a subsequent increase in the enzyme telomerase which can be observed in prostatic intraepithelial neoplasia (PIN) and carcinomas [9]. Carcinoma arises predominantly from the peripheral zone compared to the central zone of the prostate [11].

27.3.2 Hormones

Hormones are an integral part of the prostate as they regulate its growth, differentiation, and maintenance. Androgenic hormones such as dihydrotestosterone are found in the prostate. Testosterone diffuses into the prostate and is converted to dihydrotestosterone in the prostate which is the major form of androgen metabolized in the prostate. Prostate cancer shows high levels of androgens when first diagnosed and androgen

W.B. Coleman, G.J. Tsongalis (eds.), *The Molecular Basis of Human Cancer*, DOI 10.1007/978-1-59745-458-2_27

ablation therapy is commonly used to counter the growth of the cancer which results in the blockade of the androgen supply. However, it has not been confirmed that androgenic hormones are the cause of prostate cancer [4, 12, 13].

27.3.3 Genetic Factors

Hereditary and familial cancer account for ~9 % of prostate cancer cases [4, 6, 9]. Prostate cancer is hereditary when there are at least three first-degree relatives or three consecutive generations or two or more relatives (at a young age) affected by the disease. The loci and the candidate genes affected in hereditary prostate cancer differ from those affected in sporadic cancer [6]. Linkage analysis of the hereditary prostate cancer families identified 6 loci that are associated with the disease. HPC1 or hereditary prostate cancer gene 1 is the name given to one of the loci, 1q24–25, and the gene that maps to the HPC1 locus is called *RNASEL*. In addition the other loci affected are 1p36 (gene *CAPB*), 1q42.2–43 (*PCAP*), 8p22–23 (*MSR1*), 17p11 (*HPC2*), 20q13 (*HPC20*), and Xp27–28 (*HPCX*) [6, 14, 15]. The two main candidate genes in the list are *RNASEL* and *MSR1*. *RNASEL* encodes an endoribonuclease involved in the proapoptotic activity of the interferon induced 2-5A system. Mutation in *RNASEL* reduces the enzymatic activity. *MSR1* is a macrophage specific receptor binding to Gram-positive and Gram-negative bacteria. It is difficult to distinguish hereditary cancer from sporadic cancer especially when dealing with families that have a high penetrance of prostate cancer. The detection of hereditary cancer only in older patients prevents the simultaneous identification of the cancer in a younger generation to confirm the hereditary aspects of the disease [15]. Sporadic prostate cancer accounts for >90 % of prostate cancer. The chromosomal loci involved in sporadic prostate cancer differ from those affecting hereditary cases. The loss of chromosomal loci indicates the loss of potential candidate genes which may be tumor suppressor genes. These genes encode proteins that function as hormone receptors, cell-signaling molecules, and cell adhesion factors. Some of the loci that are affected are 3p22–26, 5q22, 10q23, 13q14, 18q21, and others.

27.3.4 Diet

Dietary factors are known to affect the incidence of prostate cancer. It has been shown that Asian men are less likely to develop prostate cancer compared to their counterparts in the Western countries [1, 4]. The incidence of prostate cancer in African-American males is 15 % compared to 10 % in Caucasian-American males. The incidence of prostate cancer is 120 times lower in Asian men [16]. This is due to differences in diet in the two parts of the world. In addition, it has also been observed that when Asian men migrate to the west, there is an increase in prostate cancer incidence in the first and second generations of these men. Selenium and Vitamin E levels are inversely correlated to prostate cancer incidence [1, 4, 10, 16].

27.4 Diagnostic and Screening Tests

Langstaff reported the first case of prostate cancer in 1817. Since then the reported cases of incidence of prostate cancer have steadily increased due to the screening methods that have been employed to detect prostate cancer. Digital rectal examination (DRE), Prostate-Specific Antigen (PSA) test, Transrectal UltraSound (TRUS), Needle Biopsy are some of the tests used to diagnose prostate cancer. DRE detects palpable tumors which however can result in false positives if the growth is benign prostatic hyperplasia. The PSA test is the universal test used to detect prostate cancer or the initiation of the disease by measuring the serum concentrations of PSA. The normal concentration range for PSA is 0–4 ng/ml. TRUS is an imaging technique where a handheld transducer is used with a frequency between 6 and 7 MHz and rotated around in the prostate to give an idea of any potential outgrowths and their size range. Needle Biopsy is used to confirm a diagnosis of prostate cancer. The diagnosis obtained from either of the above three methods warrants confirmation by performing a biopsy. While each method identifies prostate cancer, the sensitivity is higher when two or more methods are combined to detect the cancer [4].

ABCD and TNM staging are the popular forms of staging of prostate cancer. In the ABCD system, early stage prostate cancers are referred to as stage A cancers and subsequent increases in tumor growth are labeled stages B, C, and D. The TNM classification identifies the cancer based on initial growth, presence of positive lymph nodes, and burden of metastasis. DRE, PSA, TRUS, and DNA ploidy are used to identify the stage of prostate cancer. Computed tomography (CT), magnetic resonance imaging (MRI), and radionuclide bone scans confirm the clinical staging results. Biopsies are histologically graded as per the Gleason grading system which is the most popular form of cancer grading. For most solid tumors, the histopathological indicators of biological aggressiveness have been determined through the comparison of tumor morphology with corresponding clinical outcome. Surgical staging is done by radical prostatectomy or lymphadenectomy [4].

The histological grade of the primary prostate cancer is evaluated using the Gleason grading system [17]. In this system, grading is based upon the degree of glandular differentiation and growth pattern of the tumor as it relates to the prostatic stroma. The pattern may vary from well differentiated (grade 1) to poorly differentiated (grade 5). This system

takes into account tumor heterogeneity by summing the score of both the primary and secondary tumor growth patterns. For example, if the majority of the tumor is well differentiated (grade 1) and the secondary growth pattern is poorly differentiated (grade 5), the combined Gleason sum would be a 6. Low (i.e., score = 5) Gleason sum prostate cancers predictably have minimal aggressive behavior whereas very high (score = 8–10) Gleason sum tumors are usually highly aggressive [18]. Unfortunately, the intermediate (score = 5–7) Gleason sum tumors are highly unpredictable in their clinical aggressiveness [18]. This limitation is of particular importance as the majority of tumors (76 %) fall into this intermediate Gleason sum category [19]. Thus, predicting the biologic potential of the majority of prostate cancer in asymptomatic patients based upon histology alone is problematic.

27.5 Anatomy and Histology of the Prostate

To understand the molecular aspects of prostate cancer, it is essential to understand the anatomy and histology of the prostate gland. The prostate gland arises from different segments of the urethra and is located at the base of the bladder. It is a fusion of glandular and non-glandular regions [9, 20]. The prostate gland can be divided into three main glandular zones: (1) the peripheral zone, (2) the central zone, and (3) the transition zone, and in addition, a smaller periurethral gland region [9, 20, 21]. The basic function of the prostate is to secrete proteins to the seminal fluid [9]. The prostate develops from the urogenital sinus during embryogenesis and the differentiation process requires the interaction of the epithelial cells with the mesenchyme. This interaction is essential since absence of either component fails to generate the prostate and this has been elegantly shown through the recombination experiments of the laboratory of Cunha [22]. Androgen signaling also plays an important role in this interaction by acting on the mesenchymal component for the initial development of the prostate and subsequently on the epithelial component instructing the cells to secrete proteins.

The prostate epithelium consists of three types of cells: luminal, basal and neuroendocrine.

27.5.1 Luminal Cells

The luminal cells are secretory cells which secrete the seminal fluid. These cells also exhibit the androgen receptor and other proteins such as cell surface marker CD57 and prostate-specific antigen (PSA) [9]. The secretory cells of the peripheral, transition, and periurethral gland zones are more uniform in structure compared to the irregular luminal secretory cells [21].

27.5.2 Basal Cells

The basal cells lie between the basal lamina and the luminal cells. These cells do not have a secretory function, possess the androgen receptor in very low quantities, and cannot be detected immunohistochemically by staining for PSA. They express anti-apoptotic genes such as *Bcl2*, DNA damage protecting genes, for example, *Gst-π, c-Met,* p53-related protein *p63*, and prostate stem-cell antigen (*PSCA*) [20, 23]. The basal cells are made up of stem cells and the transit-amplifying cells which are intermediate cells of the prostate. These transit-amplifying cells are postulated to act as the precursors of prostatic inflammatory atrophic cells (PIA) which go on to become prostatic intraepithelial neoplasia followed by carcinoma [23].

27.5.3 Neuroendocrine Cells

In all the zones of the glandular prostate, a small population of endocrine–paracrine cells is located on the basal cell layer but do not grow into the lumen. These are called neuroendocrine cells and were first described by Pretl [24]. These cells have no specific function but may play a regulatory role in the development of the prostate as well as in the secretory aspect of the luminal cells. Somatostatin, bombesin, serotonin, and calcitonin are some of the peptides secreted by the neuropeptide cells and can be used as markers to identify these cells [24]. During androgen ablation therapy, prostate cancer cells regress and subsequently regrow in the absence of androgen. Neuroendocrine cells are observed during the stage when the prostate cells start to develop in the absence of androgen [24].

27.5.4 Glandular Tissues of the Prostate

The urethra is the base around which the zones of the prostate develop. The urethral wall forms the backdrop for the development of the ducts of the peripheral and central zones. The prostatic urethra is divided equally into the distal peripheral and proximal central halves divided at the point of the verumontanum by an angular (35°) wall between the apex and the bladder neck. The ejaculatory ducts lie along the proximal part of the urethra ending at its base [20].

27.5.5 Peripheral Zone

The peripheral zone forms approximately 70 % of the prostate. The ducts protrude from the lateral side and posteriorly from the urethral wall. Most carcinomas arise in the peripheral region.

27.5.6 Central Zone

The central zone covers 25 % of the prostate and the ducts surround the ejaculatory ducts which lie in the distal urethra. Carcinomas rarely arise in the central zone.

27.5.7 Transition Zone

Benign prostatic hyperplasia (BPH) arises in the transition zone which lies in the angular region of the urethra between the verumontanum and the bladder neck. This zone consists of 5 % of the prostate.

27.5.8 The Periurethral Gland Region

This region consists of small ducts and acini that lies within the proximal urethral segment and is the site where BPH arises [20, 21]. There are ducts and acini in all the glandular regions of the prostate which terminate in either the capsule or the anterior fibromuscular stroma. The ducts and acini stain for PSA and prostatic acid phosphatase (PAP) [20, 21].

27.5.9 Non-glandular Tissues of Prostate

Preprostatic sphincter, striated sphincter, anterior fibromuscular stroma, and prostatic capsule are the non-glandular tissues of the prostate. The preprostatic sphincter lies posterior to the urethra and its fibers spread and connect with the ducts of the transition zone. Anteriorly, the fibers end in the anterior fibromuscular stroma. The anterior fibromuscular stroma extends up to the prostate apex and into the capsule laterally. It is also in contact with the preprostatic sphincter and indirectly with the transition zone. The prostate is covered with striated sphincter muscles that end incompletely at both the distal and proximal ends. The prostatic capsule encloses a major part of the prostate and the terminal acini of the peripheral and central zones are in contact with the capsule. The capsule does not extend over the ejaculatory ducts or the bladder neck. Neurovascular bundles innervate the lateral portion of the capsule.

27.6 Prostate Cancer Progression Pathway

How is the morphology of the prostate and prostatic cells interconnected with the tumorigenic process? The three major processes affecting the prostate are prostatitis, BPH, and prostatic adenocarcinoma [25].

27.6.1 Prostatitis

Inflammation of the prostate, prostatitis, affects 2–10 % of men who are under the age of 50. The National Institutes of Health (NIH) classified prostatitis into four categories: (1) acute bacterial prostatitis, (2) chronic bacterial prostatitis, (3) non-bacterial prostatitis, and (4) prostatodynia. Acute and chronic bacterial prostatitis are rare occurrences affecting 2–5 % of men. They are caused by infection from bacteria such as *Escherichia coli* and *Serratia marcescens*. Local symptoms are urinary frequency and pelvic pain and systemic symptoms are fever and chills. Local and systemic symptoms are seen in acute prostatitis while intermittent local symptoms are observed in chronic prostatitis. Treatment normally involves anti-microbial agents and drainage of urine. The common form of prostatitis is category III which is chronic non-bacterial prostatitis. It affects 90–95 % of men. Infectious cause is not seen in non-bacterial prostatitis. The National Institutes of Health Chronic Prostatitis Symptom Index Questionnaire (NIH-CPSI) is used to assess the condition. There are two subcategories of non-bacterial prostatitis which are inflammatory (IIIA) and non-inflammatory (IIIB). Treatment involves the use of anti-inflammatory drugs, thermal therapies. However, specific direct treatment of the condition has not been resolved. Category IV or asymptomatic inflammatory prostatitis does not require any treatment. It is observed in some cases where the PSA levels are high but there is no correlation to prostate cancer [26–28].

27.6.2 Benign Prostatic Hyperplasia (BPH)

BPH and prostate cancer are observed with a high frequency in men of advanced ages. How does BPH differ from prostate cancer? BPH develops in the region of the prostate that is adjacent to the urethra. BPH nodules, unlike prostate cancer, arise in the transition epithelial zone of the prostate. BPH involves an increase in the size of the prostate from its normal size of 15–20 g to three times the size of approximately 33–52 g during autopsy and surgery, respectively [29]. BPH accounts for a large percentage of surgeries in the Western world due to improved screening procedures. The prevalence of BPH is low in men of approximately 30 years of age. However, the prevalence of BPH increases linearly with increasing age and is maximum in men who are in their seventh decade of their lives [29, 30]. There are two stages in BPH: microscopic and macroscopic. The microscopic stage is found to be present in almost all men of the world during their lifetime. This consists of the development of the BPH nodules. One-half of the microscopic nodules develop further resulting in a macroscopic enlargement of the prostate

now termed as the macroscopic stage. The macroscopic stage consists of the pathological phase and the clinical phase [30]. Detection of the clinical stage of BPH or dysuria involves surgical intervention. A couple of factors resulting in the development of BPH are a functioning testis providing a steady supply of testosterone coupled with a steady increase in age of the individual. The influence of hormones is very obvious since BPH fails to develop in castrated men [29, 30]. However, the changes that occur within the cells of the prostate also contribute to the development of BPH. There are three theories that have been proposed which may explain the etiology of BPH. The first theory deals with the influence of hormones for e.g. DHT. The DHT hypothesis states that a functioning testis, supplying androgens, is involved in the development of the prostate. With aging the androgen balance shifts resulting in an increase in androgen levels which may explain the hyperplastic growth of the prostate leading to BPH. The second theory involves the stem-cell-epithelial cell interaction. This was proposed by Reischauer in 1925 and restated by McNeal where they observed that BPH results from an initial glandular budding and branching of the stromal cells of the prostate evolving into alveoli consisting of epithelial cells [30]. In subsequent analyses on animal models, this induction of epithelial cells from stromal cells could be demonstrated. Cunha et al. have shown the induction of bladder epithelial cells to form prostate cells by mouse embryonic urogenital sinus mesenchyme which essentially are prostate stromal cells [22]. The induction is sensitive to androgens as castrated animals fail to show the stromal-epithelial induction. The third hypothesis is the stem-cell hypothesis. Stem cells are regenerative cells that can grow in conditions where the cell number is very low due to extreme physiological conditions or environmental influences. The prostate is a self-renewing tissue comprised of equal numbers of proliferating cells and cells undergoing apoptosis. This equilibrium in the tissue allows the prostate to maintain its size in an individual. Originating from the stem cells, the amplifying cells exhibit limited proliferation and are active in the regeneration of tissue within the prostate. The limited proliferation results in an amplification of the number of cells added to the regenerating prostate. The transit cells are a subset of the amplifying cells and have very limited clonal expansion. Unlike the amplifying cells, are dependent on the supply of androgens. The possible explanation for the development of BPH can be attributed to the clonal expansion of these stem cells which results in the overgrowth of the prostate. However, with androgen ablation, the transit cells which, make up majority of the prostate, die to cause involution of the prostate. This stem cell theory explains the regeneration of the prostate when androgen therapy is given to castrated men resulting in the prostate regaining its maximal size. Other factors also play a role in the development of BPH. The changes observed in BPH cells compared to normal are androgen metabolism and receptor differences, variable degrees of cytosine residue methylation and variations in levels of secretory proteins [30]. The incidence of BPH is similar to prostate cancer exhibiting racial differences with blacks showing a large frequency of the disease and Asians show the least [31].

Latent prostate cancers are most often observed during screening tests. Some of the latent cancers develop into malignant metastatic cancers. The prostate cancer progression pathway has been shown to consist of four predominant molecular chromosomal aberrations. The normal epithelium of the prostate cell develops into prostatic intraepithelial neoplasia (PIN) when the basal cells are lost. A candidate gene that is a cause of this transformation is NKX3.1, which is a result of loss of the locus 8p21. LOH is observed in *PTEN* and *Rb* which lie on loci 10q and 13q resulting in loss of the basal lamina. Invasive carcinoma is generated with the breach of the basal lamina. Eventually with the loss of 17p containing the candidate gene p53, the cancer cells metastasize to distant sites such as bone [25, 30, 32].

Understanding the molecular aspects of cancer is vital to understand the underlying pathways actively playing a role in tumorigenesis. The tumorigenic process results in the transformation of the cells in the prostate resulting in the following stages. Inflammation due to damage to the tissue results in damage to the cells and subsequently the genome. It also triggers the production of cytokines and other DNA repair mechanisms. Oxidative radicals such as hydrogen peroxide, singlet oxygen, superoxide, and nitric oxide are produced to counter the infectious agents. Their action affects the infectious agents as well as the bystander host cells. The damage to the host cells can result in genomic damage and mutations which may initiate the tumorigenic process. GSTP1 hypermethylation or the reduced effect of the DNA glycosylase/AP lyase-OGG1 reduces the ability of normal cells to counter the damage of oxidants [25]. Besides inflammation, other factors such as unequal levels of androgens and dietary factors can initiate the tumorigenic process.

27.6.3 Prostatic Inflammatory Atrophy (PIA)

DeMarzo in 1999 proposed the development of PIN from prostatic inflammatory atrophy or PIA through the atrophy of the luminal secretory cells with surrounding inflammation and is observed adjacent to cells that have undergone PIN and carcinoma. Such cells are found in the peripheral zone of the prostate and very rarely in the central zone of the prostate [23, 33]. The epithelial cells undergoing atrophy are associated with acute or chronic inflammation. Such cells undergo morphological changes to resemble prostatic intraepithelial

neoplasia (PIN) or may resemble minute carcinoma cells directly without a precursor lesion of PIN. Chromosome 8 is amplified in PIA cells and show other changes similar to PIN and cancer such as GSTP1 promoter methylation and p53 mutations. Certain cells that do not show inactivation of GSTP1 activity are able to counter the effects of oxidative damage [15, 33]. Cells undergoing PIA are proliferative, expressing AR and bcl-2 and rarely undergo apoptosis [23]. They also exhibit low levels of the cyclin-dependent inhibitor $p27^{Kip1}$ which may be responsible for the initiation and proliferation of cells [33]. High levels of COX-2 and glutathione S-transferase A1 (GSTA1) are observed in cells undergoing PIA [30, 32, 33]. PIA may give rise to PIN in some cases while in other cases this is not observed. Hence, PIA can be considered as a precursor or intermediate lesion in the tumorigenic process of the prostate.

27.6.4 Prostatic Intraepithelial Neoplasia (PIN)

When the luminal cells undergo proliferation with dysplasia along the ducts, it results in prostatic intraepithelial neoplasia or PIN. PIN has two forms, low-grade (LGPIN) and high grade (HGPIN). In 1986, McNeal and Bostwick proposed diagnostic criteria to detect PIN in the prostate which resulted in the three grade system [34]. However in 1989, the American Cancer Society and National Cancer Institute converted this into a two grade system where Grade 1 is LGPIN and Grades 2 and 3 together are HGPIN. In 1987, Bostwick and Brawer coined the term prostatic intraepithelial neoplasia. In general, HGPIN is considered to be a precursor of invasive carcinoma, but some studies have implicated the possible involvement of LGPIN as a precursor as well [16]. It is possible that the changes accumulating in LGPIN and HGPIN ultimately evolve into carcinoma despite the long latency period. LGPIN have enlarged nuclei, small nucleoli, normal chromatin content which may be slightly increased as well. The basal cell layer is intact in LGPIN. HGPIN on the other hand, have large uniform nuclei and nucleoli which are similar to carcinoma cells. The basal cell layer is disrupted in HGPIN and is absent in carcinoma [35]. A key marker protein to indicate the presence or absence of the basal cell layer is the anti-keratin stain 34βE12 through immunohistochemical analysis. Some of the marker proteins, amplified in the transition of HGPIN to carcinoma, are bcl-2, C-erbB-2, C-erbB-3 oncoproteins, racemase, c-Met protooncogene, telomerase, AMACR, and PSCA [35, 36]. Secretory marker proteins such as prostatic acid phosphatase (PAP) and PSA are downregulated with advanced PIN and carcinoma. Common allelic loss is observed in PIN and invasive carcinoma in loci such as 8p, 10q, and 16q. Epigenetic regulation of GSTP1 where the promoter is hypermethylated is observed in both PIN and carcinoma [37]. Digital rectal examination, TRUS, and PSA tests may be used to detect PIN. Repeat biopsies for cancer detection have reduced following a diagnosis of HGPIN. This is due to screening of younger males and as a result a reduction in tumor volume. Androgen deprivation therapy reduces the number of cases of PIN due to apoptosis in these cells [35].

27.6.5 Intraductal Prostatic Adenocarcinoma (IDC-P) and Invasive Carcinoma

Melicow and Pachter identified the differences between IDC-P and HGPIN. IDC-P is the next stage after HGPIN and coexists with adjacent invasive carcinoma [20, 38]. IDC-P is a late event in prostate cancer found adjacent to tumors with sizes greater than 4 cm^3. IDC-P comprises 0.4–0.8 % of prostatic adenocarcinomas and is characterized histologically by Gleason grade 3 and 4 cribriform carcinoma [20, 38–40]. This histology of the prostate is seen in the ducts and acini where the lumen is filled with malignant cells [41]. Endometrioid carcinoma is another term given to IDC-P due to the observation of ductal outgrowths near the verumontanum of the prostate resulting in an enlarged palpable prostate. Distant metastases were observed in the bone, brain, lymph nodes, and lungs [39]. Histologically, the tumor cells show pseudostratification with elongated nuclei and ample amounts of amphophilic cytoplasm. Other histologies include papillary form cells, glandular gland like cells with slit-like lumen spaces and central necrosis (comedonecrosis). Invasive carcinoma is classified as Gleason grade 5 where the cells lost the basal cell layer as compared to HGPIN and IDC-P. Invasive lesions contain tiny blood vessels and can be detected by immunostaining for basal cell-specific keratin. While IDC-P is restricted to the ducts and acini of the prostate, invasive carcinoma can metastasize [42]. The tumors involving IDC-P originated from the periphery of the prostate or secondary prostatic ducts [40]. Ultrastructurally, IDC-P cells reveal the following features of gland like cells with distinct basal lamina, microvilli in the lumen, large nuclei, and nucleoli. In addition, prostatic origin is confirmed in IDC-P cells due to the presence of prostatic acid phosphatase (PAP) and prostate-specific antigen (PSA). There are a few variables that are strongly correlated with tumor volume. The volume of IDC-P tumor is strongly correlated with the extent of penetration of the capsule in terms of its thickness and width [42]. IDC-P tumors have much in common with invasive carcinomas in terms of genomic instability with higher frequencies of allelic imbalance (60 %) observed compared to HGPIN or BPH. Allelic imbalance in the form of loss of heterozygosity is seen in IDC-P and invasive carcinoma. LOH in certain loci are shared between IDC-P and invasive carcinoma while there are areas of LOH unique to each of them. If IDC-P evolves

into invasive carcinoma, the unique areas of LOH in IDC-P can only be explained as the result of selective clonal growth in IDC-P which gives rise to invasive carcinoma. The LOH observed in IDC-P indicates its correlation with a poor prognosis of prostate cancer. Gene amplification of *c-myc* on 8q24 and gene fusion of *TMPRSS2-ERG* are seen commonly in IDC-P as well as invasive carcinoma [38, 41]. McNeal et al. [42] observed that rather than being a precursor to invasive carcinoma, IDC-P was found as large foci within invasive carcinoma which was larger than 2–4 cm^3. When IDC-P arises within invasive carcinoma, it generates a malignant potential within the invasive tumor. IDC-P that develops as foci within invasive carcinoma can be distinguished based on its cribriform cells which still retain the basal cell layer [42]. IDC-P possesses two types of cells, tall pleomorphic, mitotically active cells staining poorly for prostate-specific antigen (PSA) and cuboidal, cells containing a secretory layer along with abundant cytoplasm expressing large amounts of PSA [41]. The treatment regimen for IDC-P is similar to that followed for hormone dependent prostate cancer. Transurethral resection, hormone ablation using diethylstilbestrol or orchiectomy, and radiation therapy are some of the techniques utilized [43].

27.6.6 Androgen-Independent Prostate Cancer

It is well known that hormone ablation treatment of prostate cancer initially causes the cancer to regress. Most patients are disease free for approximately 1.5–3 years before the cancer reappears with intense ferocity and gains the capability to proliferate independent of the supply of androgens. Androgens maintain the ratio of cells within the prostate where there is a balance between dividing proliferating cells and the cells undergoing death. On hormone deprivation, the cells undergoing apoptosis increases and the equal ratio of cells is affected leading to cancer cell death and the regression of prostate cancer. Charles Huggins and Clarence V. Hodges showed the effect of castration on acid phosphatase and alkaline phosphatase. Acid phosphatase levels decreased sharply on castration while alkaline phosphatase levels decreased gradually. Alkaline phosphatase is an enzyme found in bone and cartilage and is indicative of activity of cells outside the prostate gland. Acid phosphatase is found in the cells of the prostate and is an effective indicator of the growth of prostate cells [44].

Androgens comprise testosterone, dihydroepiandrosterone (DHEA), androstenediol, and androstenedione. Testosterone makes up 90 % of the androgens and freely diffuses into prostate cells. Testosterone which is synthesized in the testes is found in blood in the bound form where albumin or sex-hormone-binding-globulin binds the hormone. On entering prostate cells, the enzyme 5α-reductase (SRD5A2) converts testosterone to the active hormone, dihydrotestosterone (DHT), which binds to the androgen receptor (AR). This causes a conformational change in the receptor which then dissociates from the heat shock proteins and is translocated into the nucleus where it binds to androgen response elements in the promoter regions of genes to activate their transcription [45–47]. So what causes the cells in the prostate to get recharged after castration and to proliferate resulting in a more aggressive androgen-independent cancer? There have been many theories proposed on the causes of recurrence of prostate cancer. Five main theories are: (1) Hypersensitive pathway, (2) Outlaw pathway, (3) Promiscuous pathway, (4) Coactivators and Corepressors, and (5) Bypass pathway [45–47]. These theories deal with the androgen receptor and the role it plays in the development of the hormone refractory or androgen-independent cancer. In the hypersensitive pathway, the androgen receptor becomes extremely sensitive to very low amounts of androgens that may be present even after castration or medical blockade of androgens. The androgen receptor through mutations or overamplification or increased 5α-reductase enzyme levels may become sensitive to low levels of androgens. 30 % of androgen-independent cancers show amplification of androgen receptor in cells which may be a result of selective outgrowth following death of cells during castration [46, 48]. Increased 5α-reductase enzyme levels result from a polymorphism where there is a substitution of valine with leucine at codon 89. This is commonly observed in African men indicating the ethnic influence in prostate cancer [46, 47]. Androgen-independent prostate cancer, though independent of the supply of androgens tend to express the androgen receptor at high levels in most cases. The outlaw pathway is functional when the AR pathway is activated by growth factors and receptor tyrosine kinases. In these cases, growth factor pathways such as insulin growth factor (IGF), keratinocyte growth factor (KGF) can bind and activate the androgen receptor in the castrated state as they are overexpressed. Receptor tyrosine kinases such as HER-2/neu are overexpressed in androgen-independent cancers that results in the activation of the androgen receptor. IL-4 and IL-6 are also activators of the androgen receptor pathway in the hormone refractory state [45, 46]. The cross talk between NF-kappa B and AR have indicated the role of the NF-kappa B signaling pathway in the development of androgen-independent cancer. The promiscuous pathway results in the androgen receptor (AR) being receptive to ligands other than DHT. Non-androgenic steroids, anti-androgens can activate the AR due to missense and other mutations which may expand the ligand-binding specificity of the AR. LNCaP cells possess an AR where threonine is substituted with alanine at codon 877 which is sensitive to a wide range of steroid ligands. CWR22 cells also show a substitution of

histidine with tyrosine at codon 874 in the sequence that encodes AR. Mutations in the AR are observed in TRAMP mice in three regions: (1) the signature loop of the receptor, (2) the flanking region where p160 coactivators bind, and (3) the ligand-binding domain [46]. Coactivator levels are increased in androgen-independent cancers which enhances the sensitivity of the androgen receptor to various ligands other than androgens. Coactivators such as ARA70, ARA55, SRC-1, P/CAF, and GRIP1/TIF2 are overexpressed in prostate cancer [45, 46, 49]. Bypass pathway, as the name suggests, circumvents the AR pathway and utilizes other pathways in stimulating the prostate cells to proliferate in an androgen-independent environment. The activation of *bcl2* in PIN lesions can cause the cells to avoid utilizing the androgen receptor pathway. Similarly, the activation of oncogenes or inactivation of tumor suppressor genes may result in other bypass pathways. Neuroendocrine cells secrete neuropeptides such as bombesin which enhance the proliferative rate of cells in a cancerous environment in the absence of hormones [45, 46, 49]. Shi et al. [50] have examined the alterations involved in the transition of LNCaP cells into androgen-independent cells and have observed upregulation of growth factors, the Bcl-2 protein and the Akt pathway. The three sublines generated were representative of the theories proposed of development of androgen-independence [50]. Chen et al. [51] also performed similar analyses using LNCaP and the androgen-independent C4-2 cells and analyzed genes such as TMEFF2, NKX3.1, and AMACR to compare the gene expression differences. In addition, these genes were further analyzed in xenografts of these cells to observe consistency in expression. The study analyzed 51 candidate genes and compared the results to human prostate cancer tissues and showed a correlation. The study by Shi et al., as well as Chen et al., showed the difference in gene expression in androgen-dependent and androgen-independent prostate cancer [51].

Besides the androgen receptor, the microenvironment plays a role in the development of androgen-independent cells. Studies by Cunha et al. have shown the effect of the stroma on the epithelial cells of the prostate. Recombination of mice epithelial cells with inactive AR with stromal cells of mice containing functional AR showed that the mice epithelial cells developed normal prostatic cells yet the reverse combination failed to yield functional epithelial cells despite the addition of androgens. This indicated the importance of the stroma in prostate cell development [48]. The stromal cells can activate the epithelial cells through paracrine signals while the growth of prostate cells in an androgen-independent environment can also occur in an autocrine manner. This was observed in experiments where prostate cancer cells could proliferate in nude mice that possessed either wild type AR or where the AR was inactive. The proliferation of prostate cells in an AR-null environment indicated autocrine signaling of cells to activate pathways besides the AR signaling pathway to survive in a hormone refractory environment [48]. Akakura et al. [52] have demonstrated the effect of intermittent androgen therapy on androgen-dependent tumors where it was observed that androgen-dependent tumors transplanted in castrated mice showed a regression. When the tumors had regressed 30 %, they were transferred to intact mice. The tumors started to develop only to be transplanted back into castrated mice. This intermittent procedure was conducted to observe the rate at which the tumors became androgen independent. The time taken for the tumors to develop into androgen-independent tumors was threefold. Such intermittent therapy could delay the development of the aggressive tumor that is hormone refractory [52]. Research has been carried out on androgen-dependent prostate cancer cells to observe their growth into androgen-independent cells and to analyze the changes that occur with this transition. Hendriksen et al. [53] have analyzed the androgen receptor pathway in LNCaP cells as well as xenografts from intact and castrated mice to observe the genes that are upregulated or downregulated in the transition to androgen independence. It was observed that androgen receptor genes that were not stroma-associated were upregulated in primary prostate cancer with low levels of stromal cells. In low grade carcinoma, genes that were involved in cell growth, proliferation, and apoptosis were expressed to higher levels compared to high-grade carcinoma where differentiation is lowered. The genes that are upregulated in low and high-grade carcinomas were involved in metabolism, exocytosis, and protein folding. *SIM2* and *AMACR* were upregulated in prostate carcinoma. The study showed that stress response genes, *HERPUD1* and *STK39* were downregulated and were good indicators of metastasis [53].

27.7 Epigenetic Regulation in Prostate Cancer

The term epigenetics refers to the external modification of DNA bases which are inherited but do not cause a change in the DNA sequence. Epigenetic modifications vary from methylation of DNA to acetylation, phosphorylation, and methylation of histones [54]. DNA methylation occurs when a methyl group is added to the 5′ carbon of cytosine. Such modifications are generally observed in CpG islands that are 0.5–2 kb long and found in the promoter regions of genes. CpGs comprise 1 % of the genome. DNA methyltransferases or DNMTs are enzymes that catalyze the methylation of cytosines where S-adenosylmethionine (SAM) is the methyl donor for the reaction [54, 55]. In the cancer context, DNA methylation can be of two types, hypermethylation

and hypomethylation. Hypermethylation results in the silencing of genes by methylation of the promoters of genes. Thus, loss of heterozygosity (LOH) observed in many cancers may be the result of methylation of an allele resulting in the loss. Hypomethylation on the other hand results when there is a loss of methylation leading to activation of genes. Genes such as *GSTP1* and *14-3-3* are methylated and silenced in prostate cancer [55]. Yegnasubramanian et al. [56] analyzed the hypermethylation patterns in 73 primary and 91 metastatic human prostate cancer and compared the changes in methylation observed in the progression of cancer. They identified a unique methylation pattern involving the genes *GSTP1*, *APC*, *PTGS2*, *MDR1*, and *RASSF1a*. Hypermethylation of the CpG islands at the promoter region of the above genes was found at a high frequency in prostate cancer and was a distinguishing characteristic from other cancers. Recurrence in prostate cancer was correlated independently with high Gleason grade, pathological stage as well as methylation of the *PTGS2* gene which encodes a cyclooxygenase gene that converts arachidonic acid to prostaglandins which are involved in inflammation. The methylation pattern did not differ between primary and metastatic carcinomas which indicated that methylation arose early in the progression of prostate cancer. There was a striking difference in the number and frequency of genes that were methylated between BPH and primary prostate cancers [56]. Lodygin et al. [57] in a similar study identified genes that were silenced in prostate cancer and analyzed 50 genes that were induced by treating prostate cancer cell lines (LNCaP, PC3, DU145) with the demethylating and inhibition of deacetylase agents 5-aza-2′deoxycytidine and trichostatin A (TSA). These genes were selected based on their functions and can be considered as potential candidates for therapy in prostate cancer. *SFRP1* and *DKK3* were genes that downregulated the Wnt pathway, *p57/KIP2* regulates the cell cycle negatively, Glutathione peroxidase 3 (*GPX3*) protects cells against oxidative stress. These genes were shown to be methylated in prostate cancer which explains the release of the prostate cells from regulating factors and the development of dedifferentiation [57]. Histone modifications such as acetylation, methylation, ubiquitinylation regulate the transcriptional activities of genes. Histone acetyltransferases (HAT) catalyze the transfer of acetyl groups to histones. The androgen receptor is regulated by p300, PCAF that are histone acetyltransferases and upregulate AR gene expression. Similarly, histone deacetylation of the vitamin D receptor is observed in prostate cancer cells which inhibit the anti-proliferative activity of the receptor. Deacetylation is promoted by the histone deacetylase enzyme (HDAC). Histones are additionally modified by methylation of lysine and arginine residues. Global hypomethylation which involves a reduction in the overall CpG methylation content of the genome is observed in benign as well as malignant prostate cancer. Gene-specific hypomethylation in prostate cancer is observed in genes such as *PLAU* which encodes a tumor invasive gene urokinase plasminogen activator and heparanase [54, 55]. Epigenetic mechanisms contribute to the process of tumorigenesis in prostate cancer along with mutations and are also involved in the progression to androgen-independence. As in the study by Murillo et al. [58], it was observed that methylation of specific genes can be observed in androgen refractory prostate cancer cell lines. LNCaP and its derivative androgen-independent cell lines, Rf and RfL were analyzed for genetic changes as well as epigenetic alterations. The locus 6q24-q26 was studied since it is known to have high allelic loss in cancer. The gene PLAG1 was identified in this locus and was seen to be downregulated in the androgen refractory cell lines. On further analysis, this downregulation and loss of one allele of the 6q locus was attributed to methylation [58]. Treatment of epigenetic modifications is universal irrespective of the cancer. Methyltransferase inhibitors such as 5-aza-2′deoxycytidine and decitabine (DAC) restore expression of genes such as GSTP1 and histone deacetylase inhibitors such as MS-275, SAHA can be used to reverse the deacetylation of genes resulting in their activation. These treatments are effective for short periods of time and do not completely shrink the tumors. Combination therapies involving demethylase and HDAC inhibitors are used [54, 55].

27.8 Genome-Wide Allelotyping of Prostate Cancer

Allelotyping of the genome with the help of techniques such as loss of heterozygosity (LOH), microsatellite instability (MSI), fluorescence *in situ* hybridization (FISH), spectral karyotyping (SKY), and comparative genomic hybridization (CGH), informs us of the regions within the genome that exhibit loss, amplifications, or duplications. Most often, regions of loss within the genome are interpreted to harbor tumor suppressor genes that function as the caretakers of the genome. Loss of a tumor suppressor initiates changes within the genome that may trigger the tumorigenic pathway. Many laboratories have attempted to analyze the prostate cancer genome utilizing the above mentioned techniques. The difficulty in procuring prostate cancer samples hampers the large scale analysis of the genome. Allelotyping the different stages of cancer gives an indication of the genomic changes that occur in the process of developing a tumor or in other words elucidate the tumor progression pathway.

Allelic loss in prostate adenocarcinoma has been reported predominantly in chromosomal arms, 8p, 10q, and 16q [59–62]. Kunimi et al. [62] showed 50 % loss on chromosome 8, 60 % on chromosome 16, and 30–55 % on the short and long

arms of chromosome 10, respectively, in 18 prostate adenocarcinoma samples. Similarly, Carter et al. [60] showed in 28 prostate cancer samples, approximately 30 % loss on chromosomal arms 10q and 16q. Other chromosomal arms were lost at a lower frequency for e.g. gains in the long arms of chromosomes 7 and X. Gains were observed on chromosomes 2p, 3p, 12p and 12q, 13q, 17q, 8q, 9q, 16p, 20, and 22 [61]. Losses have been recorded at 18q which is lost only if another allele is lost indicating a minimal role in the initiation of cancer. This high frequency of 18q loss was reported by Joos et al. and Kunimi et al. [61, 62]. Tumor histological grade is directly correlated to the frequency of allelic loss. The greater the number of losses, the higher the tumor grade [62]. The number of samples analyzed by the above researchers was small ranging from 10 to 28 samples. However, the results were obtained by techniques such as LOH and CGH. The use of different techniques to arrive at the same result shows that the loss is real on the chromosomes. In addition to identifying the allelic loss patterns, it was also essential to narrow down the specific regions that were lost within the loci.

The Kunimi study showed ~50 % loss of the 8p locus [62]. High density mapping of the 8p locus revealed losses in the 8p22 region where the MSR gene resides. However, the losses were not restricted to 8p22 alone. There was heterogeneity in the region of loss on the 8p arm with some tumors showing complete loss of the 8p arm or intermittent losses either distal or proximal to the 8p12-8p21 region [63]. Similar LOH mapping was carried out for chromosomes 8, 10, and 16 in another study by [59]. Allelic loss was observed across both the arms of chromosome 10 using ten markers spread across the entire chromosome. Similarly nine markers used for chromosome 16 were localized to the long arm and confirmed the region proximal to the centromere to be frequently lost [59]. A comparative CGH analysis carried out on ten prostate adenocarcinoma cases confirmed the LOH on 8p, 10q, and 16q. Gains were observed on 7q the X chromosome, 8q, 9q, and 16p. LOH analysis did not detect the gains on 8q, 9q, and 16p. Loss of chromosome 12p was reported only in the CGH data [61]. MSI allelotyping of 100 prostate adenocarcinoma samples provided clues to the presence of three genetic progression pathways that may operate in the development of prostate cancer. The first pathway results when there is a loss of 8p and 13q and these may be early events since the losses were recorded in >70 % of the cases. An alternative pathway involves the loss of 7q, 17p, and 18q which also eventually acquire losses in 8p and 13q. This accounts for 13 % of the prostate cancer cases. A third pathway is observed in advanced states of prostate cancer where losses are observed on 5q, 9p, and 17p. Loss of 5q is predominantly associated with lymph node metastasis of prostate cancer. These observations were obtained from pure tumor samples which had been procured through the highly specific laser capture microdissection technique [64].

27.9 Candidate Genes in Hereditary and Sporadic Prostate Cancer

Genes implicated in hereditary prostate cancer differ from those affecting sporadic cancer. In hereditary cancer, based on linkage analysis studies, loci implicated in disease progression have been analyzed to identify candidate genes. Some of the genes identified in hereditary cancer are HPC1, HPCX, PCaP, HPC2, and CaPB.

27.9.1 HPC1

Hereditary prostate cancer gene 1 (HPC1) was identified through linkage analysis of hereditary prostate cancer families. The region 1q24–25 was identified as a candidate region in families with high risk of hereditary prostate cancer. *RNASEL* is a gene that has been mapped to the *HPC1* locus. RNASEL contains somatic mutations in hereditary prostate cancer and is regulates antiviral and anti-apoptotic effects in the cells which are induced by interferons [65].

27.9.2 HPCX

HPCX is found on the X chromosome indicating sex chromosome linkage in hereditary prostate cancer [14]. *HPCX* is found in the region between Xq27–28 which spans approximately 10 Mb. Evidence of association between HPC1 and HPCX has been observed in some hereditary prostate cases though this is not observed in all the cases.

PCAP: PCAP was detected at locus 1q42–43 through combined fine mapping and a genome screening technique [14]. It is observed in hereditary families with early onset of the disease [65].

27.9.3 HPC2/ELAC

HPC2 is found at the locus 17p11. Truncating mutations such as missense and presence of a premature stop codon were found at this locus in high-risk hereditary prostate cancer families. These mutations modify the risk to prostate cancer. HPC2 encodes a hydrolase which acts like DNA repair enzymes [65].

27.9.4 CaPB

CaPB has been reported to be linked to the locus at 1p36. There is a linkage between this locus and brain cancer since families with no history of brain cancer that have prostate cancer do not show this locus to be affected [14].

Genome-wide allelotyping of sporadic prostate cancer has identified regions that are consistently lost in disease progression. The genes of interest that lie within these regions have been identified and analyzed further for their relevance to sporadic cancer development.

27.9.5 NKX3.1

The 8p21 locus showed nearly 50 % allelic loss in prostate cancer. *NKX3.1* is a candidate prostate-specific homeobox gene at this locus and maps within the critical region of 8p12–21 [9, 65, 66]. The protein is expressed largely in the prostate and expression is lost with the progression to prostate cancer. This indicates that NKX3.1 acts as a tumor suppressor gene. Somatic mutations have not been observed in this gene despite allelic loss and so its role in sporadic prostate cancer is debated though the presence of loss and haploinsufficiency may be the cause of disease progression. Haploinsufficiency of NKX3.1 in mice gives rise to lesions similar to PIN in humans [9, 65]. NKX3.1 is a transcription factor and activates as well as represses genes [65]. PSA is repressed by NKX3.1 by binding to the promoter region of the DNA (Nelson WG). Although protein expression is lost in cancer, NKX3.1 mRNA is still expressed [32, 65]. NKX3.1 expression has been found to be ~20 % in PIN, 6 % in low stage, 22 % in high stage prostate cancers, 34 % in hormone refractory cancer and 78 % in prostate metastases [33, 65].

27.9.6 PTEN

Allelic loss at 10q24 has been observed in prostate cancer. *PTEN* (phosphatase and tensin homologue) was discovered in gliomas which showed the same allelic loss and is considered a candidate tumor suppressor gene. PTEN encodes a lipid phosphatase that negatively regulates phosphoinositol-3-kinase (PI3K/Akt) signaling and cleaves 3-phosphorylated phosphoinositides [32, 33, 65]. The PI3K/Akt pathway regulates cell cycle and apoptosis by phosphorylation of p27 and BAD, respectively. Thus, PTEN is considered to regulate cell proliferation and cell death [65]. Similar to NKX3.1, somatic mutations have not been observed in PTEN. However, haploinsufficient PTEN appears to be associated with later stages of prostate cancer. These studies have been carried out in mice which have led to the development of prostatic hyperplasia and dysplasia lesions [9, 65]. Haploinsufficiency observed in PTEN is not observed universally in all the prostatic cells though its importance in prostate cancer progression cannot be underscored with observations of decreased expression in primary tumors and xenografts [9]. Studies in mice have also shown that when NKX3.1 and PTEN are haploinsufficient, prostatic hyperplasia arises. PTEN also modifies the androgen receptor pathway by affecting the PI3K/AKT signaling pathway. This interaction will be described in the section on the androgen receptor signaling pathway.

27.9.7 CDKN1B

A cyclin-dependent kinase inhibitor, CDKN1B/p27^{kip1}, is downregulated frequently in prostate cancers [9, 32]. p27^{kip1} maps to the 12p12–13 locus. Loss has been observed at this locus although p27^{kip1} itself is not mutated. Phosphorylation or ubiquitinylation alters the localization of p27^{kip1} [9]. PI3K/AKT signaling pathway negatively regulates the levels of p27^{kip1}. PTEN which negatively regulates the PI3K/AKT pathway increases the levels of p27^{kip1}. Mice, where p27 has been targeted for disruption develop prostatic hyperplasia while those that have heterozygous alleles of PTEN and loss of both alleles of p27 develop prostate cancer [25, 32]. p27 loss is correlated to tumor grade with no loss observed in BPH and maximum loss observed in prostate cancer [9].

27.9.8 Rb

Allelic loss has been reported on 13q, a locus that contains the retinoblastoma gene (*Rb*). Mutations as well as loss of protein expression have been detected in localized and metastatic prostate cancer. *Rb* regulates apoptosis of prostate cells in the presence of androgen. Tissue recombination studies have shown that loss of Rb can cause dysplasia and invasive carcinoma in the prostate yet many studies have failed to show the similar association [9].

27.9.9 GSTP1

Hypermethylation of glutathione S-transferase (GSTP1) is a common event observed in sporadic prostate cancer. GSTP1 protein is observed in basal epithelial cells and in cells that have undergone prostatic inflammatory atrophy (PIA). However, absence of the GSTP1 protein is observed in cells that have undergone prostatic intraepithelial neoplasia (PIN). This loss of protein expression is attributed to hypermethylation of the promoter sequence of GSTP1. GSTP1 is a detoxifying enzyme that protects epithelial cells from genomic damage by carcinogens [25]. GSTP1 is generally not expressed in the luminal secretory cells. The role of GSTP1 in cancer is that of a caretaker gene rather than a tumor suppressor gene. GSTP1 may be required to detoxify PhIP-DNA adducts which form during the consumption of red meat or oxidating radicals-DNA adducts that form during oxidative stress [32].

27.9.10 AMACR

α-Methylacyl-CoA racemase (AMACR) is a mitochondrial and peroxisomal enzyme and influences metabolism of substrates by β-oxidation. The expression of the enzyme is increased with increasing grade of prostate cancer with normal prostate cells showing low frequency of enzyme expression. It has been found to be overexpressed in all prostate cancers [25].

27.9.11 AR

The androgen receptor found on the X chromosome is subjected to mutations or changes in protein expression in prostate cancer. Changes in the androgen receptor gene sequence affect the signaling pathway and other interconnecting pathways. More details will be given on the androgen receptor in the section on androgen receptor signaling.

27.10 Signaling Pathways in Prostate Cancer

Signaling pathways are activated in the process of development of prostate cancer. In prostate cancer, the signaling pathways are interconnected and ligands affect more than the immediate downstream target in their respective signaling pathway. This can be observed in the NF-kappaB and Stat3 pathway or the PI3K/AKT and AR pathway.

27.10.1 Androgen Receptor Signaling

The androgen receptor is a transcription factor, a 110 kDa phosphoprotein, and plays an important role in the development of the prostate. The AR belongs to the steroid hormone receptor superfamily [45, 49]. The androgen receptor mediates the activity of androgens such as testosterone and dihydrotestosterone (DHT) which bind to the androgen receptor elements in the promoter sequences of genes responsive to androgens and influence their transcription [45, 49, 67, 68]. The androgen receptor signaling pathway is essential for the development of prostate cancer and its influence can be observed in prostatic hyperplasia and prostatic adenocarcinoma [67–69]. The androgen receptor maintains the homeostasis in the prostate. Lowered androgen receptor activity results in cell death while increased activity induces the proliferative capacity of the prostate cells [70]. Despite androgen ablation therapy, an active androgen receptor signaling pathway is observed in hormone refractory prostate cancers. The cause for the activation of this receptor pathway is due to myriad reasons. To understand the full potential of the androgen receptor signaling pathway, it is necessary to start at the basic level of the androgen receptor structure.

The androgen receptor is found on the X chromosome between Xq11 and Xq12. It comprises 8 exons and is 110 kDa in size. Exon 1 is the largest and encodes the amino-terminal domain (NTD), exons 2 and 3 encode the DNA-binding domain (DBD), part of exon 4 encodes the hinge region while the remaining part of exon 4 to exon 8 encode the ligand-binding domain (LBD) [68, 71]. The NTD contains the polymorphic trinucleotide repeat sequences, CAG and GGC, which are 6–39 and 7–20 repeats, respectively and encode polyglutamine and polyglycine, respectively. Ethnic differences observed in repeat sequences are linked to the incidence of prostate cancer. African-Americans have shorter CAG repeat sequences, Caucasians have intermediate repeat length sequences and Asians have the longest CAG repeat sequences. The highest incidence of prostate cancer is seen in African-Americans compared to Asians and Caucasians. CAG repeat length of greater than 40 results in neuromuscular atrophy termed as Kennedy's disease [12, 68, 70, 71]. The correlation between the CAG repeats and the incidence of prostate cancer risk is fluid with few studies indicating a positive correlation while others have shown a negative correlation [12, 71]. Contrary to the distribution of the CAG repeats, African-Americans show the least frequency of the 16-GGC repeats while Asians show the highest. It may be assumed that the GGC repeats play a role in preventing the development of prostate cancer. In prostate cancer, an association of short CAG repeats and low frequency of GGC repeats have been found [71]. Besides the repeat sequences, two forms of polymorphisms are associated with the risk of prostate cancer. The R726L polymorphism, observed at codon 726 in the hinge region, occurs in linkage disequilibrium with the long CAG repeats in prostate cancer patients. Similarly, a single nucleotide polymorphism results in either an allele that can be digested by the Stu1 restriction enzyme or an allele that cannot. All these polymorphisms give rise to male baldness which is an initiator of prostate cancer.

The AR when translated is complexed with heat shock proteins to form a heterocomplex. Hsp40, Hsp70, Hsp90, and co-chaperones p23 and Hop bind to the AR when it is not bound to any ligand and stabilize the receptor protein. This multiprotein complex enables the androgen receptor to bind androgens. The binding of androgens releases the heat shock protein complex from the androgen receptor and causes the translocation of the androgen receptor into the nucleus. Within the nucleus, the androgen receptor dimerizes and binds DNA at sequences containing the androgen response elements. This assembly recruits additional transcription factors and coactivators or corepressors to regulate gene expression. Following the dissociation of the ligand, AR is shuttled back to the cytoplasm where heat shock proteins bind to form the multiprotein complex [68, 71].

27.10.2 AR Gene Alterations

Prostate cancer initially develops in the presence of androgens and a functioning androgen receptor signaling pathway. Hormone ablation therapy, in the form of surgical or medical castration, results in remission of prostate cancer. However, this sets a stage for the development of mutations and adaptive changes to the androgen receptor. AR gene amplification, mutations in the androgen receptor have been observed as adaptations to hormone deprivation. Approximately 25–30 % of prostate cancer patients show overamplification of the androgen receptor following hormone deprivation. Overamplification of the receptor enables it to be responsive to extremely low levels of androgens found in conditions of androgen deprivation. Overamplification develops only in response to the hormone ablation therapy as patient samples that showed this phenotype did not show the same prior to the treatment. Such patients showed a better response to hormone treatment, a longer survival rate, increased response to second-line hormone therapies [67, 68]. AR gene overexpression may result either due to amplification of the gene, increased gene transcription, enhanced stability of the transcript or protein [45].

AR gene mutations cause the AR to undergo changes that improve the transactivation of the AR and enhance its activity in the presence of coactivators [67]. The gene mutations cause androgen-insensitivity syndrome (AIS) which downregulates the development of internal and external male organs [45]. The first AR gene mutation was studied in the LNCaP cell line where it was found the cell line became responsive to anti-androgens. The mutation T877A causes a change in threonine to alanine in the androgen receptor and broadens the ligand specificity of the receptor [67]. AR point mutations occur in the range of 20–40 % in the male population [68]. Point mutations rarely arise in the receptor in primary prostate cancers but occur with increasing frequency in patients undergoing hormone ablation therapy. AR mutations are observed in three regions of the receptor spanning approximately 15 % of the receptor [45, 71]. The mutations are observed in the ligand-binding domain (LBD), the DNA-binding domain (DBD), and amino-terminal transactivation domain. In the LBD, the mutations are observed in a 20 amino acid signature sequence which is required for ligand specificity. Mutations are also observed in the boundary of the hinge region with the LBD and the AF-2 binding site for p160 cofactors. These changes in the AR sequence affect the transactivation of the AR and its specificity to ligands. Mutations have been observed at the carboxy terminal of the DBD which affect transactivation and transrepression of the AR and also it's DNA-binding capability. Signaling pathways are activated or repressed due to the broader specificity of AR with mutations for ligands [71]. Amino-terminal transactivation domain mutants are observed in the NTD of the receptor. Mutations are observed at the region of the polyglutamine tract or at a region amino terminal to the DBD which affects the transactivation of the receptor either in a ligand-dependent or ligand-independent manner. The carboxy terminal region of the NTD is also subjected to mutations which affect the receptor activation [71].

The p160 and p300/CBP coactivators interact with the NTD at a glutamine rich region and are affected by mutations in the region. Coactivators can increase transactivation of variant AR and thus raise the frequency of incidence of prostate cancer. In the presence of coactivators such as ARA70 and ARA160, the activity of agonists such as 17β-estradiol and antagonists such as hydroxyflutamide are enhanced. P160 coactivators can enhance the transactivation activity of AR in the presence of unconventional ligands such as estradiol and progesterone. Similarly, the coactivator Tat interactive protein 60 kDa (Tip60) is found to be increased in expression in hormone refractory prostate cancer [67, 71].

Mutations in the NTD of AR are more common in prostate cancer that has developed after androgen ablation when compared to mutations of the C-terminal which are more common in prostate cancer before hormone deprivation [69].

27.10.3 Signaling Pathways Interacting with AR

There are a number of growth factors and coactivators that interact with the AR and influence the AR signaling pathway in androgen-independent prostate cancer. They are growth factors such as epidermal growth factor (EGF), interleukin-4 and interleukin-6, cell cycle proteins, Ras-the Raf-MAPK pathway, and the PI(3)K/Akt pathway [68, 70, 72].

27.10.3.1 Growth Factors

Epidermal growth factor (EGF), insulin growth factor (IGF), and keratinocyte growth factor (KGF) activate AR. The EGF receptor family member ErbB2/Her-2/neu has a tyrosine kinase activity which is active in the absence of ligand. It activates AR and causes an increase in PSA expression even in the absence of ligand. The expression of Her2 is linked to the activation of MAP kinase and PI3K/Akt pathways which are active in the hormone refractory state of prostate cancer. Such cells have an added growth advantage [68, 70, 71].

27.10.3.2 Interleukin-4 and Interleukin-6

The interleukins are cytokines which increase the expression of AR in the androgen refractory state. PSA expression is increased in the presence of IL-4 while IL-6 activates the STAT3-AR interactions. STAT3 interacts with AR at a specific region on the AR and disruption of this direct interaction affects the activity of AR [68, 70]. IL-6 causes a signal transduction effector in the IL6 receptor, gp130, to homodimerize

resulting in the activation of the Janus Kinase (JAK)/signal transducer and activator of transcription (STAT) pathway. STAT3 is phosphorylated by JAK. IL-6 converts an androgen-dependent prostate cell into an androgen-independent cell by enhancing androgen receptor activity as well as the STAT3 and MAPK signaling pathways [73]. IL-6 prevents the apoptosis in prostate cells which is mediated by the STAT3 pathway [74]. The PI3K/AKT pathway is not affected by IL-6 overexpression. PSA expression is increased in the presence of IL-6 overexpression [73, 74]. A recent publication has shown that IL-6 mediates its growth stimulatory effect on androgen-deprived prostate cancer cells by acting in an autocrine manner. Studies carried out on LNCaP cells which are androgen-dependent show inhibition of growth in the presence of IL-6 with reduced AR expression while prolonged exposure to IL-6 causes the LNCaP cells to develop into androgen-independent cells. This shows two phases of activation of IL-6 on prostate cells, a paracrine effect in the initial stage and an autocrine effect in the androgen-independent growth of prostate cancer cells. It is at this stage that the AR signaling pathway is activated [73, 74].

27.10.3.3 Cell Cycle Proteins

AR is either activated or repressed by different cell cycle proteins. Cyclin D1 represses AR transactivation and P/CAF competes with this interaction and prevents the inhibition of AR. Cyclin E is an activator of AR and is not inhibited by any other protein and may be responsible for the androgen-independent growth of prostate cancer cells. pRB also activates AR but in an androgen-dependent manner. The corepressors are c-Myc, cyclin-dependent kinases (CDKs), Bcl-2, NK-kB, and others [70].

27.10.3.4 Ras-Raf-MAPK Pathway

Guanine nucleotide proteins such as Ras are activated during growth factor mediated signaling. Cell cycle proteins are activated by phosphorylation by the Ras-Raf-MAPK pathway. This pathway plays a role in the progression of cells from Go/G1 to the S phase. Overexpression of mutated Ras leads to proliferation of cells. This pathway is activated in both hormone-sensitive and hormone-deprived prostate cells.

27.10.3.5 Protein Kinases

Protein kinases A, B, and C activate AR and are induced by growth factors mentioned above.

27.10.3.6 Calcium and Calmodulin

Calmodulin binds to AR in the presence of calcium and stabilizes it. Calmodulin activates a number of kinases including Akt which interact with AR and form a complex and influences the stability.

27.10.3.7 Proteasome

The 26S proteasome ubiquitinates AR and the proteins that form a complex with AR cause timely degradation of the complex and enable cell cycle progression. The proteasome pathway activates NF-kB which leads to AR transcription and translation into protein [68, 70, 72].

27.10.4 NF-Kappa B Signaling

Nuclear factor-kappa B (NF-kappa B) signaling consists of the canonical and the non-canonical pathways. NF-kappa B is a complex of proteins that are present as dimers. These proteins fall in two classes. The first class consists of RELA (p65), RELB, and c-REL, and the second class consists of NF-kB1 (p105) and NF-kB2 (p100). The REL proteins dimerize with the second class to activate the expression of genes. p105 is a precursor protein which is proteolytically processed into the mature protein p50 while p100 is processed into p52. The canonical pathway consisting of dimers containing RELA, NF-kappa B1/p50, and c-REL are present in the inactive form in the cytoplasm by the inhibitors of kappa B proteins (IkB). IkB proteins are phosphorylated by the IkB kinase (IKK) complex specifically IKKβ that inactivates IkB through ubiquitinylated degradation. This releases the NF-kappa B complex which translocate to the nucleus and activates targets of inflammation, cell proliferation, anti-apoptosis, and negative regulators of NF-kappa B proteins. The second non-canonical pathway consists of RELB and NF-kappa B2/p52. Members of the tumor-necrosis factor (TNF) cytokine family activate IKKα along with a second protein kinase NIK which in turn induces the proteolytic processing of NF-kappa B2 resulting in the translocation of RELB/p52 dimers to the nucleus [75, 76].

At which stage is NF-kappa B activated in the tumorigenic process of the prostate? NF-kappa B is expressed variably in different stages and is present in different locations based on the tumor stage of the prostate. Domingo-Domenech et al. [77] have shown in their study that NF-kappa B is localized in the cytoplasm in luminal cells and in the nucleus in basal cells. Cytoplasmic NF-kappa B is observed in PIN lesions while cytoplasmic as well as nuclear NF-kappa B staining is seen in prostatic adenocarcinoma. It was also observed in the analysis of patients that nuclear NF-kappa B could be considered as an indicator of biochemical relapse. The risk of biochemical recurrence increased when nuclear NF-kappa B was present along with high PSA levels and high Gleason score [77]. Sweeney et al. showed the similar result of increased NF-kappa B staining in advanced stages of prostate cancer compared to the benign state. Increased NF-kappa B expression was seen in hormone-independent cell lines [78].

Chen and Sawyers [98] have shown the role of the canonical pathway, RELB/p50 dimers, in activating PSA by binding to four sites in the enhancer region of the PSA gene. AR also binds to the enhancer region of PSA indicating a cross talk between the NF-kappa B and the AR pathways. Studies in the androgen-independent cell line, LAPC-4, have shown that NF-kappa B to be present in high levels and the activation is observed in the nucleus with lower levels of IKKβ. This provides a role for NF-kappa B in androgen-independent tumors [51]. In another study by Catz [79], the activation of *bcl-2* expression by NF-kappa B has been shown. NF-kappa B binds to two consensus site on the bcl-2 promoter sequence p2. TNF-α regulates the activation of *bcl-2* by NF-kappa B. *bcl-2* expression is reduced in the presence of hormones which is indicative of its role in hormone-independent prostate cancer [79]. Suyun Huang et al. have shown that blocking the NF-kappa B pathway in prostate cancer cells inhibits the expression of proteins related to the angiogenic, invasive, and metastatic pathways. The androgen-independent prostate cancer cell line PC-3 was utilized in this study where stable cell lines transfected with control vector or with a dominant negative mutant form of IkBα (IkBαM) were generated. Though the cell viability is not affected, the expression of angiogenic factor, VEGF, invasion protein, IL-8, metastasis protein, MMP9 was reduced at the transcriptional and translational levels. The vascularization of cells transfected with IkBαM was significantly lowered compared to the normal cells and the cells transfected with the control vector indicating the effect of downregulating the NF-kappa B pathway [80]. A similar result was shown by Andela [81] by suggesting a role for NF-kappa B in prostate cancer metastasizing to the bone. In this study, the expression levels of MMP9 and IL-6 were markedly reduced when PC-3 cells were transfected with a mutant form of IkBα. The role of NF-kappa B is reinforced in metastasis and bone resorption through the expression differences in MMP9 and IL-6. The study also showed a subsequent increase in the anti-metastatic factor, TIMP1, in the stable cell line transfected with the mutated IkBα [81].

Our laboratory has shown the processing of NF-kappa B2/p100 is mediated by Stat3 and involves the acetylation of cyclic AMP-response element binding protein (CBP/p300). Stat3 when activated involves the processing of p100 to p52. Activation of Stat3 occurs through acetylation mediated by CBP/p300. Active Stat3 was shown to mediate the anti-apoptotic activity of p52. This interaction of Stat3 with the noncanonical NF-kappa B pathway regulated anti-apoptosis [82]. Stat3 regulation of NF-kappa B is mediated by LIGHT. LIGHT induces phosphorylation of Stat3 with the help of NIK which is phosphorylated. Only in the presence of NIK, can LIGHT mediate Stat3 phosphorylation and this phosphorylation increases with increase in LIGHT dosage. These results indicate the NF-kappa B and the Stat3 pathways are interlinked in prostate cancer [83].

27.10.5 STAT3 Signaling

Signal Transducers and Activators of Transcription (STAT) are a group of seven genes named as STATs 1, 2, 3, 4, 5A, 5B, and 6 [84]. The STAT signaling cascade originates through growth factors and cytokines in the plasma membrane of the cell resulting in STAT proteins being phosphorylated in the cytoplasm, at the tyrosine and serine residues, dimerizing of the phosphorylated STAT proteins and its subsequent translocation to the nucleus [84, 85]. Members of the Janus Kinase family (JAK) such as JAK1, JAK2, and Tyk2 or other kinases such as Src and BCR-Abl kinases phosphorylate the STAT proteins. The STAT signaling controls cell differentiation, development, proliferation among other functions [84]. There is a significant role played by the STAT signaling pathway in prostate cancer when it is upregulated and is involved in cross talk with other signaling pathways such as NF-kappa B pathway. Huang et al. [85] have shown the effect of constitutively active STAT3 on prostate cancer progression. It was observed that benign prostate epithelial cells that expressed constitutively active STAT3 did not require JAK kinases to phosphorylate the STAT3 proteins. However, inhibition of the STAT3 pathway in the STAT3 stable cell lines compromised the cell viability as these cells showed a significantly higher growth rate in unsupplemented medium. In addition these cells gained androgen insensitivity indicating self-sufficiency in the presence of STAT3 signaling [85]. In a similar study by Tam et al. [86], hormone sensitive tumor samples were compared to those that were hormone insensitive for the levels of IL-6 and phosphorylated STAT3. Immunohistochemical staining was performed for IL-6 and phosphorylated STAT3 to identify the risk of obtaining prostate cancer. Increased IL-6 was associated with hormone insensitive patients and also indicated shorter time to relapse. Increased phosphorylated STAT3 was observed in hormone insensitive patients and indicated a greater survival rate [86]. IL-6 activation of STAT3 was enhanced by AR in the presence of DHT. DHT could influence the activation of STAT3 in the presence of IL-6 which was inhibited by flutamide, the anti-androgen. Conversely, inactive STAT3 inhibited AR activation by IL-6 in the presence of DHT [87]. Azare et al. [88] showed the effect of fibronectin in the transition of epithelial to mesenchymal phenotype in prostate cells which contain constitutively active STAT3. The cell motility is enhanced in the presence of integrin β6 and fibronectin with a reduction in the expression of E-cadherin. The significance of this finding however could not be observed in the immunohistochemical staining of human prostate tissues [88]. EGF signaling activates STAT3 signaling in prostate cells and enhances migration and invasiveness of cells [89]. EGF can enhance AR activation by increasing STAT3 levels. STAT3 levels are increased in the presence of IL-6 which increases the interactions between STAT3 and AR. The increase in EGF signaling causes AR signaling to be dependent on STAT3 [90].

27.10.6 PI3-K/Akt Signaling

Akt or protein kinase B is a serine/threonine kinase family of proteins and is a proto-oncogene. Akt1, Akt2, and Akt3 are members of the Akt family. It derives its name protein kinase B from its homology in the catalytic domain of the protein structure to protein kinase A and C. It plays a role in cancer through the phosphatidylinositol 3-kinase PI3-K/Akt pathway. The Akt protein structure consists of an N-terminal pleckstrin homology (PH) domain and a C-terminal regulatory domain. Akt is located in the cytoplasm in its inactive state. On activation by ligands such as growth factors, cytokines, T-cell receptors, PI3-K, a lipid kinase, is activated by receptors, such as tyrosine kinase receptors. This results in second messengers including phosphatidyl3,4,5-trisphosphate (PI-3,4,5-P_3) or phosphatidylinositol 3,4-bisphosphate (PI-3,4-P_2) to recruit Akt to the plasma membrane by binding to the PH domain. Akt undergoes a conformational change which results in the phosphorylation of the kinase activation domain at Thr308. A second phosphorylation site is at Ser473. On getting phosphorylated, Akt translocates into the nucleus to regulate the proteins involved in angiogenesis, cell survival, and proliferation. The levels of PI-3,4,5-P_3 and PI-3,4-P_2 are regulated by PI3-K and phosphatases. One of the phosphatases is the phosphatase and tensin homologue (PTEN) which converts PI-3,4,5-P_3 to PI-4,5-P_2. The SHIP phosphatases, SHIP1 and SHIP2, convert PI-3,4,5-P_3 to PI-3,4-P_2. Similarly, Akt is negatively regulated by protein phosphatases and positively regulated by proteins such as caveolin-1 (cav-1). Serine/threonine protein phosphatases, PP1 and PP2A, dephosphorylate Akt at Thr308 and Ser473. PP1 and PP2A regulate processes such as glycogen metabolism, protein synthesis. Caveolin-1 positively regulates Akt by inactivating PP1 and PP2A. Caveolin-1 is upregulated in prostate cancer. Akt promotes anti-apoptotic pathways by regulating genes involved in apoptosis such as forkhead receptor (FKHR). Akt phosphorylates FKHR which results in its sequestration in the cytoplasm by 14-3-3 proteins preventing it from activating proapoptotic proteins such as BIM and FAS ligands [91].

Yamaguchi et al. [92] have demonstrated the anti-apoptotic activity of Akt through techniques ranging from flow cytometry to fluorescence in situ hybridization (FISH) in lymphoid cells. In experiments designed to study a range of apoptotic proteins, the study showed using FISH that Akt prevented Bax from translocating to the mitochondria even when the cell survival factor, IL-3, was absent. It was observed that the active phosphorylated form of Akt inhibited caspase activation and maintained the membrane potential of the mitochondria. Contrary results would have been observed if the proapoptotic factor, Bax, was active [92]. Akt can activate NF-kappa B signaling by phosphorylating the IkB kinases which inactivate its interaction with NF-kappa B proteins. This leads to the translocation of the NF-kappa B proteins into the nucleus to activate the transcription of downstream target genes. Similarly, the AR signaling pathway is regulated by Akt. The androgen receptor mediated apoptotic pathway is negatively regulated by Akt. In a study by Lin [93], it was observed that Akt phosphorylates AR at two distinct sites, Ser-210 and Ser-790. The specificity of Akt for the AR signaling pathway was observed when constitutive Akt was transfected into DU145 cells. It was observed that in the presence of constitutive Akt, the androgen receptor is phosphorylated. Subsequent to AR phosphorylation, the interaction between AR and its coactivators are inhibited by Akt. The use of inhibitors of PI3-K/Akt and PI3-K/p70S6K showed that the PI3-K/Akt signaling pathway was effective in regulating the AR signaling pathway. The rates of apoptosis were significantly lower in prostate cancer cells that were treated with inhibitors to PI3-K. Stable cell lines of LNCaP treated with a dominant negative mutant of Akt showed an increase in p21 protein expression which is a proapoptotic factor and this was specific to prostate cancer cells [93]. Akt may influence the progression of prostate cancer to hormone-independent prostate cancer by inhibiting apoptosis and promoting G1 cell cycle progression [94].

Brunet et al. [95] have shown the interaction of Akt with the forkhead receptor ligand 1 (FHRL1) which results in its phosphorylation and inactivation. The FKHRL1 functions in the nucleus where it stimulates apoptosis in the cell. In the cancer arena, Akt is activated which then phosphorylates FKHRL at three sites causing FKHRL to get sequestered in the cytoplasm. Immunolocalization confirmed the subcellular staining of FKHRL. The protein that cooperates with Akt in the sequestration is the 14-3-3 protein which is a cytoplasmic phospho-serine binding protein. FKHRL binds to a consensus sequence similar to the insulin response sequence (IRS). The activation of apoptosis by FKHRL is through the consensus sequence termed FH-responsive element (FHRE). This sequence can be found on ligands such as Fas. The interaction of FKHRL with Fas which induced apoptosis was confirmed by determining the percentage of apoptotic cells in cell lines that were transfected with the Fas ligand and the FKHRL. This study elegantly showed the specificity of the interaction of Akt with FKHRL in regulating the apoptotic pathway.

Another cellular aspect that is controlled by the PI3-K/Akt pathway is prostate cancer cell invasion [95, 96]. In a study by Shukla et al. [97] the effect of the PI3-K/Akt pathway on the invasive properties of prostate cancer cell lines, LNCaP, 22RV1, PC-3, and DU145 were analyzed. The levels of PTEN and activated Akt were inversely correlated in prostate cancer cells. PI3-K protein levels were lowered in androgen-dependent cells in the presence increasing concentrations of the PI3-K inhibitor while they were minimally affected in androgen-independent cell lines, DU145 and PC-3. With the lowering of PI3-K, the levels of p-Akt were lowered resulting in decreased invasive capacities. When the levels of p-Akt were high, the levels of invasion proteins matrix metalloproteinase (MMP-9) and urokinase plasminogen activator (uPA)

were increased. When human prostate tissue samples were analyzed, the PI3-K levels were found to be high in high Gleason grade tumors. With the increase in PI3-K levels, active Akt was increased and PTEN levels were lowered. This seems to indicate the role of PI3-K/Akt in prostate cancer progression and cell invasion [97]. A study in mice showed that PTEN deficient mice were tumorigenic. This tumorigenic capacity was seen to be inhibited by Akt deficiency and haploinsufficient Akt also inhibited the development of prostate cancer [98]. Another aspect of Akt signaling is in indicating the risk of recurrence of prostate cancer. It is unknown how prostate cancer recurs despite hormone ablation therapy. Initially, prostate cancer is dependent on androgen and on removal of androgens from the environment, prostate cancer regresses. Yet, 18 months later, cancer reappears. In order to determine the factors that may cause prostate cancer to recur, Bedolla et al. [99] looked at the effect of PTEN expression and the presence of active Akt or p-Akt in prostate cancer tissue. Paraffin-embedded samples were analyzed through immunohistochemistry for the status of PTEN and p-Akt. It was observed that PTEN negative samples showed prostate cancer recurrence that was close to twice the rate for samples that were positive for PTEN expression. Conversely, high p-Akt levels give rise to five times the frequency of recurrence as compared to samples that have low levels of p-Akt. Univariate analysis indicates p-Akt and PTEN are predictors of recurrent disease in converse ways. A multivariate analysis has shown the combination of Gleason score, p-Akt and PTEN levels are important predictors of recurrent prostate cancer [99]. Besides interacting with the AR signaling pathway, PI3-K/Akt also interacts with NF-kappa B and this has been demonstrated in TRAMP mice. It was observed with increase in age of TRAMP mice, the levels of NF-kappa B increased in both the nucleus and cytosol. Simultaneously, the inhibitory kinase, IKKα, is decreased and IkBα is increased in TRAMP mice while no significant change was observed in the non-transgenic controls. Invasion proteins such as MMP-9, cell cycle proteins such as cyclin D, angiogenesis proteins such as VEGF all showed high rates of expression in TRAMP mice. PTEN levels were measured in TRAMP mice compared to non-transgenic mice and the non-phosphorylated and phosphorylated forms of PTEN were found to increase as the age of the transgenic mice increased. This study showed the connection between the tumor suppressor gene PTEN and the PI3-K/Akt pathway [100].

27.11 Prostate Cancer Metastasis

Distant site metastases are seen in the metastatic stage of prostate cancer. Some of the sites of metastases are bone, lymph nodes, lung, liver, and brain. Metastases to the lymph nodes and bone are the most frequent and predominant. Lymph node metastases account for 70 % while bone account for 90 % of prostate cancer metastases. This review will focus on bone metastases and the genes that regulate the development of the cancer.

27.11.1 Bone Metastases

Prostate cancer that becomes androgen independent is very aggressive resulting in highly invasive cancers. The bone is the primary site of invasion of aggressive prostate cancer and accounts for ~90 % of distant site metastases. Skeletal bone cancer results in severe pain, hypercalcemia, and frequent fractures [101, 102]. Bone metastases are seen in cancers of the lung, breast, and kidney. However, the unique feature of bone metastases in prostate cancer is that the cells are predominantly osteoblastic. Breast, kidney, and lung cancer bone metastases are mainly osteolytic [103]. Bone cells are made up of osteoblasts and osteoclasts. Osteoblasts are bone-forming cells while osteoclasts are bone-resorbing cells. Once bone metastasis sets in, it signifies the terminal stage for patients diagnosed with prostate cancer. There is no cure for these skeletal metastases [102, 104].

The bone comprises of a homeostatic balance between osteoblasts and osteoclasts. The basic function of osteoblasts is to produce the bone matrix which becomes mineralized. Growth factors such as bone morphogenetic protein (BMP), transforming growth factor-β (TGFβ), fibroblast growth factor (FGF), endothelin-1 (ET-1), serine proteases such as urokinase and prostate-specific antigen (PSA) activate osteoblast proliferation or differentiation [105, 106]. Alkaline phosphatase is an enzyme found on the surface of osteoblasts and is involved in bone mineralization [106]. Osteoclasts on the other hand are bone-resorbing cells and differentiate after osteoblasts develop [107]. Osteoblasts activate osteoclast precursors by expressing osteoprotegerin (OPG) and receptor activator of nuclear factor-kB ligand (RANKL). RANKL binds RANK on the osteoclast precursor cell causing it to differentiate into an osteoclast. OPG is an alternate receptor for RANKL which acts as an internal control for the development of osteoclasts [108]. When imbalance sets in between the osteoblasts and osteoclasts, cancer is initiated [105].

Bone metastases develop in two stages. Prostate cancer cells initially home into the bone followed by tumor development. The exact method of development of bone metastases has not been elucidated. However, work done by Sikes et al. [109] has shown that cells migrate toward bone based on their invasive capacity compared to their adhesive potential. In the study, the highly invasive cell line C4-2 was compared to LNCaP and the non-tumorigenic cell line P69 for their adhesive and invasive properties. It was observed that the tropism for bone by prostate cancer cells was inversely proportional to the tumorigenicity of cells with C4-2 cells showing the least tropism toward bone cells. Conversely, the

invasive capacity of C4-2 cells was higher in bone cells compared to P69. This study indicated the possible form of interaction of prostate cells with bone which depends not just on cell surface proteins to initiate contact and expansion but also on the bone microenvironment which influences different cells in varying ways. LNCaP cells though invasive toward bone are not as metastatic and this can be explained by the varying interactions of the bone extracellular matrix with the cells [109]. The androgen-independent C4-2 cells are derived from LNCaP by coculturing LNCaP cells with bone stromal cell line MS. Cell lines were derived from the bone metastases developed from the C4-2 cell line. Comparison of the invasive capacity of the C4-2 cell line and the derivative bone cell lines showed higher invasive potential compared to the parent LNCaP cell line. The progression of the LNCaP cell line into an androgen-independent cell metastasizing toward the bone imitates the situation in vivo in humans [110]. The clonal nature of bone metastatic cells is obvious when PSA levels are measured. PSA protein is expressed at high levels in the cells although one of the cells failed to show sufficient RNA. On growing out the cell line, some of the cells showed sufficient RNA levels of PSA. This indicates the heterogeneity of prostatic bone tumors [110].

A study of the factors responsible for prostate cancer death due to metastases to the bone analyzed 68 prostate carcinoma patients and clinical features such as Gleason score, time of survival between diagnosis, and surgical treatment, levels of PSA, staining for biomarkers (including chromogranin A) showed three features to be responsible for increased death due to metastasis of prostate carcinoma in the bone. It was observed that a high Gleason score of 8 or more is responsible for bone metastases and greater frequency of death. The time of survival reduces with increasing time difference between time of diagnosis and surgical treatment. This is due to the fact that the longer it takes to detect the metastasis the more developed the cancer, resulting in a greater likelihood of death. In addition, staining of chromogranin proved to be an indicator of decreased survival in prostate cancer patients with bone metastasis. However, the sample set of this study is small to consider the observations to be entirely representative of prostate cancer bone metastases in the population. A larger sample study is required to confirm the above results. It was also observed in the sample set that androgen receptor was positive in the bone metastatic cells [111].

Vascular endothelial growth factor (VEGF) induces osteoblast differentiation but not mineralization. A study of PC-3, LNCaP, and C4-2B cells showed VEGF levels are present at high levels. C4-2B conditioned medium stimulates osteoblast differentiation and was used in culturing cells such as PC3 and LNCaP in addition to C4-2 itself. An inhibitor to the receptor of VEGF showed that VEGF when inhibited reduces the capacity of osteoblast differentiation. Alkaline phosphatase and osteocalcin levels are reduced concomitantly with the reduction of VEGF levels. C4-2B cells when injected into mice tibia show increase in bone marrow density as compared to injected C4-2B cells that are exposed to VEGF inhibitor clearly indicating the role of VEGF in the ossification process [101].

Prostate cancer that metastasizes to the bone shows an increased activity of osteoblasts compared to osteoclasts and thus increased bone formation. However, this bone formation does not improve the strength of the skeletal structure because the internal bone structure is weaker than that formed in a normal process. The collagen bundles formed in the normal lamellar bone are arranged in straight long bundles which are tightly packed giving the bone its strength. However, when osteoblasts are activated by prostate cancer cells, they induce bone formation where the collagen is loosely packed in a random manner resulting in weak bones. This is the reason for bone fractures in such a condition. The combination of weak bone structure coupled with osteolytic activity further reduces bone strength [108]. Berruti et al. [112] have surveyed the various skeletal damages that can occur due to prostate cancer metastasizing to the bone. Some of these skeletal damages in order of greater prevalence are spinal instability, spinal compression, hypercalcemia, bone fractures. Alkaline phosphatase is the predominant marker that correlated significantly with bone formation and deoxypyridinoline is a significant marker of bone resorption. Deoxypyridinoline correlated significantly with skeletal damages in the study of 112 patients [112].

Parathyroid hormone-related peptide (PTHrP) released by the tumor cell induces osteoblasts to overexpress RANKL and downregulate OPG. RANKL then acts on osteoclast precursors to develop into osteoclasts which then perform bone resorption. The process of bone resorption releases various growth factors such as TGF-β, IGF1, and calcium. SMAD and MAPK are activated as separate signaling pathways which lead to the release of PTHrP resulting in the repetition of the cycle of osteoblast-osteoclast interactions [106].

Prostate cancer can metastasize to the bone with the help of the Wnt proteins. It has been shown that the Wnt signaling pathway is activated in prostate cancer where Wnt1 and β-catenin are upregulated. Wnts 3a and 11 are present in androgen-independent cancer. Wnt3a activates AR signaling pathway in the absence of androgen and regulate the level of β-catenin [103]. Hall et al. have shown that prostate cancer promotes osteoblast differentiation through Wnt proteins [104]. DKK1 is an antagonist of Wnt and binds to the lipoprotein receptor-related proteins (LRP) and causing it to internalize to be degraded by lysosomes [103]. Prostate cancer cells that express Wnt proteins show metastasis to the bone. However, when DKK1 is expressed in the cells, the activity of Wnts is reduced resulting in reduced bone formation. The in vivo study showed a decrease in bone density

within the tibia of mice bones. There is a destruction of the lamellar bone when DKK1 is overexpressed in the prostate cancer cells. Mineralization is observed in vitro in prostate cancer cells that downregulate DKK1 expression indicating the osteolytic effect of DKK1 [104].

Current therapies related to bone metastases seek to identify the proteins that are involved in the differentiation pathways of bone cells. Bisphosphonates are pyrophosphate compounds that bind to mineralized cell surfaces and prevent the action of osteoclasts in bone resorption. It is a drug that is currently marketed. Some of the drugs that are in phase II or III trials are osteoprotegerin and PTHrP antibodies. In addition, there are endothelin receptor antagonists (atrasentan) that target osteoblast differentiation and bone morphogenetic antagonists (BMPs such as Noggin and anti-BMP-6). There are radioactive drugs such as strontium-89, Samarium-153, and Rhenium-186 that are used to prevent the development of the bone matrix and osteoblast differentiation [102, 106].

27.12 Animal Models of Prostate Cancer

The Dunning and Noble mouse models of prostate cancer initiated the study of prostate cancer in vivo [113, 114]. Greenberg at al. [115] developed a transgenic mouse model in 1995 that recapitulated the process of intraepithelial neoplasia to invasive carcinoma in humans. Transgenic adenocarcinoma mouse prostate or TRAMP is the term given to the mouse model developed by Greenberg et al. [115]. The concept involved using the rat probasin promoter to drive the expression of genes of interest. The probasin gene is a prostate-specific gene and, the probasin promoter drives the expression of genes specifically in the prostate. In the TRAMP model, the SV40 large T antigen was placed under the influence of the probasin promoter since the effect of the T antigen on initiating tumorigenesis was observed in the pancreas and mammary gland [115]. The tumors that developed were mainly in the dorsal and ventral sections of the mouse prostate and resembled the human invasive carcinoma of the prostate. The cells were pleomorphic with angular nuclei and small amounts of cytoplasm. The progression to hormone independence was an important point to study in prostate cancer. When AR immunostaining was performed in TRAMP mice, it was observed that increased loss of epithelial differentiation was inversely proportional to the level of AR staining. The time taken for the tumors to progress to cancer in the mice was approximately 20–40 weeks with hyperplasia observed around 10 weeks of age while invasive carcinoma was observed in the mice at around 20 weeks of age. This rapid progression was observed when a matrix attachment region (MAR), intended to enhance the probasin based gene expression, was added to the probasin-Tag construct. In the absence of the MAR, the rate of tumor progression though lower, still occurred in the transgenic mice. The advantage of TRAMP is that the tumors develop specifically only in the prostate making it an ideal model for a focused analysis of prostate cancer. The molecular events that occur in the development of prostate tumors as well as the transition from hormone dependence to hormone independence as observed in the reduction of AR staining can be studied in the TRAMP model [115].

In the study by Gingrich et al. [116], the progression to androgen independence was studied in the TRAMP model. The basis for the study was to study if the androgen-independent growth in cells was induced due to castration or androgen-insensitive cells were already present in a heterogeneous prostate which were activated on castration. The genitourinary weight was compared between normal mice and TRAMP mice. The GU weight was larger in the TRAMP mice but a timescale progression of weight difference between castrated TRAMP mice showed that the GU weight of castrated TRAMP mice at 12 weeks was lower than those that were castrated at 18 weeks. This increase in GU weight with increase in time following castration indicated a subsequent growth of the prostate cells. This experiment showed the presence of androgen-independent cells that were present in the prostate but were activated only under conditions of castration [116].

Besides the TRAMP mouse model, there have been mouse models that look at the effect of growth factors on the development of the prostate and the effect of drugs on the prostate. The mouse model, Tag/Ghr$^{-/-}$ was generated by crossing a GH receptor knockout mouse with the C3[1]/Tag mouse. The resulting Tag/Ghdr$^{-/-}$ mouse failed to develop PIN lesions as compared to Tag/Gh$^{+/+}$ mice despite the presence of the T antigen, and androgen receptor expression indicating the importance of growth factors for prostate cancer progression [117]. A transgenic mouse model termed ARR2 Pb-Lux expresses luciferase specifically in the prostate under the influence of the androgen receptor and provides a useful model to test the effect of androgen receptor inhibiting drugs. The luciferase signal is diminished when the androgen levels are reduced due to the use of bicalutamide, an androgen receptor inhibiting drug, or due to castration. This transgenic mouse provides a useful method of analyzing histological and molecular changes in the prostate in a noninvasive manner [118].

Prostate tumor cell lines are widely used to study the tumorigenic process in the prostate. Commonly used prostate cell lines are LNCaP, CWR-22, PC-3, DU145, RWPE-2, TSU-PRI, RWPE-2, and ALVA101 [119]. LNCaP is an androgen-dependent cell line that was derived in 1977 from a metastatic lymph node of a 50 year-old Caucasian male. This cell line is most commonly used to study the properties of prostate cells in the presence of androgen. In addition,

LNCaP cells are used to develop androgen-independent cell lines in an effort to study the progression of androgen-dependent cells to an androgen-independent state. Our laboratory has generated the androgen deprivation induced androgen suppressed cell line, LNCS from LNCaP [120]. LNCaP cells were cultured in a charcoal stripped medium which was devoid of hormones and after approximately 20 passages, the cells changed in morphology and androgen-dependence. While LNCaP cells have filamentous processes and a functional androgen receptor, LNCS cells grow in clumps and do not possess a functional androgen receptor. LNCS cells when grown in FBS medium are growth suppressed and resume normal growth in charcoal stripped medium. PSA levels are found to be insignificant in LNCS compared to LNCaP. The LNCS cell provides a useful model to analyze the progression of androgen-dependent cells to an androgen deprivation induced androgen suppressed state [120]. A Q640X mutation in AR in LNCaP cells exhibits a paracrine effect on neighboring cells which have normal AR resulting in a ligand-independent increase in overall AR and PSA expression of cells that do not possess the mutated AR. This is another mechanism by which cells can develop in the absence of androgen [121]. LN-REC4, LNCaP-SF, C4-2 cells are derived from LNCaP cells and are all androgen independent [110, 122]. LNCaP-CR is a cell line derived from LNCaP which is cytokine resistant [123].

The PC-3 cell line was established in 1979 from a lumbar vertebra metastasis in a 62-year-old Caucasian male. The PC-3 cell line is an androgen-independent cell line where the androgen receptor is absent. High levels of transforming growth factor (TGF-α) and epidermal growth factor-receptor (EGF-R) are observed in the PC-3 cell line indicating growth factors and not androgen are responsible for the growth of the prostate cells. PC-3 cells are in general unresponsive to androgens. DU145 cells are androgen-independent cells derived from a metastatic central nervous system lesion. The growth factors that stimulate the growth of DU145 are TGF-α, fibroblast growth factor (FGF), and insulin growth factor (IGF-1) [119, 124].

The ALVA101 cell line is derived from a bone metastasis and expresses the androgen receptor, PSA as well as 5α-reductase activity. These cells are consequently androgen responsive [119]. Cell lines are a vital in vitro tool to analyze the events that occur in the tumorigenic process in vivo. Most cell line studies provide the basis for in vivo analyses of tumorigenic progression and enable drug studies.

27.13 Conclusion

This review has covered the broad aspects of the tumorigenic process of prostate cancer. No doubt, there are many discoveries that may not have been touched upon in the article. However, one can observe the different angles with which prostate cancer has been studied. There have been advances made in the androgen refractory state of prostate cancer where a number of cell line models and xenograft models are providing us with clues to the functioning of the prostate cell in a hormone-free environment. Genome-wide allelotyping studies have provided us with a base on which further exploration of candidate genes can be conducted. One can observe that the study of cancer is ultimately a combined analysis using different techniques, cell lines, animal models, tissue analyses to give a more comprehensive overview of the disease. The heterogeneity of prostate cancer also increases with age and environment. To this end, the results reviewed in this chapter emphasize the need for the use of different techniques in analyzing prostate cancer.

Molecular Basis of Lung Carcinogenesis

28

Kwun M. Fong, Jill E. Larsen, Casey Wright, Krishna Sriram, Morgan Davidson, Marissa Daniels, Yoshitaka Sekido, Rayleen V. Bowman, Ian A. Yang, and John D. Minna

28.1 Introduction

Lung cancer is the leading cause of cancer deaths in the Western world, estimated to account for over a quarter of the cancer deaths in both men and women [1]. The World Health Organization has estimated that perhaps about one million people die from lung cancer worldwide each year. Lung cancer has surpassed breast cancer as the leading cause of cancer death in women in several western countries. Changes in smoking habits have meant that the incidence and death rates due to lung cancer are decreasing in men, but increasing in women.

Clinically, lung cancer is usually classified into non-small-cell lung cancer (NSCLC) and small cell lung cancer (SCLC), with the latter representing 15–20 % of cases (Table 28.1). This classification relies on differences in histological and neuroendocrine (NE) features. A characteristic neuroendocrine phenotype is observed in the pulmonary NE cells of normal lung and in a subset of lung malignancies including SCLC, bronchopulmonary carcinoids, and NSCLC with neuroendocrine features, which includes the presence of cytoplasmic dense core granules [2, 3], and expression of L-dopa decarboxylase, chromogranin A, synaptophysin A, neuron specific enolase (NSE) and neural cell adhesion molecule (NCAM). In contrast, most NSCLC lack these properties and are comprised of three major subtypes: adenocarcinoma, squamous cell carcinoma, and large cell carcinoma. In vitro, NSCLC and SCLC subtypes also tend to have different biological properties such as the adhesion of NSCLC cells to substrate which is generally absent in SCLC cell lines. This is relevant to molecular pathogenesis as the CD44 adhesion molecule which is involved in intercellular interactions was found to be predominantly associated with the NSCLC phenotype, indicating that it may be a useful differentiation marker [4]. Nonetheless, there are some lung cancers with features of both NSCLC and SCLC.

Although it is still uncertain whether SCLC and NSCLC are derived from the same or different cell lineage, much progress has been made towards understanding the molecular basis of lung cancer, particularly involving classic oncogenes and tumor suppressor genes (TSGs or recessive oncogenes). The current paradigm suggests that human epithelial tumors, such as lung cancer, arise as a result of the accumulation of multiple independent molecular events that target critical genetic pathways in key cells. These events appear distinct from the random background genetic damage that is often seen in advanced neoplasms. Specific oncogenes and tumor suppressor genes (TSGs) are the likely targets of somatic aberrations resulting from the genotoxicity of tobacco smoke carcinogens.

The critical cellular pathways affected directly or indirectly by these somatically acquired aberrations are becoming increasingly recognized as biochemical functions of the proteins encoded by mutated genes are unraveled. Cancer is not only caused by abnormal cell proliferation with loss of the usual cellular growth control mechanisms but is also influenced by abnormalities in apoptosis (programmed cell death). Indeed, solid tumors ensue from a balance between cell proliferation and cell death. The regulation of these processes is complex. There are positive factors such as cytokines, hormones, growth factors, and their specific receptors which, upon ligand binding, then signal effector genes via

Table 28.1 Selected characteristics of small cell and non-small-cell lung cancer

	SCLC	NSCLC
Frequency	~20–25 %	~75–80 %
Histology	Scant cytoplasm, small hyperchromatic nuclei, fine chromatin, indistinct nucleoli, tumor in sheets	Abundant cytoplasm, pleomorphic nuclei, coarse chromatin, prominent nucleoli, squamous/glandular architecture
Neuroendocrine phenotype	~100 %	Large cell neuroendocrine carcinomas and carcinoids
Peptide secretion	ACTH, AVP, calcitonin, ANF	PTH
Radiation-sensitivity	80–90 % Shrinkage	30–50 % Shrinkage
Chemo-sensitivity	High	Low
Oncogenes		
RAS mutation	<1 %	~15–20 %
MYC amplification/overexpression	~15–30 %	~5–10 %
ERBB2 overexpression	<10 %	~30 %
EGFR mutation	Rare	~10 % (Higher in Asians, nonsmokers, adenocarcinomas, females)
EML4/ALK fusion		~5 %
ROS1 fusion		~1–2 %
LKB1 mutation		~9-
HER2 mutation/amplification		~2–4 %
PIK3CA mutation/amplification		~2–18 %
TTF1 amplification		~15 %
BRAF		~2–3 %
MET mutation/amplification	? Rare	~1–20 %
FGFR1 amplification		~22 % SCC
SOX2 amplification		~23 %
Putative autocrine loops	GRP/GRP receptor, SCF/KIT	HGF/MET, neuregulin/ERBB
Tumor suppressor genes		
CDKN2A mutation	<1 %	~10–40 %
TP53 mutation	~75–100 %	~50 %
17p LOH	~80–90 %	~70 %
Abnormal TP53 expression (immunohistochemistry)	~40–70 %	~40–60 %
Absent RB1 expression	~90 %	~15–30 %
13q LOH	~75 %	~40–60 %
3p allele loss	>90 %	~50–80 %
9p LOH	~20–50 %	~50–75 %
Absent CDKN2A expression (immunohistochemistry)	~0–10 %	~30–70 %
Other genetic deletions, e.g., 5q, 8p, 11p, 18q	Variable	Variable
Telomerase expression	~100 %	80–85 %

various signal transduction cascades, as well as negative regulators of cell growth and proliferation.

Karyotypic and molecular analyses have demonstrated that lung cancer cells have accumulated several genetic lesions, with perhaps ten or more such events required for the development of an overt lung cancer. Knowledge of the temporal sequence and timing of these genetic lesions in the multistep process of lung carcinogenesis is increasing with improvements in techniques allowing examination of DNA from tiny preneoplastic bronchial lesions, such as with laser capture microdissection. Nonetheless, there appears considerable inter-individual heterogeneity in the timing and number of genetic lesions that occur during lung carcinogenesis; with various alternate pathways leading to bronchogenic carcinoma. While some of the molecular events are commonly found in both SCLC and NSCLC, others show greater specificity for one or other of the subtypes (Table 28.1). These events can largely be categorized into the original and emerging hallmarks of cancer: self-sufficiency in growth signals, insensitivity to antigrowth signals, evasion of apoptosis (programmed cell death), limitless replicative potential, sustained angiogenesis, tissue invasion and metastasis, reprogramming of energy metabolism, and evasion of immune destruction [5].

28.2 Molecular Changes in Overt Lung Cancers

28.2.1 Aneuploidy and Copy Number Variations

Aneuploidy, an abnormal number of chromosomes representing an abnormal total DNA content, is another common characteristic of tumor cells. In solid tumors, aneuploidy is linked to genomic instability, which includes chromosome instability (CIN). With the onset of genomic studies came reports of gene expression signatures associated with aneuploidy and cell proliferation. Many solid tumors, including lung cancers, often have marked aneuploidy, ranging from hypoploidy to hyperploidy [6, 7]. Several studies have assessed the value of aneuploidy as a marker of biological aggressiveness, but the prognostic value of aneuploidy in lung cancer is controversial [8, 9]. Newer techniques have allowed the identification of extensive areas of aneuploidy in the respiratory epithelium of lung cancer patients, a finding consistent with the field cancerization theory [10].

Early pivotal cytogenetic studies in tumors demonstrated karyotypic features of double-minute chromosomes (DMs) and novel staining regions called homogenously staining regions (HSRs), corresponding to amplified DNA sequences which may contain between twenty and several hundred copies of a specific chromosomal sequence. As the amplified sequences often involve several hundred thousand base pairs, it is possible that more than one oncogene is contained within the amplified region. Chromosomal comparative genomic hybridization (CGH) and array CGH are molecular cytogenetic techniques that can detect gains and losses of DNA in a tumor genome. CGH techniques led to the identification of several new chromosomal regions affected by either deletions or increased DNA copy number in lung cancer genomes [11–15] and include specific allelic loss at 3p, 4q, 9p, and 17p and gain at 1q, 3q, 5p, and 17q [16–20]. More recently, array CGH was developed for high-throughput, high-resolution DNA dosage analysis, where microarrays are spotted with unique genomic probes. Early array CGH microarrays consisted of large genomic clones, such as bacterial or P1 artificial chromosomes (BACs and PACs) or cosmids, robotically spotted onto glass slides, whereas later platforms used short, 25–70-mer oligonucleotides. Moreover, bioinformatic advances have also facilitated the use of single nucleotide polymorphism (SNP) arrays initially developed for genotyping to be used to detect DNA copy number variations [21]. A number of studies have reported microarray-based CGH analyses to detect genomic aberrations in lung cancers, but few in primary SCLC because of its rare resectability (Table 28.2).

Likewise, loss-of-heterozygosity (LOH) events as indicators of inactivation on one allele of TSGs were more finely mapped using these high-throughput technologies. Nonetheless, the earlier polymorphic DNA marker-based technologies of Southern Blot and repetitive sequence PCR (e.g., microsatellite) contributed greatly to the localization and identification of candidate TSGs by identifying allele loss in tumor cell lines, primary tumor cells and preneoplastic cells associated with invasive cancers.

With the advent of newer technologies such as digital PCR and massively parallel sequencing (commonly referred to as next generation sequencing or NGS), comes even more capacity to detect and identify copy number variation in lung cancer. Rapid technological advances mean that NGS can be applied to the study of formalin-fixed, paraffin-embedded (FFPE) samples with relatively small quantities of DNA starting template [22], using next-generation sequencing for high resolution multiplex analysis of copy number variation from nanogram quantities of DNA from formalin-fixed, paraffin-embedded specimens. Indeed, NGS has largely superseded older techniques for detecting tumor CNVs.

28.3 Oncogenes and Growth Stimulation

Proto-oncogenes encode proteins that are positive effectors of the transformed phenotype and may be considered positive growth regulators. The normal cellular counterparts of these proto-oncogenes are often components of normal growth signaling pathways. Activation of these proto-oncogenes usually occurs via aberration of a single allele, including by gene amplification, point mutation and constitutive overexpression, leading to a gain in function or dominant effect. These proto-oncogene products include various growth factors, receptor tyrosine kinases, non-receptor tyrosine kinases, membrane-associated G proteins, cytoplasmic serine/threonine kinases, and nuclear transcription factors.

28.3.1 ERBB Receptor Tyrosine Kinases

The epidermal growth factor receptor or ErbB family of tyrosine kinases consists of four members—ErbB1 (EGFR), ErbB2, ErbB3, and ErbB4 [72]. The family of tyrosine kinases is important for many developmental and physiological processes. ERRB receptors are activated in response to peptide binding resulting in receptor hetero- or homo dimerization [73]. The peptide growth factor ligands that interact with the ERBB family of transmembrane receptor tyrosine kinases are called neuregulins, neu differentiation factors, or heregulins [74]. The neuregulin and ERBB (ERBB2, ERBB3, and ERBB4) families may be considered to be potential growth stimulatory loops involved in the development of lung cancer [75]. On binding neuregulin, ERBB receptors homodimerize or heterodimerize,

[c]*SCLC* small cell lung carcinoma, NSCLC non-small-cell lung carcinoma, *AC* adenocarcinoma, *SCC* squamous cell carcinoma, *LCC* large cell carcinoma, *BrAC* bronchioloalveolar carcinoma, *LCNEC* large cell neuroendocrine carcinoma, *NL* normal lung, *PBMC* peripheral blood mononuclear cell

subsequently inducing intrinsic kinase activities that initiate intracellular signal transduction cascades such as the MAP kinase pathway. Although ERBB2 (also commonly known as ERBB2/neu) by itself lacks ligand binding ability, it plays a major coordinating role by enhancing and stabilizing dimerization. Each directly liganded receptor appears to dimerize preferentially with ERBB2, and resulting ERBB2-containing heterodimers have very high signaling potency. Activation of ERBB2 plays an important role in the development of many human cancers. The three major mechanisms leading to ERBB activation in cancer are gene amplification, altered ligand expression, and mutations in the receptor kinase or extracellular domain. The ERBB2 gene maps to chromosome 17q21, and its amplification and overexpression has been implicated in the development of several human cancers. Although amplification appears uncommon in lung cancer, ERBB2 is highly expressed in over a third of NSCLCs, especially in the adenocarcinoma subtype [76–78]. Experiments with transfected ERBB2 suggested that ERBB2 overexpression on its own was insufficient, but did contribute, to tumor induction in immortalized human bronchial epithelial cells [79]. Additionally, an anti-ERBB2 monoclonal antibody has been developed which can inhibit the in vitro growth of NSCLC cell lines expressing ERBB2 [80]. Some but not all studies have suggested that ERBB2 overexpression correlates with shorter survival in lung cancer [81–83]. In any case, other observations including the enhanced metastatic potential resulting from transfection of the ERBB2 gene into a NSCLC cell line in a xenograft model [84] support the idea that ERBB2 overexpression may be an adverse clinical indicator in some lung cancer patients. Transfection and overexpression of the ERBB2 gene in a constitutively low ERBB2 expressing NSCLC cell line also led to the induction of a drug resistant phenotype [85]. In vitro assays further suggest that ERBB2 overexpression may be associated with intrinsic multidrug resistance to chemotherapy agents in NSCLCs [86]. ERRB2 mutations in themselves are fairly rare in NSCLC [87, 88], with mutations being in-frame insertions situated in exon 20 (reminiscent of EGFR mutations). It is well recognized that increased copy numbers of ERBB2 in breast cancer predict response to trastuzumab [89]. Interestingly it appears that this may also be important for a group of non-small-cell lung cancer patients. ERBB2 amplification is found in 11 % of NSCLC specimens [90]. Clinical studies demonstrated that the subgroup of NSCLC patients with ERBB2 amplification achieve clinical benefit when trastuzumab is added to chemotherapy regimens [91].

28.3.2 EGFR

Another ERBB member, ERBB1 (better known as epidermal growth factor receptor, EGFR), has a role in regulating epithelial proliferation and differentiation. Epidermal growth factor (EGF) and transforming growth factor-α (TGFα) are prominent amongst the six characterized mammalian ligands that bind to the EGFR receptor. While no ligand has yet been identified for ERBB2, it is the most frequently used partner in heterodimerization with EGFR. The production of EGFR ligands, especially TGFα by lung cancer cells expressing cognate receptors, has led to suggestions that this system represents an important autocrine loop in lung cancer [75, 92,,93]. Ligand binding to EGFR results in homodimerization or heterodimerization which initiates autophosphorylation of tyrosine residues in the intracellular domain [94]. This initial phosphorylation event is thought to trigger a phosphorylation mediated signal transduction cascade through two major pathways—the Ras/Raf/MAP kinase and the PI3K-Akt pathway. Ras/Raf/MAPK activates MAPK3 and MAPK1 transcription factors resulting in increased cell

proliferation, survival, and transformation, while PI3K-Akt inactivates BCL2 family proteins and caspase 9, thus promoting survival in the face of apoptotic stimuli including radiation and DNA damage. Both pathways are implicated in development of malignancy [95]. Transgenic mice lacking EGFR have been generated. These mice develop abnormal epithelia in several organs, including the lung, in which there was impaired branching, deficient alveolization and septation [96, 97].

Activation of EGFR in lung cancer cells generally occurs by overexpression, with mutations and gene amplification being mechanistically implicated. Activation appears to be more common in NSCLC than in SCLC and may be related to tumor stage and differentiation [92, 98]. In NSCLC, amplification of EGFR is a common event resulting in overexpression in 60 % of metastatic NSCLC and is associated with an adverse prognosis [99–101]. In addition, in NSCLC there is increased expression of EGFR ligands (EGF and TGFα), which establish an autocrine loop of hyperactivation [102]. EGFR mutations of the tyrosine kinase domain are of two main types—either small in-frame deletions or missense substitutions clustered within the ATP binding pocket encoded by exons 18–21 [103–105]. Mutations occur more often in individuals with adenocarcinoma histology, East Asian origin, female gender, and never smoker status. In addition, they appear to be inversely correlated with KRAS mutations [106]. Mutations associated with tyrosine kinase inhibitor (TKI) responsiveness occur in the ATP-binding pocket of the tyrosine kinase domain of EGFR and are referred to as activating mutations [107]. In the presence of an activating mutation there is decreased affinity of this binding site for ATP and increased affinity for TKIs [108]. Interestingly, transgenic mice models have demonstrated that induction of activating EGFR mutations results in the development of adenocarcinoma like lung cancer [109]. Activating mutations are categorized into three classes: (1) class I mutations consist of deletions (in exon 19), (2) class II mutations consist of single nucleotide substitutions causing an amino acid change in exon 21, and (3) class III mutations consist of in-frame deletions or insertions (in exon 20). A 15 bp deletion involving amino acid residues leucine 747 to glutamic acid 749 (ΔLRE) in exon 19 and a point mutation substituting arginine for leucine at codon 858 (L858R) in exon 21, account for 44 and 41 % respectively of all NSCLC EGFR mutations [107, 110]. Preliminary evidence suggests that patients with the exon 19 mutation (ΔLRE) respond better to TKIs than patients with the exon 21 point mutation, L858R [111–113]. Further, there are polymorphisms associated with increased EGFR protein production (shorter CA-SSR1 length and variant forms of SNPs-216 and -191). These were found to be rare in East Asians as compared to other ethnicities, but in tumors from East Asian patients, EGFR mutations were found to favor the shorter CA-SSR1 allele, and selective amplification of the shorter allele of CA-SSR1 occurred frequently in tumors harboring a mutation [114]. Interestingly, another specific EGFR mutation, T790M, has been linked to acquired TKI resistance, and also to familial NSCLC [115–117] and was found to display a growth advantage over wild-type EGFR in a human bronchial epithelial (HBEC) cell line [118]. This immortalized HBEC model system which can be easily manipulated is likely to gain increasing prominence in the functional testing of candidate molecules [119].

Both types of activation mutations are associated with increased autophosphorylation of Tyr1068 at the C-terminal indicating increased EGF-dependent receptor activation [104]. Consistent with the association found between tumor p-Akt expression and gefitinib response, is mechanistic evidence that signaling through the antiapoptotic STAT/Akt may be an important downstream pathway of activation for mutated EGFR [120]. Parallels may be drawn with the clinical effectiveness of another TKI, imatinib mesylate, in chronic myeloid leukemia and gastrointestinal stromal tumors expressing activating c-Kit mutations, in which constitutive STAT activation is frequent. The story in lung cancer may be more complex, since several EGFR signaling pathway genes have been found to be mutated in NSCLC. EGFR and KRAS mutations are detected in ~10 % and 15–20 % of NSCLCs, respectively. Somatic mutations are much less common in ERBB2 (~2 %; exons 19 and 20) and HER4 (~2 %, exons 20, 23), the lipid kinase PIK3CA (~4 %; exon 9), and the serine/threonine kinase BRAF (~2 %; exons 11 and 15) [121]. Other rare mutations remain to be discovered for example in FGFR4 [121]. Most of these alterations have been found to be gain-of-function mutations and are not usually associated with co-mutations in the other genes apart from PIK3CA mutations.

There is evidence that some cancers may become dependent upon certain growth pathways or upon specific components of the pathway, possibly to the extent of requiring their signaling to maintain the malignant phenotype. This phenomenon has been described as a state of oncogene addiction of cancer cells. Thus, lung cancers most dependent upon signaling through EGFR and its downstream cascade may be more susceptible to drugs targeted to this pathway. Clinical responses to the EGFR TKIs, gefitinib and erlotinib, have been shown to be largely independent of expression of EGFR, but were discovered to be strongly associated with the presence of mutations in the EGFR tyrosine kinase domain [103–105] and possibly gene amplification [122–124]. Second-generation agents, such as afatinib, are also effective GFR TKIs, and have distinguishing properties such as being irreversible inhibitors.

Some experimental molecular studies provide evidence that oncogenic kinases produce both pro-survival and pro-apoptotic signals that decay at different rates upon

oncogene inactivation; pro-survival signals are rapidly attenuated, whereas pro-apoptotic signals are relatively longer-lived. This differential signal decay creates a temporal window during which pro-apoptotic outputs from the oncogenic kinase predominate to actively promote tumor cell death upon kinase inhibition, known as oncogenic shock [101, 125].

28.3.3 EML4/ALK Fusion Genes

Chromosomal rearrangements involving the tyrosine kinase anaplastic lymphoma kinase (*ALK*) occur in cancers including NSCLC. *EML4-ALK* fusion was first discovered by screening a cDNA library derived from the tumor of a Japanese male patient with adenocarcinoma of the lung [126]. The *EML4-ALK* fusion represents an inversion on the short arm of chromosome 2 (Inv(2)(p21p23)) that joins exons 1–13 of EML4 (echinoderm microtubule associated protein-like 4) to exons 20–29 of ALK [126], resulting in a chimeric protein consisting of an EML4 N-terminus and an ALK C-terminus.

Since then, multiple other variants of EML-ALK have been reported, all of which encode the same cytoplasmic portion of *ALK* but contain different truncations of EML4 as well as rarer fusions of *ALK* with other partners such as *TFG* and *KIF5B* [127]. The aberrant activation of ALK signaling is consistent with the notion of oncogene addiction as it is associated with marked sensitivity to ALK inhibitors such as crizotinib [128, 129]. Understanding the role ALK fusion genes play in lung carcinogenesis has meant a relatively rapid translation of ALK-fusion targeted treatment to the clinic for the genetically definable subset of affected patients representing a few percent of NSCLC tumors and more common in female never smokers. Like EGFR mutations, these aberrations are the so-called actionable mutations which enable the concept of precision medicine to be realized.

28.3.4 ROS1 Fusion Genes

Another gene that has recently been discovered to be rearranged in a subset of NSCLC is ROS1, an orphan receptor tyrosine kinase which is phylogenetically related to ALK [130]. Like tumors with ALK1 fusion gene drivers, tumors with ROS1 fusions also appear more common in never smokers and are also sensitive to crizotinib [131].

28.3.5 RAS Signal Transduction Pathway

The RAS gene family represents oncogenes which are important in a subset of lung cancers. RAS genes encode 21 kDa proteins, members of a large family of proteins including rho, rac, rab that regulate cytoskeletal changes, vesicular and nuclear transport, and proliferation. Mutations in the *RAS* genes are common in several cancers, including lung cancer [132]. The RAS proto-oncogene family (KRAS, HRAS, and NRAS) is usually activated by point mutations at codons 12, 13, or 61. Mutations affect 15–20 % of all NSCLC and approximately 20–30 % of lung adenocarcinomas but are very uncommon in SCLC [133]. Mutations in KRAS account for approximately 90 % of the RAS mutations in lung adenocarcinomas, and 85 % of KRAS changes involve codon 12. In unstimulated cells, RAS is inactive. Following ligand binding, receptor tyrosine kinases signal the RAS protein by interaction with downstream molecules such as GRB2 and the guanine nucleotide exchange factor, SOS. Wild-type CDKN1A-RAS protein is able to bind to guanosine triphosphate (GTP) but also has intrinsic GTPase activity which can hydrolyze bound GTP to guanosine diphosphate (GDP). Active GTP-bound RAS stimulates a downstream cascade ending with MAP kinase which migrates to the cell nucleus and subsequently activates various transcription factors. When GTP is hydrolyzed to GDP, the molecule assumes its inactive configuration and the signal transduction pathway returns to its inactive state. When a RAS gene undergoes oncogenic missense mutations, the mutant CDKN1A-RAS oncoprotein loses its capability to hydrolyze GTP and the molecule can no longer switch back to its inactive configuration. The resultant inappropriate growth signal to the cell nucleus is thought to contribute to unrestrained cellular proliferation; effectively causing a gain of function. This model underscores the general concept that proto-oncogenes encode proteins with important regulatory functions and that oncogenic activation results in mutant proteins with altered function.

The majority (70 %) of KRAS codon 12 mutations are G-T transversions, with either cysteine (TGT) or valine (GTT) replacing the wild-type glycine (GGT). This type of mutation also affects the TP53 gene in lung cancer cells, and represents the type of DNA damage expected from bulky DNA adducts caused by the polycyclic hydrocarbons and nitrosamines in tobacco smoke [134]. The correlation of KRAS mutations with a smoking history further implicates a causative role of tobacco smoke carcinogens in the acquisition of these mutations [135]. KRAS mutations are associated with distinct clinical characteristics in patients with NSCLC. They occur more frequently in lung adenocarcinomas from former or current smokers [136]. Furthermore in early stage lung cancer, the presence of RAS mutations is predictive of early relapse [137]. The relationship of KRAS mutations to a poor prognosis in both early and late stage NSCLC is debated and may be technique related [138–146]. Although it has also been suggested that RAS mutations induce resistance to chemotherapy and radiation, no association between RAS mutation and in vitro resistance against a

range of chemotherapeutic agents was found in a panel of NSCLC cell lines [147]. In lung adenocarcinomas the presence of KRAS mutations predict resistance to anti-EGFR therapies (gefitinib and erlotinib) [148]. Consequently in many centers routine testing for KRAS mutations in lung adenocarcinomas is performed to predict response to anti-EGFR therapy [149]. The reason for the predilection of RAS mutations for the adenocarcinoma histological subtype of lung cancers is unclear. One possible explanation is that the activation of certain oncogenes may result in disparate tumor differentiation pathways. To study this, various oncogenes have been introduced into a non-tumorigenic cell line BEAS-2B, derived from normal bronchial epithelial cells transfected with SV40. Overexpression of c-myc and c-raf-1 for instance resulted in the development of large tumor cells with certain neuroendocrine markers [150]. Indeed, the subtype specificity may be even more intriguing as a study has reported that KRAS mutations were seen in parenchymal, but not in bronchial adenocarcinomas, indicating genetic heterogeneity [151]. Furthermore, the goblet-cell subtype appears to have the highest frequency of KRAS mutations compared with other adenocarcinoma subtypes [152]. Some investigators have also suggested that rare alleles of the HRAS minisatellite locus represent a major risk factor for common types of cancer, including lung cancers, but this possibility has not been firmly established [153]. Considerable attention has been directed towards the development of RAS inhibitors, however to date none has achieved clinical utility [149]. Consequently, novel approaches to block posttranslational activation of RAS have been pursued, such as farnesyl transferase inhibitors and other inhibitors of downstream RAS effectors [149].

Another proto-oncogene, BRAF, which encodes a direct downstream effector of RAS may also be relevant to lung carcinogenesis. BRAF somatic missense mutations are common in malignant melanomas and are occasionally found in a range of human cancers. In lung cancer perhaps 3 % of NSCLC may have mutated BRAF1 [154–156]. Most melanoma BRAF mutations involve codon 599, but NSCLC BRAF mutations are different, most being non-V599. This may result in therapeutic differences between lung cancer and melanoma in response to RAF inhibitors, which are now subject to clinical trial.

The other signal transduction molecules downstream of RAF in this pathway include MEK (MAP kinase/ERK-activating kinase), and ERK (extracellular signal-regulated kinase) as well as their regulatory phosphatases (such as PP2A). Although constitutively active mutants of MEK were shown to be capable of transforming cells suggesting that MEK can function as a dominant oncogene, studies have shown that the MAP2K1 and MAP2K2 genes are only rarely mutated in lung cancer [157]. On the other hand, the mitogen-activated protein kinase kinase 4 (MKK4) gene, located approximately 10 cM centromeric of TP53 on 17p, has been found to be homozygously deleted in a NSCLC cell line, leading to speculation that it may be a candidate tumor suppressor [158].

28.3.6 FGFR1

Overall, unlike adenocarcinomas which have a number of actionable mutations (EGFR mutations, ALK and ROS1 fusions), these potential targets appear less common in the other major NSCLC subtype, SCC. Recently, focal fibroblast growth factor receptor 1 (FGFR1) amplification was discovered in squamous cell lung cancer ($n = 155$), and appears to be a relatively frequent finding (up to 22 % in an independent cohort) [159].

28.3.7 MYC

Stimulation of the RAS signal transduction cascade ultimately activates nuclear proto-oncogene products, including MYC which belongs to the basic helix–loop–helix leucine zipper (bHLH-LZ) class of transcription factors. MYC has been implicated in normal cell growth and proliferation through interaction with genes involved in DNA synthesis, RNA metabolism, and cell-cycle progression [160]. MYC proto-oncogenes are the cellular homologs of a gene present in several highly oncogenic avian retroviruses. Of the well-characterized myc genes, MYC is the most frequently activated in SCLC and NSCLC. On the other hand, its closely related cellular homologues, MYCN and MYCL1, are usually only activated in the SCLC subtype. In fact, MYCL1 was initially isolated from the DNA of a SCLC [161]. Activation of the myc genes has been observed by gene amplification or transcriptional dysregulation, leading to protein overexpression [162]. These genes may be amplified to 20–115 copies per cell, and in most cases, only one member of the MYC family is amplified. Gene amplification is generally associated with enhanced mRNA expression and increased protein production. A review of 17 different studies calculated that 36 of 200 (18 %) SCLC tumors and 38 of 122 (31 %) SCLC cell lines had gene amplification of one member of the MYC family [133]. In comparison, 25 of 320 (8 %) NSCLC tumors and 3 of 15 (20 %) NSCLC cell lines had MYC amplification. Thus, MYC family activation in general appears to be more frequent in SCLC than NSCLC. MYC amplification appeared to occur more frequently in cell lines which are often derived from metastatic lesions than in primary tumors, in patients previously treated with chemotherapy, and in the variant subtype SCLC [163]. These observations may help explain why MYC amplification has been reported to correlate with adverse survival.

Rather than the translocation and point mutations seen in lymphomas, there have been reports of MYCL1 amplification with rearrangement in which MYCL1 fuses to the RLF gene, thereby resulting in a chimeric protein [164, 165]. In some cases, MYCL1 expression may be associated with neuroendocrine differentiation. For instance, all-trans-retinoic acid mediated growth inhibition in a SCLC cell line was associated with increased neuroendocrine differentiation and MYCL1 expression but decreased MYC expression [166].

28.3.8 Other Nuclear Proto-oncogenes

MYB, JUN, and FOS have also been implicated in lung cancer although their precise functional importance and biological role is still being investigated. JUN and FOS are heterodimeric proteins that function as immediate early transcription factors regulating cellular proliferation. There is conflicting data in lung cancer regarding their role in lung carcinogenesis. Some investigators have described higher expression of these genes in normal lung tissue adjacent to tumor than in the tumor itself. Conversely, other studies have reported higher expression in tumors with lack of expression in normal epithelium [167–170].

28.3.9 Oncogenes and Growth Stimulatory Loops

The hepatocyte growth factor/scatter factor (HGF/SF) stimulates epithelial cells to proliferate, move and also carry out complex differentiation programs, such as morphogenesis and angiogenesis. HGF appears be a potent mitogen for normal and neoplastic bronchial epithelium [171]. During lung development, HGF levels increase during postnatal lung maturation and its receptors are expressed on bronchial and alveolar type II cells. HGF is involved in embryonal lung budding and branching, and stimulates mitogenesis and/or motogenesis of human bronchial epithelial, and alveolar type II, and SCLC cells in vitro. HGF is expressed at very low levels in normal lung but these levels increase in response to local lung or distant injury [172]. The MET proto-oncogene which encodes the HGF receptor was generally expressed in normal lung, as well as in SCLC and NSCLC. On the other hand, HGF was expressed in many NSCLCs but not in SCLCs, thereby indicative of an autocrine loop in the former [173–175]. A study of resected lung cancer tissue showed MET expression in 34 of 47 adenocarcinomas and 20 of 52 squamous carcinomas by western blotting and immunohistochemistry [176]. This study also suggested a poorer prognosis for tumors expressing the receptor especially for adenocarcinomas. Western blotting of proteins extracted from 56 NSCLCs (predominantly adenocarcinomas) using a polyclonal anti-HGF showed that high levels of immunoreactive HGF were associated with poorer survival for stage I tumors [177]. Recently, a gefitinib-sensitive lung cancer cell line that developed resistance to gefitinib as a result of focal amplification of the MET proto-oncogene was reported, also MET amplification was detected in 4 of 18 (22 %) lung cancer specimens that had developed resistance to gefitinib or erlotinib [178]. This suggests that MET amplification causes gefitinib resistance by driving ERBB3 (HER3)–dependent activation of PI3K, a pathway thought to be specific to EGFR/ERBB family receptors.

Another autocrine growth loop may involve the insulin-like growth factors, IGF-I and IGF-2, and the type I IGF receptor, IGF-R, which are frequently co-expressed in both SCLC and NSCLC [179]. Of the insulin-like growth factor family, it appears that IGF-2 may be the predominant member involved with the autocrine growth stimulation of lung cancer. The KIT proto-oncogene which encodes a tyrosine kinase receptor and its ligand, stem cell factor (SCF), are co-expressed in many SCLCs, and may thus represent another autocrine loop for lung cancers [180, 181]. In SCLC, activation of this putative SCF/KIT autocrine loop could conceivably provide a growth advantage or mediate chemoattraction. Unlike gastrointestinal stromal tumors, mutations in KIT are rare, although KIT expression can be demonstrated in SCLCs [182–184]. Platelet-derived growth factor (PDGFB), which is the proto-oncogene counterpart of v-sis, and its receptor (PDGFBR) were also found to be co-expressed in lung cancer, generating another potential autocrine loop [185].

In essence, many proto-oncogenes encode growth factors, regulatory peptides or their receptors and are expressed by lung cancer cells or adjacent normal cells, thus providing a number of autocrine or paracrine growth stimulatory loops [186]. Other autocrine systems not obviously involving established proto-oncogenes also exist. In fact, the autocrine loop comprising gastrin-releasing peptide, other bombesin-like peptides (GRP/BN) and their receptors is arguably the best characterized growth stimulatory loop in lung cancer. GRP/BN has been associated with many physiologic effects including regulation of secretion, growth, and neuromodulation. There are three human GRP/BN receptor subtypes which belong to the G-protein coupled receptor superfamily with seven predicted transmembrane domains [187]. The cellular responses of SCLC to GRP/BN stimulation have been extensively studied [188]. Preliminary data also suggests that GRP/BN may regulate the MAP kinase Cascade, at least in certain tumor cells [189]. IHC studies showed that approximately 20–60 % of SCLC cancers expressed GRP, while NSCLCs expressed GRP less frequently [133]. In comparison, expression of the three GRP/BN receptors is widespread in both SCLC and NSCLC cell lines, with most cell lines expressing at least one of the three receptors and many cell lines expressing more than one receptor [187].

28.3.10 BCL2 Proto-oncogene and Apoptosis

Tumor cells can acquire the ability to escape apoptotic pathway by which normal cells would usually undergo programmed cell death (apoptosis) in response to appropriate conditions such as DNA damage. A large and growing number of apoptosis regulatory gene products are classifiable into cell death agonists (Bax, Bak, Bcl-XS, Bad, Bid, Bik, Hrk) or antagonists (BCL2, Bcl-XL, Bcl-w, Bfl-1, Brag-1, Mcl-1 and A1) [190]. Two key members of the apoptotic pathway are the BCL2 proto-oncogene product and the TP53 tumor suppressor gene product. BCL2 antagonizes the induction of programmed cell death by TP53. By protecting cells from the apoptotic process, BCL2 probably plays a role in determining the chemotherapy response through repression of apoptosis in cancer cells. A BCL2-transfected human SCLC cell line showed higher resistance to some anticancer agents by inhibiting apoptosis [191], and SCLC cells transfected with antisense oligodeoxynucleotides to BCL2 mRNA showed reduced cell viability with decreased BCL2 levels facilitating apoptosis [192]. BCL2 expression may correlate with neuroendocrine differentiation [193]. BCL2 expression is also relatively higher in squamous cell carcinoma (25–35 %) than in adenocarcinoma (~10 %) [193–196]. An inverse relationship between immunohistochemical BCL2 expression and abnormal TP53 expression in resected NSCLCs has been reported [197, 198]. These results suggest the hypothesis that either TP53 mutation or upregulation of BCL2 expression is sufficient to modify the apoptotic pathway in NSCLC, and that BCL2 positive tumors may show less aggressive behavior [197]. In contrast, SCLCs usually have both TP53 mutations and BCL2 overexpression. Previous IHC studies of BCL2 in lung cancer have shown highest expression in small cell cancers. For instance BCL2 protein is immunohistochemically expressed in most SCLCs (75–95 %) [193, 199, 200]. This observation initially seems inconsistent with the finding that SCLCs are often much more sensitive than NSCLCs to chemotherapy; a situation in which tumor death usually occurs by apoptosis. In addition, there was a paradoxical trend, albeit nonstatistically significant, towards longer survival in patients whose SCLC tumors express BCL2 [200]. Likewise, a better survival of BCL2 positive lung cancer cases was observed in NSCLC [194–197]. Thus the role of BCL2 in lung cancer is complex and likely to further unfold. Notably, the suggestion that BCL2 may be converted to BAX-like death effectors by the caspase family of cysteine proteases may be relevant [201]. Alternatively, increased BCL2 immunoreactivity may possibly indicate reduced rather than enhanced function, similar to the situation of overexpression of nonfunctional mutated TP53. A BCL2 related protein called BAX promotes apoptosis and may act as a tumor suppressor [202]. Furthermore, BAX may be a downstream transcription target of the TP53 pathway. BAX complexes with BCL2 to form homodimers or heterodimers, and it has been suggested that the BCL2–BAX ratio determines cellular apoptotic susceptibility. For instance, the immunohistochemical staining of BAX and BCL2 were inversely related in 121 neuroendocrine (NE) lung cancers. Most carcinoids showed low BCL2 and high BAX expression in contrast to the inverse situation in most SCLCs and large cell NE cancers [203]. This would potentially lead to a higher degree of apoptosis in carcinoids compared to SCLCs, correlating with clinical behavior where carcinoids are markedly less metastatic than SCLC.

28.4 Tumor Suppressor Genes and Growth Inhibition

28.4.1 Genetic Loss in Lung Cancer

Apart from aneuploidy, lung cancer cells are also characterized by many other structural cytogenetic abnormalities including deletions and nonreciprocal translocations. Frequent deletions of chromosome region 3p14-23 was one of the initial cytogenetic observations made in SCLC, this finding was later found to be also applicable to NSCLC [204]. Subsequently, many specific deletions at a range of chromosomal regions have been revealed by cytogenetics, molecular allelotyping, and chromosomal and array CGH, data which suggests the presence of underlying tumor suppressor genes in lung cancers.

TSG (e.g., TP53, RB1) products are negative growth regulators. It is their loss of function, classically by loss of one allele and point mutation of the other allele, which contributes to malignant transformation. The requirement for the mutations to affect both alleles of the tumor suppressor gene represents the two-hit hypothesis initially proposed by Knudson for retinoblastomas. Using allelotyping, chromosomal regions 1p, 1q, 3p (several sites), 5q (APC/MCC cluster), 8p, 9p21 (CDKN2A), 11p13, 11p15, 13q14 (RB1), 17p13 (TP53), and 22q as well as several other sites have been found to be frequently involved in lung cancer cells or cell lines derived from lung cancer tissues [205]. This leads to the notion that if most of these sites encode tumor suppressor genes, then individual tumors must have acquired inactivation of multiple genes to become clinically evident. Some of these are common to both SCLC and NSCLC, and some are more frequent in a given histologic type. The best characterized of these deletions appear to target genes which are now accepted as classical tumor suppressor genes such as TP53, RB1, and CDKN2A. On the other hand, there is also mounting evidence that there may be other closely situated genes that are also affected by the chromosomal deletions, particularly as some of these deletions may be quite large and even involve the whole chromosomal arm or chromosome.

28.4.2 TP53

Mutations in the TP53 gene are the most common genetic alteration found in human cancers. The TP53 gene encodes a protein that functions as a transcription factor, particularly in response to DNA damage by γ or ultraviolet irradiation and carcinogens [206]. It has been called the guardian of the genome and the guardian of the G1 checkpoint. TP53 is believed to play a major role in maintaining the integrity of the genome since loss of TP53 function allows inappropriate survival of genetically damaged cells, leading to the evolution of a cancer cell. DNA damage is a major upstream event in TP53 activation and results in a rapid increase in the level of TP53 protein, and activation of TP53 as a sequence specific transcription factor regulating expression of downstream genes. The net effect is either a stop to cell cycle progression to permit repair, or apoptosis if the damage is too great. TP53 can itself detect and bind sites of primary DNA damage, using its C-terminal domain. Hypoxia is also able to stimulate TP53 levels and lead to apoptotic cell death [207]. Oxygen delivery and blood supply becomes rate-limiting when a tumor reaches a critical size and tumor. Hypoxia may thus act as a physiological selective agent against apoptosis-competent cells in tumors. On the other hand, such selection may allow for the expansion of clones with acquired defects in their apoptotic program genes. The genes downstream of TP53 include CDKN1A (also called WAF1/CIP1), MDM2, GADD45A (growth arrest and DNA damage-inducible), BAX, IGF-BP2, and cyclin G, which participate in controlling cell cycle arrest at the G1/S phase transition and apoptosis. A link between mutant TP53 and aneuploidy has been revealed by studies implicating TP53 as an active component of a mitotic spindle checkpoint and as a regulator of centrosome function. Thus, TP53 appears to participate in the DNA damage checkpoints of the cell cycle at both the G1/S transition and at the G2/M boundary.

The TP53 gene plays a critical role in lung cancer as well as in many other types of cancers, and genomic interrogation indicates consistent features across tumor types [208]. Many somatic TP53 mutations in human tumors and cell lines have been published, and compiled into large databases. In both SCLC and NSCLC, one copy of the chromosomal region 17p13 which contains TP53 is frequently deleted; one hit. Structural abnormalities in TP53 and also p16 occur commonly in lung cancer, as shown by structural aberrations on FISH analysis (especially breaks and loss) [209]. Mutational inactivation of the remaining allele, the second hit, occurs in 75–100 % of SCLCs and ~50 % of NSCLCs [134], leading to loss of TP53 function. Although found throughout the entire coding region, TP53 mutations in lung cancer are most common in the evolutionarily conserved exons 5–8. The types of TP53 mutations include missense and nonsense mutations, splicing abnormalities, as well as larger deletions. Evidence supporting a causative role for tobacco smoke in inducing TP53 mutations comes from observing that TP53 mutations in lung tumors correlate with cigarette smoking, and that the most common TP53 mutations in lung cancer are the G-T transversions expected from tobacco smoke carcinogens [134]. Additional evidence for a pulmonary oncogenic role for TP53 dysfunction comes from the finding that transgenic mutant TP53 mice develop lung cancers in addition to bone and lymphoid tumors [210]. Furthermore, reintroducing a wild-type TP53 gene into lung cancer cells dramatically blocked tumor cell growth due to apoptosis (not G1 arrest) despite concurrent abnormalities of several other tumor suppressor genes and oncogenes [211, 212].

Many TP53 mutations are missense mutations which prolong the half-life of the TP53 protein to several hours, leading to increased protein levels which can be detected by immunohistochemistry as a surrogate for molecular analysis [213]. IHC studies have shown abnormal TP53 expression in 40–70 % of SCLCs and 40–60 % of NSCLCs [203, 214–217]. Most studies have shown that the frequency of TP53 overexpression is higher in squamous cell carcinomas than in adenocarcinomas. The predictive value of TP53 mutations for survival, whether assayed by immunohistochemistry or by molecular analysis, is controversial. A summary of 14 studies of the prognostic importance of TP53 mutations or overexpression in NSCLC (mutational analysis (4 studies); immunostaining (8 studies) and both techniques (2 studies) yielded controversial results [218]. TP53 mutations predicted shortened survival in half of the four reported mutational analyses, whereas the other two found no such difference. Of the 10 IHC studies, aberrant TP53 expression was associated with a shortened survival in five studies, an improved survival in three studies, and no survival effect in two studies. In one study that simultaneously analyzed both mutations and protein expression, TP53 overexpression but not gene mutation predicted shortened survival. Perhaps the various TP53 mutants or types of wild-type TP53 overexpression have different effects on lung cancer behavior. Alternatively, wild-type TP53 expression may be immunohistochemically detectable in certain tumors. Finally, different antibodies which may not be strictly comparable for detecting aberrant TP53 expression have often been used.

In certain cancers, such as that of the uterine cervix, TP53 can be alternatively inactivated through binding of the oncogenic E6 protein of human papilloma virus (HPV) to the TP53 protein; a process which inactivates its tumor suppressor activity by promoting TP53 degradation. The epitheliotropic HPV may also be involved in some respiratory tract lesions, for example, HPV subtypes 6 and 11 have been associated with most cases of tracheal and bronchial papillomatosis. While there are reports of neoplastic transformation of these benign papilloma, it has also been suggested that HPV may also play a part in the development of de novo

bronchogenic carcinomas [219–221]. Morphological studies have shown occasional presence of HPV-suggestive lesions in primary squamous cell carcinomas, and DNA hybridization studies to detect HPV DNA in lung cancers show conflicting results, ranging from 0 to 40 % [222–224]. Most PCR studies looking for HPV sequences suggest that any potential involvement of HPV in primary lung cancer is likely to be limited [225–228] although some investigators have found more frequent involvement using in-situ hybridization and PCR [229].

CDKN1A, also known as WAF1 (wild-type TP53-activated fragment 1), CIP1, or p21, is a TP53-responsive gene, which inhibits cyclin/cyclin dependent kinase complexes in the G1 phase of the cell cycle as well as proliferating cell nuclear antigen (PCNA). Although not somatically mutated in lung cancer [230], CDKN1A RNA and protein overexpression was seen in ~65 % of NSCLC cases, especially in well differentiated tumors. This high frequency suggests that CDKN1A can be expressed independently of TP53 gene/protein alterations which are so frequent in lung cancers [231]. A case control study has suggested that a C to A codon 31 polymorphism (ser->arg) in CDKN1A is associated with the development of lung cancer [232].

MDM2 is an oncoprotein that can inhibit both TP53 and RB1. By binding its transcriptional activation domain, MDM blocks the ability of TP53 to regulate target genes. It also causes rapid reduction of TP53 levels through enhanced proteasome-dependent degradation. Conversely, TP53 activates the expression of the MDM2 gene in an autoregulatory feedback loop. However, phosphorylation of TP53 by DNA-dependent protein kinase (DNA-PK) after DNA damage leads to reduced interaction of TP53 with MDM2, most likely due to a TP53 conformational change [233]. In some human sarcomas and brain tumors, the chromosome 12q MDM2 gene is amplified and its protein overexpressed. In lung cancer MDM2 gene amplification was only detected in 2 of 30 NSCLCs. Nonetheless, these investigators also found MDM2 protein expression in 48 of 201 NSCLCs by immunohistochemistry and suggested that MDM2 expression without abnormal TP53 expression was a favorable prognostic factor [234]. Sp1 can further activate MDM2 and repress TP53, and this is associated with overexpression of DNA 5′-cytosine-methyltransferase1 (DNMT1), which can epigenetically dysregulate tumor suppressor genes [235].

A gene encoding TP73, a protein that shares considerable homology with TP53 was mapped to 1p36 [236]. This is of interest as 1p36 is also a site of frequent allelic deletion in lung and other cancer cells [205]. Although TP73 mutations were not detected in neuroblastomas despite frequent LOH, TP73 can activate the transcription of TP53-responsive genes and inhibit cell growth in a TP53-like manner by inducing apoptosis [237].

28.4.3 The RB1/Cyclin D1/CDK4/CDKN2A Pathway

28.4.3.1 The Retinoblastoma (RB1) Gene

The retinoblastoma (RB1) gene located in chromosomal region 13q14 encodes a nuclear phosphoprotein that was initially identified as a tumor suppressor gene in retinoblastomas. The RB1/cyclin D1/CDK4/CDKN2A pathway is central to the regulation of the G1 to S phase transition of the cell cycle. Hypophosphorylated RB1 binds and controls other cellular proteins including the transcription factor E2F which is essential for the G1/S phase transition when bound to E2F sites in cooperation with the DP family of transcription factors. Transcriptional activation is mediated by free E2F whereas hypophosphorylated RB1 antagonizes heterodimers formed by E2F and DP, thereby resulting in inhibition of S phase entry. Cyclin D1/cyclin dependent kinase 4 (CDK4) and other cyclin/CDK complexes phosphorylate RB1 with subsequent loss of its binding pocket activity that is needed to sequester the transcription factors, thereby releasing E2F and allowing entry into S phase. It is becoming more apparent that one of the four genes responsible for RB1/cyclin D1/CDK4/CDKN2A pathway is mutated or functionally altered in many cancers including lung cancers. It has also been shown that the RAS signaling pathway may functionally link to cell cycle regulation by RB1 [238]. Furthermore, RB1 also appears to have other functions; it can for instance repress transcription of all three nuclear RNA polymerases classes (Pol I, Pol II, and Pol III) [239]. RB1 also appears to inhibit apoptosis and may be actively involved in induction of differentiation. In terms of interacting partners for RB1, overexpression of E2F1 or E2F1/TFDP1 cooperates with activated ras in fibroblast transformation assays, and these transformed cells can form tumors in nude mice. Studies of E2F1 deficient transgenic mice have however suggested that E2F1 may also have a tumor-suppression function since mice lacking E2F1 developed a broad spectrum of tumors including highly invasive lung adenocarcinomas [240]. Nonetheless, studies of E2F1 in lung cancer cells have not yet been reported.

RB1 mutations together with loss of the wild-type allele have been consistently demonstrated in lung cancers [241, 242]. The RB1 protein is abnormal in over 90 % of SCLCs and 15–30 % of NSCLCs [243–245]. RB1 mutations in lung cancers include truncation by deletions, nonsense mutations, or splicing abnormalities. There are only a few studies of RB1 point mutations in lung cancer at least partly due to its 200 kb genomic size and 27 exon structure. However, from these limited studies, most mutations result in RB1 truncation [246], although a rare missense mutation in the RB1 pocket domain has been shown to cause defective RB1 phosphorylation and binding to oncoproteins [247]. The

sensitivity for detecting RB1 abnormalities in SCLCs varies by detection method: ~20 % by Southern blot analysis detecting band loss; ~60 % by Northern blot analysis detecting absent or abnormal RNA; and ~90 % by protein or immunohistochemical (IHC) analysis. Thus RB1 abnormalities are very frequent in SCLC, particularly in comparison to NSCLC. In NSCLC, a large study showed RB1 abnormalities in 2/219 (0.9 %) by Southern analysis, 22/219 (10 %) by Northern analysis, and 53/163 (32 %) by IHC [243]. The absence of RB1 expression was associated with poor prognosis in NSCLCs, particularly stage I and II disease, in some but not all studies [245, 248–250]. On the other hand, the observation of frequent LOH on chromosome 13q but relatively less frequent RB1 inactivation in NSCLCs, have prompted the notion that the allele loss on 13q targets other tumor suppressor genes on this chromosome apart from RB1 [251].

The relatives of retinoblastoma patients who are also germ line carriers of an RB1 mutation, are about 15 times more likely to die from lung cancer than the general population [252]. Furthermore, it has been shown that reintroduction of a wild-type RB1 gene led to growth suppression of SCLC cells [253]. There are two other members of the RB1 gene family, p107 and pRB2/p130, which are structurally and functionally related genes. They have also been implicated in lung cancer to a limited extent [254]. One SCLC cell line was shown to have a point mutation of p130 in a splice acceptor site leading to loss of exon 2 and production of a truncated p130 protein [255].

28.4.3.2 Cyclin D1 and CDK4

The relatively infrequent involvement of RB1 in NSCLC compared to SCLC suggested that alternative members of this growth suppressive pathway might be affected. As cyclin D1 inhibits the activity of RB1 by stimulating its phosphorylation by CDK4, cyclin D1 overexpression was an attractive candidate for disrupting the RB1 growth control pathway. In keeping with this, cyclin D1 was found to be overexpressed in some NSCLCs with normal RB1 protein expression [256, 257]. Cyclin D1 is encoded by the CCND1 (also known as PRAD1 or BCL1) proto-oncogene which is situated on chromosome 11q13. Compared with an immortalized bronchoepithelial cell line, cyclin D1 was overexpressed by several to 100-fold in 11/12 NSCLC cell lines [256]. Amplification of cyclin D1 was detected in 15 % and overexpression in 47 % of 53 primary NSCLC tumors [257]. Cyclin D1 immunohistochemical overexpression has been reported to correlate with Ki67 labeling and with patient survival [258, 259]. Abnormal immunostaining of CCND1 and RB1 has also been frequently seen in epithelial cells from the resection margin of lung cancers, raising speculation that these changes may be relatively early events in lung carcinogenesis [260]. Although gene amplification of CDK4 has been reported in 10–15 % of malignant gliomas and certain other malignancies, its role in lung cancer has not yet been reported. Interestingly, the chromosome 12q13-15 region which harbors the CDK4 gene also contains the MDM2 locus. While CDK4 and MDM2 often show co-amplification in sarcomas and glioblastomas, some tumors show only CDK4 amplification but not MDM2 amplification, and vice versa, indicating that each gene is an independent amplification target [261].

28.4.3.3 CDKN2A and Other CDK Inhibitor Genes

The CDKN2A protein functions as a cell cycle modulator which appears to regulate RB1 function by inhibiting CDK4:cyclin D1 kinase activity, and represents another important genetic target for disrupting the RB1/cyclin D1/CDK4/CDKN2A pathway. The CDKN2A (or MTS1) tumor suppressor gene is situated at chromosome 9CDKN1A. The short arm of chromosome 9, including 9CDKN1A frequently undergoes allele loss and mutation in a variety of human cancers including lung cancer [262–265]. A summary of a wide variety of cancers identified several mutational hot spots (point and other mutations including deletions, insertions and splice mutations), including some at conserved residues within the ankyrin domains of CDKN2A [266].

CDKN2A abnormalities have been extensively reported in lung cancer and are found frequently in NSCLC but rarely in SCLC. Homozygous deletion or point mutations have been observed in 10–40 % of NSCLCs [267–275]. Absent expression of CDKN2A was detected by Northern blot, Western blot or IHC analyses in 30–70 % of NSCLC. Epigenetic hypermethylation of 5′ CpG islands cause the functional downregulation of CDKN2A in lung cancers carrying no genetic mutations of CDKN2A [276, 277]. The multiple mechanisms of CDKN2A inactivation may account for the relatively low rates of inactivating deletions and point mutations seen in the earlier genetic studies [278]. Since higher frequencies of deletions or mutations have been observed in cultured cell lines and metastatic sites compared to primary lesions, it has been suggested that CDKN2A mutations may be associated with tumor progression and more advanced lung cancer [279]. While an IHC study of primary NSCLCs demonstrated an association of CDKN2A -negativity with more advanced with clinical stage [250], this finding was not confirmed in another study [280]. Nevertheless, both studies showed that about 30–40 % of early stage primary NSCLCs had absent CDKN2A expression. Finally, there is conflicting data as to whether the absence of CDKN2A expression is a predictor of adverse survival in NSCLC [250, 281]. CDKN2A abnormalities are perhaps the most common mechanism for inactivating the RB1/cyclin D1/CDK4/CDKN2A cell cycle control pathway in NSCLC. Conversely, direct RB1 inactivation appears to be the preferred mechanism in SCLC. Consequently, lung cancers are in general character-

ized by either RB1 inactivation (~90 % of SCLC and 15–30 % of NSCLC) or CDKN2A inactivation (30–70 % of NSCLC); either scenario leading to loss of this growth inhibitory pathway. The apparently mutually exclusive inactivation of either RB1 or CDKN2A has been well documented in NSCLC case series [250, 280, 282–286]. Furthermore, the simultaneous inactivation of both RB1 and CDKN2A is uncommon, but cyclin D1 overexpression can coexist with each of these abnormalities [278]. It is also noteworthy that a significant proportion of NSCLCs (10–30 %) appear to be normal for both RB1 and CDKN2A, thereby implicating cyclin D1 and CDK4 alterations.

The CDKN2A locus also encodes a second protein product which originates from an unrelated exon of CDKN2A (exon 1b) spliced onto exon 2 in an alternate reading frame (human p16b, murine p19ARF) [287]. Thus, exon 2 which is often deleted or mutated in NSCLC, is common to both CDKN2A and p19ARF. Intriguingly, mice lacking p19ARF but expressing functional CDKN2A were prone to tumor development, possibly through the TP53 pathway as TP53-negative cell lines were resistant to p19ARF-induced growth arrest [288]. Thus the extent of p19ARF damage through deletions and mutations to the CDKN2A locus, and its possible contribution to human lung carcinogenesis requires further investigation.

There are a number of other CDK inhibitor genes including CDKN2B, CDKN2C, CDKN2D, CDKN1A, CDKN1B, and CDKN1C. However, apart from CDKN2B, mutational analyses of these genes have not detected significant genetic changes in lung cancer. CDKN2B (also called CDKN2B or MTS2) shares ~70 % amino acid similarity and is situated immediately centromeric to CDKN2A. It also functions to restrain cell growth, probably by acting as an effector of TGFβ-mediated cell cycle arrest [289]. Co-deletion of CDKN2B and CDKN2A frequently occurs in NSCLC but point mutations targeting CDKN2B itself appear to be uncommon. The CDKN2C and CDKN2D genes have not been shown to be mutated in lung cancer [290]. Similarly, CDKN1B has not been found to be mutated in lung cancers [291], but low levels of CDKN1B protein were associated with a poor outcome in NSCLC patients [292]. The CDKN1C CDK inhibitor which maps to 11p15, is usually imprinted with expression of the maternal allele only. Thus, CDKN1C expression can be downregulated by selective loss of the maternal alleles, and this was found to occur in 11/13 lung cancer cases with LOH of 11p15 [293]. As point mutations have not been described in lung cancer, one could speculate that loss of a single allele may nonetheless represent the second hit needed to inactivate the imprinted CDKN1C gene.

28.4.3.4 Candidate 3p Tumor Suppressor Genes

It has long been known that chromosome 3p deletions occur commonly in cancers, notably lung and renal cancers. The very frequent deletion of one copy of the short arm of chromosome 3 in both SCLC (>90 %) and NSCLC (>80 %) has provided a strong basis for the hypothesis that one or more lung cancer tumor suppressor genes exist on this chromosomal arm. The karyotypes of most SCLC and many NSCLC have a del(3p) in addition to other often complex changes. These cytogenetic 3p deletions were subsequently confirmed by allelotyping which showed allelic loss not only in invasive cancers, but also in preneoplastic respiratory epithelial lesions associated with NSCLC [204, 294, 295]. The three distinct 3p regions have been identified by allelotyping are 3p25-26, 3CDKN1A.3-22, and 3p14-cen, consistent with the notion that there are probably three (or more) different tumor suppressor genes located on 3p [296]. In addition, as loss of both alleles resulting in homozygous deletions are thought to be strong markers for the locations of tumor suppressor genes, it is notable that five separate homozygously deleted regions have also been found in several lung cancer cell lines. There is one in the 3p14.2 region (FHIT gene location), one at 3p12-13 (U2020 cell line deletion) [297, 298], and three at the 3CDKN1A region.

The FHIT gene comprising 10 exons encoding a 1.1-kb transcript, maps to 3p14.2 and encompasses approximately 1 Mb of genomic DNA which includes the human common fragile site (FRA3B) and the t(3:8) translocation breakpoint of familial renal cell carcinoma. FRA3B is the most frequent of the common fragile sites which are chromosomal sites prone to breakages under stress, such as aphidicolin treatment. FHIT is a candidate tumor suppressor gene for lung cancers on the basis of frequent loss of heterozygosity in lung cancer and homozygous deletion in several lung cancer cell lines; the latter particularly affecting NSCLC [299–301]. Although reverse transcriptase PCR showed that 40–80 % of lung cancers demonstrated aberrant FHIT transcripts, these were nearly always also accompanied by wild-type FHIT transcripts [299–301]. As in other cancers, point mutations of FHIT appear to be rare in lung [299, 300], and there were initial concerns that the deletions noted merely represented the susceptibility of the FRA3B fragile site to breakages. Nevertheless, although FHIT abnormalities differ from the mutations and loss of wild-type transcript expression expected of classic tumor suppressor genes, absence of FHIT protein in primary lung tumors and cell lines correlating to DNA and/or RNA abnormalities has been detected by Western blot and immunocytochemical analyses [302]. Additionally reintroduction of exogenous wild-type FHIT suppressed tumorigenicity in nude mice of human cancer cell lines including a NSCLC cell line [303]. Furthermore, the much more frequent FHIT allele loss in lung cancers from smokers (80 %) compared to nonsmokers (22 %) suggests that this chromosomal region is selectively targeted by the carcinogens in tobacco smoke [304].

The 3CDKN1A.3 region has been extensively examined for putative tumor suppressor genes by several groups. The

finding of several homozygously deleted lung cancer cell lines suggested a role for two distinct 3CDKN1A.3 regions. One region is defined by three distinct homozygous deleted SCLC cell lines with a minimum common deleted region mapped to span 370 kb [305–307]. The other 3CDKN1A region illustrated by several homozygous deletions has an estimated ~800 kb deletion [308]. Apart from these regions, hMLH1 (the human homolog of the yeast mutL gene) also resides on chromosome 3CDKN1A and while mutations of the hMLH1 gene have been found in hereditary colon cancer, lung cancer studies have not been reported [309]. Other well characterized candidate 3CDKN1A TSGs are SEMA3B and SEMAF, RASSF1A, and FUS1 [310]. SEMA3B and SEMAF are close to the other genes and part of the semaphorin axonal guidance gene family, both encode secreted proteins [311]. RASSF1A is frequently hypermethylated in lung cancer but rarely mutated. RASSF1A is part of a complex similar to the Drosophila Hippo/Salvador/Lats tumor-suppressor network, is conserved in mammalian cells, and may be involved in controlling mitotic exit [312]. Fus1 is next to RSSF1A and while mutation of FUS1 is infrequent in lung cancers, protein under expression has been reported and exogenous overexpression of Fus1 protein inhibited colon formation in some NSCLC cell lines [313].

Other candidate 3p lung cancer suppressor genes include the von Hippel–Lindau (VHL) tumor suppressor gene at 3p25 which is frequently mutated in renal cell carcinoma but only uncommonly involved in lung cancers [314]. Abnormalities of retinoic acid receptors (RARs) have also been implicated in lung cancer pathogenesis. Several studies have indicated abnormalities of the expression or function of the RARB gene which maps to chromosome region 3p24, another site of frequent allele loss in lung cancer [315–320]. Mutational analysis however has failed to demonstrate mutations in RARB. Additionally, the TGFβ-type II receptor (TGFβ RII) gene at 3p22 is another candidate tumor suppressor gene as discussed below.

28.4.3.5 LKB1/STK11

Frequent losses of chromosome 19p in lung adenocarcinomas led to the fine mapping of the short arm of chromosome 19 and the discovery of the LKB1/STK11 gene which mapped in the minimal-deleted region [321]. Germ-line mutations at LKB1/STK11 result in the Peutz–Jeghers syndrome and an increased risk of cancer, and there is a relatively high frequency of somatic alterations (mainly nonsense mutations) in primary lung adenocarcinomas and in lung cancer cell lines [321]. These mutations may be linked to KRAS mutations and smoking and male gender in a subset of poorly differentiated lung adenocarcinomas, and are associated with transcriptional deregulation of molecules involved in signal transduction (e.g., FRAP1/mTOR, ARAF1, and ROCK2), cytoskeleton (e.g., MPP1), transcription factors (e.g., MEIS2, ATF5), metabolism of AMP (AMPD3 and APRT), and ubiquitination (e.g., USP16 and UBE2L3).

28.4.3.6 Other Candidate Tumor Suppressor Gene Locations

Apart from the known and candidate tumor suppressor gene locations discussed above, cytogenetic and allelotyping studies have shown allelic loss of many other chromosomal regions in lung cancer, thereby implicating involvement of other tumor suppressor genes. The chromosomal regions include 1p, 1q, 2q, 5q, 6p, 6q, 8p, 8q, 10q, 11p, 11q, 14q, 17q, 18q, and 22q. CGH and array CGH are helping to more precisely define these regions (Table 28.1).

Several of these chromosomal regions contain known or candidate tumor suppressor genes (such as WT1 at 11p13, DCC at 18q21, NF2 at 22q12), but these genes have not been found to be mutated in lung cancer [322, 323]. Regions on chromosome 5q, around the APC and MCC gene cluster are also frequently deleted in both subtypes of lung cancer. However, APC mutations have not been detected in lung cancer [323, 324]. In addition, others have reported high rates of allelic loss as well as a homozygous deletion in the 5p13-12 region [325, 326]. There has also been cytogenetic and molecular evidence of frequent allele loss of parts of chromosome 11p in lung cancer [327–330]. Apart from allele loss in the 11p13 region, refined mapping of the telomeric 11p15.5 region has suggested the location of two distinct tumor suppressor genes [331]. Loss of genetic material from 11q including the chromosomal region which houses the ATM tumor suppressor gene (11q23) is seen in a number of human cancers including lung [332], breast, ovary, cervix, colon, and skin. Nonetheless, ATM mutations have not been reported in lung cancer.

In addition, the presence of homozygously deleted chromosomal regions 2q33, 8, and X/Y in lung cancer imply yet other unidentified tumor suppressor genes [333]. The comparative genomic hybridization (CGH) technique also detected deletions at 1p, 2q, 3p, 4p, 4q, 5q, 6q, 8p, 9p, 10q, 13q, 17p, 18p, 18q, 21q, and 22q, and characterized the different deletion patterns between SCLC and NSCLC, as well as between adenocarcinoma and squamous cell carcinoma subtypes [11–13, 15].

At 10q23, a candidate tumor suppressor gene, PTEN, is somatically mutated in various tumors including glioblastoma, and prostate, kidney, and breast cancers [334]. PTEN mutations appear infrequent in lung cancers [335] but PTEN expression can be downregulated in lung cancers [336]. PTEN is a part of the PI3K/AKT pathway, and like other examples in lung cancer, other members of this pathway can be involved. Phosphatidylinositol 3-kinase (PI3K) activity is implicated in diverse cellular responses triggered by mammalian cell surface receptors, such as cellular proliferation,

growth, apoptosis, and the cytoskeleton, and which are activated in multiple advanced cancers. Unlike other tumors such as colorectal cancers, PIK3CA (encoding the catalytic subunit of PIK3) is only mutated in a small subset of lung cancers [337, 338]. A downstream effector of PI3K is the protein kinase AKT. AKT is negatively regulated by PTEN. AKT appears to be activated in NSCLC lines and seemed to promote survival [339]. Furthermore, nicotine or the tobacco-specific carcinogen, 4-(methylnitrosoamino)-1-(3-pyridyl)-1-butanone (NNK), could rapidly and potently activate AKT in both NSCLC and SCLC cell lines. Nicotinic activation of AKT increased phosphorylation of multiple downstream AKT substrates including GSK-3, FKHR, tuberin, mTOR, and S6K1 [340].

28.5 Molecular Genetic Changes in Preneoplasia

Much of our knowledge about the series of preneoplastic changes in bronchial epithelium has been based on the histological appearances of bronchial epithelial cells. Before the appearance of a clinically overt lung cancer, a sequence of morphologically distinct changes (hyperplasia, metaplasia, dysplasia and carcinoma in situ) can be observed in bronchial epithelium. The sequential changes for cancers which arise from the proximal airways and bronchi (predominantly squamous cell carcinomas) have long been recognized, whereas changes in peripheral bronchioles and alveoli in evolution to cancers (adenocarcinomas and large cell carcinomas) have been recognized more recently. A number of studies have shown that the preneoplastic cells and bronchial epithelium adjacent to cancers contain a number of genetic abnormalities which are identical to some of the abnormalities found in overt cancer cells. These include abnormalities of MYC and RAS upregulation, cyclin D1 expression, TP53 immunoreactivity, and DNA aneuploidy [10, 260, 341–346]. A follow-up longitudinal study of ex-chromate workers confirmed that some TP53 immuno-positive dysplasias progress to subsequent squamous cell carcinoma [345]. Based on the observation that bronchial dysplastic lesions with elevated telomerase levels, increased Ki-67 index, and expression of TP53 do not regress, it has been suggested that lesions with these molecular changes may progress to invasive squamous carcinomas [347].

In elucidating the temporal sequence of molecular changes, allelotyping analysis of precisely microdissected foci of preneoplastic cells suggests that 3p allele loss is the earliest change followed by 9p allele loss, 17p allele loss (and TP53 mutation), 5q allele loss, and RAS mutations [341, 348–351]. It has been hypothesized that one or more 3p tumor suppressor gene(s) may be critical for proximal squamous lung cancer pathogenesis as abnormalities of 3p appear to be amongst the earliest detectable genetic lesions.

For the adenocarcinoma subtype, based on topographical analysis, it is speculated that KRAS activation may occur early during adenocarcinoma tumorigenesis [346]. In this context, KRAS mutations can be found in atypical adenomatous hyperplasia (AAH), postulated by some to be the precursor lesion for adenocarcinomas [151, 352]. In addition, with laser capture microdissection, EGFR mutations can be demonstrated in apparently morphologically normal appearing bronchial epithelial cells adjacent to tumors known to harbor EGFR mutations [353]. A study of EGFR and KRAS gene mutations in synchronous pulmonary lesions including AAH, carcinomas in-situ (non-mucinous bronchoalveolar carcinoma—BAC), minimally invasive adenocarcinomas, and overtly invasive adenocarcinomas indicated different mutation rates for each gene along this presumed temporal sequence of carcinogenesis [354]. KRAS was mutated in 33 % of AAH, 12 % of carcinomas in situ, 8 % of minimally invasive adenocarcinomas, and 0 % of well-differentiated adenocarcinomas, compared with EGFR mutation rates of 25, 51, 36, 86, and 67 %, respectively. EGFR mutations are found in normal bronchial epithelium and non-malignant epithelium adjacent to tumors in a proportion of patients with AAH and bronchoalveolar carcinoma (BAC), and in 40 % of patients with EGFR mutated adenocarcinomas [353]. In contrast, EGFR mutations are rare in squamous cell carcinomas and therefore EGFR is not implicated in squamous carcinogenesis.

These observations are consistent with the multistep model of carcinogenesis as well as the field cancerization theory proposed by Slaughter. This theory suggests that as the whole aerodigestive tract is repeatedly exposed to carcinogenic damage (tobacco smoke), it is at risk for developing multiple, separate foci of neoplasia [355]. Interestingly, the 3p, 9p, and 17p deletions showed allele-specific loss, defined as deletion of the same allele in preneoplastic tissues as in the primary tumor, even when these lesions were geographically and morphologically distinct [349]. Possible explanations for these allele specific changes include: clonal spread of mutated cells throughout the lung; inherited differences in alleles predisposing to their loss; or some event occurring during lung embryogenesis affecting a particular set of alleles. In support of the clonal spread theory, an identical TP53 point mutation was identified in multiple dysplastic lesions from both lungs of a smoker with chronic obstructive pulmonary disease, thereby indicating an unusual field cancerization mechanism and clonal spread [356].

28.6 Lung Cancer Genome

The combination of the Human Genome Project characterization of human genome sequence and very rapid technological improvements in sequencing tools and bioinformatic analyses has enabled genome-wide investigation of

somatic mutations in human cancers. Several large scale sequencing projects have been reported that aim to identify genes that contain driver somatic mutations in tumor samples compared to passenger mutations that do not contribute to carcinogenesis. For instance in one study, more than 1000 somatic mutations were found in 274 megabases (Mb) of DNA corresponding to the coding exons of 518 protein kinase genes in 210 diverse human cancers, of which perhaps 120 genes were thought to harbor driver mutations [357].

In lung cancer, an earlier study used SNP arrays to identify homozygous deletions and chromosome amplifications in primary lung carcinoma and cell lines. Two homozygous deletion regions were identified, one near PTPRD on 9p23 and another in 3q25. High-level amplifications were identified within 8q12-13 in two SCLC specimens, 12p11 in two NSCLC specimens, and 22q11 in four NSCLC specimens. Tyrosine kinase genes which showed high-level amplification included EGFR (3 NSCLC), FGFR1 (2 NSCLC), ERBB2 (1 NSCLC), and MET (1 NSCLC) [31].

Some studies have focused on candidate genes. DNA sequencing of 623 candidate genes in 188 lung adenocarcinomas revealed more than 1000 somatic mutations including in 26 genes that are mutated at significantly high frequencies, such as tyrosine kinase genes; ephrin receptor genes, vascular endothelial growth factor receptor KDR and NTRK genes. These data also provided evidence of somatic mutations in primary lung adenocarcinoma for tumor suppressor genes implicated in other cancers including NF1, APC, RB1, and ATM and for sequence changes in PTPRD as well as the frequently deleted gene LR 1B [358]. Another study searched for somatic mutations in 1507 coding genes from 441 tumors (breast, lung, ovarian, and prostate). These investigators discovered 2576 mutations, with heterogeneity in rates and mutated genes across tumor types and subtypes. The 77 statistical significantly mutated genes included protein kinases, G-protein-coupled receptors such as GRM8, BAI3, AGTRL1, and LPHN3. Another 35 altered genes including GNAS were identified by the integrated evaluation of somatic mutations and copy number alterations [359].

Unbiased studies analyzing the entire genome have recently been reported. Massively parallel sequencing of a SCLC line, NCI-H209 demonstrated 22,910 somatic substitutions, including 134 in coding exons, evidence of different mutation signatures, as well a tandem duplication affecting CHD7 [360]. A comparison of the complete sequences of a primary lung tumor (60× coverage) and adjacent normal tissue (46×) revealed >50,000 high-confidence single nucleotide variants including KRAS [361]. The investigators estimated a 17.7 per megabase genome-wide somatic mutation rate; with a distinct pattern of selection against mutations within expressed genes compared to non-expressed genes and in promoter regions up to 5 kb upstream of all protein-coding genes, as well as a higher rate of amino acid-changing mutations in kinase genes.

Since then, the field is rapidly progressing and an increasing number of NGS studies are now reported, summarized in Table 28.3. Perhaps the most striking findings include identification of novel lung cancer genes, increasing recognition of actionable mutations in adenocarcinoma [362], and emerging molecular themes in cancers arising in different organs [208, 363].

28.6.1 Gene Expression Profiling of Lung Cancer

The expression of regulatory genes of a cell determines its phenotype. Expression can be assessed by measuring its end product, protein, or its intermediate product, mRNA. Microarray technology allows the simultaneous analysis of expression of thousands of genes, generating gene expression patterns that may characterize a disease state. Tumor gene expression data or profiles/signatures can identify unique expression patterns, with implications for predicting cause, i.e., etiology; source, i.e., tissue of origin, and behavior such as prognosis (prognosticator) and response to therapy (predictor). Whilst mRNA levels do not necessarily correlate with protein concentrations in the cell, the efficiency by which mRNA microarrays provide genome wide quantitative information of gene expression data means that expression-based classification of many cancers has now been reported (Table 28.4).

In lung cancer, most of the work has been performed in NSCLC, where gene expression profiling is often correlated with diagnosis and histology, survival and prognosis, treatment response including sensitivity to epidermal growth factor receptor tyrosine kinase inhibitors [377–384], and smoking [385, 386]. In SCLC, gene expression profiling studies have likewise been used to correlate with diagnosis and the identification of novel markers [387–392], survival and prognosis [383], and treatment response and sensitivity [382, 383, 390]. These analyses provide critical insight into the different pathways which may be involved in different phenotypes. The publication requirement that microarray data be made publicly available (through facilities such as Gene Expression Omnibus) which can then be mined using associated resources at the NCBI, Oncomine [393], Connectivity Map [394] and many others will mean that there will be significant ability for researchers to use the collective data sets for testing and formulation of new hypotheses. It also provides the opportunity for peer review and independent replication—a crucial step if genomic profiling is to advance into the clinic.

Table 28.3 Next-generation sequencing studies of lung cancer

First author	Year	Project design	Principal findings
Campbell [364]	2008	Illumina genome analyzer 2 Lung cancer cell lines WGS	306 germ line structural changes; 103 somatic rearrangements
Pleasance [360]	2010	SOLiD; 1 SCLC cell line WGS	22,910 somatic mutations; 134 in coding regions. 58 structural changes. Tobacco associated mutation signatures
Lee [361]	2010	cPAL; 1 NSCLC/normal lung pair WGS	>50,000 SNPs, 392 in coding regions; 43 structural variants
Ju [365]	2011	Illumina HiSeq 2000 and genome analyzer IIx; 1 NSCLC/normal lung pair WGS	10,724 SNPs, 334 in coding regions. Novel KIF5B-RET fusion
Imielinski [366]	2012	Illumina HiSeq: 183 ACs and matched normal tissue; 159 WES, 23 WES + WGS, 1 WGS	Novel recurrently mutated genes: ARID1A, RBM10, U2AF1. In-frame exonic alterations in EGFR and SIK2
The Caner Genome Atlas Research Network [367]	2012	Illumina HiSeq: Integrated analysis of 178 SCCs and matched germ line; 19 WGS, 178 WES	Novel mutation in HLA-A; significantly altered pathways: NFE2L2/KEAP1 (34 %), squamous differentiation (44 %), PI3K/AKT (47 %); CDKN2A/RB1 (72 %)
Peifer	2012	Illumina genome analyzer IIx. 29 SCLC exomes, 2 genomes and 15 transcriptomes	High mutation rate: 7.4 ± 1 protein changing mutations per 106; TP53 and RB1 inactivation in all; recurrent mutations in histone modifiers CREBBP, EP300, and MLL
Govindan [368]	2012	Illumina genome analyzer II; 17 WGS; 16AC and 1 large cell carcinoma	Novel mutations in chromatin modification and DNA repair pathways; 14 fusions including ROS, ALK and metabolic enzymes. Possible roles of EGFR and KRAS as tumor initiators
The Pan-Cancer Project [369]			
Ciriello [370]	2013	Hierarchical classification of genetic (WES, SNP array, and epigenetic (methylation array) events 3229 tumors of 12 cancer types including 229 lung AC and 182 SCC.	AC are characterized by either mutations or copy number alterations, SCC are characterized by primarily copy number alterations
Lawrence [371]	2013	WGS and WES of 3083 tumors of 12 cancer types including 514 lung cancers: 179 SCC (14 WGS and 165 WES) and 335AC (WES)	Lung AC and SCC have high rates of somatic mutations relative to other tumors: C → A mutations predominate
Zack [372]	2013	Somatic copy number alteration (SCNA) profiling of 357 AC, 344 SCC using SNP array and WGS	Lung AC and SCC have high rates of whole genome duplication relative to other tumor types (59 % AC and 64 % SCC); recurrent focal SCNAs seen in lung SCC and head and neck SCC
Kandoth [373]	2013	Mutational analysis of 3281 tumors from 12 cancer types including 230 lung AC and 178 SCC	The highest mutation rates of all cancers studied were seen in Lung AC and SCC; this was related to *TP53* mutations; *KEAP1* mutations predominate in lung AC and SCC; *EPHA*, *SETBP1*, and *STK11* mutations predominate in Lung AC
Tamborero [374]	2013	Mutational analysis of 3205 tumors from 12 tumor types including 226AC and 174 SCC	Lung AC and SCC have high rates of protein activating mutations in high confidence driver mutations relative to other tumor types (median of 9 per tumor)
Gonzalez-Perez [375]	2013	Resequencing data from 4623 exomes from 13 tumor types including 390AC, 31 NSCLC, 174 SCC, 69 SCLC	Int0Gen-mutations platform is a Web based analysis pipeline which is able to summarize genomic data systematically
Lawrence [376]	2014	Predominantly WES of 405AC tumor-normal pairs and 178 SCC tumor-normal pairs	Estimates suggest the number of driver mutations detected in SCC may more than double given sufficient sample size. In excess of 3000 tumor-normal pairs required to detect alterations in 90 % of genes mutated at 2 % above background with 90 % power

WGS whole genome sequencing, *WES* whole exome sequencing, *CNV* copy number variation, *SNP* single nucleotide polymorphism, *AC* adenocarcinoma, *SCC* squamous cell carcinoma, *SCLC* small cell lung cancer, *cPAL* combinatorial probe anchor ligation

Moreover, a gene expression study of human airway epithelial cells obtained bronchoscopically in smokers and never smoker controls has contributed to knowledge of the smoking transcriptome, including persistent gene deregulation even after smoking cessation (information deposited in the SIEGE (smoking induced epithelial gene expression) database) [448, 449]. These investigators have also identified an 80-gene biomarker in histologically normal large-airway epithelial cells obtained at bronchoscopy that distinguishes smokers with and without lung cancer [450], paving the way for potential development of a diagnostic tool.

Table 28.4 A selection of gene expression microarray studies in lung cancer (N.B. Some studies appear more than once)

Analysis type	Reference	Platform[a]	No. of probes/ elements	Samples in training set (TNM stage)[b]	Samples in test set (TNM stage)[b]	Analysis and findings[c]
Diagnosis/subtype comparison						
	[388]	Affymetrix U95Av2	20,951	127AC, 21 SCC, 20 carcinoid, 6 SCLC, 12 metastases, 17 NL	–	Unsupervised clustering found histology subclasses
	[387]	cDNA	>23,000	41AC (6 pairs), 16 SCC (5 pairs), 5 LCC, 5 SCLC, 5 NL	–	Unsupervised clustering separated tumors histologically
	[389]	cDNA	2400	10 SCC, 10AC, 2 SCLC, 5 SCLC cell lines, 1 carcinoid, 2 colon Ca, 1 NL	–	209 Genes overexpressed in SCLC
	[395]	Affymetrix HuGeneFL	>7000	86AC (I,III), 10 NL	–	Unsupervised clustering found subclasses associated with cancer/ non-cancer, stage and differentiation
	[396]	cDNA	47,650	19AC, 14 SCC, 4 LCC, 2 carcinoid	–	Genes overexpressed in cancer vs non-cancer
	[397]	cDNA	1185	14AC (I–III), 4 NL	–	DE genes between AC and NL
	[398]	Oligo		32 NSCLC	–	Expression profiles correlated with histology
	[384]	cDNA	23,040	22AC, 14 SCC, 1 AdSq	–	Unsupervised clustering found subclasses associated with histology and ± lymph node metastasis
	[399]	cDNA	425	10 NSCLC (I–III) (7AC, 3 SCC) and matched NL	–	DE genes in tumor compared to normal lung. DE genes in stage IA ($n=5$) compared to advanced stage ($n=5$)
	[392]	Affymetrix U95Av2	20,951	21 SCLC cell lines, 18 NL, 8 xenografts	–	Identified DE genes between the two variants of SCLC
	[400]	cDNA	5184	11 SCC, 9AC, 5 non-SCLC, 3 met LC, 3 NL	9 NSCLC (4AC, 4 SCC, 1 LCC), 4 met LC	Gene expression predicted tumor (vs. non-tumor), and histology
	[401]	cDNA	2400	12AC, 3 SCC (I, III)	–	75 Genes DE between no metastasis, micrometastasis, and overt metastasis
	[402]	cDNA	1185	13 SCC (I–III), 13AC [397], 4 NL	–	DE genes in SCC and AC compared to NL. DE genes in SCC compared to AC
	[391]	cDNA	1185	13AC [397], 13 SCC [402], 2 LCC, 1 AdSq, 1 LCNEC, 7 SCLC	–	Identified genes DE between high-grade neuroendocrine carcinomas (SCLC and LCNEC) and other lung cancers
	[403]	cDNA	10,750	42 NSCLC (I–III)	–	62 DE genes between angiogenic compared with non-angiogenic tumors
	[404]	cDNA	2305	6 SCC, 4 NL	–	26 DE genes between SCC and NL
	[52]	Oligo	10,416	79 NSCLC (I–III) (30 pN-, 49 pN+)	33 NSCLC (I–III) (21 pN0, 12 pN+)	33-gene signature to predict lymph node metastasis
	[379]	Affymetrix U133A	>22,000	36 Cell lines: 18AC, 4 SCC, 14 SCLC	–	Compared NSCLC to SCLC to identify subtype specific differences. Correlated expression with copy-number differences

(continued)

Table 28.4 (continued)

Analysis type	Reference	Platform[a]	No. of probes/ elements	Samples in training set (TNM stage)[b]	Samples in test set (TNM stage)[b]	Analysis and findings[c]
	[405]	Affymetrix U95Av2 and HuGeneFL, cDNA	2848	231AC (I–IV) 31 [387], 72 [395], 128 [388]	–	Bronchoid, squamoid and magnoid subtypes within AC
	[406]	Affymetrix Custom	59,000	89 NSCLC (I–IV) (49 SCC, 40AC), 15 NL	–	344 DE genes between NSCLC and NL. 72 DE genes between AC and SCC
	[407]	Oligo	21,619	149 NSCLC (90AC, 35 SCC, 18 LCC, 4 AdSq, 2 LCNEC)	–	293 DE genes between TRU and non-TRU type AC
	[390]	cDNA	32,256	15 SCLC, 37 NSCLC [384], 14AC [381]	–	DE in SCLC vs. NL and NSCLC
	[408]	Affymetrix U95A and U95Av2	20,951	(1) 48 NSCLC (27 SCC, 21AC), 17 NL; (2) 45 NSCLC (25AC, 20 SCC), 33 NL	(1) 160 NSCLC (139AC, 21 SCC), 6 SCLC, 17 NL; (2) 17 NSCLC (10 SCC, 7AC), 20 NL	162 DE genes comparing AC, SCC and NL (training set 1). 96 % classification accuracy in 183 samples (test set 1). 20-gene signature (training set 2) had better accuracy (97 %) (test set 2)
	[409]	cDNA	7237	69 NSCLC (36 SCC, 30AC, 3 LCC)	75 NSCLC (39AC, 29 SCC, 7 LCC) (IHC validation)	Identified genes correlating with histopathology and EGFR mutation
	[410]	Affymetrix U133A	>22,000	100AC (I–III)	–	Identified clusters that correlated with histological subtypes and KRAS and EGFR mutation status
	[411]	Affymetrix U133Plus2	>54,000	46 NSCLC (32 SCC, 14AC) and paired NL	48 NSCLC, 22 NL	Signatures for SCC and AC histology
Prognosis						
	[388]	Affymetrix U95Av2	20,951	127AC, 21 SCC, 20 carcinoid, 6 SCLC, 12 metastases, 17 NL	–	Unsupervised clustering found subgroups with significantly poorer survival
	[387]	cDNA	>23,000	41AC (6 pairs), 16 SCC (5 pairs), 5 LCC, 5 SCLC, 5 NL	–	Unsupervised clusters in AC with significant survival differences
	[395]	Affymetrix HuGeneFL	>7000	86AC (I,III), 10 NL	84AC (stage I–III)	Correlating expression with survival identified 50-gene signature
	[385]	cDNA	18,432	19AC (I–II)	–	27 DE genes between survivors and non-survivors (at 5 years)
	[412]	Affymetrix HU6800	4578	63AC (I)	–	303 DE genes between ± active lymphocytic response. *RANTES* genes was a predictor of survival
	[413]	cDNA	19,200	19AC, 14 SCC, 4 other (I–III)	–	22 Genes correlating with to early recurrence
	[414]	Affymetrix HuGeneFL	>7000	36AC (I) [395]	60 Stage I AC	5 DE genes between recurrence vs. no-recurrence. Three gene-ratio tests could predict outcome
	[415]	Affymetrix Hu6800 and Hu35KsubA	16,063	64 Primary AC, 12 metastatic AC (lung, breast, prostate, colorectal, uterus, ovary)	62AC (I–II) [388]	128-gene signature to predict metastasis, refined to 17-gene signature
	[383]	cDNA	1185	29 NSCLC (II–IV), 18 SCLC	–	3 Genes correlated with survival

(continued)

Table 28.4 (continued)

Analysis type	Reference	Platform[a]	No. of probes/ elements	Samples in training set (TNM stage)[b]	Samples in test set (TNM stage)[b]	Analysis and findings[c]
	[416]	Affymetrix U95Av2 and HuGeneFL	6124	79AC, 10 NL [395]	83AC, 16 NL [388]	16-gene signature for survival
	[417]	Affymetrix U133A	>22,000	10 SCC (I)	5 SCC (stage I)	246 DE genes between high-aggressive vs. low-aggressive tumors. 27 top genes could predict group
	[418]	cDNA	11,168	50 NSCLC (30AC, 16 SCC, 4 LCC)	6 NSCLC (3 SCC, 3 non-SCC)	98-gene NSCLC signature (refined to 25-gene signature), 19-gene SCC signature and 12-gene non-SCC signature.
	[419]	Affymetrix U95Av2	20,951	25AC (5 BAC, 10 invasive, 10 BAC + invasive)	–	319 DE genes between 3 invasive subclasses. 30 DE genes between BAC and BAC + invasive subclasses
	[420]	cDNA	>40,000	48 SCC, 9AC, 30 NL	–	432 DE genes separated SCCs into two subgroups with significant survival differences
	[421]	Affymetrix U95Av2 and HuGeneFL	5377	86AC (69 pN0, 17 pN+) [395]	69AC (52 pN0, 17 pN+) [388]	318-gene set to predict pN status, predicted pN+ patients had worse DFS and OS
	[422]	Affymetrix U95Av2 and HuGeneFL		86AC (I, III) [395]	84AC(I–III) [388]	37-gene signature for survival
	[405]	Affymetrix U95Av2 and HuGeneFL, cDNA	2848	231AC 31 [387], 72 [395], 128 [388]		Bronchoid, squamoid and magnoid subtypes within AC correlated with OS
	[423]	Meta-analysis of 7 datasets, in-house and published (5 as training set, 2 as test set)	4905	197 NSCLC (156AC, 37 SCC, 4 other)	(1) 63AC (stage I) (unpublished data sets), (2) 64AC and SCC (stage I)	Correlating expression with survival identified a 64-gene signature for stage I NSCLC
	[424]	cDNA	1185	17AC, 11 SCC (I–III)		12 Genes correlated with survival
	[425]	Affymetrix U133Plus2	>54,000	45AC, 44 SCC (I–III)	(1) 11AC, 14 SCC; (2) 84AC; (3) 15 SCC	Lung metagene model predicted likelihood of recurrence
	[426]	Affymetrix U133A	>22,000	129 SCC (I–III)	36 SCC (25 stage I, 9 stage II, 1 stage III, 1 stage IV)	50-gene signature correlated with survival
	[427]	Affymetrix U95Av2 and HuGeneFL	>4000	41AC (I) [395] and 60AC (I) [388] (Patients selected if alive/dead at 30 months)	34AC (I) [378]	80-gene model (comprising a 49-gene meta-analysis model, 28-gene cancer-biased model [428], and 3 genes from literature) to predict prognosis. Refined to 10-gene model
	[429]	Oligo	22,575	10 pN+ AC and matched lymph node metastases, 11 pN- AC	–	Unsupervised HC clustered 8/10 primary/metastases pairs together. 75-gene signature of metastasis (comparing pN+ with pN-ACs)
	[430]	Oligo	22,323	48AC (I–II)	55AC [388], 40AC [378]	54-gene signature to predict recurrence
	[431]	Oligo	22,323	51 SCC (I–III)	58 SCC (I–III) [426]	111-gene signature correlated with recurrence

Table 28.4 (continued)

Analysis type	Reference	Platform[a]	No. of probes/ elements	Samples in training set (TNM stage)[b]	Samples in test set (TNM stage)[b]	Analysis and findings[c]
	[432]	cDNA	11,168	2 LCC cell lines (1 highly metastatic, 1 parent)	50 NSCLC [418], and 62AC, 78 breast AC, 60 medulloblastomas [415]	45-gene metastasis signature could predict prognosis in lung and breast data sets
	[433]	Oligo	672	60AC, 52 SCC, 13 other	24AC, 31 SCC, 5 other	16-gene signature to predict OS, 5-gene signature confirmed with qRT-PCR
	[434]	Affymetrix U133Plus2	>54,000	138 NSCLC (I–III) (75 SCC, 63AC)	56 NSCLC (I–III) (32 SCC, 25AC)	6-gene clinicopathologic signature to predict DFS
	[435]	Affymetrix HU6800	4966AC; 12,990 SCC	86AC (I,III) [395], 129 SCC (I–III) [426]	84AC [388], 45AC and 46 SCC [378]	Developed two 50-gene signatures in AC and SCC datasets to predict OS
	[436]	Affymetrix U133A	>22,000	256AC (I–III)	186AC (I–III)	Multi-site blinded study developed several classifiers to predict OS where prediction accuracy was improved with inclusion of clinical data
	[437]	Oligo	44,000	103 NSCLC (57 SCC, 33AC, 13 other) (I–II)	69 NSCLC (35 SCC, 23AC, 11 other) (I–II)	72-gene signature to predict RFS and OS
	[438]	qRT-PCR	158	147 [439]	91AC and SCC [425], 130 SCC [426], 59 SCC [430], 48AC [440]	6-gene signature to predict OS
	[441]	Affymetrix U133A, U133Plus2	>22,000	129 SCC [426]	85 NSCLC (44 SCC, 41AC) [425], 138 NSCLC (76 SCC, 62AC) [434], 327AC [436]	12-gene signature for OS
Treatment						
	[384]	cDNA	23,040	22AC, 11 SCC	–	Correlation of sensitivity to 6 anticancer drugs
	[383]	cDNA	1185	29 NSCLC (II–IV), 18 SCLC	–	3 Genes correlated with survival
	[381]	cDNA	27,648	17AC (III–IV)	10AC, 1 SCC (III–IV)	12-gene signature to predict gefitinib sensitivity
	[382]	cDNA	1185	[383]	–	3 Genes correlated with outcome of chemotherapy
	[442]	Affymetrix U133Plus2	>54,000	42 NSCLC cell lines	–	Identified signature correlating with erlotinib sensitivity
	[377]	Affymetrix U133A	>22,000	29 LC cell lines	19AC, 40AC [378]	180-gene signature for EGFR TKI sensitivity
	[378]	Affymetrix U133Plus2	>54,000	74 NSCLC	–	Gene expression signature that reflects activation status of oncogenic pathways which in turn, can predict sensitivity to components that target pathway
	[380]	Affymetrix U133	45,000	11 NSCLC cell lines (3AC, 3 SCC, 2 LCC, 2 BsAC, 1 AdSq)	12 NSCLC cell lines (7AC, 3 LCC, 2 SCC)	Gene signature associated with EGFR-TKI sensitivity
	[443]	Affymetrix U133A	>22,000	10 NSCLC cell lines	19 NSCLC cell lines	Identified signatures of sensitivity to docetaxel, paclitaxel, gemcitabine, vinorelbine, 5-FU, SN38, cisplatin, and carboplatin

(continued)

Table 28.4 (continued)

Analysis type	Reference	Platform[a]	No. of probes/ elements	Samples in training set (TNM stage)[b]	Samples in test set (TNM stage)[b]	Analysis and findings[c]
	[390]	cDNA	32,256	15 SCLC, 37 NSCLC [384], 14AC [381]	–	Identified DE in SCLC and advanced AC with history of extensive chemotherapy
	[444]	Affymetrix U133A	>22,000	16 NSCLC cell lines	9 NSCLC cell lines	Nine-gene classifier to predict sensitivity to HDAC inhibitors
	[445]	Affymetrix U133A	>22,000	62 NSCLC (I–II)	96 NSCLC [436], 48 NSCLC [425], 79 SCC [426], 133 NSCLC [437]	15-gene signature to predict sensitivity to cisplatin/vinorelbine
Smoking						
	[385]	cDNA	18,432	19AC (I–II)	–	45 DE genes between smokers and nonsmokers
	[386]	Affymetrix U133A	>22,000	18 SCC, 9AC, 8 NL	–	23-gene signature that differentiated between bronchial epithelium of nonsmokers, smokers, and cancers
	[446]	Affymetrix U133A and B		66 NSCLC (54AC, 6 SCC, 5 LCC, 1 AdSq), 13 NSCLC cell lines (12AC, 1 NSCLC), 7 NL, 6 HBEC lines	LOOCV (Train 2/3, Test 1/3)	65-gene signature of NSCLC nonsmoking *nAChR* α6β3 phenotype
	[447]	Affymetrix U133A		58AC, 49 NL (20 never, 26 former, 28 current smokers)	19 NSCLC, 21 NL	Signature of cigarette smoking

Unless otherwise specified, all samples were primary lung tumor samples
[a] *Affymetrix* Affymetrix GeneChip®, *cDNA* cDNA microarray or membrane, *Oligo* Oligo microarray
[b] *AC* adenocarcinoma, *SCC* squamous cell carcinoma, *LCC* large cell carcinoma, *LCNEC* large cell neuroendocrine carcinoma, *SCLC* small cell lung carcinoma, *NL* normal lung
[c] *OS* overall survival, *DFS* disease-free survival, *DE* differentially expressed, *HC* hierarchical clustering, *TRU* terminal respiratory unit, *nAChR* nicotine acetylcholine receptor

28.6.2 DNA Methylation

The spatial arrangement and three-dimensional structure of DNA in the nucleus is controlled through the interdigitation of DNA binding proteins such as histones and their modifiers, the Polycomb-Trithorax proteins, and the DNA methyltransferase enzymes [451]. DNA methylation is involved in the epigenetic gene regulation in mammals. Cellular transformation coincides with multiple changes in chromatin architecture, thereby affecting genome integrity and gene expression. The process of DNA methylation involves the covalent modification at the fifth carbon position of cytosine residues within CpG dinucleotides which tend to be clustered in islands at the 5′ ends of many genes, and can be considered an epigenetic modification of DNA. In general, methylated genes are inactive whereas unmethylated genes tend to be active. DNA methylation appears to be associated with genetic repression and is necessary for proper embryonic development. The methylated CpG residues could either interfere directly with the binding of specific transcription factors to DNA, bind to specific repression factors or convert chromatin to an inactive form by altering its structure. The mammalian DNA methylation process requires two components, the DNA methyl-transferases (DNMTs) and the methyl CpG binding proteins (MBDs) [452, 453]. DNMTs establish and maintain methylation patterns whereas MBDs are thought to be involved in reading methylation marks. Potential mechanisms include spreading of DNA methylation from repetitive sequences into promoter-associated CpG islands secondary to loss of transcriptional activators, gain of methylation secondary to hyperexpression of transcriptional repressors, primary hypermethylation due to hyperexpression of methyltransferases, and inter-allelic transfer of methylation via gene pairing [454]. A proposed model of DNA methylation and cancer proposes that global hypomethylation in at-risk cells contributes to genomic instability through increased mitotic recombination events, whereas CpG island methylation in cancer cells leads to transcriptional silencing of growth regulatory genes [452]. One of the major reasons for the explosion in knowledge regarding tumor methylation is thanks to the rapid technological advances in this area. Frommer et al. demonstrated that bisulfite deamination of cytosine and 5-methylcytosine differentially to yield uracil and thymine respectively coupled

with PCR techniques allowed simplified analysis of DNA methylation [455]. More recently, Weber et al. has developed an antibody based immunocapture method termed methyl-DNA immunoprecipitation (MeDIP) involving purification of methylated DNA using a monoclonal antibody raised against 5-methylcytidine [456]. When combined with high-resolution genomic microarrays, this approach allows correlations between DNA methylation and histone modifications to be made, demonstrating its usefulness in epigenetic research [457]. These days, the very sensitive bisulfite based methylation specific PCR (MSP) is perhaps the most popular tool for examining DNA methylation patterns, although whole-genome microarray-based and next-generation sequencing based approaches are gaining popularity due to their ability to profile several thousands of genes in a single experiment. The principles of MSP and other methylation detection techniques, such as restriction digestion by methylation sensitive enzymes, COBRA, PyroMeth, SnaPmeth, bisulfite SSCP, and bisulfite sequencing have been reviewed [458]. Some techniques such as restriction landmark genomic scanning (RLGS) and arbitrarily primed PCR (AP-PCR) are genome wide techniques, often methylation sensitive restriction enzyme based, for analyzing the DNA methylation status of CpG islands [459]. Other high throughput techniques including array based tests, MethyLight, MALDI-TOF mass spectrometry and next-generation sequencing approaches based on bisulfite conversion are increasingly being utilized and will result in better understanding of lung cancer epigenomics [460–462]. Nonetheless, the ease of detection means that there is great interest in developing potential clinical useful lung cancer biomarkers for diagnosis and prognosis [463, 464].

28.6.3 DNA Hypomethylation

The link between cancer and abnormal methylation has been known since 1983, with the demonstration that cancer genomes are relatively hypomethylated compared to normal counterparts [465]. Hypomethylation in cancer cells is thought to be primarily due to loss of methylation from repetitive regions of the genome, with resulting genomic instability [452]. Apart from global genomic demethylation which in many cancers is an early event, gene specific hypomethylation also occurs which can result in functional changes in gene expression. Studies of oncogene transformed normal human bronchial epithelial (NHBE) cells and clinical lung cancer samples have demonstrated alterations in methylation [466, 467] during lung carcinogenesis. The global demethylation is known to results in the derepression of parasitic DNA, loss of imprinting, and upregulation of the expression of a number of usually silent genes. Examples of genes altered in these ways include loss of imprinting of the H19, IGF2, and MEST genes. Imprinting is the epigenetic modification in a specific parental chromosome that leads to differential expression of the two alleles in the offspring, thus loss of imprinting is loss of the normal allele specific gene expression, which may result in deregulated cell growth. Other genes upregulated as a result of global hypomethylation include those encoding cancer testes antigens (CTAs) proteins including the MAGE family [453]. Surrogate markers of global hypomethylation including repetitive elements such as long interspersed nuclear element 1 (LINE-1) and Alu elements which constitute approximately 30 % of the genome [468] have been implicated in several cancer types [469]. Recent investigations of LINE-1, have demonstrated its potential utility as a prognositic marker for stage IA lung cancer showing poorer survivals in subjects with LINE-1 hypomethylation [470]. LINE-1 hypomethylation also appears to be strongly associated with genomic instability [468].

28.6.4 DNA Hypermethylation

In contrast, site-specific hypermethylation of CpG islands in gene promoters is now the most well characterized epigenetic modification in cancer. It is found in nearly every human cancer type and is associated with transcriptional silencing of gene expression. The genes silenced by promoter hypermethylation tend to be tumor or growth suppressor genes, and is an alternative to the classic loss of one TSG and mutation of the other to satisfy Knudson's two hit hypothesis. Indeed there are regions of chromosomes where allele loss and hypermethylation may be the predominant method on TSG inactivation, e.g., RASSFI1 at chromosome 3 CDKN1A and HIC1 are 17p13.3. It is known that exposure to cigarette smoke induces lung cancer in mice via both genetic and epigenetic pathways [471]. Indeed some of the DNA methylation changes involve the same genes that are altered in human lung cancers [472]. There are now many reports of somatically acquired DNA methylation in the genes involved in lung cancer. We have reported on methylation specific PCR to examine gene promoter methylation in lung cancer. DNA was examined from 107 resected NSCLC and corresponding normal lung tissue [473–475]. Methylation in the tumor samples was detected in 40 % for RARB, 26 % for TIMP-3, 25 % for CDKN2A, 21 % for MGMT, 19 % for DAPK, 18 % for ECAD, 8 % for p14 ARF, and 7 % for GSTP1, whereas it was not seen in the vast majority of the corresponding non-malignant tissues. A total of 82 % of the NSCLCs had methylation of at least one of these genes; 37 % had one gene methylated, 22 % had two genes methylated, 13 % had three genes methylated, 8 % had four genes methylated, and 2 % had five genes methylated. Aberrant CDKN2A and FHIT methylation corresponded with downregulation [473, 476] of gene expression. The advent of whole-genome methylation

profiling has provided new means of identifying novel methylation biomarkers. Rauch and colleagues utilized this technology to characterize DNA methylation changes in the genome of lung SCC [477] identifying 57 CpG islands consistently hypermethylated in all samples. Most of these mapped to homeobox genes which are increasingly being implicated in lung carcinogenesis [478]. Twelve of the 57 CpG islands were independently validated using combined bisulfite restriction analysis (COBRA) with methylation frequencies ranging from 70 to 100 % [477]. Whole genome methylation profiling has also been used to investigate the role of methylation in radiosensitivity of cancer cells [479]. Kim and colleagues identified 1091 genes differentially methylated between cell lines treated with ionizing radiation and normal lung cell lines concluding that examination of key differentially methylated genes in radiosensitive patients is necessary considering the use of DNA methylating agents currently in clinical use [479]. The Cancer Genome Atlas (TCGA) project has also provided extensive insights into epigenomic changes occurring in lung adenocarcinomas and squamous cell carcinomas [367, 480]. Assessment of 230 lung adenocarcinomas using Illumina Beadarray technology identified a distinct CIMP positive phenotype for lung adenocarcinomas while interrogation of 178 lung squamous cell carcinomas, showed that DNA hypermethylation was accompanied by distinct changes in mRNA expression [367, 480]. Similarly, methylation differences have been associated with cisplatin resistance, and prognostic methylation signatures identified for early stage tumors [481, 482]. In addition, several groups have identified differences in the methylation profiles of smoking and never smoking lung adenocarcinomas, with Tan et. al. identifying a potential diagnostic signature that could distinguish smoking related lung adenocarcinomas with a sensitivity of 88.9 % and specificity of 83.2 % [483, 484]. Several studies have also used integrative approaches to identify methylated candidates accompanied by concordant changes in mRNA expression [481, 485, 486]. The explosion in methylation based studies, highlights the potential for DNA methylation changes to be used as diagnostic and prognostic biomarkers in NSCLC. Thus, we and others have documented examples of epigenetic gene silencing by de novo methylation of TSGs in lung cancers, e.g., RB1, VHL, CDKN2A, DAPK, GSTP1, and MGMT [473–475]. Conversely in SCLC, regional hypermethylation has been found at chromosome 3p, but the precise gene target is uncertain [487]. Many other genes are now shown to be methylated to varying degrees in the different subtypes of lung cancer, from primary lung cancers and also lung cancer cell lines. These include genes such as TSLC1 [488]; CDH13[489], hSRBC [490], SPARC [491], DBC1 [28], TCF21 [492], LHX6 [493], and KEAP1 [494] among others. The genes altered by DNA methylation include those involved in cell cycle regulation (e.g., CDKN2A), DNA repair (e.g., MGMT), apoptosis (e.g., DAPK, caspase 8, FAS, TRAILR1), RAS signaling (RASSF1A, NORE1A), and invasion (e.g., cadherins, TIMP3, laminin family) with more detailed lists available from reviews [464, 495]. Some of these pathways affected by epigenetic change are those described as being hallmarks of cancer [5].

28.6.5 Histone/Chromatin Modifications

Chromatin remodeling and histone modifications including methylation, acetylation, and phosphorylation contribute to gene silencing and activation. Mutations, amplifications, and other genomic alterations can disrupt the balance between histone deacetylases (HDAC) and histone acetylases (HATs) resulting in repression or activation of genes [496]. Hypoacetylation may result in repression of tumor suppressor gene function through activation of HDACs and suppression of HATs while hyperacetylation can activate genes that would normally be silenced. Suberoylanilide hydroxamic acid (SAHA), a novel HDAC inhibitor, has been shown to inhibit tumor cell growth by decreasing the number of cells in S-phase [497] and decreasing tumor development in mice treated with the tobacco specific carcinogen 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) [498]. Other HDAC inhibitors including CI-994, trichostatin A, and OSU-HDAC-44 have also been shown to significantly decrease tumor cell growth in NSCLC [499–501]. Interestingly, the novel HDAC inhibitor YCW1 has been shown to have synergistic effects with cisplatin, inhibiting tumor growth and significantly suppressing lung cancer metastases via inhibition of the focal adhesion complex [502]. Therefore, HDAC inhibitors may be useful in increasing histone acetylation and gene transcription through inhibition of lung cancer cell growth.

28.6.6 microRNAs

miRNAs are a recently discovered family of small, RNA molecules encoded in the genomes of plants and animals. These highly conserved ~21-mer RNAs regulate gene expression by binding to the 3′-untranslated regions (3′-UTR) of specific target mRNAs. Acting as a crucial member of the RNA Induced Silencing Complex (RISC), miRNAs control gene expression at the posttranscriptional level by degrading or repressing target mRNAs [503–506]. The biogenesis and control of miRNAs involves complex regulatory networks that control cropping and dicing [507]. miRNAs are expressed in animal cells and are dynamically regulated in response to physiological and developmental cues. It is thought that there are cell-type specific miRNA milieus with unique sets of miRNAs controlling gene expression.

Furthermore, each miRNA may, in computational predictions, have as many as hundreds of target genes—if correct, this means that up to a third of protein-encoding genes are regulated by miRNAs in humans [508]. There is mounting evidence of the importance of miRNA mediated gene regulation in human cancers. Firstly, miRNAs participate in the regulation of a wide range of cellular pathways including development, proliferation, differentiation, apoptosis, angiogenesis, methylation, metastasis, and invasion [509–518]. Second, miRNA expression profiling shows differential expression of nearly all miRNAs across cancer types, expression profiles parallel the developmental origins of tumors, expression patterns reflect the mechanisms of transformation, and extensive dysregulation of miRNA expression in tumors compared with normal tissues [519]. Third, several genes implicated in human cancers have been experimentally validated as miRNA targets including PTEN TSG, SMAD-1 transcriptional regulator, polycomb gene EZH2, and MYCN basic HLH transcription factor proto-oncogene [520, 521]. Furthermore, miRNA genes are located nonrandomly in the genome. Although only representing 2–3 % of all human genes, more than half of them are clustered at fragile sites, minimal regions of LOH, and breakpoint sites which are implicated in cancer [522, 523]. In addition to this association with genomic regions involved in cancers, aberrant methylation, SNPs, mutations, miRNA regulation by cancer-associated transcription factors, and dysfunctional miRNA biogenesis, have all been implicated in their altered expression in human malignancy [524–529].

The miR-17-92 cluster of miRNAs is highly expressed in many lymphomas that contain amplified 13q31-31 chromosomal sequences [530]. When co-expressed with MYC in hematopoietic stem cells in mice, miR-17-92 appears to augment the oncogenic effect of MYC. This miRNA cluster, when upregulated by MYC, actually translationally downregulates a MYC transcriptional target, E2F1 [528]. These interesting findings suggest that this cluster may act as either an oncogene or a TSG, depending on circumstances, functioning within a regulatory network with c-Myc and E2F1 to balance cell death and proliferation [528, 531]. Nonetheless overexpression of an oncogenic miRNA may therefore posttranscriptionally downregulate target TSGs [532]. In keeping, miR-17-92 is similarly implicated in lung cancer, with miR-17-92 cluster overexpression and occasional gene amplification, especially in small-cell lung cancer [511].

Conversely oncogenes may also be regulated by miRNAs and miRNAs are frequently downregulated in cancers, with loss of a tumor suppressing (TSG) miRNA potentially causing posttranscriptional overexpression of target oncogenes—the archetype being RAS and let-7. Several studies have demonstrated that let-7 expression is reduced in lung cancers and that let-7 causes growth inhibition and regulates the RAS oncogene in vitro [533–535]. These findings, together with the demonstration of RAS overexpression in cancers with low let-7, strongly implicate let-7 as a tumor suppressor in lung, whereby downregulation of let-7 causes increased expression of the RAS oncogene, and thus contributes to carcinogenesis [527, 535]. Moreover, some let-7 family members are located in genomic regions commonly deleted in lung cancer and reduced let-7 expression correlated with a worse prognosis in resected lung cancers [522, 535].

Microarrays can also be used to detect miRNA deregulation in cancers [536]. Comparing primary lung cancers and corresponding lung tissues, differentially expressed miRNAs appear to be associated with FRA fragile sites [537]. Others were located in regions deleted or amplified in various types of cancers. For example mir-21 at 17q23.2 was amplified and upregulated in neuroblastoma and lung cancer [527], and mir-126 at 9q34.3, was associated with FRA17B and downregulated in NSCLC and hepatocellular carcinoma [537]. Of clinical importance is the finding that high mir-155 and low let-7a-2 expression correlated with reduced survival in adenocarcinomas [537]. Numerous studies have now published potential miRNA gene signatures for prediction of outcome and survival in lung cancer patients [538–542], however little consistency has been observed between these signatures. This may be due to differences in methodology (microarrays compared to real time PCR), sample type (tumor tissue compared to serum) or cohorts (ethnicity). Differences in miRNA expression profiles between histological subtypes of lung cancer have sparked interest in identifying single miRNAs or miRNA signatures for histological differentiation. Indeed, miR-205, has been reported as a lung squamous cell carcinoma (SCC) specific miRNA, able to identify lung SCCs with 96 % sensitivity and 90 % specificity [543].

Recent advances in our understanding of the involvement of miRNAs in lung carcinogenesis have demonstrated that miRNA expression is altered from the early stages of bronchial carcinogenesis [544]. Furthermore, dysregulated miRNA expression has been shown to be associated with exposure to established or potential lung carcinogens, including cigarette smoke and diesel exhaust particles [545–547]. Schembri et al. observed downregulation of miR-218 in human bronchial epithelial cells exposed to cigarette smoke extract [545]. Subsequently, our work demonstrated significant downregulation of miR-218 in the tumors of smokers compared to never smokers [546] and Wu et al. reported downregulation of miR-218 in combination with upregulation of its target gene Paxillin as an independent predictor of survival in NSCLC [548]. Specific miRNAs have also been implicated in EGFR and p53 signaling pathways involved in response to chemotherapeutic agents such as EGFR tyrosine kinase inhibitors, Carboplatin and Cisplatin [549–554]. Further exploration of the role these miRNAs play may lead to the identification of novel approaches to maximize chemosensitivity and reduce development of chemoresistance.

Finally, recent reports have demonstrated that these single stranded miRNAs are able to be detected in multiple clinical specimens including whole blood, serum, plasma, sputum and malignant effusions [555–560]. This important discovery enhances the potential for development of clinical miRNA biomarkers. Despite these significant advances in our understanding of miRNA biology in lung cancer, further investigation is required to fully demonstrate the extent of their involvement in lung carcinogenesis and potential use as diagnostic or prognostic biomarkers and novel therapeutic agents in lung and other human malignancies.

28.7 Tobacco Smoke Carcinogens

It is thought that tobacco smoke is responsible for 85–90 % of all cases of lung cancer [561]. Tobacco smoke contains thousands of substances including carcinogens, co-carcinogens, and tumor promoters. The polycyclic hydrocarbons (such as benzo(a)pyrene), nitrosamines, and aromatic amines are the three major classes of carcinogens in tobacco smoke. There has been much study of the nitrosamines which are derived from nicotine during the burning of tobacco, especially 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK). Indeed, NNK and its metabolite, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL), are potent carcinogens that are specific for the lung in rodents. The carcinogenic effects of tobacco smoke in the lung involve the induction of carcinogen-activating and inactivating enzymes, as well as covalent DNA adduct formation which may result in DNA misreplication and mutation. DNA adducts have been identified in the bronchial tissue of lung cancer patients and their levels correlate with the amount of tobacco smoke exposure. Furthermore, benzo(a)pyrene, a major cigarette smoke carcinogen, was shown to form adducts selectively along the TP53 gene of bronchial epithelial cells, at the nucleotide positions known to be the major mutational hot spots in lung cancer [562]. Thus, targeted adduct formation rather than phenotypic selection may determine the pattern of TP53 mutations in lung cancer, and the data provided a direct etiological link between a defined chemical carcinogen and lung cancer.

28.8 Lung Cancer Susceptibility: Candidate and Genome Wide Association Studies (GWAS)

Only a proportion of smokers develop lung cancer despite the fact that tobacco smoke is implicated in most cases of lung cancer. Clearly, there are other important factors operating apart from the simple inhalation of tobacco smoke. It has, for instance, been postulated that individuals may exhibit genetic polymorphisms in carcinogen metabolizing pathways that would lead to inherited differences in lung cancer risks associated with tobacco smoking. The relationships of human lung cancer to polymorphisms of phase I pro-carcinogen-activating and phase II-deactivating enzymes and intermediate biomarkers of DNA mutation, such as DNA adducts, oncogene and tumor suppressor gene mutation, and polymorphisms have been compiled [563].

The important genetic variations in lung cancer include polymorphisms at the cytochrome P450 gene (CYP) loci and the glutathione S-transferases (GST) M1 gene cluster. An important enzymatic group relevant to lung cancer includes the phase II GST enzymes, which are encoded by a multigene family whose proteins serve to detoxify mutagenic electrophiles [564]. The gene products are suggested to play a part in detoxifying epoxides of certain carcinogenic polycyclic aromatic hydrocarbons (PAH). These enzymes conjugate glutathione to a substrate generally resulting in its inactivation and excretion, although in certain cases this can lead to activation of a pro-carcinogen to a mutagenic product. Four gene families are known (A, M, P, and T) and large inter-individual variations in enzyme activity are known to exist for several GSTs [565]. The GSTM1 locus is homozygously null or deficient in approximately 40–50 % of the population. Several case–control studies have linked the null phenotype to an increased risk of lung cancer [566, 567], but there have also been conflicting studies [568, 569]. A meta-analysis of 12 comparable studies suggested that GSTM1 null is overrepresented in lung cancer cases with an overall odds ratio (OR) of 1.41 (95%CI of 1.23–1.61), which did vary depending on ethnic origin, being lower in Caucasians (OR 1.17) [570]. Although the increased risk was modest, it potentially translates to a large number at the population level, and the authors suggested that ~17 % of new lung cancer cases could be attributable to GSTM1 deficiency. As GSTM1 is only weakly expressed in the lung, interest has also focused on the protein product of GSTP1, which in fact, is the major GST protein in the lung [565, 571]. This enzyme has activity for many epoxides of PAH and could theoretically compensate for loss of GSTM1 activity. Increased expression of the GSTP1 gene has been reported in lung tissue [565]. In the only study of lung cancer, the combination of GSTM1 null and the G allele at a GSTP1 codon 104 polymorphism (A to G substitution replacing isoleucine with valine) was shown to be associated with more hydrophobic-DNA adducts and lung cancer risk in Norwegian patients [572]. Importantly, this polymorphism is known to functionally change enzyme kinetics [573].

The structural gene for the phase I enzyme, cytochrome CYP1A1 which catalyzes a range of human carcinogens, has a MspI restriction polymorphism (m2) associated with an amino acid substitution in the enzymatically active site that results in a protein of high activity [574]. In the Japanese

population, this polymorphism has been shown to be associated with an increased lung cancer risk [575]. On the other hand, the data in Caucasians is controversial as this association was not demonstrated in some older studies of Caucasians where the polymorphism is much rarer [576–578]. On the other hand, a study of 490 Caucasians found an estimated OR of 2.08 for the CYP1A1 m2 allele (heterozygotes and homozygotes) and lung cancer development [579]. Finally, NSCLC patients with at least one susceptible allele of the MspI polymorphism were associated with a shortened survival [580]. Another polymorphism at residue 462 (Ile/Val) of the CYP1A1 heme-binding region, has also been associated with lung cancer risk in Japan [581]. The Val protein demonstrates twice as much activity as the isoleucine protein [575] but there appear little or no in vitro difference in their kinetic properties [582, 583]. In any case, the results are mixed as CYP1A1 Val/Val was twice as prevalent in Brazilian lung cancer patients [584], borderline in a German cohort [585] and not increased in a Finnish cohort [576]. In our case–control study of predominantly Caucasian Australian NSCLCs, we reported that carriers of the valine allele (Ile/Val or Val/Val genotypes) were significantly overrepresented even when adjusted for potential confounders, particularly in women [586]. In the complex process of multistep carcinogenesis, it is unlikely that a single factor can completely account for an individual's susceptibility to lung cancer. For any given exposure to an environmental carcinogen, it is more likely that it is the interaction between several genetic susceptibility factors that determines the risk of lung cancer. Consequently, the possibility that it is the combination of the bioactivating phase I (P450) and the inactivating phase II (e.g., GSTs) carcinogen metabolizing enzyme polymorphisms that is crucial to lung cancer risk is biologically plausible and attractive. The CYP1A1 MspI polymorphism in conjunction with the GSTM1 null genotype has been reported to carry a ninefold increased risk of lung cancer [567]. This was confirmed in a second cohort of Japanese subjects where the OR of a combined CYP1A1 m2/m2 and GSTM1 null genotype versus nonsmoker controls was 21.9 (95 % CI 4.7–112.7), albeit lowered when smoking controls were compared. In the only non-Japanese cohort to be tested, a Swedish study found too few appropriate subjects for analysis [577]. Thus, whilst the data suggests a link for combination genotypes and lung cancer risk in Japanese populations, the relatively lower prevalence of the m2 and Val allele in non-Japanese populations (estimated 12 % and 3–16 % respectively) [563] has meant that it may not have been adequately studied in Caucasian populations. We have studied CYP1A1 haplotypes in a case–control study of 1040 non-small-cell lung cancer (NSCLC) cases and 784 controls to investigate three CYP1A1 variants, CYP1A1*2A (rs4646903; thymidine to cytosine substitution at nucleotide 3801 (3801T>C)), CYP1A1*2C (rs1048943; 2455A>G; substitution of isoleucine 462 with valine (exon 7)) and CYP1A1*4 (rs1799814; 2453C>A; substitution of threonine 461 with asparagine (exon 7)) [587]. CYP1A1 haplotypes (in allele order CYP1A1*4, CYP1A1*2C, CYP1A1*2A) CGC and CGT were associated with an increased risk of lung cancer, whereas AAT was associated with decreased lung cancer risk in this population. Thus, risk haplotypes were identified for CYP1A1 in NSCLC, and CYP1A1 polymorphisms were identified as a minor risk factor for NSCLC. In the Australian setting, we reported that another pair of polymorphisms in carcinogen metabolizing enzymes (CYP1A1 Ile462Val and MPO G-463A) interacted to increase risk of adenocarcinoma [588] supporting the concept that multiple genes of modest effect can interact to confer genomic-based susceptibility to lung cancer. In the context of the explosion of epidemiologic studies on the prevalence of gene variants and their associations with human lung cancer that will result from completion of the human genome sequence a proper assessment of genome based risk will require collaborative efforts such as the Human Genome Epidemiology (HuGE) Network and careful meta-analyses of many primary studies [589].

CYP2D6 (debrisoquine 4-hydroxylase), another P450 metabolizing enzyme, bioactivates nicotine as well as NNK. The relationship between lung cancer risk and the CYP2D6 polymorphism has been the subject of numerous studies and is still controversial [590, 591]. While some studies have suggested a reduction in the risk of lung cancer with the poor metabolizer phenotype and/or genotype [592], others have indicated little or no role for the CYP2D6 polymorphism in lung cancer [591, 593, 594].

In addition to linkage studies and candidate gene approaches, the genome-wide association study (GWAS) methodology uses an association testing approach on a genome-wide scale, testing large numbers of SNPs using standard microarray platforms [6]. The key advantage of this approach is that it enables testing of SNPs across the entire genome without needing a prior hypothesis about the identity of causal genes [6] as traditionally done through genetic association studies. Disadvantages include lack of coverage of rare variants, or ability to analyze gene-gene interaction, gene-environment interaction, epigenomics, or other principles that can explain variance in heritability.

A number of genome-wide association studies have now been published for lung cancer (Table 28.5). The most frequent genetic association for lung cancer in smokers was observed with SNPs in chromosomal region 15q25 containing the genes for the neuronal nicotinic acetylcholine receptor (nAChR) subunits (cholinergic receptor, nicotinic, alpha 3 and 5: *CHRNA3* and *CHRNA5*). This chromosomal region has also been associated with smoking behavior and intensity, e.g., cigarettes per day, in a number of GWAS. Whilst the association of smoking behavior with nicotine receptor SNPs could partly explain the relationship with lung cancer, many of the GWAS and subsequent validation studies [595]

Table 28.5 Genome-wide association studies of lung cancer

Study	Lung cancer cases (discovery set)[a]	Controls (discovery set)	Arrays (nos. of SNPs)	Chromosomal regions and main associated genes
Spinola [599]	335 Smokers	338 Smokers	Affymetrix (116, 204)	10p *KLF6*
Amos [600]	1154 Smokers	1137 Smokers	Illumina (317, 498)	15q *CHRNA3*
Hung [601]	1989 Smokers	2625 Smokers	Illumina (139, 317)	15q *CHRNA3, CHRNA5*
Liu [602]	194 with familial lung cancer	219 Smokers and nonsmokers	Affymetrix (500, 568, 906, 703)	15q various genes
Thorgeirsson [603]	1024 Smokers	32,244 Controls	Illumina (207, 306)	15q *CHRNA3*
McKay [604]	3259 Smokers	4159 Smokers	Illumina (194, 315)	5p *TERT-CLPTM1L,* 15q *CHRNA3*
Wang [605]	1952 Smokers	1438 smokers	Illumina (511, 919)	5p *CLPTM1L*, 6p *BAT3-MSH5,* 15q *CHRNA3*

have adjusted for measures of smoking intensity. With this adjustment, the association with nicotine receptor SNPs has remained positive in many studies. The mechanism postulated is that variation in the nicotine receptor pathway, due to genetic variation, is contributing directly to lung cancer susceptibility, in addition to or independent of smoking intensity. Another chromosomal region, at 13q, has been associated with lung cancer in never smokers [596].

28.9 Familial Lung Cancer

Hereditary predisposition to lung cancer is rare. However, analysis of the genomic aberrations provide insight into lung cancer susceptibility and biology. Gazdar et al. reported a 29-year-old female proband with a minimal smoking history and a 4.4 cm lung adenocarcinoma [597]. *EGFR* analysis of

the tumor revealed an L858R mutation, as well as a T790M mutation which was also detected in her germ line DNA in peripheral blood monocytes. 14 of the tested family members over a number of generations were also carriers, and of these, three, who were never smokers, also developed lung cancer (in addition to the proband). Yamamoto et al. reported a family of Japanese descent with multiple members with lung adenocarcinoma, inherited in an autosomal dominant pattern [598]. The proband was a 53-year-old lady who was a very light former smoker with multiple lung adenocarcinomas. The use of whole-exome sequencing found a novel germ line mutation (G660D) in the transmembrane domain of the human epidermal growth factor receptor 2 (*HER2*) gene, which, on functional testing, activated akt and p38. Overall, these reports of germ line mutations in familial lung cancer are very uncommon and their applicability to sporadic lung adenocarcinoma remains to be determined.

28.10 Differentiation Factors

Some genetic abnormalities of oncogenes and tumor suppressor genes are common to all lung cancers but others appear more specific for certain histological subtypes. RAS mutation is specific to NSCLC, RB1 mutation relatively predominant in SCLC and CDKN2A/CDKN2A mutation mostly occurs in NSCLC. Aberrant expression of CD44 is considered to be a marker for NSCLC [4, 619]. It is possible that such specificities may be important for the phenotypical development of that histological subtype, but the possibility that it is a secondary phenomenon remains. In support of the former paradigm, the in vitro introduction of oncogenes and tumor suppressor genes into lung cancer cell lines can induce phenotype transition among subtypes of lung cancer. For instance, the v-Ha-RAS gene was shown to change SCLC phenotype of lung cancer cells into a NSCLC phenotype [619].

A few normal bronchial epithelial cells and a substantial proportion of lung cancers, particularly exemplified by SCLC, exhibit a neuroendocrine phenotype. The genetic factors responsible for neuroendocrine differentiation in either normal lung or lung cancer are not well elucidated. Candidate molecules include the achaete-scute family of basic helix-loop-helix transcription factors which play a critical developmental role in neuronal commitment and differentiation of both Drosophila and vertebrates. The human achaete-scute homologue-1 (hASH1) gene is selectively expressed in normal fetal pulmonary neuroendocrine cells, as well as in lung cancers with neuroendocrine features [620]. Additionally, pulmonary neuroendocrine cells appear absent in newborn mice with ASH1 disruptions and antisense mediated ASH1 depletion from lung cancer cells results in a significant decrease in the expression of neuroendocrine markers [620].

28.11 Transgenic Animal Models

Transgenic and knockout mice are being increasingly used to understand lung cancer pathogenesis. Different transgenic animals have been generated which show dramatic developmental abnormalities including lung structure, suggesting crucial roles of the genes in normal lung development [97]. Early animal models included mice overexpressing mutant alleles of TP53, lacking E2F1, or which express a truncated nuclear retinoic acid receptor β (RARβ) [210, 240, 621].

Since then an increasing variety of transgenic animals have been developed for human lung cancer [622]. Expectedly perhaps, many of molecular aberrations identified in human tumors or cell lines are also found in the mouse models. There are mouse models for spontaneous and chemically induced lung tumors. These make use of the inherent differences in susceptibility to and incidence of spontaneous lung tumors between different inbred strains such as A/J or SWR mice [622]. Indeed three pulmonary adenoma susceptibility (PAS) loci were mapped from recombinant inbred strain crosses derived from susceptible A/J and resistant C57BL/6 strains [623]. Transgenic murine lung cancer models are based on the introduction of human lung cancer genetic aberrations into the mouse germ line or pulmonary tissue. The resulting murine lung tumors resemble in many aspects their human lung tumors counterparts. Various transgenic models have also been developed where oncogene expression is targeted to a specific subset of lung epithelial cells, thus allowing us to examine the role of these oncogenes in lung tumor initiation and progression. The models include transgenic (CC10, Sp-C, TGFβ, RARB, HRas), conditional transgenic (KRas), regulatable by mifepristone or doxycycline (Sp-C, FGF), spontaneous knockin (KRas and Kras/Trp53−/−), and conditional knockouts (Trp53, RB1) [622]. Interestingly, most models are for adenocarcinoma, with no currently reported somatic models for SCCs, and only a single model for SCLC (several others for neuroendocrine lung cancers).

Transgenic animal models are likely to contribute in the future to the currently limited knowledge of the functional relationship between the genes required in normal lung development and those mutated in lung cancer. These will be useful for many purposes, including testing agents for chemoprevention, e.g., with EGFR inhibitors [624] and for better understanding of the biology of oncogene stimulation (e.g., the requirement for continuous stimulation in a KRas adenocarcinoma model [625], experimentally supporting the oncogene addiction paradigm). Another important goal is improved understanding of the metastatic cascade through the generation of compound, inducible mouse models with relevant conditional dominant or recessive oncogenes that lead to a metastatic phenotype.

28.12 Telomerase Activation

Vertebrates have special structures at the ends of their chromosomes (telomeres) which are composed of 5–15 kb pairs of a guanine-rich hexameric repeat (TTAGGG)n. In normal somatic cells there is a progressive degradation of telomeres with aging. The loss of these telomeric repeats during normal cell division is thought to represent an intrinsic cellular clock by gradually shortening the telomere. The progressive telomere shortening is believed to lead to senescence and thus govern normal cellular mortality. Germ cells and some stem cells compensate for the telomere shortening as they possess a telomerase activity which replaces the hexameric repeats at the chromosomal ends. Normal somatic cells however, do not express telomerase, presumably because they do not need to replicate or only replicate to a finite degree. Thus, immortal cells may be able to proliferate indefinitely because they express telomerase activity whereas the vast majority of normal adult cells do not. The length of terminal telomeric restriction fragments is altered in various types of tumors, including lung cancer. Telomere shortening was detected in 14 of 60 primary lung cancers, while 2 cases showed telomere elongation [626].

Telomerase is upregulated or reactivated in almost 90 % of all human cancers. Approximately all SCLC and 80–85 % of NSCLC were demonstrated to express high levels of telomerase activity as measured by a highly sensitive telomere replication amplification protocol (TRAP) [626–628]. A high level of telomerase activity was associated with increased cell proliferation rates and advanced pathologic stage in primary NSCLC [628]. In addition, telomerase activity and/or expression of the RNA component of human telomerase were frequently dysregulated in carcinoma in situ lesions, implicating its early involvement in the multistage development of lung cancer [629]. Catalytic subunits of human telomerase have been cloned and appear expressed in human cancers [630]. Their expression and regulation need to be studied in lung cancer. It also remains to be seen whether a novel mechanism for lengthening their telomeres, named ALT (Alternative Lengthening of Telomeres) found in some immortalized cell lines with no detectable telomerase activity, is relevant to those lung cancers without high levels of telomerase expression [631, 632].

28.13 Lung Cancer Stem Cells

Somatic stem cells can be regarded as cells with a relative undifferentiated phenotype but with multipotent differentiation capacity. Other features include a low rate of self-renewal, an extended life span, and existence in a specific microenvironment, termed stem cell niches [633]. The cancer stem cell hypothesis suggests that tumors are derived from a single cell which is transformed into a cancer-initiating cell (cancer stem cell) that has the capacity to give rise to another stem cell and also a progenitor cancer cell that proliferates and form tumors [634]. This concept is important to cancer medicine since one explanation for the observation of cancer recurrence despite curative intent chemotherapy or radiotherapy has been postulated to result from survival of cancer stem cells because of their low proliferation rate and potential drug resistance.

Distal airway epithelial cells have the capacity to self-renew after naphthalene inhalation, implying the presence of stem cells in the pool of (neuro) epithelial cells along the bronchial lining [635]. Stem cells can produce daughter cells or transient-amplifying (TA) cells, which often have a limited proliferation capacity and a distinct marker profile before they enter a terminal differentiation state. In the lung, Clara and alveolar type II cells seemingly fit this TA cell phenotype since both do proliferate but finally differentiate into ciliated and alveolar type I cells, respectively.

Direct proof of lung cancer stem cells is so far lacking. However, a population of bronchoalveolar duct junction cells called bronchoalveolar stem cells (BASCs) have been isolated—these were resistant to bronchiolar and alveolar damage, proliferated during epithelial cell renewal in vivo, exhibited self-renewal and were multipotent in clonal assays [636]. Moreover, BASCs expanded in response to oncogenic K-ras in culture and in precursors of lung tumors in vivo, leading to the hypothesis that BASCs are a stem cell population that maintains the bronchiolar Clara cells and alveolar cells of the distal lung and that their transformed counterparts give rise to adenocarcinoma. Recently, a small sample of lung cancers were shown to displayed a small side population subset of cells where the side population phenotype is linked to their ability to efflux Hoechst 33342 dye, a characteristic found in stem cells [637].

Stem cells do not generally exhibit DNA hypermethylation at tumor suppressor genes [638]. Transcription of these genes is governed by patterns of promoter chromatin histone methylation under the control of polycomb proteins [639, 640]. Malignant stem cells have additional repressive histone marks of the type associated with aberrant DNA hypermethylation in adult cancers. In colorectal cancers these same marks occur more frequently in promoters of genes specifically methylated in tumors than in genes with a constitutive methylation state [641]. In lung cancer a high proportion of hypermethylated loci have at least one polycomb repressive complex 2 mark [642], which is further evidence of the presence of a stem cell phenotype within lung cancers. Biological properties specific to lung cancer stem cells present opportunities to target this cell population with the aim of preventing tumor reconstitution after treatment.

28.14 Evading Host Immunity

The major role of the immune system is to distinguish between self and nonself. The concept of immune surveillance postulates that tumor cells express various novel tumor-specific epitopes which represent potential immune non-self-targets. Thus, established cancers are thought to have effectively avoided immune recognition and elimination. Several different genetic mechanisms for escaping this immune surveillance have been elucidated in lung cancer patients. It has been shown that the class I major histocompatibility complex (MHC) antigen expression is downregulated in human cancers including lung cancer [643, 644]. These class I MHC molecules mediate presentation of endogenous antigenic peptides to cytotoxic T-lymphocytes. In addition, rare mutations of the β2-microglobulin gene whose protein product comprises a component of the class I molecules, have also been reported in lung cancer cells [645]. Indeed, reintroduction of the β2-microglobulin gene into the mutated cells restored the MHC class I expression [645]. For the stable assembly of MHC class I complex and subsequent recognition by cytotoxic T-lymphocytes, transporters associated with antigen presentation (TAP1 and TAP22), are necessary for conveying intracellular peptides into the endoplasmic reticulum for complex formation with class I MHC. The TAP1 transporter has been shown to be downregulated in lung cancer [644, 646]. Although the TAP1 gene does not appear somatically mutated in lung cancer, one SCLC cell line was found to be transcriptionally silent for its wild-type allele and only expressed a genetically defective TAP allele, leading to an acquired loss of antigen presenting ability [647]. The Fas (CD95) system is an important mediator of T-cell cytotoxicity. The FasL ligand can induce activated T-cells to undergo apoptosis, and this mechanism is thought to contribute to development of immune privilege sites. It is notable that lung cancer cells (both lines and primary tumors) express FasL and coculture of lung cancer cell lines with a Fas-sensitive human T-cell line induced apoptosis in the T-cells [648]. Thus, the expression of FasL by neoplastic lung cells can be speculated to be a potential mechanism for evading host immunity by the peripheral deletion of tumor-reactive T-cell clones [649, 650].

28.15 Tumor Angiogenesis

For either primary or metastatic tumors to grow, it is essential that they receive an adequate blood supply which is provided by recruiting new blood vessels from the surrounding host vasculature. The development of new vessels toward and within the tumor is required for adequate nutrient delivery and necessary at the beginning and end of metastatic dissemination. Without angiogenesis, tumors are unable to grow larger than 2–4 mm in diameter. During angiogenesis, normally quiescent endothelial cells become invasive, breaching their own basement membrane to invade the stroma during the development of new capillary buds. The number of microvessels in the tumor area, representing an index of angiogenesis, has been shown to correlate with an increased risk of metastatic disease and a worse overall survival for several types of human cancer including lung cancer. The higher the microvessel density, the poorer is the clinical outcome [651, 652]. The process of tumor angiogenesis is complex and controlled by a diverse family of inducers and inhibitors governing angiogenesis and regulating endothelial cell proliferation and migration [653]. Vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) are amongst the most important tumor angiogenesis inducers. In lung cancer, VEGF expression was significantly lower in TP53-immunohistochemically negative (wild-type) and lowly vascularized NSCLCs [654, 655]. VEGF expression was higher in lung cancers with nodal metastasis than those without [656]. In squamous cell lung carcinomas, VEGF expression was inversely correlated with overall survival of patients and Flt-1, the receptor of VEGF, was also shown to be frequently expressed [657]. Both the basic fibroblast growth factor (bFGF) and its receptor (FGFR-1, Flg) are variably expressed in NSCLCs. Whether there is an association between bFGF expression and prognosis is currently controversial [658, 659]. In either case, expression of another angiogenic/endothelial cell chemotactic factor, platelet-derived endothelial cell growth factor (PD-ECGF, also called gliostatin), correlated with tumor angiogenesis and adverse prognosis in a study of N0 NSCLC patients [660]. Many angiogenesis inhibitors are stored as cryptic parts of larger molecules. These inhibitors include angiostatin, a fragment of plasminogen, and endostatin, a fragment of collagen XVIII. Endostatin administered to Lewis lung carcinoma-bearing mice was shown to regress tumors without inducing drug resistance during six treatment cycles [661]. Another inhibitor, thrombospondin-1 (TSP-1) is regulated by the wild-type TP53, such that loss of TP53 function (a common feature of lung cancers) was associated with a reduction in the levels of this angiogenesis inhibitor [662]. Restoration of TP53 function upregulates TSP-1 and impairs tumor cells angiogenesis. Another angiostatic factor, interferon-γ-inducible protein 10 (CXCL10) was shown to inhibit human NSCLC tumorigenesis and spontaneous metastases [663].

Thus, it is the balance between angiogenesis inducers and inhibitors expressed from tumor cells which appears to affect the ability of the normally quiescent vasculature to form new capillaries [653]. Another example comes from the finding that an imbalance in the expression of the angiogenic or angiostatic CXC chemokine family favors angiogenesis in NSCLC [664]. The isolation and synthesis of molecular

regulators has enhanced our understanding of angiogenesis and, angiogenesis inhibitors as well as inducers need to be carefully studied in lung cancer. Such studies have led to the development of targeted therapies against pro-angiogenic molecules particularly against one of the key mediators, VEGF. Bevacizumab, a recombinant humanized monoclonal anti-VEGF antibody, is the most clinically advanced antiangiogenic agent in NSCLC [665]. In a phase III study, bevacizumab showed significantly improved overall and progression-free survival when used in combination with standard first-line chemotherapy in patients with advanced NSCLC but some tumor-related bleeding adverse events occurred, predominantly those with squamous cell histology or centrally located tumors.

28.16 Conclusions

Our understanding of the role of the molecular genetic changes that occur during lung cancer pathogenesis, although in its early stages, is advancing rapidly with several specific genes and pathways being identified. The gene products are being classified into several important growth and cell cycle regulatory pathways. Some of these markers appear to be important for carcinogenesis in general, whereas others show more frequent involvement in lung cancers.

There has been much emphasis on the molecular diagnosis of early disease or pre-invasive changes. Most cases of lung tumors which are detected by imaging, have grown to at least 1 cm in diameter, with a mass of a gram or more, and contain at least 10^8–10^9 cells, estimated to be about 30 doubling times from single malignant cell. This only leaves a narrow window of opportunity for intervention before the tumor burden reaches the lethal range, about 10^{12} cells (about a kilogram or another 10 doubling times) or metastatic disease develops. In other words, about three quarters of the natural history of the cancer has occurred by the usual time of clinical detection by traditional methods. The considerable number of genetic lesions identified in overt lung cancer justifies attempts to detect corresponding lesions in preneoplastic lung tissue. If there are a few critical and consistent early lung cancer clonal markers, one could envisage an opportunity to detect preneoplastic or early lesions by testing a panel of selected markers. An example frequently cited is the finding of TP53 mutations in a retrospective analysis of sputum samples obtained from patients undergoing screening procedures who subsequently developed lung cancer [666]. The hope is that intervention with chemoprevention or other means can block progression to multiple other genetic lesions in these same cells and the development of overt malignancy. Otherwise early lung cancer biomarkers including genetic susceptibility markers are also likely to impact on clinical efforts to identify people most at risk of lung cancers for most effective and cost-effective screening and early detection techniques such as low dose spiral CT scans.

The challenge is to continue translating understanding of the disrupted cellular physiology into clinical benefit for the patient by expanding the diagnostic and therapeutic armamentarium. Effective strategies may include: early molecular diagnosis; identification of high risk individuals for developing lung cancer; early treatment studies; rational development of novel therapies such as tumor vaccines; genetic inhibition of growth factor loops by regulation of agonists and antagonists and by other mechanisms such as monoclonal antibodies; epigenetic alteration of gene expression such as by alteration of methylation; manipulating intrinsic tumor chemo- or radiosensitivity; blocking the expression of activated oncogenes; and replacing defective tumor suppressor genes. Knowledge from molecular studies has already spawned new agents at the bedside, particularly the targeted therapies of EGFR tyrosine kinase inhibitors, angiogenesis inhibitors, and agents targeted to the EML-ALK and ROS1 fusion abnormalities. Dual specificity or combination targeted drugs are in clinical trials. Individualizing treatment based on molecular tumor characteristics will increasingly become practical, with the ultimate aim of maximizing therapeutic success and minimizing toxicity aided by post-genomic tools such as arrays, proteomics, and animal models. Stem cell directed strategies also appear highly promising, as do emerging immunomodulatory medicines, including monoclonal antibodies that target key immune molecules, anti-CTLA4, anti-PD1/PDL1. So far, these treatments appear to have potential efficacy in metastatic lung cancer in early clinical trials.

Thus, the classic paradigm proposed by Boveri and Little that cancer is essentially a genetic disease at the cellular level, and now confirmed by modern genetic/genomic, epigenetic/epigenomic techniques, and coupled with the emergence of proteomics will afford us new approaches to the prevention, early detection, and treatment of lung cancer. There is now a rational hope that new therapies directed against one or more likely several of these targets that are drivers of the carcinogenic process may be successful in more effectively treating advanced lung cancer.

Molecular Basis of Skin Carcinogenesis

29

Alessia Pacifico, Giovanni Leone,
and Honnavara N. Ananthaswamy

29.1 Introduction

The incidence of skin cancer exceeds the incidence of all other human cancers combined [1]. Epidemiologic, clinical, and biologic studies indicate that solar ultraviolet (UV) radiation is the major etiologic agent in skin cancer development. Wavelengths in the UVB range of the solar spectrum (290–320 nm) are absorbed by the skin producing erythema, burns, immunosuppression, DNA mutations, and nonmelanoma skin cancers (NMSC) [2].

Multiple genetic alterations have been shown to have a direct correlation with cancer development. The majority of these mutations can be found within three categories of genes: proto-oncogenes, tumor suppressor genes, or DNA repair genes. A mutation in one of these groups or any combination can cooperate to induce a neoplastic condition. The proto-oncogenes act as crucial growth regulators in normal cell division, while the tumor suppressor genes act as negative growth regulators [3].

The *p53* tumor suppressor gene is involved in the cell cycle arrest and activation of programmed cell death. Mutations in the *p53* gene have been detected in 50 % of all human cancers and in almost all skin carcinomas [4]. The majority of carcinomas have missense mutations that produce a full-length protein with altered function. Often the other allele is lost resulting in loss of heterozygosity (LOH) which is particularly high (40–80 %) in carcinomas of the colon, lung, and bladder [5]. Several studies have shown that the p53 tumor suppressor gene is susceptible to UV-induced mutations and plays a critical role in the induction of NMSC.

In squamous (SCC) and basal (BCC) cell carcinomas of the skin the frequency of LOH is much lower with a higher proportion of both p53 alleles being independently mutated [6]. Mouse skin models have shown that standard chemical initiation/promotion protocols results in LOH, whereas repeated carcinogen experiments (like UV exposure) results in independent mutations on both p53 alleles [7]. Upon repeated exposure to UV radiation, DNA lesions in the *p53* gene are transformed into mutations, mainly C→T or CC→TT transitions at dipyrimidine sites (UV signature mutations), thereby initiating the molecular process of skin carcinogenesis [8]. Thousands of p53 mutant cell clones are found in sun-exposed skin that appears quite normal. The frequency of UV signature mutations in the *p53* gene is high in precancerous lesions and reaches 50–90 % in human BCCs and SCCs and 100 % in murine UV induced skin tumors [9, 10].

In addition to the disrupted p53-dependent mechanism, development of NMSC also may involve dysregulation of the Rb-controlled pathway of the cell cycle progression including inactivation of the *CDKN2A* tumor suppressor gene in the 9p21 region [11].

29.2 Acute Effects of UV Radiation

29.2.1 UV-Induced DNA Damage

Irradiation of DNA or cells with ultraviolet light induces the formation of several types of mutagenic DNA lesions. The most frequent lesions induced by UVB radiation are the cis-syn cyclobutane pyrimidine dimers (CPDs) and the pyrimidine pyrimidone photoproducts (PPs) [12, 13]. Several minor photoproducts such as purine dimers and pyrimidine mono-adducts are also formed [14].

CPDs are formed between the 5,6 bonds of any two adjacent pyrimidine bases. PPs are characterized by a stable bond between position 6 and 4 of the neighboring pyrimidines and appear to form preferentially at 5′-TC and 5′-CC

W.B. Coleman, G.J. Tsongalis (eds.), *The Molecular Basis of Human Cancer*, DOI 10.1007/978-1-59745-458-2_29

sequences. They are formed at levels considerably lower than those of CPDs [15, 16]. These unique lesions in the DNA give rise to unique mutations in the *p53* tumor suppressor gene. Consequently UVB induces mostly C→T and CC→TT transitions at the dipyrimidine sequence which are therefore called UV signature mutations [17].

The genotoxicity of UVA has most commonly been linked to endogenous photosynthesizers causing reactive oxygen species mediated induction of DNA damage [18, 19]. More recently it has been reported that UVA can induce CPDs in rodent cells. The poor absorbance of UVA by DNA itself favors the idea that type I (direct reaction) or type II (indirect through reaction of the excited photosensitizer molecule with oxygen) photosensitization reactions occurring within cells are primarily responsible for UVA induced DNA damage [20]. In addition, UVA may produce H_2O_2 through activation of flavin containing oxidases or through release of free iron in the irradiated cells from the iron storage protein ferritin [21, 22]. UVA has been shown to induce 8-oxo-7,8-dihydro-2′-deoxyguanosine (8-oxodG), a typical oxidative DNA lesion, as well as generate DNA strand breaks in a variety of experimental systems [23, 24].

29.2.2 Induction of p53 Tumor Suppressor Protein

p53 codes for a 53 kDa phosphoprotein involved in gene transcription and control of the cell cycle by coordinating transcriptional control of regulatory genes. Human *p53* is a highly conserved 11 exon gene that is located on the short arm of chromosome 17 that is about 20 kb in size. p53 protein forms tetramers through interactions between recognize specific binding sites on target genes and stimulate their activation. Mutant forms of *p53* rarely exhibit mutations in the DNA binding domain [25, 26].

Normally there is little p53 protein in the cell, but numerous studies have shown that in response to UV damage, high levels of p53 protein are induced. This has been demonstrated in cell culture, mouse epidermis, and human tissue [27]. With high levels of p53 protein, there is a G1 arrest, allowing the cellular repair pathway to remove DNA lesions before DNA synthesis and mitosis and an increase in apoptosis. Therefore *p53* aids in the DNA repair or the elimination of cells that have excessive DNA damage [3, 25]. *p53* is stabilized as early as 6 h after UV exposure reaching a peak at 12 h. Nelson and Katzan found the DNA lesions induced by UV radiation were pyrimidine dimers and that *p53* was induced when these lesions were accompanied by excision repair-associated DNA strand breaks [28].

UV radiation induces the activating phosphorylation of the p53 protein at multiple serine residues, including Ser15, Ser20, Ser33, Ser37, Ser46, and Ser392. It has been also shown the involvement of the ATM, ATR, p38, ERK1/2, and JNK-1 mitogen activated protein (MAP) kinases in the phosphorylation of various p53 serine residues in response to UV radiation [29–31].

29.2.3 Cell Cycle Arrest and DNA Repair

Accumulation of activated p53 protein induces a cell cycle arrest at G1 phase which allows the repair of DNA damage before is replication in the S phase.

The p21Waf1/CIP1 gene encodes an inhibitor of cyclin dependent kinase (CDK) whose induction is associated with the expression of wild-type p53. p21 inactivates the CDK cyclin complex by forming a complex of CDK2, cyclin A, PCNA, and p21 leading the cell into G1 arrest. Formation of these complexes leads to the accumulation of hypophosphorylated retinoblastoma protein (Rb) causing the release of the E2F transcription factor which is necessary for DNA synthesis [32, 33].

The tumor suppressor activity of p53 is in turn inhibited by the Mdm2 protein, which targets p53 for rapid degradation. The gene encoding Mdm2 is itself activated by p53 thus providing a negative autoregulatory loop. If normal DNA repair is not achieved, cells proliferate abnormally which can lead to carcinogenesis [34].

The induction of DNA damage appears to play a central role in photocarcinogenesis and efficient removal of DNA lesions by cellular repair processes appears to be a critical step in the prevention of tumor formation. Interaction of UV with DNA can give rise to different forms of DNA damage which is normally removed by nucleotide excision repair (NER). The most relevant DNA damage generated after UV irradiation is the formation of CPDs. These lesions are primarily repaired by NER which removes bulky DNA damage in two distinct sub-pathways [35]. Damage existing in actively transcribed genes is removed by a quick mechanism called transcription-coupled repair (TCR) [36]. Damage prevailing in other parts of the genome is removed with a slower mechanism by the global genome repair (GGR) [37]. Defects in both sub-pathways of NER can lead to three distinct diseases: Xeroderma pigmentosum (XP), Cockayne syndrome (CS), and trichothiodystrophy (TTD). These diseases provide important model systems for investigating aspects of DNA repair since they are all deficient in NER but in different sub-pathways.

p53 directly affects NER by inducing the transcriptional activation of several downstream genes. Cells lacking functional p53 are defective in removing DNA photoproducts which are normally repaired by NER complexes [38].

In addiction to that, there is the base excision repair pathway (BER) which removes lesions caused by oxidative damage. It has been postulated that p53 affects BER by

regulating DNA polymerase β which is directly involved in DNA repair/synthesis [39]. Cells lacking p53 are deficient in BER [40].

29.2.4 Apoptosis

Keraratinocytes respond to UV-induced DNA damages by growth arrest or induction of the programmed cell death—apoptosis. *p53* plays a major role in the control of both of these processes. In fact these two *p53*-dependent mechanisms are believed to maintain the integrity of the genome and to protect cells from the accumulation of mutations. Consequently, induction of apoptosis of keratinocytes by UV radiation is a protective phenomenon relevant in limiting the survival of cells with irreparable DNA damage [41].

p53-induced apoptosis involves several mechanisms and among them the bcl-2 gene family seems to play a crucial role. The bcl-2 gene family is composed of the pro-apoptotic gene group (*Bax, Bad, Bak, Bcl-xs, Bik, Bim,* and *Mtd/Bok*) and the anti-apoptotic gene group (*Bcl-2, Bcl-w, Bcl-xL,* and *Mcl-1*). Bax and Bcl-2 proteins are homologous but they have opposing effects on apoptosis and they may form heterodimers in cells [42]. Thus their interaction is critical to the ability of Bcl-2 to block cell death. p53 induces apoptosis by disrupting the balance between these proteins, upregulating the *Bax* gene, and downregulating the *Bcl-2* gene [43].

Another *p53* induced apoptotic mechanism is through the expression of Fas (APO-1/CD95) and its ligand. Fas receptor is a target for transcriptional activation by *p53* and a target for *p53*-mediated cytoplasmic redistribution to the cell surface [44]. The Fas-Fas ligand interaction results in the cleavage of pro-caspase 8 and release of cytochrome c from mitochondria, followed by activation of the Apaf-1-caspase 9-caspase 3 pathway which results in apoptosis [45]. Hill et al. in 1999 demonstrated that Fas-Fas ligand interactions are essential for the induction of sunburn cells in UV-irradiated mouse skin and the elimination of aberrant cells following skin exposure to UV radiation. UVB irradiation induced the rapid overexpression of Fas and Fas ligand in murine skin. The formation of sunburn cells was found to depend on Fas ligand expression since their formation was significantly reduced in Fas ligand-deficient mice [46].

29.3 Chronic Effects of UV Radiation

29.3.1 Mutations in p53 Tumor Suppressor Gene

Following chronic UV exposure, mistakes associated with DNA repair and replication can result into mutations in the *p53* gene, especially C → T and CC → TT transitions at dipyrimidine sites, considered as UV molecular signature. The p53 mutation in keratinocytes is probably an initiating event in UV skin carcinogenesis [8].

As UV signature mutations in the *p53* gene are already present in benign precursor lesions of squamous cell carcinomas (AK), they appear to be an early step in the UV carcinogenesis. In the experiments with hairless mice, microscopic clusters of epidermal cells overexpressing mutant *p53* occur long before skin carcinomas become visible [47]. Such clusters are also found in sun-exposed human skin [48]. Most of human NMSC found to bear mutations in the *p53* gene. Brash et al. in 1991 showed *p53* mutations in 58 % of human SCCs analyzed (3/24 showed CC → TT transition and 5/24 had C → T base change) [49]. In a recent study, Bolshakov et al. analyzed 342 human NMSC and found *p53* mutations in 28/80 aggressive SCCs and in 28/56 non aggressive SCCs. About 71 % of the detected *p53* mutations were UV signature mutations [50].

Experiments to determine the timing of p53 mutation in relation to skin cancer development have been performed in the mouse model of photocarcinogenesis because this model is easily referable to UV irradiation and sample collection at various time points during the carcinogenesis protocol. Ananthaswamy et al. have shown that p53 mutations in mouse skin arise very early during UV carcinogenesis by using a very sensitive mutation-specific PCR technique for the early detection of *p53* mutations in UVB irradiated C3H mice. They were able to detect p53 mutations at 4th week of UV irradiation and the frequency of p53 mutations increased progressively and reached 50 % at 12th week of chronic UV exposure. The real *p53* mutations frequency observed in this study is probably higher than the one described because only tandem CC → TT mutations were analyzed [51]. In addition to C3H mice, Ouhtit et al. used SKH-hr1 mice to determine the timing of p53 mutations during UV carcinogenesis. Interestingly, *p53* mutations were detected as early as 1st week of chronic UV irradiation and the mutation frequency reached 80–90 % by 4–8 weeks [52]. Both the early appearance and the high frequency of *p53* mutations in UV irradiated SKH-hr1 mice skin can be explained with the fact that either C → T or CC → TT mutations were analyzed in this study.

29.3.2 Fate of p53 Mutations After Discontinuation of UV Exposure in Mice

It has been widely demonstrated in animal models that UV acts as a tumor promoter and induces cell proliferation by stimulating the production of various growth factors and cytokines as well as activation of their receptors [53]. Repeat UV exposure of the skin results in clonal expansion of initiated p53-mutant cells. Two mechanisms are believed to con-

tribute to the selective expansion of p53-mutant cells: (1) their resistance to UV-induced apoptosis, and (2) their proliferative advantage over normal keratinocytes in response to stimulation with UV radiation [54, 55].

Zhang et al. have shown that every successive UVB exposure allows p53-mutant keratinocytes to colonize adjacent epidermal stem cell compartments without incurring any additional mutation [56]. Chronic UV irradiation of the skin quickly induces apoptosis resistance and stimulates hyperproliferation throughout the epidermis as an adaptive response [52]. Nevertheless, discontinuation of UV irradiation has been shown to result in the fast spontaneous regression of some mutant p53 clones in mouse skin [57]. Melnikova et al. investigated whether discontinuation of UV exposure before the onset of skin tumors results in the disappearance of *p53* mutations in the skin of SKH-hr1 mice. Their results indicated that despite discontinuation after 8 weeks, UV irradiation results in 100 % skin tumor incidence, although the kinetics of tumor occurrence is greatly delayed. In terms of human relevance these results suggest that early life exposure to UV may introduce *p53* gene mutations in epidermal keratinocytes as well as keratinocytes progenitors. While some *p53* mutated keratinocytes may be eliminated via differentiation and epidermal desquamation, others, may still persist and eventually give rise to skin tumors even in the absence of further UV exposure. Thus, cancer development can be delayed but not definitively abrogated upon further avoidance of exposure to UV radiation [58].

29.4 Oncogene Activation and Tumor Suppressor Inactivation in Skin Carcinogenesis

29.4.1 Ras Oncogene Activation and Skin Cancer

The *ras* family of proto-oncogenes encodes small GTP binding proteins involved in intracellular signal transduction of mitogenic signals arising from activation of growth factor receptors. Mammalian *ras* genes are important constituents of these mitogenic signalling pathways and when activated, they contribute to dysregulated cellular growth [59].

In mammals, keratinocytes respond to UVB irradiation with a marked downregulation of the ras extracellular signal regulated kinase (ERK) signalling cascade. The downregulation precedes a decrease in the steady state levels of cyclin D1 that mediates the action of ERK. The increased activity of *ras* and phosphorylation of ERK in these cells are maintained by the production of molecules that stimulate the epidermal growth factor receptor (EGFR). Irradiation of keratinocytes increases the phosphorylation of EGFR above the basal levels. This leads to the increased recruitment of the adaptor proteins to the UVB activated EGFR. At the same time, UVB causes the inactivation of *ras* and a subsequent dephosphorylation of ERK [60].

Normal skin has some *ras* mutations in the form of T:A → C:G base change at codon 27. Exposure of the skin to UVR induces photoproducts along several exons of the *ras* proto-oncogenes (*H-ras, K-ras,* and *N-ras*). These photoproducts included both cyclobutane pyrimidine dimers and pyrimidine pyrimidone photoproducts [61].

In NMSC activated *ras* genes were frequently found in BCCs, AK, and SCCs of the sun-exposed areas. This *ras* gene activation is the result of an aberrant repair of UV induced pyrimidine dimers. Those activating mutations were found mostly at codon 12 of the *K-ras* gene and codons 12, 13, and 61 of the *H-ras* gene [62].

29.4.2 PATCH Tumor Suppressor Gene Inactivation

PATCH gene is located on chromosome 9q22.3 regions and spans about 34 kb in genomic DNA. It is formed of 24 exons with two alternate exon1. The encoded protein is the receptor for sonic hedgehog, a secreted molecule implicated in tumorigenesis. The normal function of PATCH protein is to convey extracellular growth regulatory signals to the nucleus [63].

PATCH gene is the candidate tumor suppressor gene for familial and sporadic BCCs. Its mutations are frequent in BCCs and they are predominantly UV specific C–T transitions. This mutation are significantly more frequent in BCCs associated with xeroderma pigmentosum than in sporadic BCCs and they may be associated with allelic loss at the chromosomal region 9q22.3 harboring PATCH gene [64, 65]. Alternatively, occasional nonsense mutations were found in SCCs isolated from individuals with histories of multiple BCCs [66].

29.4.3 CDKN2A Inactivation

The CDKN2A locus at 9p21, is frequently inactivated in human cancers and it consists of two overlapping genes that encode two unrelated proteins, $p16^{INK4a}$ and $p14^{ARF}$, functioning as cell cycle inhibitors. $p16^{INK4a}$ and $p14^{ARF}$ share the same exon 2 but have a distinct exon 1, exon 1α and exon 1β, respectively. Because exon 1β splices into common exons 2 and 3 in a different reading frame, the resulting $p14^{ARF}$ bears no similarity to $p16^{INK4a}$. It is well established that $p14^{ARF}$ plays a role in cell cycle control linking the $p16^{INK4a}$/Rb pathway and the p53/Rb pathway. Upon phosphorylation of Rb, E2F is activated and promotes induction of $p14^{ARF}$, which in turn sequesters MDM2 and thereby prevents degradation and nuclear export of p53. Both $p16^{INK4a}$ and $p14^{ARF}$ transcripts

by their interactions with pRb and p53, are important in regulating the proliferation of normal and tumorigenic squamous epithelial cells [66, 67].

Inactivation of the tumor suppressor gene *CDKN2A* can occur in a variety of genetic mechanisms including mutations and deletions. In addition, hypermethylation of the CpG islands of gene promoters is an effective means of gene silencing in a variety of cancers. Inactivation of *CDKN2A* by deletion, mutation or promoter hypermethylation in a wide range of malignancies has been documented [68].

It has been shown by Soufir et al. that SCCs from xeroderma pigmentosum patients contain mutations in *CDKN2A* gene in 13/28 SCCs and 54 % of mutations detected at CDKN2A locus were UV signature mutations [69].

In order to determine the involvement of *CDKN2A* gene in sporadic SCCs, Saridaki et al. performed the allelic imbalance analysis and the mutational analysis on 22 SCCs and on 5 Bowen's disease specimens. Their results indicated that 52 % of specimens exhibited loss of heterozygosity (LOH) in at least one microsatellite marker whereas only 2/27 samples exhibited microsatellite instability. Mutational analysis revealed the presence of a base substitution in exon 1α of 1 tumor and the presence of a C → T transition in exon 2 in a second tumor [70].

Brown et al. analyzed 30 cutaneous SCCs from immunosuppressed 29 patients and 10 immunocompetent patients and have shown that the total frequency of 9p21 alterations was 76 %, with abnormalities of $p16^{INK4a}$ detected in 53 % of tumor analyzed and of $p14^{ARF}$ in 64 % of the tumors. Promoter methylation was the predominant mechanism of inactivation for both genes. Biallelic events were common [71].

Murao et al. examined the epigenetic abnormalities of a wide range of cancer related genes (*CDH1*, *p16*, *p15*, *RB1*, *p14*, *DAPK1*, *MGMT*, *RASSF1*, *PTEN*, *PRDM2*, and *p53*) in 20 sporadic SCCs from 20 immunocompetent patients. Their results showed that although the frequency of methylation of $p16^{INK4a}$, Rb1 and $p14^{ARF}$ was not high, methylation of these genes in combination with mutation analysis of *CDKN2A* and *p53* revealed that 70 % of cases had abnormalities of the RB1/p16 and/or p53 pathway through either genetic or epigenetic mechanisms, except for epigenetic abnormalities of *p53* itself [72].

All these findings emphasize the importance of *CDKN2A* tumor suppressor gene in the pathogenesis of NMSC.

29.5 Conclusions

UV radiation present in the sunlight is a potent carcinogen. Recent advances in cellular and molecular biology have clarified some of the mechanisms of photocarcinogenesis including the formation of DNA photoproducts, DNA repair, mutation of proto-oncogenes and tumor suppressor genes. It is well established that UV radiation induces mutations in the *p53* gene and that these mutations arise very early during photocarcinogenesis. Accumulation of several mutations in key genes due to chronic exposure to sunlight may lead to the development of skin cancer. Skin cancers do not arise immediately after exposure to UV light, mutated p53 or other tumor suppressor genes must remain latent for a long period of time. In addition to mutations in the *p53* tumor suppressor gene, genetic alterations in *CDKN2A* gene leading to loss of expression of $p16^{Ink4a}$ and $p14^{ARF}$ proteins may also play an important role in the development of human NMSC. Several studies have shown that human NMSC harbor unique mutations in the *p53* gene as well as inactivation of the *CDKN2A* gene. While mutations in the *p53* gene are induced by UV radiation and represent tumor initiating events, the majority of the alterations detected in the *CDKN2A* gene do not appear to be UV dependent. Probably these genetic alterations arise spontaneously, probably during tumor progression.

Molecular Biology of Leukemias

30

L. Jeffrey Medeiros and Sergej N. Konoplev

30.1 Introduction

Normal hematopoiesis is a meticulously controlled process of cell division and differentiation arising from hematopoietic stem cells with self-renewal capacity. This process is regulated through several signaling pathways that appear to be, to some degree, redundant. In many neoplastic processes, alteration of one or several signaling pathways has been observed, implicating these pathways in pathogenesis.

Conventional cytogenetics analysis, which began in the 1970s, was a great boon to our understanding of acute and chronic leukemias. Approximately 50 % of de novo acute leukemias have distinctive molecular abnormalities, most frequently chromosomal translocations [1] (Table 30.1). These translocations typically affect genes that are involved in transcription and differentiation. In many translocations, two genes are disrupted and recombined to form a novel fusion gene from which chimeric mRNA is transcribed and protein is translated. Other translocations involve the juxtaposition of intact genes adjacent to genes with strong promoters or enhancers that upregulate gene expression. Inversions and interstitial deletions can also occur that juxtapose genes and have the same effects as translocations [1].

The advent of additional molecular methods and their application to leukemias furthered our understanding of the molecular pathogenesis of these neoplasms. Methods that contributed greatly included Southern, Northern and Western blot analysis, fluorescence in situ hybridization, various polymerase chain reaction (PCR)-based methods, and Sanger (first generation) sequencing. In general, molecular methods were used initially to assess single genes, or small numbers of genes. More recently, high-throughput methods such as array-based comparative genomic hybridization (aCGH), single nucleotide polymorphism (SNP) arrays, and next (or second)-generation sequencing have resulted in an explosion of new data. It is now clear from the results of studies that have used whole genome, whole exome, transcriptome (mRNA), and targeted sequencing studies that acute and chronic leukemias are commonly associated with a number of somatic gene alterations and that involve key cellular pathways. Examples of involved pathways include transcriptional regulation of hematopoietic cell development, cell signaling related to tyrosine kinases or cytokine receptors, and chromatin modulation. These studies also have uncovered abnormalities in genes previously unknown to be involved in oncogenesis.

Although next-generation sequencing has shown many gene mutations in leukemias, other molecular mechanisms also have been implicated in leukemogenesis. Gene amplification can result in gene overexpression. Numerical gains or losses of chromosomes, such as trisomies or monosomies due to nondisjunction, are detected in a large subset of acute and chronic leukemias. Gene deletions, like those arising from partial chromosomal deletions or unbalanced translocations, can result in tumor suppressor gene inactivation or loss. Hypermethylation (i.e., epigenetic changes) is another mechanism of gene inactivation. Often more than one mechanism is involved, leading to the accumulation of genetic lesions culminating in leukemogenesis, or subsequently contributing to disease progression.

Traditionally, genes implicated in cancer pathogenesis have been divided into oncogenes and tumor suppressor genes. Oncogenes are considered to play an important role in pathogenesis having acquired constitutive activation through translocation or sporadic mutation, whereas tumor suppressor genes are involved in pathogenesis through their inactivation of gene/protein function. Point mutation, causing missense or nonsense mutations resulting in abnormal or truncated protein products, is a common mechanism of tumor suppressor gene inactivation. Although some genes involved in leukemogenesis follow this paradigm (for example, typical oncogenes *HOX* and EVI-1 and typical tumor-suppressor genes *PU.1*

	BCR	Unknown function

and *RARα*), some genes demonstrate overlapping features of both oncogenes and tumor-suppressor genes (such as *CBF*, *CEBPA*, *GATA-1*, and *NPM1*), suggesting that this traditional dichotomy is an oversimplification [2–7].

A new concept of gatekeeper genes has been recently introduced to our understanding of hematologic malignancies. This concept was first established in solid tumors (e.g., colon cancer) where inactivation of a particular pathway is thought to be the first genetic alteration in pathogenesis [8]. Several studies suggest that the genetic alterations affecting hematopoietic transcription factors may be the initiating event resulting in the establishment of a malignant clone, but then secondary events are required for disease manifestation. For example, a myelodysplastic syndrome (MDS) known to precede acute myelogenous leukemia (AML) is often associated with *RUNX1* mutations, which might be an initiating event in AML [9]. Additionally, cytogenetic and genetic abnormalities identified in therapy-related MDS and AML might be initiating genetic events in leukemogenesis [10]. Concordant AML in identical twins, which share the initiating clone carrying the same translocation affecting the *MLL* gene, supports the idea of gatekeepers in leukemias, as does the observation of *RUNX1* or *CEBPA* mutations in hereditary AML syndromes [11].

Some authors have proposed the concept that leukemogenesis requires the collaboration of at least two classes of mutations: class I, which activate signal-transduction pathways and confer a proliferation advantage to hematopoietic cells; and class II, which affect transcription factors and serve primarily to impair hematopoietic differentiation [12]. While some hematologic malignancies appear to follow this scheme, for example, acute promyelocytic leukemia (APL) carries *PML-RARα* impairing differentiation and many cases also have *FLT3* mutations leading to increased proliferation, there are too many exceptions to believe that this concept can be universally applied for all hematologic malignancies.

30.2 Acute Myeloid Leukemia

Acute myeloid leukemia (AML) is an umbrella term for a group of neoplasms composed of immature cells demonstrating differentiation into one of the myeloid lineages. The approach to classification of AML has changed dramatically over the years, from a purely morphologic system used in the French–American–British (FAB) classification [13] to a system that incorporates morphologic, immunophenotypic, genetic, and clinical features as proposed by the World Health Organization (WHO) classification [14]. The WHO classification divides AML in four major categories: (1) AML with recurrent genetic abnormalities, (2) AML with myelodysplasia-related changes, (3) Therapy-related myeloid neoplasms, and (4) AML, not otherwise specified (NOS).

From the point of view of molecular mechanisms, cases of AML with recurrent genetic abnormalities represent biologically unique entities. Cases of therapy-related AML and AML with myelodysplasia-related changes have overlapping biologic and cytogenetic features. The fourth category, which basically recapitulates the older approach of FAB classification, represents a heterogeneous group driven by a large variety of molecular alterations.

30.2.1 AML with Recurrent Genetic Abnormalities

30.2.1.1 AML Associated with t(8;21)(q22;q22.3): *RUNX1–RUNX1T1* (*AML1/ETO* or *RUNX1/MTG8*)

The t(8;21)(q22;q22.3) has been identified in 8–12 % of de novo AML [14]. Less commonly, t(8;21) has been identified in therapy-related myeloid neoplasms [15]. In adults, de novo AMLs with t(8;21) respond well to AraC-containing chemotherapy with a high rate of complete remission and relatively long survival. However, the presence of t(8;21) in pediatric AML cases may be less predictive of good prognosis [16]. Morphologically, most cases are classified as M2 using the FAB classification although only a subset of M2 cases carry t(8;21). The myeloblasts in these leukemias typically have distinctive cytological features, characterized by abundant evidence of maturation, including single slender Auer rods with tapered ends and salmon-colored cytoplasmic granules (Fig. 30.1) [17].

The t(8;21) is a reciprocal chromosomal translocation involving the *RUNX1T1* (*ETO)* gene on chromosome 8 and the *RUNX1* (*AML1*) gene on chromosome 21. As a result of

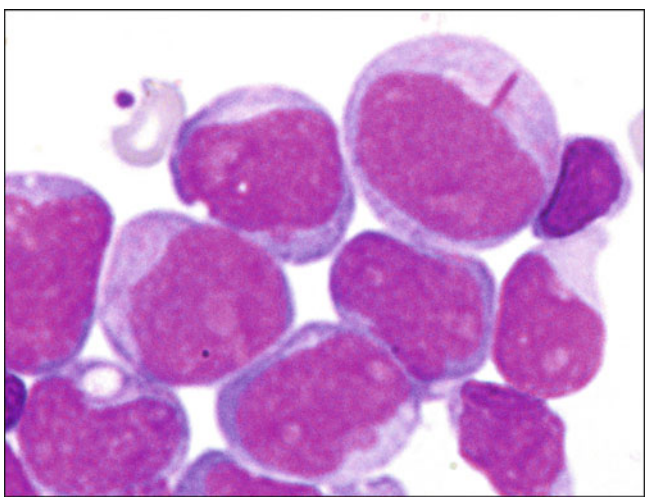

Fig. 30.1 Typical morphology of acute myeloid leukemia with t(8;21). Blasts show single long slender Auer rods with tapered ends. Wright-Giemsa stain, 1000×.

this translocation, the *RUNX1T1* and *RUNX1* genes are disrupted and fused forming an *RUNX1-RUNX1T1* fusion gene, located on the derivative chromosome 8. The *RUNX1* and *RUNX1T1* genes are fused in a $5' \rightarrow 3'$ orientation. The fusion protein includes the promoter and *runt*-like domains of the *AML1* protein; the translocation domain of normal *RUNX1* is replaced by sequences derived from the *RUNX1T1* gene. A reciprocal *RUNX1T1- RUNX1* fusion gene located on the derivative chromosome 21 has not been identified. One proposed mechanism for the role of *RUNX1-RUNX1T1* in leukemogenesis is competitive inhibition of normal RUNX1 protein. The breakpoints in the *RUNX1* gene are consistently detected in intron 5. The breakpoints in the *RUNX1T1* gene are also relatively uniform, in the 5′-end of the gene.

The *RUNX1* gene encodes for one of many members of a family of heterodimeric transcriptional regulatory proteins. The *RUNX1* gene is highly homologous with the *Drosophila runt* gene, and encodes core binding factor (CBF) α, the human counterpart of the murine nuclear polyoma enhancer binding protein (PEBP2). The binding of RUNX1 protein to DNA occurs via the *runt*-like central domain and also requires heterodimerization with CBF. The latter protein does not bind to DNA but improves the binding affinity of RUNX1. The *RUNX1* gene is normally expressed by myeloid and T-cells and is thought to play an important role in hematopoietic differentiation. The *RUNX1T1* gene (also referred to in some studies as *CDR* or *MTG8)* encodes a transcription-factor protein that has two zinc-finger-motifs at its C-terminus. The *RUNX1T1* gene is expressed in brain, lung, and gonads, but is not normally expressed in hematopoietic cells.

A variety of methods are available to detect t(8;21). This translocation is not difficult to recognize using conventional cytogenetics, which detects t(8;21) in over 95% of cases (Fig. 30.2). However, rare cases have been reported in which the translocation was not detected by cytogenetics, but was detected by other molecular methods [18]. FISH effectively identifies the t(8;21) (Fig. 30.3). RT-PCR methods detect

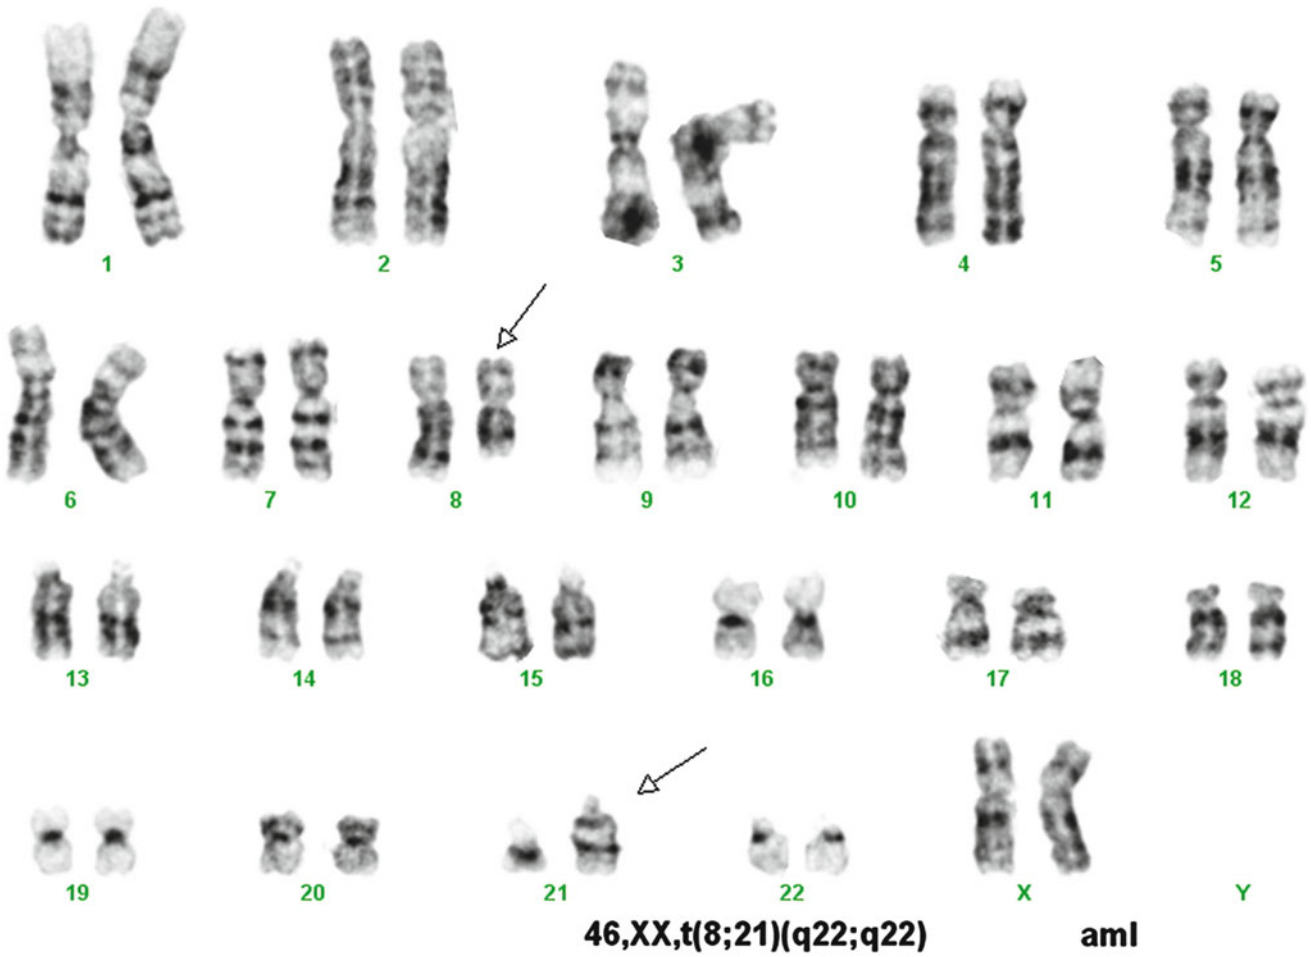

Fig. 30.2 Karyotype of a case of acute myeloid leukemia with t(8;21). Conventional cytogenetic analysis demonstrates t(8;21) as a sole cytogenetic abnormality. GTG banding technique.

almost all cases with the t(8;2l). RT-PCR methods, because of their extraordinary sensitivity, also have been used to monitor residual disease. However, studies have shown the persistence of low level *RUNX1-RUNX1T1* transcripts in patients in complete clinical remission after chemotherapy or stem cell transplantation, and who have remained in complete remission with prolonged clinical follow-up [19, 20]. Thus, RT-PCR results do not appear to effectively predict risk of relapse after therapy in patients in clinical remission [19, 20].

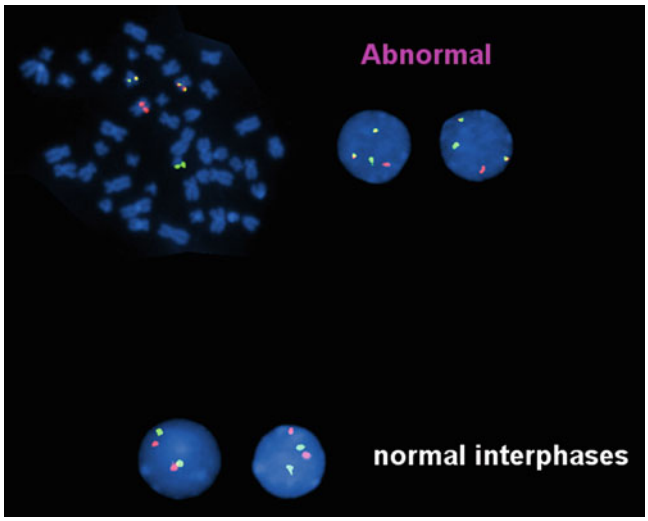

Fig. 30.3 Fluorescence in situ hybridization (FISH) analysis of a case of acute myeloid leukemia with t(8;21). Dual color, dual fusion probe (Vysis) in which an *RUNX1T1* probe is *red* and an *AML1* (*RUNX1*) probe is *green*. In the event of t(8;21) (*upper panel*) the involved chromosomes show juxtaposition of the *red* and *green* probes producing a *yellow* fusion signal. The uninvolved chromosomes 8 and 21 show *red* and *green* signals, respectively. This technique allows analysis of both metaphase (*left*) and interphase (*right*) cells. In the absence of t(8;21), cells show two *red* and two *green* signal (*lower panel*).

Cases with *RUNX1-RUNX1T1* transcripts appear to follow the class I and class II mutation rule as *RUNX1-RUNX1T1* fusions can be detected in long term survivors who are presumably cured of their disease. Knockin mice expressing an *RUNX1-RUNX1T1* fusion gene do not develop leukemia until they are exposed to mutagens presumably causing mutations that complement *RUNX1-RUNX1T1*. Taken together, these findings support the hypothesis that a single genetic event is not sufficient to cause acute leukemia.

30.2.1.2 AML with inv(16)(p13q22) or t(16;16)(p13;q22), (*CBFβ/MYH11*)

The inv(16)(p13q22) and, more rarely, the t(16;16)(p13;q22) have been identified in 5–12 % of de novo AMLs (Fig. 30.4) [21]. In most cases, the blasts have monocytic cytological features and are associated with immature eosinophils containing coarse basophilic cytoplasmic granules (Fig. 30.5) [21]. The inv(16) also has been identified in rare cases of CML in blast crisis [22].

The detection of inv(16) in de novo AMLs is a favorable prognostic finding. Patients with AML with inv(16) usually have a higher rate of complete response to chemotherapy, longer duration of remission, and prolonged survival as compared with patients with other forms of AML. The inv(16)(p13q22) involves the *CBF* (core binding factor or *PEBP2*) β subunit gene situated on chromosome 16q22 and the *MYH11* (smooth muscle myosin heavy chain) gene located at chromosome 16p13. The inversion results in a *CBPβ-MYH11*

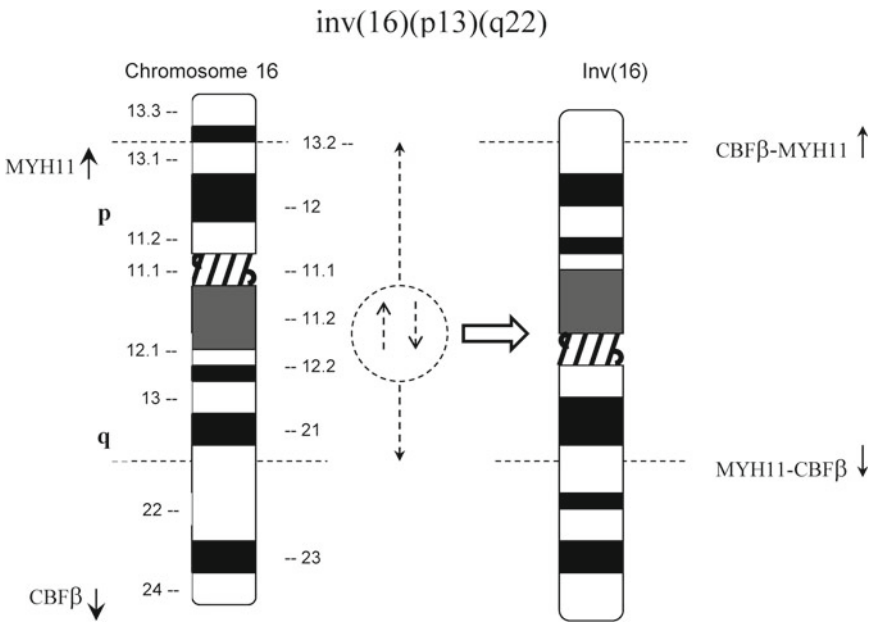

Fig. 30.4 Schematic representations of inv(l6)(p13q22) and t(16;16)(p13;q22). *Top panel*, In inv(l6), most of the *CBFβ* gene at 16q22 is joined upstream of the 3′ end of *MYH11* at 16p13 forming a chimeric *CBFβ-MYH11* fusion gene. *Bottom panel*, The t(16;16) results in a similar chimeric gene on 16p+.

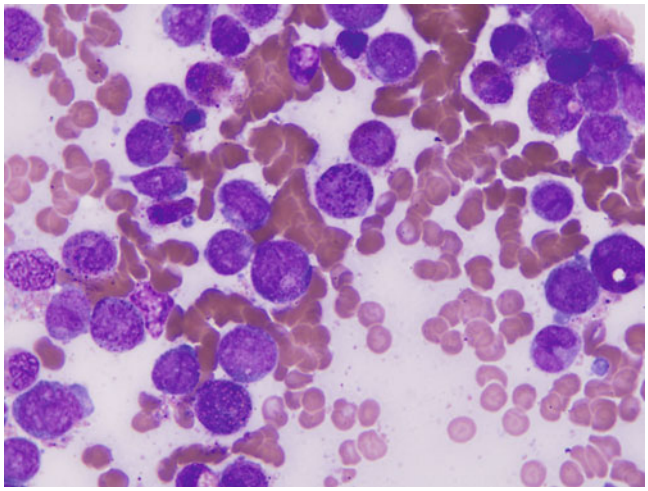

Fig. 30.5 Typical morphology of acute myeloid leukemia with inv(16)(p13q22) or t(16;16)(p13;q22). Immature eosinophilic precursors demonstrate coarse, irregularly sized basophilic granules. Wright-Giemsa stain, 1000×.

fusion gene from which chimeric mRNA and a novel protein are generated [23]. Both *CBFβ* and *MYH11* are oriented 5′→3′ and are transcribed in the centromeric to telomeric direction. The t(16;16) also involves the *CBFβ* and *MYH11* genes, and results in an identical *CBFβ-MYH11* fusion gene. A reciprocal *MYH11-CBFβ* mRNA or protein has not been identified.

The CBF protein has two components, α and β, of which there are three α subunits and one β subunit. The α subunits share a *runt* domain sequence that allows binding of protein to DNA and the β subunit. The β subunit binds to an α subunit and stabilizes CBF binding to DNA. The normal *CBFβ* gene spans 50 kb with 6 exons. The breakpoints in the *CBFβ* gene are relatively constant. In most cases, the breakpoint occurs in intron 5, at nucleotide 495 (corresponding to amino acid 165). However, a small subset of cases with a more proximal breakpoint at nucleotide 399 (amino acid 133) has been reported. The normal *MYH11* gene encodes for the smooth-muscle form of the myosin heavy chain, and the gene is a member of the myosin II family [23]. Although the function of the CBFβ-MYH11 protein is not completely known, it is thought to bind to the enhancer or promoters of a number of genes involved in hematopoietic cell differentiation [21]. Gene expression profiling studies of cases of AML with inv(16)(p13q22) have shown upregulation of the NF-κB pathway and genes associated with high cell proliferation [24].

The breakpoints in the *MYH11* gene are more variable than *CBFβ*; a number of different breakpoint sites have been reported, although most occur in a small 370 bp intron [21, 24]. This common breakpoint corresponds to nucleotide 1921 in the *MYH11* gene. Despite the variability in the different fusion genes generated by the inv(16) and t(16;16), one form of the fusion gene is created in approximately 85 % of cases, involving nucleotide 495 of the *CBFβ* and 1921 of *MYH11* genes. This fusion gene results in the generation of CBFβ-MYH11 protein that includes the first 165 amino acids of the normal CBFβ protein and a relatively small tail portion of the normal MYH11 protein.

Conventional cytogenetic methods, Southern blot analysis, and RT-PCR, have been used to detect the inv(16)(pl3q22) and t(16;16). One major advantage of conventional cytogenetics is that this method will also identify additional chromosomal abnormalities that are present in up to 50 % of cases. However, one potential disadvantage of karyotyping is that the inv(16) can be difficult to recognize or it may be misinterpreted as a del(16). RT-PCR analysis identifies *CBFβ-MYH11* transcripts in most cases of AML, with either the inv(16) or the t(16;16), demonstrating that the genetic consequences of the inversion and translocation are identical [22]. Immunohistochemical analysis using an antibody specific for the C terminus of CBFβ-MYH11 also can be used. Cases with inv(16) show nuclear expression, unlike other types of AML [23].

30.2.1.3 Acute Promyelocytic Leukemia (AML with t(15;17)(q24.1;q21.2), *PML/RARα* and Variants)

The t(15;17)(q24.1;q21.2) occurs exclusively in acute promyelocytic leukemia (APL), classified in the FAB system as M3. APLs represent 5–13 % of all de novo AMLs [26]. There is variation in the genetic predisposition to the development of APL with a higher incidence of APL in adult Latinos compared with non-Latinos in the USA, and a higher incidence in children from Central and South America and Italy [27]. The presence of t(15;17) consistently predicts responsiveness to a specific treatment, all-*trans* retinoic acid (ATRA). Retinoic acid is a ligand for the retinoic acid receptor alpha (*RARα*) that is involved in the t(15;17). ATRA is thought to overcome the block in cell maturation, allowing the neoplastic cells to mature and be eliminated. Additional genetic abnormalities are rare in APL suggesting that the t(15;17), by itself, is sufficient for neoplastic transformation. This hypothesis was confirmed by an animal model in which transgenic mice expressing the PML-RARα protein in myeloid cells developed APL and responded to ATRA therapy [28]. Of interest, ubiquitous and unrestricted expression of *PML-RARα* in embryos is lethal.

Two morphologic variants of APL have been described, typical and microgranular; both variants carry the t(15;17). In the typical or hypergranular variant (Fig. 30.6) promyelocytes have numerous azurophilic cytoplasmic granules that often obscure the border between the cell nucleus and cytoplasm. Cells with numerous Auer rods in bundles (the so-called faggot cells) are common. In contrast, in the microgranular variant (Fig. 30.6) promyelocytes contain

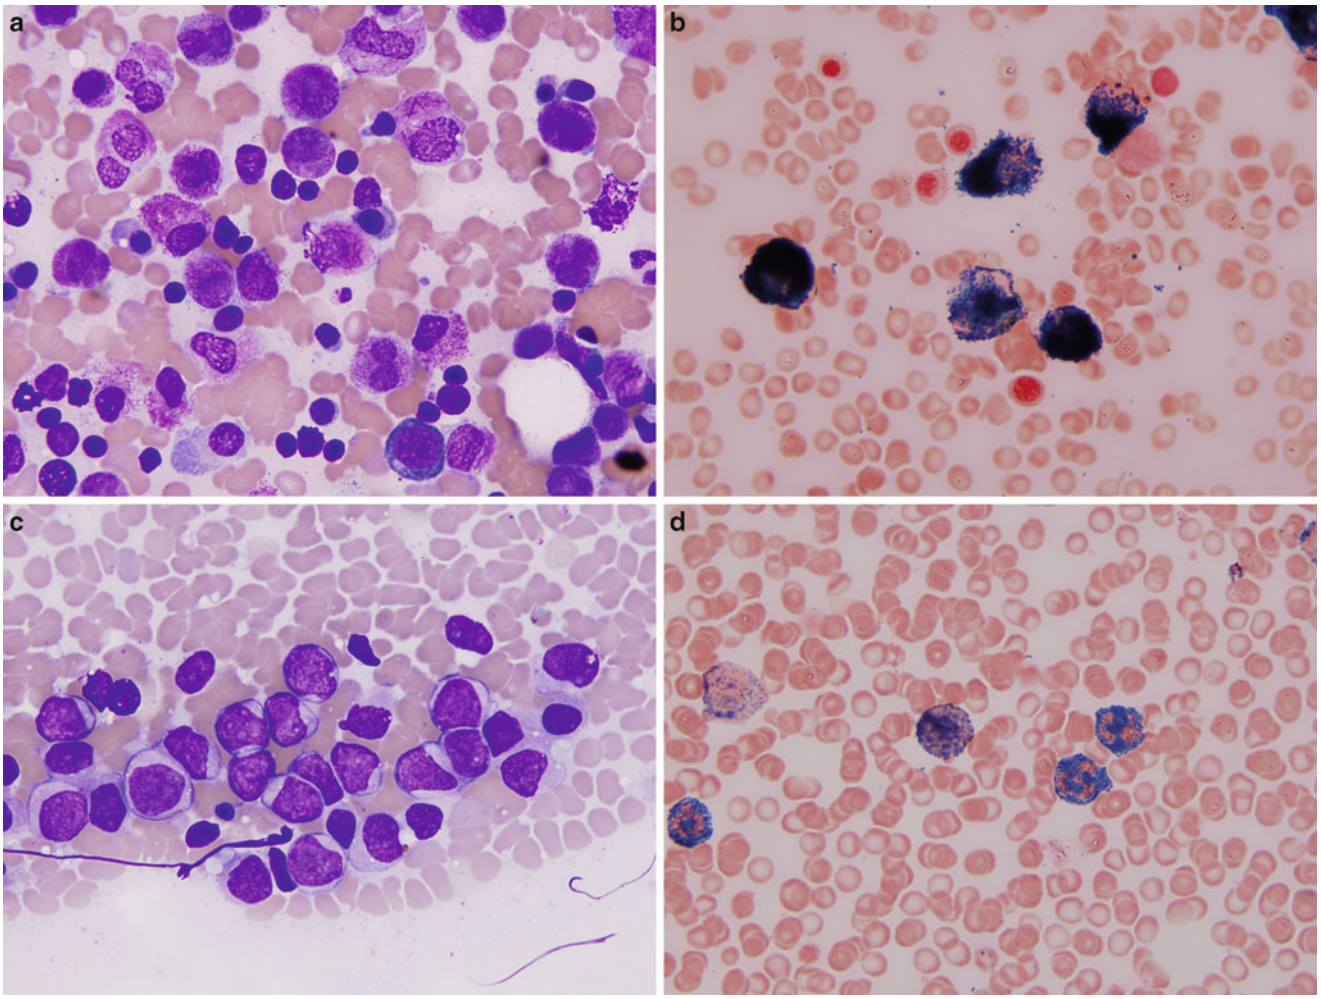

Fig. 30.6 Morphologic variants of acute promyelocytic leukemia. (**a**, **b**) *Classical variant.* Wright-Giemsa stain (**a**) shows abundant progranulocytes with numerous granules and occasional bundles of Auer rods (faggot cells). Myeloperoxidase cytochemistry (**b**) shows numerous positive granules in all neoplastic cells covering entire cell surface. (**c**–**d**) *Microgranular variant.* Wright-Giemsa stain (**c**) shows immature cells with irregular shaped, convoluted nuclei, and abundant cytoplasm containing small granules that are difficult to appreciate by routine microscopy. However, myeloperoxidase cytochemistry (**d**) highlights numerous granules similar to the classical variant. Original magnification 1000×.

numerous small cytoplasmic granules that are difficult to discern with the light microscope on routinely stained smears, but which are highlighted by myeloperoxidase cytochemical staining and are easily detected by electron microscopy.

The t(15;17) is a balanced and reciprocal translocation in which the *PML* (*promyelocytic leukemia*) gene on chromosome 15 and the *RARα* gene on chromosome 17 are disrupted and fused to form a hybrid gene (Fig. 30.7) [29]. The *PML-RARα* fusion gene, located on derivative chromosome 15, encodes a chimeric mRNA and protein. The *PML* and *RARα* genes are oriented in a head-to-tail orientation. The function of the normal *PML* gene is poorly understood. The gene is ubiquitously expressed and encodes a protein characterized by an N-terminal region with two zinc-finger-like motifs, known as a ring and a B-box, and thought to be involved in DNA binding [29]. A dimerization domain is also present. The normal PML protein appears to have an essential role in cell proliferation. The *RARα* gene encodes a transcription factor that binds to DNA sequences in *cis*-acting retinoic acid-responsive elements. High-affinity DNA binding also requires heterodimerization with another family of proteins, the retinoic acid X receptors. The *RARα* protein, from N-terminal to C-terminal, has transactivation, DNA binding, heterodimerization, and ligand-binding domains. The normal *RARα* protein plays an important role in myeloid differentiation.

There are three major forms of the *PML-RARα* fusion gene, corresponding to different breakpoints in the PML gene. The breakpoint in the *RARα* gene occurs in the same general vicinity in all cases, within intron 2. Approximately 40–50 % of cases have a *PML* breakpoint in exon 6 (the so-called long form, termed *BCR1*), 40–50 % of cases have the

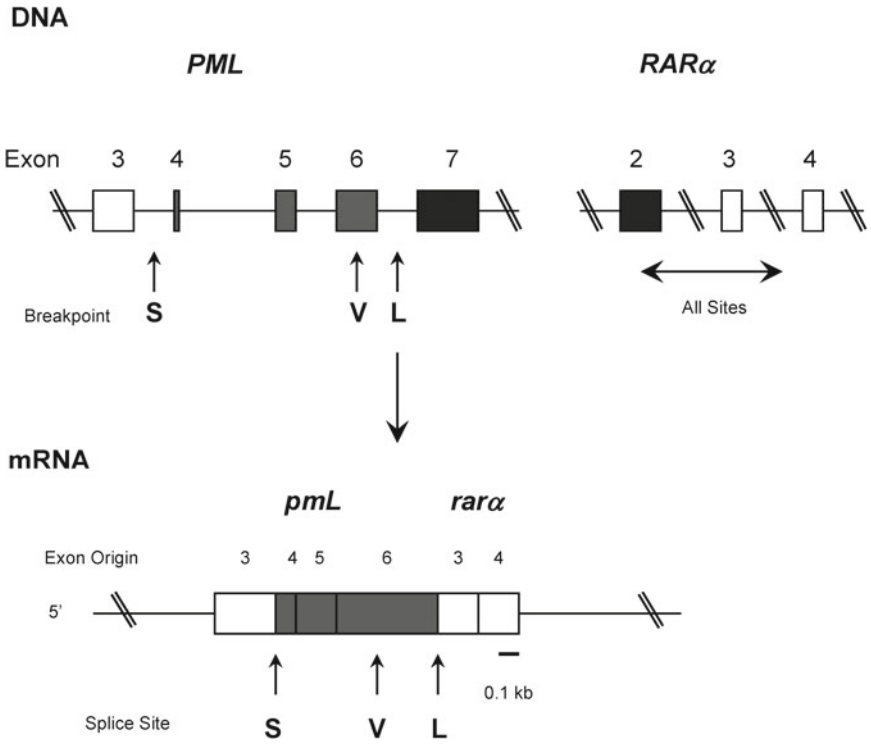

Fig. 30.7 Structure of the PML and RARα genes. Schematic representation of the germ line *PML* and *RARα* genes (*top*), the *PML-RARα* fusion mRNA transcript (*middle*), and the long (L) form of the fusion protein (*bottom*). The lines represent introns, *arrows* indicate three breakpoints, *open boxes* represent the exons present in each type of *PML-RARα, shaded boxes* represent exons excluded from the short (S) form but included in the long (L) or variable (V) forms, and *solid boxes* indicate exons excluded from all types.

PML breakpoint in exon 3 (the so-called short form, termed *BCR3*), and 5–10 % of cases have a breakpoint in *PML* exon 6 that is variable (the so-called variable form, termed *BCR2*). In each form of the translocation, the PML-RARα fusion protein retains the 5′-DNA binding and dimerization domains of PML and the 3′-DNA binding, heterodimerization, and ligand (retinoic acid) binding domains of *RARα*. Recent studies indicate that the different forms of *PML-RARα* fusion mRNA correlate with clinical presentation or prognosis. In particular, the BCR3 type of *PML-RARα* correlates with higher leukocyte counts at time of presentation and is more commonly present in the microgranular variant. Higher leukcocyte count and microgranular variant morphology are adverse prognostic findings in APL patients. PML-RARα transcript type does not correlate with survival [30].

In addition to the PML-RARα protein, the t(15;17) results in two other abnormal proteins. An aberrant PML protein is expressed in virtually all cells with the t(l5;17), as a result of alternative mRNA splicing. This PML protein retains its DNA binding capacity and could possibly play a role in neoplastic transformation. A *RARα-PML* fusion gene is also formed, located on the derivative chromosome 17, and RARα-PML protein is expressed in approximately 75 % of cases of APL. Because this protein lacks the DNA-binding regions of both normal PML and RARα, it is not thought to play a role in leukemogenesis. Furthermore, RARα-PML expression does not correlate with response to ATRA in vitro or with clinical outcome in vivo.

A number of methods can be used to detect the t(15;17). Conventional cytogenetic methods detect the t(l5;l7) in 80–90 % of APL cases at time of initial diagnosis (Fig. 30.8). Suboptimal clinical specimens and poor-quality metaphases explain a large subset of cases with negative results. Fluorescence in situ hybridization (FISH) (Fig. 30.9) is another useful method for detecting the t(15;17) in APL. Different methods employ probes specific for either chromosome 15 or chromosome I7 (or both), and commercial kits are available. In the past, Southern blot hybridization was used to detect gene rearrangements that result from the t(15;17) but this approach is cumbersome. RT-PCR is another method, convenient and reliable, and detects the various *PML-RARα* fusion transcripts.

Polyclonal and monoclonal antibodies reactive with the PML and RARα proteins have been generated and immunohistochemical studies assessing the pattern of staining are useful for diagnosis [29, 31, 32]. In normal cells, PML protein is localized in 5–20 spherical structures per nucleus, known as PML oncogenic domains (POD) that are highlighted in a punctate pattern of staining by the anti-PML antibody (Fig. 30.10). RARα protein is not present in these structures. In contrast, in APL cells immunostaining for either PML or RARα reveals a microgranular pattern. Thus, the PML-RARα fusion protein is present in the microgranules. The fusion protein may prevent PML from forming normal PODs because treatment with ATRA allows PML reorganization into these domains.

Fig. 30.8 Karyotype of a case of acute promyelocytic leukemia. Conventional cytogenetic analysis using G banding by using trypsin and Giemsa stain (GTG banding technique) demonstrates t(15;17) as a sole cytogenetic abnormality.

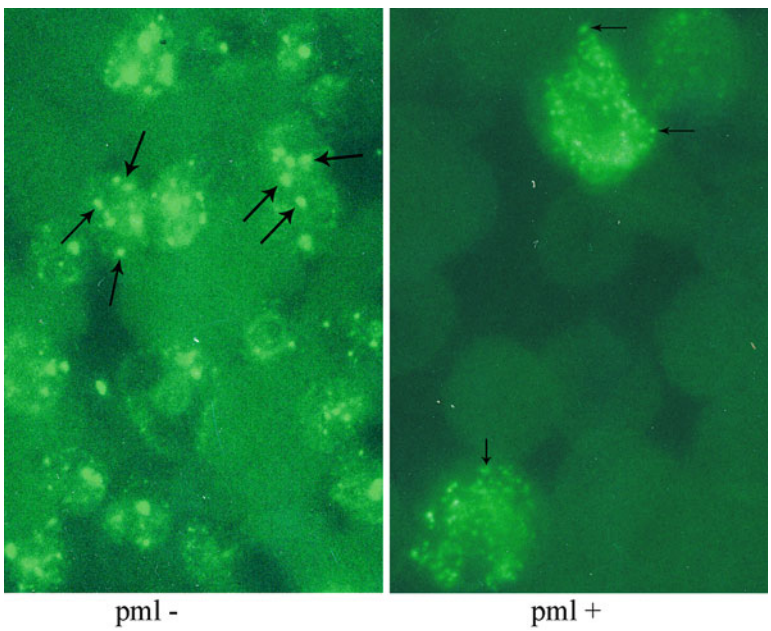

Fig. 30.9 Immunofluorescence study using an antibody specific for PML is used to highlight cellular PML oncogenic domains (POD). In the absence of t(15;17), a chunky granular or punctate pattern is observed (left). In the presence of t(15;17), a microgranular pattern is observed (right).

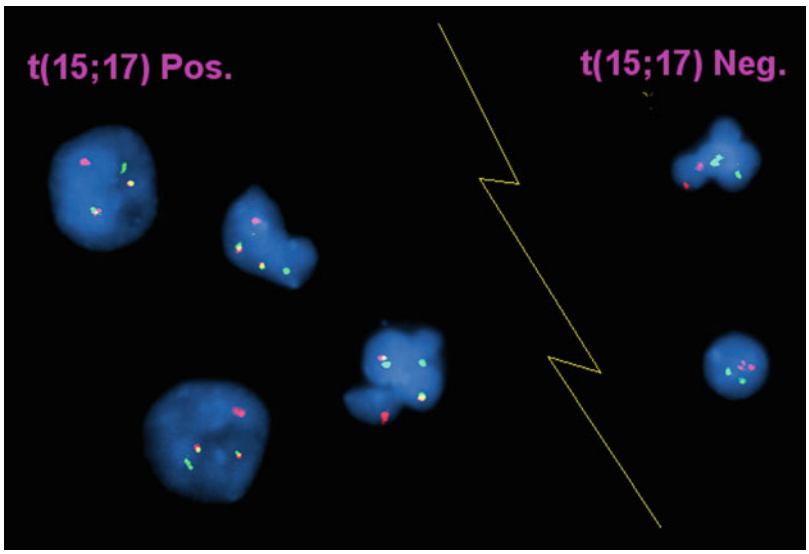

Fig. 30.10 Interphase FISH of acute promyelocytic leukemia. Dual color, dual fusion probe (Vysis) in which the *PML* probe is red and the *RARα* probe is green. In the event of t(15;17) (4 cells to the left of the image) the involved chromosomes show juxtaposition of the red and green probes producing a yellow fusion signal. Uninvolved chromosomes show red and green signals, respectively. In the absence of t(15;17), cells show two red and two green signals (2 cells to right of the image).

For the diagnosis of residual disease or early relapse after therapy, conventional cytogenetic studies, Southern blot analysis, and immunohistochemical methods are limited by low sensitivity. In contrast, RT-PCR and FISH methods are very useful. The sensitivity of RT-PCR, which can detect one cell with the *PML-RARα* gene in 1×10^5 benign cells, makes this method most useful for monitoring residual disease after therapy. For the first few months after therapy, RT-PCR results may be positive with no correlation with relapse rate. However, longer than 3 months after therapy a positive RT-PCR result significantly correlates with an increased rate of relapse [30]. FISH methods offer an advantage over RT-PCR as FISH studies may detect variant forms of the t(15;17) that are negative by RT-PCR. However, several *bona fide PML/RARα* APL cases with negative FISH results and positive PCR results have been reported in the literature [32]. These cases stress the role of morphological assessment in the establishing the diagnosis of APL and also illustrate that a negative FISH result does not eliminate the diagnosis of APL [32].

t(11;17)(q23;q21)

The t(11;17)(q23;q21) has been rarely identified in AML, in <1 % of all cases. Many patients with t(11;17)-positive AML present with a bleeding diathesis. The blast cells in these cases have cytological features intermediate between the blasts of M2 and the promyelocytes of M3 (FAB). Others have noted that many of these cases have distinctive cup-like nuclei [33]. Unlike APL, patients with t(11;17)-positive AML respond poorly to ATRA.

The t(11;17) is a reciprocal and balanced translocation involving the *PLZF* (*promyelocytic leukemia zinc finger*) gene on chromosome 11 and the *RARα* gene on chromosome 17 [34]. There is some variability in the breakpoints within the *PLZF* gene. The breakpoints in the *RARα* gene occur in the second intron, similar to those that occur in the t(15;17). The translocation results in the creation of two fusion genes, *PLZF-RARα* and *RARα-PLZF*. Both fusion genes may play a role in leukemogenesis as the structure of both chimeric proteins suggests that either can bind to DNA and influence transcription. The normal *PLZF* gene is expressed in a tissue specific manner, particularly in cells of myeloid lineage. *PLZF* is a member of a large family of zinc-finger transcription factors and is probably involved in myeloid differentiation. The poor ability of ATRA to induce differentiation in t(11;17)-positive AML suggests that disruption of the normal *PLZF* gene, rather than the *RARα* gene (as is the case in APL), is the primary leukemogenic event [35]. RARα-PLZF binds to normal PLZF which represses CRABP1 (cellular retinoic acid binding protein 1), thereby resulting in CRABP1 upregulation and thought to be involved in retinoic acid resistance. PLZF-RARα induces MYC expression and may repress normal PLZF in a dominant negative fashion.

Other Rare Variants

Rare partner genes fused with *RARα* have been identified, greatly aided by the advent of next-generation sequencing methods of cases in which conventional cytogenetics, FISH, and RT-PCR were negative, but the tumors were morphologically typical and had strong myeloperoxidase reactivity. One of the first partner genes was *NPM1* (*nucleophosmin*) in t(5;17)(q32;q21.2). The t(5;17) is a balanced and reciprocal translocation involving *NPM1* on chromosome 5 and the *RARα* gene on chromosome 17. The NPM and *RARα* genes are fused in a $5' \rightarrow 3'$ direction. The breakpoint region in the *RARα* gene is identical to the breakpoint in t(15;17). Other rare gene partners of *RARα* include: *NUMA1* (nuclear mitotic apparatus) [36], *STAT5B* (signal transducer and activator of transcription 5b) [37], *PRKAR1A* (cAMP-dependent protein kinase type I alpha regulatory subunit) [38], *FIP1L1* (FIP1-like 1) [39], *BCOR* (BCL6 corepressor) [40], *OBFC2A*

(oligonucleotide/oligosaccharide-binding fold containing 2A) [41], and *IRF2BP2* (interferon regulatory factor 2 binding protein 2) (C. Cameron Yin, personal communication).

30.2.1.4 AML with t(9;11)(p22;q23), *MLLT3–MLL*

The t(9;11)(p22;q23) represents the most common translocation involving chromosome 11q23 in patients with AML and accounts for approximately 2 % of all adult and 9–12 % pediatric AML cases [42, 43]. AMLs with the t(9;11) may be either de novo or therapy-related. De novo neoplasms occur in both children and adults. Patients with de novo AML with the t(9;11) tend to have a more favorable outcome than adults with AML associated with other 11q23 abnormalities. In addition, therapy-related cases of AML have been reported in patients treated previously with chemotherapeutic agents that target topoisomerase II. The t(9;11) is a balanced and reciprocal translocation that disrupts the *MLL* gene on chromosome 11q23 and the *MLLT3* gene (also known as *AF9* gene or *LTG9* for the leukemia translocation gene) on chromosome 9p22. The translocation results in the formation of an *MLL–MLLT3* fusion gene located on the derivative chromosome 11.

The *MLL* gene (myeloid–lymphoid leukemia or mixed lineage leukemia) gene, also known as *ALL1, HRX*, or *HRTX*, is a relatively large gene that is homologous to the *Drosophila trithorax* gene. *MLL* is promiscuous and translocations can involve many partners, including *MLLT3*. *MLL* consists of 36 exons distributed over 100 kb, and produces a 12 mRNA that encodes a 3968 amino acid protein with an estimated molecular weight of 430 kDa [44]. Recent experiments have indicated that MLL is normally processed via a cytoplasmic cleavage event into a 320 kDa amino terminus (MLL-N), and a 180 kDa carboxy terminus fragment [44]. A number of protein motifs/domains have been identified in the primary structure of MLL, including AT hooks, a DNA methyltransferase domain, PHD domains, a transactivation domain, and a SET domain. An important function of MLL is maintaining HOX gene expression during embryonic development. It has been shown that loss of MLL function in flies and mice results in embryonic lethality and homeotic transformation [44]. The ability of MLL fusion proteins to regulate the expression of HOX genes might be partially responsible for immortalization of myeloid progenitor cells. MLL also influences HOX gene expression via direct binding to promoter sequences [45] and HOXA9 is highly expressed in MLL leukemias [46]. MLL-ENL fusion protein was shown to immortalize immature myelomonocytic cells in vitro. The transplantation of these cells into mice resulted in myeloid leukemia [47]. By fusing a truncated MLL protein to an inducible dimerization domain, Martin et al. have shown that MLL fusion proteins must dimerize to immortalize hematopoietic cells and inhibit their differentiation [48]. Biochemical analysis of MLL suggests that it normally functions as a transcriptional regulator, and expression of MLL fusion proteins has been shown to be leukemogenic in mice.

Despite the large size of the *MLL* gene, most (but not all) *MLL* translocations associated with hematologic malignancy can be mapped to an 8.3 kb breakpoint cluster region (bcr). This region encompasses *MLL* exons originally designated exons 5–11. Subsequent studies revealed that *MLL* exon 4 actually consists of three discrete exons (now designated exons 4A, 4B, and 4C). There is a correlation between the locations of the breakpoints in de novo versus therapy-related AML. Using the *XbaI* restriction enzyme, the 8.3 kb fragment of DNA can be divided into a 5′ 4.6 kb region I and a 3′ 3.9 kb region II [49]. De novo AMLs more commonly have breakpoints in region I. In contrast, most cases of therapy-related AML have region II breakpoints [49]. The presence of scaffold-attachment regions and possible topoisomerase II consensus binding sites in region II may explain the increased likelihood of region II breakpoints in therapy-related AML [49].

Conventional cytogenetics is an excellent method to detect 11q23 abnormalities. This technique allows the detection of translocations involving 11q23 and also identifies all possible partner chromosomes. However, a subset of AMLs with 11q23 abnormalities may have a normal karyotype [50]. FISH techniques are also useful, and may detect a small subset of cases not recognized by conventional cytogenetics. The clustering of breakpoints within the *MLL* gene is well-suited to their detection by Southern blot analysis [51]. Using *BamHI* digested DNA, a single *MLL* cDNA probe spanning an 8.3 kb genomic fragment detects most of the common and uncommon 11q23 translocations as gene rearrangements. The introns between exons 5 through 11 are very large and thus standard PCR methods cannot be used for detecting 11q23 translocations. However, the cDNA corresponding to exons 5 through 11 is <700 bp, allowing RT-PCR analysis. A panel of primers needs to be used to detect the l lq23 translocations because of the number of possible partner chromosomes. Multiplex RT-PCR approaches are most convenient.

One of the more unusual features of leukemias associated with *MLL* fusion is that there is a very brief latency period. Leukemias with *MLL* fusions have been detected in newborns [52] and even in aborted fetuses [53]. The concordance rate of leukemia in monozygotic twins who have *MLL* fusions is almost 100 % [54]. It has been hypothesized that additional mutations occur very rapidly in cells that acquire *MLL* fusions [55]. One possible mechanism is that *MLL* fusion leads to a mutator phenotype [55]. *MLL* fusions have been shown to impair DNA double strand break recognition [56] and cell cycle checkpoints [57], both of which can lead to increased accumulation of mutations. It is also possible that the insult caused by *MLL* translocation can cause additional mutations, especially if the individual had an inherited deficiency in DNA repair or toxin metabolizing enzymes.

This possibility is supported by studies that show that certain isoforms of NQO1 or CYP3A4 confer an increased risk of infant leukemia [58] or therapy-related leukemia [59].

30.2.1.5 AML with t(6;9)(p23;q34); *DEK-NUP214*

The t(6;9)(p23;q34) (Fig. 30.11) occurs in 1–2 % of cases of AML [60]. Patients with AML and the t(6;9) are commonly of young age (<40 years old), and have a poor prognosis [60]. Approximately 50 % of patients achieve clinical remission with chemotherapy, but relapse is common. A subset of patients presents with aggressive MDS rather than AML; others present with overt AML with multilineage dysplasia [60].

The t(6;9) disrupts the *DEK* gene at chromosome 6p23 and the *CAN* (*NUP214*) gene at chromosome 9q34, resulting in a *DEK-CAN* fusion gene on the derivative chromosome 6 [61]. The breakpoints in t(6;9) are clustered. The breakpoints in the *DEK* gene occur in one intron, known as *icb*-6 (for intron containing breakpoint on chromosome 6). The breakpoints in the *CAN* gene also cluster in one intron, known as *icb*-9. The *DEK* gene is approximately 40 kb in size and encodes a 43 kDa protein, located in the cell cytoplasm, and thought to be a transcription factor. The *CAN* gene is relatively larger (over 140 kb) and encodes a 214 kDa protein. The normal CAN protein is a component of the nuclear-pore complex, involved in transport of mRNA and proteins between the cytoplasm and the nucleus [61]. The DEK-CAN fusion protein, of predicted size of 165 kDa, has a nuclear distribution, suggesting it is a part of the transcription factor system [61]. It has been suggested that DEK-CAN initiates AML within a subpopulation of hematopoietic stem cells [62].

The t(6;9) is effectively detected by conventional cytogenetics, which also allows the detection of additional abnormalities that may occur with disease progression; trisomies of 8 and 13 are the most common additional abnormalities [60]. The clustering of breakpoints in *icb*-6 of *DEK* and *icb*-9 of *CAN* also allows convenient detection by using RT-PCR methods. *FLT3* gene mutations are common in t(6;9)-positive AML [60, 63].

30.2.1.6 AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2); *RPN1-EVI1*

AML associated with inv(3) or t(3;3) is uncommon, representing 1–3 % of all cases of AML. This disease occurs in adults and men and women are equally affected [64]. De novo

Fig. 30.11 Karyotype of a case of acute myeloid leukemia with t(6;9)(p23;q34). GTG banding technique.

AML and cases arising from MDS have been described [65]. Inv(3) or t(3;3) is usually associated with other cytogenetic abnormalities and is rarely a sole abnormality.

Patients with AML with inv(3) or t(3;3) can present with prominent hepatosplenomegaly [65]. Platelet counts in the peripheral blood at presentation may be increased, normal or decreased, and demonstrate a wide range of values, from 20 to 1731×10^9/L [64, 65]. AML with inv(3) or t(3;3) is associated with increased number of micromegakaryocytes and monolobated and bilobated megakaryocytes in the bone marrow (BM). Many cases also show dysplastic changes in the erythroid and/or myeloid lineages [65, 66].

It has been shown that the chromosomal breakpoints in 3q26 are widely scattered in the 5′ or the 3′ regions of the *EVI1(Ecotropic viral integration site 1)* gene currently known as *MECOM* (*MDS1 and EVI1 complex locus*) gene [67], whereas the chromosomal breakpoints in the 3q21 region are restricted to a relatively narrow area. Two different clusters have been identified downstream of the *RPN1* (*ribophorin I*) gene [68]. Alternative splicing of *EVI1* results in the creation of *MDS1/EVI1* transcripts. Suzukawa et al. suggested that the housekeeping gene *RPN1* acts as an enhancer of *EVI1* expression, resulting in leukemogenesis [68]. It has been demonstrated that ectopic expression of *EVI1* in immature hematopoietic cells interferes with erythroid and granulocytic development [69]. While there is a single report in the literature describing good response of two patients with inv(3) to thalidomide and arsenic trioxide [70], in general, the prognosis of patients with inv(3) or t(3;3) is poor with short survival [66, 71].

30.2.1.7 Acute Megakaryoblastic Leukemia with t(1;22)(p13;q13); *RBM15-MKL1*

Most cases of AML with t(1;22) have been reported in infants [72]. The largest series published to date describes 39 cases with a median age of 4 months (range, 1 day to 36 months) [72]. The t(1;22) is a sole cytogenetic abnormality in more than half of the cases and is a sole cytogenetic abnormality much more often in infants younger than 6 months of age (19 of 23, 83 % of cases), than in older infants (3 of 16, 19 % of cases) [72]. There is a slight female predominance; all patients reported had not had evidence of Down syndrome [72]. In rare cases, *RBM15–MKL1* transcripts result from 3-way translocations involving 1p13 and 22q13, such as t(1;14;22) or t(1;22;4) [73]. Almost all patients present with organomegaly [72]; a subset of patients was initially diagnosed with a solid tumor [72]. Moderate leukocytosis with circulating blasts, marked anemia, and variable thrombocytopenia are usually observed at presentation [72, 73]. Most (~90 %) patients in the largest series reported [72] fulfilled the diagnostic criteria for AML M7. Patients usually have a hypercellular or normocellular BM; however, some patients have hypocellular BM [73]. Blasts may exhibit typical morphologic features of megakaryocytic differentiation (i.e., cytoplasmic basophilia, blast clumping, cytoplasmic blebs) or have an undifferentiated appearance [72]. The blasts usually express immunologic markers of megakaryocytic differentiation (i.e., CD42b, CD41a, Factor VIII) [72]. A subset of blasts also expresses CD34 and HLA-DR; some blasts may express the myelomonocytic marker, CD33 [72].

The t(1;22)(p13;q13) results in a fusion of *RNA-binding motif protein-15*(*RBM15*) and *megakaryocyte leukemia -1* (*MKL1*) genes [74]. t(1;22)-positive blasts express both reciprocal fusion transcripts, *RBM15–MKL1* and *MKL1–RBM15*, as detected by RT-PCR [74]. However, the predicted *RBM15–MKL1* chimeric protein encompasses all putative functional motifs encoded by each gene, which makes it the candidate oncoprotein of t(1;22). Ma et al. suggested in cases with *RBM15–MKL1* the *MKL1 SAP* domain is expected to aberrantly relocalize the *RRM* and *SPOC* motifs of *RBM15* to sites of transcriptionally active chromatin, deregulating RNA processing and/or Hox and Ras/MAP kinase signaling and altering the normal proliferation or differentiation of megakaryoblasts [74]. The prognosis of patients with AML with t(1;22) is intermediate and appears to have improved dramatically with modern therapy. The largest series published in 1999 reported a 53 % complete remission rate and median survival of 8 months (range, 1 day to 104 months) [72]. A more recent report of 11 pediatric patients published in 2003 described 6 of 11 patients being alive after more than 2 years follow-up [73].

30.2.1.8 AML with Mutated *NPM1*

The *NPM1* (nucleophosmin) gene, mapping to chromosome 5q35, contains 12 exons [74]. It encodes for three alternatively spliced nucleophosmin isoforms: B23.1, B23.2, and B23.3. Nucleophosmin is a highly conserved phosphoprotein that is ubiquitously expressed in tissues [74]. The bulk of NPM resides in the granular region of the nucleolus, but NPM shuttles continuously between nucleus and cytoplasm [74]. NPM, through its involvement in ribosome biogenesis, plays a central role in cell growth and proliferation. *NPM1* mutations result in cytoplasmic accumulation of NPM that can be detected by immunohistochemical analysis.

NPM1 functions both as an oncogene and a tumor-suppressor gene depending on gene dosage, expression levels, interacting partners, and compartmentalization [2]. *NPM1* appears implicated in promoting cell growth, as its expression increases in response to mitogenic stimuli and above normal amounts are detected in highly proliferating and malignant cells. On the other hand, *NPM1* contributes to growth suppressing pathways through its interaction with *ARF*.

NPM1 mutations are relatively specific for AML [75]. Although rare cases of *NPM1* mutations have been described in patients with chronic myelomonocytic leukemia and MDS, many of these patients rapidly progress to overt AML [76].

NPM1 mutations are relatively common in de novo AML, but rare in AML secondary to myeloproliferative/myelodysplastic disorders and therapy-related AML. *NPM1* mutations are characteristically heterozygous and retain a wild-type allele. In children with AML, the frequency of *NPM1* mutation ranges from 2.1 % in Taiwan to 6.5 % in Western countries accounting for 9–26.9 % of all childhood AML with normal karyotype. In adult AML patients, the frequency of *NPM1* mutations ranges between 25 and 35 % accounting for 46–64 % of adult AML with normal karyotype [74, 77–79]. Except for two cases involving the splicing donor site of *NPM1* in exon 9 or exon 11 [80], *NPM1* mutations are restricted to exon 12. Loss of *NPM1* mutations at relapse is rare and may be due either to emergence of a different leukemic clone or inability to detect mutations because few leukemic blasts are infiltrating the BM. AML patients with a wild type *NPM1* gene at diagnosis rarely acquire *NPM1* mutations during the course of disease, suggesting that mutations are unlikely to play a role in disease progression.

NPM1 mutations are associated with a normal karyotype and do not occur in core binding factor leukemias and acute promyelocytic leukemia [75]. Chromosomal abnormalities observed in 14 % of *NPM1* mutated AML cases usually arise in subclones and are probably secondary events associated with clonal evolution. Several studies have shown a strong correlation between *NPM1* mutations and *FLT3-ITD* [77, 78].

NPM1-mutated AML cases show a wide morphologic spectrum, but *NPM1* mutations are more frequent in the FAB M4 and M5 categories [78] and in AML with prominent nuclear invaginations (cuplike nuclei) [33]. More than 95 % of *NPM1*-mutated AML cases are CD34+ [81]. NPM-mutated AML cases with a normal karyotype often have high blast counts, high *FLT3-ITD* and LDH serum levels, extramedullary involvement (mainly gingiva and lymphadenopathy) and higher platelet counts. Bone marrow in *NPM1*-mutated AML cases frequently shows an increased number of megakaryocytes exhibiting dysplastic features [82]. After induction therapy, AML with a normal karyotype carrying mutated NPM shows a higher complete remission rate than AML with normal karyotype without *NPM1* mutations [83]. *NPM1* mutation status, however, is not an independent predictor for responsiveness to chemotherapy [81].

Conventional screening of *NPM1* mutations is usually performed by PCR using a fluorescence conjugated primer prior to fragment analysis by capillary electrophoresis. Immunohistochemical analysis to detect abnormal cytoplasmic localization of mutated NPM1 protein is another common screening method [81, 84]. Alternative methods for detecting *NPM1* mutation include denaturing high performance liquid chromatography and fluorescence resonance energy transfer technique, and direct sequencing.

30.2.1.9 AML with Mutated *CEBPA*

The *CCAAT/enhancer-binding protein a* (*CEBPA*) gene encodes a protein member of the basic region leucine zipper (bZIP) transcription factor family, playing a crucial role in granulopoiesis [85]. There are two main categories of *CEBPA* mutations: (1) C-terminal mutations that occur in the bZIP domain, which are usually in-frame and predict mutant proteins lacking DNA binding and/or homodimerization activities, and (2) N-terminal nonsense mutations that prevent expression of the full-length protein and result in truncated isoforms with dominant-negative activity. Some patients present with biallelic mutations at the C-terminus, whereas others are heterozygous for separate mutations or have a C-terminal mutation coexisting with a mutation in the N-terminus [86, 87].

CEBPA mutations usually occur in AML with a normal (diploid) karyotype and represent 15–19 % of cases in patients with normal cytogenetics. *CEBPA* mutations are associated with a favorable prognosis [79, 86, 88], and significantly better event-free survival [87, 89], disease-free survival [89], and overall survival [87, 89]. At diagnosis, patients with *CEBPA* mutations often have higher percentages of peripheral blood blasts, lower platelet counts, less lymphadenopathy and extramedullary involvement, less frequent *FLT3/ITD* and *FLT3/TKD* mutations, and rare *MLL/PTD* mutations compared with AML patients without *CEBPA* mutations [86]. Complete remission rates do not differ between patients with and without *CEBPA* mutations [79, 86, 88], but complete remission duration [86], disease-free survival [88], event-free survival [79], and overall survival [88, 96] are better for patients with *CEBPA* mutations. On multivariate analysis, *CEBPA* mutational status adds prognostic information to that provided by *MLL/PTD* and *FLT3/ITD* status, age, and resistant disease after the first course of induction therapy with regard to complete remission duration and by *FLT3/ITD* status, age, and WBC for overall survival [86]. In another study, *CEBPA* mutations, *BAALC* expression, and *FLT3/ITD* status were prognostic for disease-free survival, and *CEBPA* mutations, age, *BAALC* expression, and *FLT3/ITD* status were prognostic for overall survival [88]. Fröhling et al. [86] analyzed clinical outcomes in patients with N-terminal nonsense *CEBPA* mutations, patients with other *CEBPA* mutation types, and patients with wild-type *CEBPA* and found that the complete remission duration was the longest in patients with N-terminal mutations, followed by the complete remission duration in patients with other mutations and in those without *CEBPA* mutations. However, in pairwise comparisons, there were no significant differences in the complete remission duration between patients with N-terminal mutations and those with other mutations or between patients with other mutations and patients with wild-type *CEBPA* [86].

30.2.2 AML Associated with Translocations Not Included in the AML with Recurrent Genetic Abnormalities Category of the Current WHO Classification

30.2.2.1 AML with 11q23 (*MLL*) Abnormalities Other Than t(9;11)

Translocations involving the 11q23 locus are detected in 3–10 % of all patients with de novo AML [90]. In infants (age <1 year), AML with 11q23 translocations typically presents with hyperleukocytosis and has a poor prognosis [91]. Translocations involving chromosome 11q23 are found in more than 70 % of leukemia patients younger than 1 year of age whether the immunophenotype is designated AML or ALL. In adults, AMLs with 1lq23 translocations most commonly exhibit monocytic maturation and are classified as FAB M4 or M5. These AMLs do not have specific clinical features and may have a poorer prognosis than AMLs without 11q23 translocations. In addition, 80–90 % of therapy-related AMLs that occur in patients previously treated with topoisomerase II inhibitors are associated with 11q23 translocations. Translocations involving the 11q23 locus are not restricted to AML and are associated with different hematologic malignancies including precursor T or B lymphoblastic leukemia, MDS, and Burkitt lymphoma [51, 90]. In addition, *MLL* has been labeled a promiscuous oncogene since translocations involving over 60 partner genes or regions have been identified [90].

AML/MDS with t(11;16)(q23;p13.3). The t(11;16) is a rare recurrent translocation that has been identified in therapy-related AML and MDS, occurring almost exclusively in patients treated previously with agents that inhibit topoisomerase II [92]. The t(11;16) is a reciprocal translocation that disrupts the *MLL* gene at 11q23 and the CBP cAMP response element or CREB-binding protein) gene at 16p13.3, resulting in the formation of an *MLL-CBP* fusion gene located on the derivative chromosome 11 [92]. A *CBP-MLL* fusion gene is also produced, but not in all cases, and therefore is not thought to be leukemogenic. The normal CBP protein is a transcriptional adaptor/coactivator protein.

Other 11q23 translocations in AML. Other 11q23 translocations less commonly identified in AMLs include the t(6;11)(q27;q23), t(11;19)(q23;p13.3), t(11;19)(q23;p13.1), t(1;11)(p32;q23), t(l;11)(q21;q23), t(11;17)(q23;q21), and t(10;11)(p11;q23). In each of these translocations, the *MLL* gene is disrupted and its 5′ end is fused with the 3′ end of the partner gene: *AF6* (*MLLT4*) in the t(6;11), *ENL* (*MLLT1*) in the t(11;19)(q23;19p13.3), *ELL* in the t(11;19)(11q23;19p13.1), *AFlp* in the t(1;11)(p32;q23), *AFlq* in the t(l;11)(q21;q23), *AF17* (*MLLT6*) in the t(11;17), and *AF10* (*MLLT10*) in the t(10;11) [93]. The formation of these fusion genes, all located on the derivative chromosome 11, results in the generation of a novel chimeric protein.

30.2.2.2 11q23 Rearrangements Identified in AMLs with Normal Cytogenetics and Trisomy 11

MLL gene rearrangements have been shown in ~10 % of AML with a normal karyotype. All were shown to have partial tandem duplications (PTD) of the 5′ part of the *MLL* gene [50]. These mutations occur in 3–10 % of adult AML cases, but are uncommon in pediatric AMLs. MLL-PTDs are extremely frequent in conjunction with trisomy 11 [50, 94, 95] and are associated with an unfavorable outcome [50, 96]. Another type of intrachromosomal rearrangement of the *MLL*, intrachromosomal amplification, also occurs. This type most likely leads to increased *MLL* expression in AML and MDS [97].

30.2.2.3 AML with inv(11)(p15q22)

The inv(11)(p15q22) has been identified in a very small number of de novo and therapy-related cases of AML [98]. This inversion disrupts the *DDX10* gene at chromosome 11q22 and the *NUP98* gene at 11p15, creating the *NUP98-DDX10* fusion gene. A reciprocal *DDX10-NUP98* fusion gene is also created and may be expressed, but is not thought to be involved in neoplastic transformation [98]. The normal *DDX10* gene is large, spanning 200 kb, and is composed of at least 12 exons. This gene is a DEAD-box putative RNA helicase gene that encodes a protein that may be involved in ribosomal assembly [99]. The *DDXl0* gene is ubiquitously expressed in normal tissues. The normal *NUP98* gene encodes a nuclear-pore complex protein that is also ubiquitously expressed.

30.2.2.4 AML with t(16;21)(p11;q22)

Most neoplasms with the t(16;21) have been AMLs, but rare cases of CML in blast crisis and MDS with the t(16;21) have been described [100]. Patients with AML associated with the t(16;21) are generally young and have a poor prognosis. The t(16;21) is a reciprocal and balanced translocation that disrupts the *TLS/FUS* gene at chromosome 16p11 and the *ERG* (*ETS*-related gene) gene on chromosome 21q22 [101]. As a result two fusion genes are created, *TLS/FUS-ERG* on the derivative chromosome 21 and *ERG-TLS/FUS* on the derivative chromosome 16. Although both fusion genes may be expressed, only the *TLS/FUS-ERG* fusion gene is consistently expressed in all cases, suggesting that this chimeric protein is involved in leukemogenesis [101]. Both the *TLS/FUS* and *ERG* genes are oriented 5′ → 3′. The normal *TLS/FUS* gene encodes an RNA-binding protein that is highly homologous to the *EWS* gene involved in Ewing sarcoma. The TLS/FUS protein plays a role in activating transcription. The normal *ERG* gene, a member of the *ETS* proto-oncogene superfamily, also encodes an RNA-binding protein and is a potent transcriptional activator [101]. At least four different transcripts of the *TLS/FUS-ERG* have been identified. These

transcripts result from variability in the breakpoints and alternative RNA splicing. In most cases, the breakpoint in the *ERG* gene is tightly clustered in one intron. The breakpoints in the *TLS/FUS* gene are more variable [100].

30.2.2.5 AML with t(12;22)(p13;q11)

The t(12;22)(p13;q11) is found in AML and rare cases of MDS and CML. The t(12;22) is a reciprocal translocation involving the *ETS variant 6* (*ETV6*) gene (*known previously as TEL oncogene)* at chromosome 12p13 and the *MNI* (meningioma) gene at chromosome 22q11 [102]. The translocation disrupts the *ETV6* and *MNI* genes, resulting in the formation of *MNI-ETV6* and *ETV6-MNI* fusion genes. The *MNI-ETV6* fusion gene is likely to encode the leukemogenic protein, based on the predicted structure of the fusion protein, which is consistent with an altered transcription factor. The *MNI-ETV6* fusion gene also has been constantly expressed in the small number of neoplasms analyzed, unlike the *ETV6-MNI* fusion gene [102]. The normal *ETV6* gene is very large, exceeding 150 kb, and is a member of the *ETS* gene family of transcription factors. *ETV6* is ubiquitously expressed in tissues. The normal *MNI* gene is less well-known. The gene was originally cloned from a t(4;22)(p16;q11) identified in a case of sporadic meningioma [103]. The gene spans 70 kb, has at least two exons separated by a large intron, and encodes a protein predicted to have 1319 amino acids. The breakpoints in the *MNI* gene appear to be clustered in the 5′-region of the intron [103].

30.2.2.6 AML with t(8;16)(p11;p13)

The t(8;16)(p11;13) is identified in <1 % of all cases of AML. Most AMLs with the t(8;16) exhibit monocytic differentiation and are morphologically classified using the FAB as M4 or M5 [104]. The blasts often exhibit evidence of erythrophagocytosis. Both de novo and therapy-related AMLs with the t(8;16) have been reported. De novo cases commonly occur in children and adolescents (<18 years of age) [104]. The t(8;16) is a reciprocal translocation, involving the *MOZ* (monocytic leukemia zinc-finger protein) located at chromosome 8p11 and *CREB binding protein* (*CREBBP*) gene located at 16p13 [105]. The translocation disrupts these genes, resulting in the formation of a *MOZ-CBP* fusion gene on the derivative chromosome 8. A *CREBBP-MOZ* fusion gene is also created, but is thought to be nonfunctional. The *MOZ* gene encodes a 225 kDa protein that is widely expressed in tissues. The protein has both zinc-finger and acetyltransferase domains and may mediate leukemogenesis by aberrant acetylation of chromatin [105]. The *CREBBP* gene spans 190 kb and encodes a protein involved in transcriptional activation. Mutations in the *CREBBP* gene have been identified in a rare genetic disease, the Rubinstein–Taybi syndrome, characterized by mental retardation, dysmorphic cranial features, and digital abnormalities [106].

30.2.2.7 AML with t(3;21)(q26;q22)

The t(3;21)(q26;q2.2) has been reported in cases of chronic myelogenous leukemia (CML) in blast crisis, in MDS, and in AML following treatment with topoisomerase II inhibitors such as etoposide [107]. The breakpoint in the *AML1* gene on chromosome 21 may be identical to that in the t(8;21), but more often occurs approx. 60 kb downstream. The chromosome 3q26 locus is the site of three different genes that are involved in the t(3;21): from telomere to centromere, *EAP, MDS1*, and *EVI1*. These genes are located within 200 kb of each other. In each of these translocations, the 5′-end of the *AML1* (*RUNX1*) gene, including sequences that encode the *runt*-like domain, is fused to the 3′-end of one of these partner genes [107].

In the *AML1-EAP* fusion gene, the 3′-*EAP* sequence is very small and it is not fused to *AML1* in reading frame. Thus, the AML1-EAP chimeric protein lacks transactivation activity and may exert its effect by inhibiting normal AML1 protein. In contrast, the *AML1*-MDS1 and *AML1-EVI1* fusion genes contain 3′-sequences of the *MDS1* and *EVI1* genes, suggesting that their proteins possibly have unique functions, in addition to inhibiting normal AML1 protein. One potential explanation for the occurrence of these different translocations, not proven, is that the entire 3q26 region is transcribed as a result of the t(3;21), and different fusion genes result from alternative splicing of mRNA [108]. The normal EAP, MDS1, and EVI1 proteins are not normally expressed in hematopoietic cells, but are expressed as a result of the t(3;21).

30.2.2.8 AML with t(9;22)(q34;q11)

The existence of AML associated with t(9;22)(q34;q11) has been controversial in the past, in large part, because distinguishing AML from an initial presentation of CML in blast crisis (phase) can be difficult. The presence of Philadelphia chromosome and *BCR/ABL* fusion gene transcripts are not reliable criteria, as some cases of AML with these features have been reported [109], including cases in which *BCR/ABL* fusion transcripts were acquired in MDS. To complicate the issue, the karyotype in CML blast crisis is often very complex. Some authors believe that the only reliable way to distinguish these entities is by assessing therapeutic response or by testing maturing hematopoietic elements for the *BCR/ABL*, present in CML only. The t(9;22)(q34;q11) is rarely identified in apparently de novo cases of AML, in 1–2 % of cases [109, 110]. The t(9;22) involves the *ABL1* gene at chromosome 9q34 and the *BCR* gene at chromosome 22q11. The translocation results in a *BCR-ABL* fusion transcript. Two different forms of the t(9;22) have been detected in AML that result in either a 190 kDa or 210 kDa fusion protein [110]. In both translocations, the breakpoint in *ABL1* occurs in the same general area, in the proximal portion of the gene. In the $p190^{bcr\text{-}abl}$ form, the breakpoint in *BCR* occurs in the first

exon. In contrast, in the $p210^{bcr\text{-}abl}$ form the breakpoint occurs in the 5.8 kb major breakpoint region of *BCR*. The detection of the $p190^{bcr\text{-}abl}$form of the t(9;22) in a case of AML is evidence to support the diagnosis of de novo AML. *NPM1* mutations have been identified in a subset of de novo AML associated with t(9;22) [109], but no *ABL1* mutations, known to occur in a subset of untreated CML patients, have been reported [109].

30.2.2.9 AML with t(7;11)(p15;p15)

The t(7;11)(p15;p15) is a rare translocation in AML. Morphologically, most AMLs with the t(7;11) exhibit granulocytic maturation and are classified as FAB-M2; coexistent myelodysplastic features are common [111]. Most patients with t(7;11)-positive AML have been Japanese adults, suggesting a genetic predisposition for this type of AML [111].

The t(7;11) disrupts the *HOXA9* gene at chromosome 7p15 and the *NUP98* gene at 11p15, resulting in formation of the *NUP98-HOXA9* and *HOXA9-NUP98* fusion genes [105, 111]. The *NUP98-HOXA9* fusion gene, located on the derivative chromosome 11, is thought to be involved in leukemogenesis, based on the predicted structure of the chimeric protein [105, 111]. The reciprocal *HOXA9-NUP98* fusion gene is probably nonfunctional, and was not amplifiable by RT-PCR in a subset of cases tested [105]. The normal HOXA9 gene is a member of the homeobox gene family, and is involved in development and differentiation. The HOXA9 gene encodes a class I homeodomain protein that is expressed in hematopoietic cells and the kidney [105, 111]. The normal *NUP98* gene is relatively small, with five exons, and encodes a component of the nuclear-pore complex that is 98 kDa.

30.2.2.10 Gene Mutations Associated with AML

FLT3 Gene

FMS-like receptor tyrosine kinase 3 (*FLT3*), also known as *fetal liver kinase 2* (*FLK-2*) and *stem cell tyrosine kinase 1* (*STK-1*), belongs to a class III receptor tyrosine kinase family that also includes *KIT*, *FMS*, and *platelet-derived growth factor receptor* (*PDGFR*) [112]. The human *FLT3* gene is located on chromosome 13q12 and contains 24 exons [112]. *FLT3* has been demonstrated to exist in two forms: a membrane-bound protein of 158–160 kDa that is glycosylated at N-linked glycosylation sites in the extracellular domain and an unglycosylated protein of 130–143 kDa that is not membrane bound [113]. FLT3 is preferentially expressed by hematopoietic stem cells as well as in the brain, placenta, and liver [114]. The ligand of FLT3, which is expressed as a membrane-bound or soluble form by bone marrow stromal cells, stimulates the stem cells by itself or in cooperation with other cytokines [113, 115–117]. FLT3 is expressed on the surface of a high proportion of AML and stimulation of FLT3 enhances proliferation and reduces apoptosis [118].

Two unique forms of *FLT3* gene mutation have been described. Initially, an internal tandem duplication (ITD) in the juxtamembrane domain–coding sequence of *FLT3* was described (Fig. 30.12) [119]. Subsequently, a missense point mutation at the D835 residue and point mutations, deletions, and insertions in the codons surrounding D835 within a *FLT3 kinase domain* (KDM) were found [120, 121]. *FLT3/ITD* and *FLT3/KDM* occurs in 15–35 and 5–10 % of adults with AML, respectively, and are associated with a poor prognosis [122, 123]. In addition, extremely high levels of *FLT3* transcripts have been demonstrated in a proportion of AML patients without *FLT3* mutations, and are also associated with a poor prognosis [124]. Rarely, both types of mutations occur simultaneously in AML; this may be related to clonal progression [125].

FLT3 mutations lead to constitutive activation resulting in increased receptor signaling, which in turn is invovled in tumorigenesis. *FLT3/ITD* is constitutively phosphorylated on tyrosine residues and forms homodimers and, if the ITD-containing *FLT3* is cotransfected with wild-type *FLT3*, a heterodimer with wild type *FLT3* [122]. *FLT3/ITD* or *FLT3/KDM* result in autonomous proliferation of murine interleukin 3-dependent cell lines, such as 32D, and induce consti-

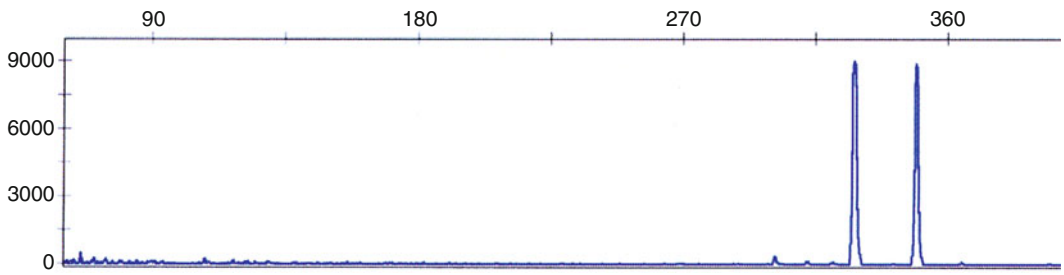

Fig. 30.12 Multiplex fluorescence-based PCR method used to detect internal tandem duplication (ITD) of FLT3. DNA is assessed by amplification of the juxtamembrane domain using primers from exons 11 and 12. The presence of second, larger peak signifies that *FLT3/ITD* is present.

tutive activation of downstream signaling molecules, such as signal transducer and activation of transcription 5 (STAT5), MAP kinase, SHC, AKT, and BAD [122, 126, 127]. 32D cells are known to differentiate into mature neutrophils in response to granulocyte colony-stimulating factor (G-CSF). However, both *FLT3/ITD*-expressing and *FLT3/KDM*-expressing 32D cells do not differentiate into mature neutrophils when they are treated with G-CSF [128]. These results indicate that *FLT3* mutations are involved in cascades for autonomous cell proliferation and differentiation block. In addition, mutant *FLT3* has antiapoptotic effects on leukemia cells [127].

It has been shown that *FLT3/ITD* induces an oligoclonal myeloproliferative disorder in mice, but not AML, suggesting that additional mutations impairing hematopoietic differentiation and/or proliferation may be necessary for AML development [129]. Transplantation of *FLT3/ITD*-transfected bone marrow cells into *PML/RARα* transgenic mice clearly shortens the latency period and increases penetrance for developing acute promyelocytic leukemia-like disease [130].

FLT3 mutations are mainly found in de novo AML, and are less frequent in AMLs that have developed from MDS or therapy-related AML [131, 132]. In low grade MDS, *FLT3/ITD* or *FLT3/KDM* occurs in approximately 3 % of cases. However, the frequency increases in advanced-stage MDS, and in up to 15 % in patients with AML that has developed from MDS [131, 132]. The frequency of *FLT3* mutations in AML is associated with patient age. *FLT3/ITD* has been found in about 25 % of adult AML patients, but is higher (~30 %) in patients older than 55 years [133]. In contrast, *FLT3/ITD* has been found in approximately 10 % of pediatric AML patients [134, 135] and is rare in infant AML. *FLT3* mutations are frequently found in AML with normal or intermediate-risk cytogenetic characteristics and with t(15;17), but are infrequent in patients with core binding factor translocations, such as t(8;21) and inv(16). Recently, it has been demonstrated that the *NPM1* gene is mutated in more than 60 % of adult AML patients harboring *FLT3* mutations [77–79].

FLT3/ITD is strongly associated with leukocytosis and an increased percentage of blast cells in the peripheral blood and BM of AML patients [131, 132]. The association of *FLT3/KDM* with leukocytosis is controversial. Only one study has demonstrated significant leukocytosis in adults who have AML with *FLT3/KDM* [121]. Several large-scale studies have shown the impact of *FLT3* mutations on patient outcome. *FLT3/ITD* is a strong adverse predictive factor for overall survival, disease-free survival, and event-free survival within the intermediate-risk cytogenetic category. The clinical impact of *FLT3/KDM* on long-term outcome is controversial. Recent meta-analysis of four published studies including 1160 adult AML patients suggests an adverse effect of *FLT3/KDM*s on long term outcome [136].

RAS Gene

RAS is a GTP-dependent, 21 kDa protein that is localized at the inner side of the cell membrane. RAS is encoded by the *RAS* gene family, including *KRAS* located at 12p12.1, *HRAS* located at 11p15.5, and *NRAS* located at 1p13.2. RAS binds guanine nucleotides, displays intrinsic GTPase activity, and transduces signals from growth factor receptors to downstream effectors. The GTPase-mediated cycling between *RAS* bound to GTP (active conformation) versus GDP (inactive conformation) serves as a regulatory switch for signal transduction.

In AML, activating somatic mutations in the first two exons of *RAS* have been described, including codons 12, 13, and 61 of *N-RAS*, and sporadically in *K-RAS* [137]. These point mutations disrupt *RAS* function by diminishing GTPase activity. The reported frequency of *N-RAS* mutations in AML ranges from 10 to 27 % [137]. *K-RAS* mutations at the same codons can be found in approximately 5–10 % of pediatric and adult AML patients [138]. *H-RAS* mutations are rare in hematologic tumors [137]. In two studies, the presence of *RAS* mutations correlated with low blast counts in the BM and a better survival of patients in an age-adjusted analysis [139]. However, in other reports patients with *RAS* mutations showed a trend to a worse outcome compared to patients without tyrosine kinase or *RAS* mutations [138].

Patients with MDS and *N-RAS* mutations have a very high risk of progression to AML suggesting that these mutations might represent an important progression factor in MDS. On the other hand, analyses of *RAS* mutation status in patients at first diagnosis and at relapse revealed a marked instability of these mutations, with loss of mutations in some cases or new mutations in different codons. This may indicate that RAS mutation is not a leukemia-initiating event [140]. *RAS* has been shown to be an important mediator of G-CSF-induced and thrombopoietin-induced differentiation and to enhance the function of CEBPA in promoting myeloid differentiation [141].

KIT Gene

Activating mutations of *KIT*, which are well-known in mast cell disorders and in gastrointestinal stromal tumors, also occur in AML. These mutations usually occur in one of two regions: the juxtamembrane region that functions as a negative regulatory region [142], and residues in the activation loop. *KIT* mutations are infrequent in AML in general, but are more common in patients with core binding factor AMLs, ranging from 2 to 20 % [143].

G-CSF Receptor

Approximately 20 % of patients with severe congenital neutropenia have *G-CSF receptor* point mutations. These mutations result in a truncation of the C-terminal region which is crucial for G-CSF signaling [144]. The mutated receptor

interrupts signals required for normal myeloid cells. Patients with these mutations have an increased risk of progression to AML [144]. In 32D cells, the expression of a truncated G-CSF receptor resulted in increased proliferation without neutrophilic differentiation [145]. Transgenic mice expressing mutant G-CSF receptor (truncated at amino acid 715) develop a form of neutropenia in which myeloid progenitors react to G-CSF with hyperproliferation and neutrophilia [146]. Transgenic mice overexpressing a form of the receptor truncated at amino acid 718 or 731 have low neutrophil counts compared with wild-type controls and increased numbers of immature myeloid cells in the bone marrow [146, 147]. These effects are attributed to ligand-induced internalization of the receptor [148], reduced ability of the mutant receptor to activate STAT3, and reduced STAT5 inhibition by SOCS3 [149]. These features might be responsible for increased risk of AML in patients with severe congenital neutropenia.

IDH1 and *IDH2*

The isocitrate dehydrogenase (IDH) family of enzymes has three members: IDH1, IDH2, and IDH3. These enzymes catalyze the oxidative decarboxylation of isocitrate to produce CO2 and α-ketoglutarate (αKG). IDH1 and IDH2 are NADP+-dependent while IDH3 is NAD+-dependent. IDH1 contains a C-terminal peroxisomal localization sequence and is localized in both peroxisomes and cytosol; IDH2 and IDH3 are located in mitochondria [150]. A mutation in the *IDH1* gene was first discovered in colorectal cancer and subsequently shown in brain gliomas. Later, mutations in *IDH1* and *IDH2* were identified in AML as well as MDS [151, 152]. In addition, *IDH2* mutations have been identified in T-cell lymphomas, but to date, there have been no reports of cancer-associated mutations in *IDH3*.

In the initial report by Mardis and colleagues, *IDH1 R132* mutation was detected in approximately 8 % of AML cases analyzed and was associated with normal cytogenetics [153]. Subsequently *IDH2* mutations were detected in patients with AML. The initial study cited the frequency of IDH1 and IDH2 mutations in patients with AML as 7.7 and 15.4 %, respectively [153]. In subsequent studies, focused on a relatively homogenous group of adult patients with de novo AML with diploid cytogenetics, mutations in *IDH1* and *IDH2* were found in 14 and 19 % of cases, respectively [151, 152]. *IDH1* and *IDH2* mutations are not mutually exclusive as several patients harboring both an *IDH1* and *IDH2* mutation have been detected [152, 155]. Unbiased sequencing also has revealed the presence of 12 nonsynonymous recurring mutations (including *IDH1*) in more than one AML genome. The data implicate these alterations as important for leukemogenesis [153].

Recent studies across large patient cohorts have shown that *IDH1 and IDH2* mutations are strongly associated with the presence of *NPM1* mutation [153–156]. An analysis of cytogenetically diploid AML patients has shown that IDH mutations adversely affect prognosis [152]. Retrospective clinical trial data also have shown that IDH1 or *IDH2* mutations are associated with a worse prognosis in younger AML patients with diploid cytogenetics and mutated *NPM1* without *FLT3-ITD* [152, 155].

TP53 Gene

The *TP53* tumor-suppressor gene, located at chromosome 17p13, is mutated in a wide variety of human cancers including AMLs. *TP53* encodes for a nuclear phosphoprotein that binds to DNA and influences the expression of a variety of genes. p53 protein appears to be involved in cell proliferation, apoptosis, and DNA repair. Over 200 cases of AML have been assessed for *TP53* abnormalities. Point mutations were identified in about 6 % of cases. *TP53* gene mutations have been identified in all morphologic types of AML except acute promyelocytic leukemia. Presence of *TP53* mutations correlates with older patient age, presence of myelodysplasia, and poorer prognosis [157].

30.2.2.11 Other Abnormalities in AML

STAT Activation

Consitutive activation (phosphorylation) of signal transducer and activator of transcription (STAT) 3 and STAT5 has been shown in cases of AML [126]. For full transcriptional activity, STAT proteins must be phosphorylated on serine residues, often by MAP kinases, and this also has been observed in AML blasts. Aberrant regulation of gene expression contributes to constitutive activation of STAT proteins. STAT3 and STAT5 can be activated by mutationally activated isoforms of KIT and FLT3 in AML blasts [126]. SOCS proteins are potent repressors of STAT activation, and their ability to repress transcription occurs through aberrant DNA-methylation of regulatory regions upstream of their transcriptional initiation site.

Constitutive activation of STAT3 and STAT5 appears to work as a signal integration site for several pathways on the way to leukemic transformation. The transforming ability of constitutively activated STAT5 protein on mouse bone marrow was demonstrated using retroviral transduction/transplantation studies. STAT3 or STAT5 are necessary for tyrosine kinase-mediated transformation of myeloid cells.

CXCR4 Expression

CXC chemokine receptor 4 (CXCR4) is one of a number of chemokine receptors defined by their ability to induce cell migration towards a chemotactic cytokine gradient (chemotaxis). CXCR4 has received much attention in the literature because it is the receptor for stromal derived factor (SDF-1α), also known as CXCL12, and the CXCR4-CXCL12 axis is

essential for the migration of normal cells to the bone marrow microenvironment [158]. CXCR4-CXCL12 also appears to play a role in metastases of both hematopoietic and solid tumors [158, 159]. CXCR4 is expressed and functional in a subset of AML cases and expression correlates with poorer prognosis [159, 160]. In addition, CXCR4 has been reported to be expressed more frequently and at a higher level in AML cases associated with *FLT3/ITD* mutations [161]. Based on this last observation, a link between CXCR4 expression and *FLT3/ITD* mutation has been proposed. One group has demonstrated that CXCR4 expression is associated with a poorer prognosis in AML patients with normal cytogenetics and unmutated *FLT3* [160].

Antigen-Receptor Gene Rearrangements in AML

Immunoglobulin heavy chain (IgH) and /or T-cell receptor (TCR) β-chain and γ-chain gene rearrangements have been detected in less than 5 % of cases of AML, using Southern blot analysis [162]. However, a study of AMLs using PCR-based methods found a substantially higher number of cases with monoclonal IgH gene rearrangements. *T-cell receptor* rearrangements are more common in AML cases with stem cell immunophenotypic features. Many AML cases with antigen-receptor gene rearrangements are undifferentiated, often TdT-positive, and express one or more lymphoid-associated antigens, suggesting that these leukemias are arising from an early BM precursor cell with multilineage potential [162]. Patients with AML associated with antigen receptor gene rearrangements are reported to have a poorer prognosis than patients with AML without these gene rearrangements.

30.2.2.12 Therapy-Related AML

Patients with therapy-related acute myeloid leukemia (t-AML) present either early, within 3 years of cessation of all chemotherapy, or late, 7 or more years after completion of therapy. Early t-AMLs often display balanced translocations, especially involving the *MLL* gene, whereas late t-AMLs often shown unbalanced rearrangements, cytogenetic abnormalities of chromosomes 5 and 7, and are often preceded by MDS [163]. Clinicopathologic studies with multivariate analysis have implicated topoisomerase II inhibitors, particularly the epipodophyllotoxins etoposide and teniposide, in the generation of balanced *MLL* translocations in the patients with early t-AML [164]. Data from the initial series of cases with t-AML related to topoisomerase II inhibitors suggested that the epipodophyllotoxins were more highly associated with t-AML than other topo II agents, and that dose and schedule of therapy were important.

Cytotoxic chemotherapeutic agents are associated with cases of late t-AML. Gene mutation studies using next-generation sequencing methods have shown that mutation profiles in t-AML differ greatly from de novo AML cases. In particular, *TP53* mutations are much more common in t-AML.

30.2.2.13 AML in Patients with Down Syndrome

Children with Down syndrome (DS) have a 10-fold to 20-fold increased risk of developing acute megakaryoblastic leukemia when compared with their non-DS counterparts [165]. Recently, an important role for the hematopoietic transcription factor *GATA1* has been demonstrated in DS patients with either transient myeloproliferative disorder (also known as transient abnormal myelopoiesis) or acute megakaryoblastic leukemia [166]. Expression of *GATA1* is essential for normal maturation of erythroid cells and megakaryocytes [167]. In two studies of 41 DS patients with acute megakaryoblastic leukemia or transient myeloproliferative disorder, missense mutations in *GATA1* were identified in over 90 % of cases; the mutations were not identified in subsequent remission samples and were determined to be acquired [168]. In contrast, *GATA1* mutations were not seen in four cases of acute lymphoblastic leukemia in DS patients [168].

Genomic profiling studies have shown that cases of transient myeloproliferative disorder often have only trisomy 21 and *GATA1* mutations. In contrast, in patients that progress to acute megaryoblastic leukemia a number of other genes are mutated including cohesin genes, genes that regulate epigenetics (e.g., *EZH2*), *CTCF*, *JAK* family genes, *MPL*, and *RAS* pathway genes [169].

30.2.2.14 Hypoxia and Hypoxia-Related Changes

Recently, hypoxia and hypoxia-related changes in the BM have attracted the attention of investigators analyzing AML and other malignancies. In normal BM, hypoxia is critical for development of hematopoietic stem cells [170]. A critical role in mediating the effect of hypoxia on hematopoietic stem cells is played by hypoxia-inducible factor 1 alpha (HIF1α) [171]. Decrease in oxygen tension in BM can lead to the selective outgrowth of AML clones with a survival advantage in the severely hypoxic microenvironment [172]. Data obtained from animal models indicate that AML progression within BM is associated with further decreases in overall oxygenation and expansion of hypoxic areas [172]. Hypoxia also affects the exposure of AML cells to systemic chemotherapy and the antitumor immune response [173]. The overexpression of HIF1α in primary AML and acute lymphoblastic leukemia BM samples correlates with poor chemotherapy outcomes [174, 175]. For these reasons, hypoxia-activated agents, novel cytotoxic drugs preferentially activated under low oxygenation conditions, may have an active role in the treatment of AML and other BM malignancies. Recent studies have demonstrated that HIF1α plays a role in cancer progression by activating transcriptional programs for maintaining the self-renewal and multipotent capacities of cancer stem cells in a hypoxic environment [176–178]. HIF1α was also shown to be required for stem cell functions in mouse lymphoma and human AML [179].

One of the new approaches in AML therapy is hypoxia-activated prodrugs such as TH-302. TH-302 is a 2-nitroimidazole hypoxia-activated prodrug of the cytotoxin bromo-isophosphoramide mustard. In vitro, TH-302 demonstrates activity against solid tumors, multiple myeloma cells, and AML cells under low oxygen tension [173, 180, 181]. In clinical trials, TH-302 alone and in combination with chemotherapy was very effective in solid tumors and hematologic malignancies including AML and multiple myeloma [182, 183].

30.3 Blastic Plasmacytoid Dendritic Cell Neoplasm

Blastic plasmacytoid dendritic cell neoplasm (BPDCN) is a rare tumor that arises from precursors of plasmacytoid dendritic cells (also known as plasmacytoid monocytes or professional type 1 interferon producing cells). The age range of patients with BPDCN is quite broad, from young children to the elderly and males are more often affected. Patients with BPDCN usually present with skin disease and involvement of bone marrow. Most patients also present with low-level peripheral blood involvement and lymphadenopathy occurs in about 50 % of patients. Overall survival is poor, in the range of 1–2 years despite therapy [184, 185].

Conventional cytogenetic analysis commonly shows a complex karyotype but there are no consistent recurrent abnormalities. Deletions of a number of chromosomal loci have been reported with del(5q) most common. Rare cases reported have had T-cell receptor gene rearrangements, but in most cases of BPDCN the *IgH* and *TCR* genes are germ line.

Gene expression profiling of BPDCN has pointed to activation of the NF-kB pathway as a potential therapeutic target [186]. A number of gene mutations have been identified using whole exome or more targeted sequencing approaches including *TET*, *IKZF3*, *HOXB9*, *UBE2G2*, and *ZEB2*. A single case of a child with BPDCN associated with a *CLTC-ALK* fusion gene has been reported [187].

TET mutations are most common in BPDCN, in up to 40 % of cases [184]. *TET* is also mutated in cases of MDS and AML. TET normally converts 5-methyl-cytosine to 5-hydroxymethylcytosine and is expressed in early hematopoietic precursors. TET is involved in epigenetic regulation and hematopoiesis. *TET* mutations are usually heterozygous and result in loss of function, presumably allowing uncontrolled expansion of hematopoietic cells [187].

30.4 Acute Lymphoblastic Leukemia

Acute lymphoblastic leukemia (ALL) is an umbrella term for a group of neoplasms composed of immature lymphoid cells that are derived from the bone marrow. Previously, the FAB system classified these neoplasms on the basis of their morphological features as L1, L2, or L3. It is now recognized that the distinction between L1 and L2 has little biological and clinical meaning, and that L3 cases represent Burkitt lymphoma/leukemia [188].

Far more important in ALL are their immunophenotypic and molecular features. Cases of ALL can be divided into immature B-cell and T-cell neoplasms and each of these categories has a number of molecular subgroups. Approximately 80–90 % of ALL cases are of immature B-cell lineage, and include neoplasms once designated as non-B/non-T, null, and common ALL. The remaining 10–20 % of ALL cases are of T-cell lineage. Heritable syndromes predisposing to ALL and *germ line* mutations in known tumor-suppressor genes are uncommon, implying that most cases probably arise from somatic mutations in immature lymphoid cells.

Immature B-cell and T-cell neoplasms can present as either ALL or lymphoblastic lymphoma. At the molecular level leukemic and lymphomatous B-cell or T-cell neoplasms appear to be similar. For this reason, the current WHO classification designates these tumors as B or T lymphoblastic leukemia/lymphoma. However, as most studies of these tumors have focused on cases that presented as leukemia we use the terms B-ALL or T-ALL or lymphoblastic lymphoma (LBL).

30.4.1 B-Cell ALL

Based on antigen expression, B-ALLs can be further subclassified into as many as five subgroups: (1) pre-pre-B-ALL, (2) early pre-B-ALL, (3) pre-B-ALL, (4) transitional B-ALL, or (5) mature B-ALL, although subdivision into fewer subgroups based on the expression of CD10, cytoplasmic IgM, and surface immunoglobulin is the usual practice. Nearly all B-ALLs carry monoclonal *IgH* gene rearrangements. In addition, 40–50 % of ALLs also contain *Igk* gene rearrangements, and 20–25 % contain *Igλ* gene rearrangements. The results suggest a hierarchy of *Ig* gene rearrangements in developing B lymphocytes: IgH rearrangement first followed by *Igk* and then *Igλ*.

Lineage infidelity is common in B ALLs and the TCR genes are frequently rearranged [189]. TCR-δ is rearranged or deleted (after rearrangement) in as many as 80 % of cases. The TCR-γ and TCR-β genes are rearranged in 50–60 %, and 20–30 % of cases, respectively. As a result, either the *TCR* or *Ig* genes can he assessed to determine clonality, but evaluation of individual antigen receptor genes is less useful for lineage determination.

Standard cytogenetic studies have shown the presence of multiple nonrandom chromosomal translocations in B-ALL. The molecular and cytogenetic findings are summarized in Table 30.2. A number of the most frequent and best-characterized molecular abnormalities are discussed more specifically here.

Table 30.2 Cytogenetic and molecular abnormalities in acute lymphoblastic leukemia

Chromosomal translocations	Genes	Comments
B-cell lineage		
t(9;22)(q34;q11)	*ABL1*	Tyrosine kinase
	BCR	Unknown function
Involving CRLF2		
t(X; 14)(p22.3;q32)	*CRLF2*	JAK-associated signaling pathway
t(Y; 14)(p11.3;q32)		Activator
	IgH	Ig heavy-chain enhancer
Involving TCF3 (E2A)		
t(1;19)(q23;q13)	*PBX1*	Homebox gene
	TCF3 (E2A)	bHLH transcription factor
(17;19)(q22;p13)	*HLF*	bZIP transcription factor
	TCF3 (E2A)	bHLH transcription factor
Involving KMT2A (MLL)		
t(11;v)(q23;v)	*KMT2A (MLL)*	*Drosophila trithorax* homology
	Variable	Many partner genes
		Infancy, high risk
Involving ETV6 (TEL) and CDKN1B (KIP1)		
t(12;21)(p12;q22)	*ETV6 (TEL)*	*ETS*-like transcription factor
	RUNX1	Runt-like transcription factor
t(5;14)(q31;q32)	*IL-3*	Cytokine gene
	IgH	Ig heavy-chain enhancer
Involving *MYC*		
t(8;14)(q24;q32)	*MYC*	bHLH transcription factor
	IgH	Ig heavy-chain enhancer
t(2;8)(p12;q24)	*Igk*	Igk chain enhancer
	MYC	bHLH transcriptor factor
	Igλ	Igλ chain enhancer
Gene amplification		
Hyperdiploid karyotype		Favorable prognosis
DHFR		Associated with p53 mutations
T-cell lineage		
Involving TAL1, TAL2, and LYL1		
Interstitial deletions	*TAL1*	bHLH transcription factor
	STIL (SIL)	Gene-expressed T cells
		Up to 30 % T-ALL
t(1;14)(p32;q11)	*TAL1*	bHLH transcription factor
	TCR-δ	TCR enhancer
t(1;7)(p33;q35)	*TAL1*	bHLH transcription factor
	TCR-β	TCR enhancer
t(7;9)(q34;q32)	*TCR-β*	TCR enhancer
	TAL2	bHLH transcriptor factor
t(7;19)(q34;q13)	*TCR-β*	TCR enhancer
	LYL1	bHLH transcription factor
del(9)(p21-22)	*P16INK4A*	Cell-cycle inhibitor
	P16INK4B	Cell-cycle inhibitor
Involving TLX1 (HOX11)		
t(10;14)(q24;q11)	*TLX1 (HOX11)*	Homeobox gene
	TCR-qδ	TCR enhancer
t(7;10)(q34;q24)	*TCR-β*	TCR enhancer
	TLX1 (HOX11)	Homeobox gene

t(7;14)(q35;q32.1)	*TCR-β*	TCR Enhancer
	TCL1A (TCL1)	Homology to *MTCP1* of T-CLL

30.4.1.1 B-ALL with t(9:22)(q34;q11.2); BCR-ABL

The Philadelphia chromosome (Ph) or t(9;22)(q34;q11), is among the most prevalent recurrent chromosomal translocations in B-ALL, detected in 20–33 % of adults and 5 % of children with this disease [190]. This translocation disrupts and fuses a portion of the *ABL1* gene at chromosome 9q34 with a portion of *BCR* locus at 22q11 forming *BCR-ABL1* (Figs. 30.5, 30.13, and 30.14). Two forms of the t(9;22) occur. In 25–50 % of adult cases of B-ALL, the translocation appears identical to that found in CML; a fusion protein with a molecular weight of 210 kDa is formed. In the remaining 50–75 % of adult cases and most childhood cases of B-ALL, the breakpoint on chromosome 22 is 100 kb upstream of the BCR region, resulting in a smaller fusion protein with a molecular weight of 190 kDa. This p190 protein has enhanced tyrosine kinase activity and transforming capability compared to p210 protein [191]. The t(9;22) is usually detected by conventional cytogenetics, FISH, and RT-PCR.

BCR-ABL1-Like B-ALL

This entity was initially identified by gene expression profiling which showed that these tumors have an expression profile very similar to B-ALL with t(9;22)(q34;q11) even though these tumors lack the translocation [192–195]. This entity is usually mutually exclusive with B-ALL with recurrent cytogenetic abnormalities such as *ETV6-RUNX1*, *E2A-PBX1*, *ERG* rearrangement, *MLL* rearrangement, or hyperdiploidy [192, 195, 196]. The reported incidence of BCR-ABL1-like B-ALL varies from 10 % in children to 30 % in young adults, and these tumors are present at higher frequency in patients with Down syndrome [192, 195, 196], but the true incidence might be higher taking into consideration the novelty of the entity and lack of reliable tools to diagnose it in the community. Patients with BCR-ABL1-like B-ALL have a poorer outcome, but these tumors have the potential to respond to tyrosine kinase inhibitors [193–195].

From the molecular perspective, *BCR-ABL1-like* B-ALL can be divided in two groups based on the underlying activation of either the JAK-associated signaling pathway or the ABL-associated signaling pathway [195, 197]. This distinction is critical for proper patient management. Most commonly, the JAK-associated signaling pathway is activated by *CRLF2 protein encoded by CRLF2* gene (chromosome Xp22.3/Yp11.3) overexpression, which can be a result of either *IGH-CRLF2* translocations or deletions that create *P2RY8-CRLF2* fusions. *CRLF2* overexpression is often (about 50 %) associated with additional mutations in *CRLF2*, *IL7R*, *JAK1*, or *JAK2* [196]. Less commonly, *CRLF2* overexpression can result from rare translocations such as *BCR-JAK2*, *STRN3-JAK2*, or *PAX5-JAK2* [195, 197]. The ABL-associated signaling pathway is usually activated via a large number of gene fusions that involve *ABL1;* partners include *NUP214*, *ETV6*, *RANB2*, and *RCSD1*. Fusion genes that involve *JAK2* and rarely *PDGFRβ* are also reported with partners that include *PAX5*, *EBF1*, and *STRN3* [195, 197, 198].

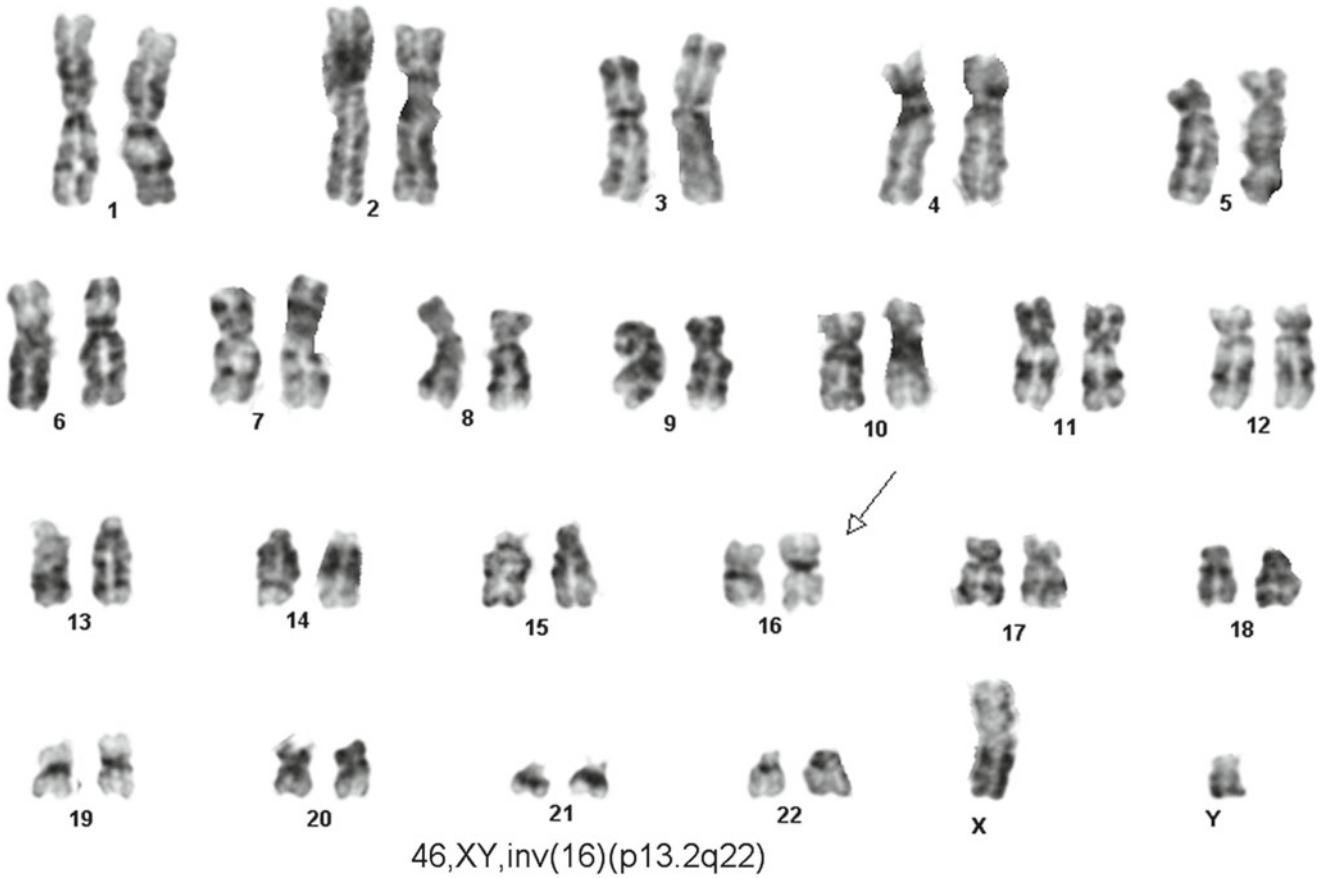

Fig. 30.13 Karyotype of a case of acute myeloid leukemia with inv(16)(p13q22). Conventional cytogenetic analysis demonstrates inv(16) as a sole cytogenetic abnormality. GTG banding technique.

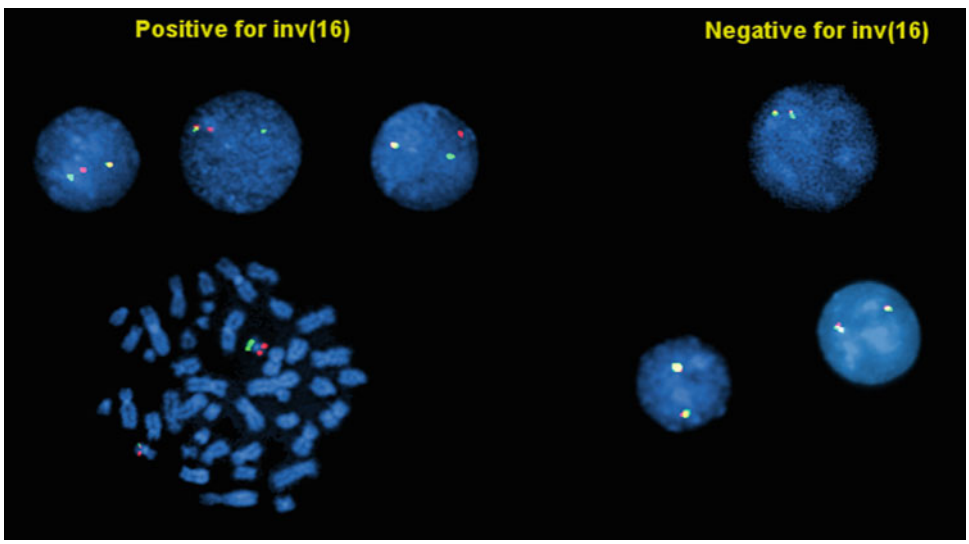

Fig. 30.14 Fluorescence in situ hybridization (FISH) analysis of a case of acute myeloid leukemia with inv(16)(p13q22). Dual color, breakapart probe (Vysis) in which the 5′ CBFβ probe positioned centromeric to the inv(16) breakpoint region is *red*, and the 3′ CBFβ probe positioned telomeric to the inv(16) breakpoint is *green*. In the event of inv(16) or t(16;16), *red* and *green* signals become separated, and a cell has one *red*, one *green*, and one fused (*yellow*) signal (*left panel*). In the absence of inv16 or t(16;16), a cell contains two fused (*yellow*) signals (*right panel*). This technique allows analysis of both metaphase and interphase cells (*right*).

30.4.1.2 B-ALL with t(v;11q23); *MLL* Rearranged

A large number of partners on different chromosomes have been reported in translocations involving *MLL* at the 11q23 locus [1]. In B-ALLs, 11q23 abnormalities are detected as translocations involving the following partner chromosome loci: 9p11, 9p21-p22, 4q21, 19p13, 1q21, 1p32, 6q27, 12p13, 17q21, 17q25, 20q13, and Xq13; of these, t(4;11), t(9;11), and t(11;19) are most prevalent. The t(4;11) (q2l;q23), which occurs in about 2 % of childhood B-ALLs and 5–6 % of adult B-ALLs, confers a poor prognosis [1]. The gene located at 4q21 is named *AF4* or *FEL*. Although most ALLs with 11q23 abnormalities are of B-cell lineage, a small subset of cases possess an immature T-cell immunophenotype and *MLL* fusions are found in 4–8 % of T-ALL [46, 199].

In infants, 11q23 abnormalities are found in more than 70 % of leukemias in patients <1 year of age whether the immunophenotype is designated AML or ALL [200]. Some infant leukemias express antigens characteristic of both lymphoblasts and monoblasts, and are sometimes designated acute biphenotyic leukemias. Infants diagnosed with ALL harboring an 11q23 rearrangement have a particularly poor prognosis. Recently it has been found that the receptor tyrosine kinase *FLT3* is highly expressed in *MLL*-rearranged ALL as compared with other acute leukemias [46].

30.4.1.3 B-ALL with t(12;21)(p13;q22); *ETV6-RUNX1* (*TEL-AML1*)

ETV6 (TEL) is an *ETS*-like gene on 12p12 that is a transcription factor. The t(12;21) results in a chimeric gene comprised of the *ETV6* gene and the *RUNX1 (AML1)* gene at 21q22. The chimeric protein contains the bHLH domain of *ETV6* fused to the DNA-binding subunit of the RUNX1/CBFP transcription-factor complex [201]. Although this translocation is detectable by routine cytogenetic studies in less than 5 % of pediatric B-ALL cases, cryptic *ETV6-RUNX1*fusions have been found using RT-PCR methods in 22–27 % of pediatric patients, representing the most frequent genetic lesion in childhood B-ALL [201]. *ETV6-RUNX11* is associated with an excellent prognosis, with event-free survival rates approaching 90 % [201–203]. The favorable prognostic impact of *ETV6-RUNX1* is independent of age and leukocyte count [202].

Epidemiologic studies have identified the *ETV6-RUNX1* translocation in neonatal blood spots indicating that the translocation is present in blood cells at birth, up to 5–10 years before the development of leukemia [11]. These data suggest that the *ETV6-RUNX1* translocation is an initiating event in this leukemia. Most, but not all, 12p cytogenetic abnormalities in childhood B ALL involve *ETV6* [204]. These cases are associated with a non-hyperdiploid DNA content and a favorable prognosis [204].

30.4.1.4 B-ALL with t(5;14)(q31;q32); *IL3-IG*

A small subset of B-ALLs is associated with eosinophilia and carries the t(5;14)(q31;q32) [205]. The chromosome 5 breakpoints are tightly clustered within the promoter region of the *interleukin-3(IL-3)* gene, whereas the chromosome 14 breakpoints occur within *IgH* [205]. The translocation results in the head-to-head juxtaposition of *IL-3* with the *IgH* gene-joining region. In all likelihood, the translocation results in overexpression of IL-3, inducing eosinophilia and stimulation of the leukemic clone, presumably via an autocrine loop.

30.4.1.5 B-ALL with t(1;19)(q23;p13.3); *TCF3-PBX1* (*E2A-PBX1*)

The t(1;19) is found in approximately 30 % of B-ALLs [206]. It is most prevalent in leukemias with a pre-B cell (cytoplasmic Ig μ positive) immunophenotype. This translocation juxtaposes the *PBX1* gene on chromosome lq23 with the *TCF3* gene on chromosome 19p13 [206]. The *PBX1* gene is a member of the homeobox gene family. The *TCF3* gene encodes an enhancer-binding transcription factor [207]. *TCF3* contains the basic helix-loop-helix (bHLH) domain responsible for sequence-specific DNA binding and dimerization, and plays a critical role in lymphocyte development [208]. Breakpoints are clustered allowing for PCR-based methods to be used for detection [207].

30.4.1.6 B-ALL t(17;19)(q22;p13); *HLF/ TCF3*

In the t(17;19) the *HLF* (hepatic leukemia factor) gene located on chromosome 17 is juxtaposed with the *TCF3* gene on chromosome 19p13 [209]. The translocation creates a fusion gene that encodes for a chimeric protein containing the basic region/leucine zipper domain of the HLF protein fused to the transactivation domain of the TCF3 protein.

30.4.1.7 Hyperdiploid B-ALL

Childhood precursor B-ALL patients with a hyperdiploid karyotype (defined as >50 chromosomes or a DNA index ≥1.16) have a favorable prognosis, presumably because their disease is more responsive to chemotherapy [210]. These tumors show non-random gains of chromosomes X, 4, 6, 10, 14, 17, 18, and 21. Studies have shown that trisomy of both chromosomes 4 and 10 identify a subgroup of pediatric patients with an extremely favorable 4-year event-free survival and are likely to be cured with antimetabolite-based chemotherapy [211]. Increased gene copy numbers on these chromosomes may contribute to leukemogenesis and/or enhance responsiveness to chemotherapy.

Gene expression studies have shown that hyperdiploid cases represent a separate genetically defined subset of B-ALL [212]. Activating mutations of *FLT3* have been identified in approximately 20 % of cases of hyperdiploid B-ALL [213, 214]. *CREB-binding protein* (*CREBBP*) mutations, mostly in the HAT domain, have been identified in about 50 % of cases [215].

30.4.1.8 Hypodiploid B-ALL

About 2–3 % of B ALL cases exhibit hypodiploidy, and these patients have a poor prognosis. Hypodiploidy is defined as less than 44 chromosomes and can be further broken out into two subgroups: near haploid with 24–31 chromosomes and low-hypodiploid with 32–39 chromosomes with each subgroup distinct at the molecular level [216].

Near haploid B-ALL cases commonly have mutations in *NF1*, *IKZF3*, and other genes that activate the RAS pathway. Low-haploid B-ALL cases are often associated with *TP53* mutations. These mutations may be sporadic or *germ line* with the latter group a part of Li–Fraumeni syndrome [216].

30.4.2 T-Cell ALL

T-cell ALLs can be subclassified based on the presence of cytoplasmic or membrane expression of CD3 [217] as follows: TI—immature subgroup or pro-T-ALL defined by the expression of only CD7; TII—pre-T-ALL expressing CD2 and/or CD5 and/or CD8; TIII—or cortical T-ALL expressing CD1a; and TIV—mature T-ALL expressing surface CD3 and lacking CD1a. Depending on the mutually exclusive membrane expression of αβ or γδ TCR, two subgroups, group A and group B, are distinguished.

In a subset of early-thymic T-ALLs, only rearrangements of *TCR-δ* or both *TCR-δ* and *TCR-γ* are identified with the *TCR-β* in the germ line configuration [189]. In the remaining early-thymic cases, and all of the mid-thymic and late-thymic ALLs, each of the *TCR* are rearranged. *TCR-δ* is often deleted after rearrangement. Although *TCR-α* is difficult to analyze due to its large size, *TCR-α* gene transcripts have been detected in late-thymic T-ALLs using Northern-blot hybridization. These findings suggest a hierarchy of gene rearrangements in normal developing T lymphocytes: *TCR-δ* rearrangement occurs first, followed by rearrangement of *TCR-γ* and *TCR-β*, followed by rearrangement of *TCR-α*. Lineage infidelity occurs frequently in T-ALLs; *IgH* rearrangements occur in about 20 % of cases. However, *Ig light chain* rearrangements are rare.

A number of nonrandom chromosomal translocations involving candidate proto-oncogenes have been described in T-ALLs. Tumor-suppressor genes also may be involved. Some of the more common abnormalities are discussed here.

30.4.3 Early T-Cell Precursor T-ALL

Early T-cell precursor (ETP) T-ALL represents a clinically aggressive subset of tumors with the following immunophenotype: cytoplasmic CD3+, CD5 dim+ or negative, myeloid antigens+, and both CD1a and CD8 negative. Early T-cell precursor T-ALL accounts for about 12 % of all pediatric T-ALL cases [218]. Cytogenetic studies found that these patients often show 5q, 13q, and 11q chromosomal deletions, and in contrast to the other T-ALL subtypes, usually do not have 9p deletions involving the *CDKN2A/B* tumor suppressor genes. Gene expression profiling studies have shown that ETP T-ALL exhibits prominent overexpression of *LYL1* and *LMO2* [219].

At the molecular level, ETP T-ALL appears to be quite heterogeneous [220]. Multiple chromosomes show structural alterations and a number of gene or pathway abnormalities have been identified in subsets of ETP T-ALL [221, 222]. Major groups of alterations in ETP T-ALL include: loss of genes that regulate hematopoietic development, such as *ETV6*, *GATA3*, *IKZF1*, and *RUNX1*; overexpression of stem cell genes, such as *BAALC*, *WT1*; gene mutations in *NRAS* or *KRAS* that activate the RAS pathway; mutations involving the cytokine receptors *JAK1*, *JAK3,* and *IL7R*), and inactivating mutations of genes involved in epigenetic regulation (e.g., *EZH2*, *MLL, DNMT3A*, *CREBBP*). *FLT3* mutations are also frequent and *NOTCH1* mutations are rare in ETP T-ALL, unlike other types of T-ALL [221, 222].

The profile of gene mutations in ETP T-ALL is closer to acute myeloid leukemia that it is to other types of T-ALL and the gene expression profile of ETP T-ALL supports this idea, being more similar to hematopoietic stem cells or early myeloid precursors than to T-lymphoblasts [221, 222].

30.4.3.1 T-ALL with *TAL-1* Rearrangements

The *TAL-1* gene is rearranged in 25–30 % of T-ALLs and is much more common in childhood than in adult T-ALL cases [223, 224]. *TAL-1* is located at chromosome 1p32. It encodes a protein with a bHLH domain that is a member of a family of transcription factors involved in growth regulation and differentiation. The *TAL-1* gene is not normally expressed in T-cells [224].

In most cases with *TAL-1* rearrangements, small interstitial deletions in the *TAL-1* locus result in the joining of the *TAL-1* gene with a gene known as *SIL* that is normally expressed in T cells. This joining is thought to be due to illegitimate recombination mediated by the VDJ recombinase mechanism using heptamer-nonamer-like sequences flanking each gene [225]. In these cases, no abnormalities are detectable by standard cytogenetic analysis. In a small subset of cases the t(1;14)(p32;11) is present. This translocation places the *TAL-1* gene in continuity with the *TCR-δ enhancer*. A similar translocation, the t(1;7)(p33;q35), places the *TAL-1* gene in continuity with the *TCR-β enhancer*. Gene rearrangements involving *TAL-1*, both deletions and translocations, are identifiable by Southern blot or PCR analyses. This group of T-ALLs also has a distinct gene expression profile.

30.4.3.2 T-ALL with del(9)(p21-22) *CDKN2B/CDKN2A*

Deletions of chromosome 9p21-p22 occur in a subset of T ALLs with a frequency of up to 50 % in childhood cases [226]. Recent studies have identified several closely related candidate tumor-suppressor genes at this locus: two cell-cycle inhibitors, *CDKN2A* (p16) at 9p21 and *CDKN2B* (p15) located 12 kb centromeric to the p16*INK4A* [226]. The *CDKN2A* and *CDKN2B* genes encode 16 and 15 kDa proteins, respectively, that inhibit CDK4 and CDK6. CDK4 and CDK6 are involved in regulating cell-cycle progression from the G_1 to S phase, and their inhibition provides a cell with a growth advantage [226].

Using FISH, homozygous (and less frequently heterozygous) *CDKN2A* locus deletions have been identified in T-ALLs [226, 227]. *CDKN2A* deletions have been identified in most cases with 9p21-p22 deletion as shown by conventional cytogenetics as well as in cases in which conventional cytogenetics are normal. The *CDKN2B* locus has a similar frequency of homozygous deletions in T-ALLs, although this locus has been analyzed less commonly. *CDKN2A* and *CDKN2B* deletions correlate with a poorer survival [210, 228].

The breakpoints in *CDKN2A* have been found to occur in two clusters (bcrα and bcrβ) that are located near heptamers whose sequences resemble those involved in VDJ recombination [228]. In one study, all T ALL cases also contained short deletions, GC-rich tandem nucleotide additions, or clone-specific junctional sequences in *CDKN2A*. These combined findings suggest tumor-suppressor gene inactivation by an illegitimate VDJ recombinational mechanism.

30.4.3.3 T-ALL with t(10;14)(q24;q11) or t(7;10)(q34;q24)

Approximately 5–10 % of T-ALLs carry the t(10;14) involving the *T-cell leukemia homeobox 1 (TLX1) previously known as homeobox 11(HOX11)* gene on chromosome 10q24. T-ALLs with the t(7;10)(q34;q24) also involve the *TLX1* gene. *TCR-α/δ* and *TCR-β* are located at 14q11 and 7q34, respectively. In adults, HOX11 was expressed by 33 % of T-ALLs, compared with only 3 % of neoplasms in children [229]. The *HOX11* gene is a homeobox gene involved in transcriptional regulation [230]. It is not normally expressed in T-cells but is expressed in the adult liver and fetal spleen of animals [230]. Overexpression of this gene in the thymus of transgenic mice appears to correlate with the development of T-cell neoplasms. In most cases, the breakpoint on chromosome 10 is upstream of *HOX11*, placing it under the influence of a TCR enhancer, thereby resulting in deregulation and increased expression of the normal HOX11 protein [230]. HOX11 expression in T-ALL is associated with a favorable prognosis in both children and adults treated with modern intensive therapy [219, 231]. Forced expression of HOX11 in murine BM gives rise to T-ALL-like malignancies after long latency intervals suggesting that additional mutations are required.

The *TLX3*/*HOX11L2* gene, located at chromosome 5q35, can be activated by translocation near the *BCL11B* locus as a result of t(5;14)(q35;q32), or by fusion to the *TCR-δ* locus as a result of t(5;14)(q35;q11). Although t(5;14)(q35;q32) and t(5;14)(q35;q11) are commonly not recognized by conventional cytogenetic techniques, almost 20 % of childhood and 13 % of adult T-ALL patients demonstrated a *HOX11L2* gene translocation by FISH [232]. Rare variants have been reported: t(5;14) that involves *NKX2-5*, another homeobox gene instead of *TLX3* [233]; t(5;7)(q35;q21) involving *TLX3* and *CDK6* [234] and t(5;14)(q35;q11) juxtaposing *TLX3* and *TCR α/δ* genes [235]. *TLX3* is very similar to *TLX1* and microarray studies indicate that *TLX1*+ and *TLX3*+ T-ALLs cluster together, suggesting common mechanisms of action [219, 236]. Patients with *TLX3* expressing T-ALL may not have the favorable outcome reported for patients with *TLX1*+ cases [219, 237].

30.4.3.4 T-ALL with t(10;11)(p13;q14)

The t(10;11)(p13;q14) is a recurrent translocation in T ALL, but it is also found in a wide spectrum of hematologic malignancies [238, 239]. The t(10;11) fuses *CALM* (clathrin assembly protein-like lymphoid-myeloid leukemia gene, also called *PICALM*) to *AF10* (also called *MLLT10*). *CALM-AF10* fusion is detected in 9–10 % of T-ALL and is restricted to cases expressing γδ TCR [240]. The translocation is often cryptic and requires molecular detection by either FISH or RT-PCR. Several different fusion transcripts have been described. AF10 breakpoints correlate with stage of maturation arrest: the more 5′ breakpoints are associated with mature γδ T-ALLs and the more 3′ breakpoints are associated with immature γδ T-ALLs [240]. These findings suggest a possible role for AF10 protein in γδ TCR lineage commitment at the early stages of hematopoietic differentiation. Prognosis is globally poor, particularly for the most immature cases [240].

Gene expression studies have disclosed upregulation of the *HOXA5*, *HOXA9*, and *HOXA10* genes and their cofactor *MEIS1* [236, 241]. This finding strongly indicates common oncogenic pathways for T-ALL with either *CALM-AF10* or *MLL* translocations. Unique to *CALM-AF10* is the overexpression of *BMI1*, a gene located at 10p12.3 in close vicinity to *AF10*. *BMI1* is essential for self-renewal of normal and leukemic stem cells [242]. *BMI1* controls cell proliferation by inhibiting the *CDKN2A* locus and is thus an alternative to deletion of the *CDKN2A* locus observed in 70 % of T-ALL cases, but is not present in *CALM-AF10* T-ALLs.

30.4.3.5 NOTCH-1 Mutations in T-ALL

The *NOTCH-1* gene was initially discovered by its involvement and activation in the rare t(7;9) in T-ALL [243] and activated *NOTCH-1* was shown to induce T-ALL in mouse models [244, 245]. *NOTCH1* is an important player in T-cell commitment decisions of the common lymphoid precursor [246] and in the assembly and signaling of the TCR in immature thymocytes [247]. *NOTCH1* may also play a role in differentiation by controlling TCF3/E2A protein turnover [248]. *NOTCH1 activating* mutations have been found in the heterodimerization domain (HD) domain and the PEST domain in ~60 % of T-ALL of all molecular subtypes [248]. Mutations in the HD result in ligand independent intracellular NOTCH1 (ICN) production; mutations in PEST extend the half-life of ICN transcription activator complex. Combined HD and PEST mutations have been found in ~15 % of cases and shown to have a synergistic effect on NOTCH1 activation [248].

The finding of *NOTCH1* mutations in all molecular subtypes of T-ALL suggests that these mutations occur in immature progenitors. When several T-cell leukemia cell lines were tested with a drug known to inhibit gamma-secretase, cell-cycle arrest was detected, which was subsequently proven to be *NOTCH-1* specific [248]. The mechanism of *NOTCH1* transforming activity is still unclear and probably results from the deregulation of its normal functions during T-cell development, and its role in maintenance of self-renewal capacity of stem cells [249].

30.4.3.6 T-ALL Associated with Translocations Involving TCR Loci

Other translocations have been identified in T-ALLs by conventional cytogenetics, often involving the TCR loci: TCR-α/δ at 14q11, TCR-β at 7q34, and TCR-γ at 7p15. These translocations, present in small subsets of T-ALL, involve known or candidate proto-oncogenes brought into continuity with an antigen-receptor locus, resulting in inappropriate oncogene overexpression. Rearrangements joining the candidate oncogene *TCL1* on chromosome 14q32 to the TCR locus at l4q11 have been described in acute as well as in chronic T-cell leukemias arising in ataxia telangiectasia [250].

The t(7;9)(q34;q32) activates the *TAL-2* gene, a transcription factor with a bHLH motif bearing great sequence homology to *TAL-1*. The *TAL-2* gene is located on chromosome 9q32, and t(7;9)(q34;q32) juxtaposes *TAL-2* next to sequences from the *TCR-β* locus on chromosome 7q34. The t(7;19)(q34;p13) is another translocation in T-ALL that involves the *LYL-1* gene at chromosome 19p13. The *LYL-1* gene encodes another member of this subgroup of bHLH transcription factors that is inappropriately altered. The t(7;19)(q34;p13) results in its head-to-head juxtaposition of *LYL-1* with the *TCR-β* locus and truncation of its mRNA.

30.4.3.7 T-ALL with t(11;14)(p15;q11) or t(11;14)(p13;q11)

The genes encoding the LIM domain only proteins *LMO1* (*RTBN1*, *TTG-1*) and *LMO2* (*RTBN2*, *TTG-2*) located on chromosome 11p15 and 11p13, respectively, are rearranged in T-ALL [251]. Most common are the t(11;14)(p15;q11) and t(11;14)(p13;q11) juxtaposing *LMO1/LMO2* to the *TCR α/δ* locus due to erroneous VDJ joining [252]. The frequency of translocations in T-ALL with *LMO1* is less than 1 %, whereas it may be nearly 7 % for *LMO2* [251]. These genes are not normally expressed in T-cells. The LMO1 and LMO2 proteins are members of a subset of nuclear-localizing zinc-finger proteins containing cysteine-rich LIM domains and likely function as regulators of transcription [252]. *LMO2* has been demonstrated to be essential in erythropoiesis using homologous recombination in mice [253]. Dysregulation may occur either by putting the gene under the control of the TCR-δ enhancer or, in those cases lacking this enhancer on the translocated allele, by disturbing the negative regulatory region of the TCR-δ gene promoter [254]. The incidence of T-cell malignancies in transgenic mice is tied to the level of transgene expression.

Translocations involving *TCR-β* and *LMO1* or *LMO2* loci also have been reported [255]. Abnormal expression of LMO1/2 has been found in 45 % of T ALL cases, even in the absence of typical chromosomal changes [256], but often in association with deregulation of LYL1 (LMO2) or TAL1 (LMO1 and 2). Aberrant activation of LMO2 via retroviral integration has been reported recently in two T-cell lymphoproliferative disorders in children participating in a gene therapy trial of X-linked severe combined immunodeficiency [256].

30.4.3.8 T-ALL with 11q23/MLL Rearrangements

MLL/KMT2A rearrangements are found in 4–8 % of T-ALL [257]. The preferential partner is *ENL* (*MLLT1*). Translocation (11;19)(q23;p13.3) encoding *MLL-ENL* is often found in young adolescents and carries a better prognosis than other *MLL* translocations [257]. Other partners (*AF10*, *AF6*, *AF4*, *AFX1*) are occasionally seen. Gene expression profiling analysis has shown increased expression of a subset of *HOX* genes (*HOXA9*, *HOXA10*, *HOXC6*) and of *MEIS1*, the *HOX* gene co-regulator. This appears to be a central mechanism of leukemic transformation by MLL-oncoprotein in T-ALL [199]. These neoplasms represent a distinct molecular subtype with a specific expression profile characterized by differentiation arrest at an early stage of thymocyte development and commitment to γδ lineage [199, 236].

30.4.3.9 T-ALL with t(7;9)(q34;q34.3)

The t(7;9)(q34;q34.3) occurs in up to 5 % of T-ALL. This translocation juxtaposes sequences from the *TAN1* gene on 9q with the TCR-β locus on 7q34, leading to inappropriate

expression of a truncated gene product [243]. The *TAN1* gene is a mammalian homolog of the Drosophila *NOTCH* gene that encodes a transmembrane protein [243, 258]. Normally, TAN1 is a membrane protein involved in signal transduction during cellular differentiation. The abnormal *TAN1* protein resulting from the translocation aberrantly localizes to the nucleus and induces T-cell neoplasms when introduced into the BM of mice [243].

30.4.3.10 T-ALL with inv(14)(q11q32.3)

The inv(14)(q11q32.3), commonly found in ataxia-telangiectasia, also has been reported in T-ALL. This inversion arises from interlocus VDJ recombination and may signify a propensity towards abnormal recombinational activity rather than being oncogenic in-and-of itself.

30.4.3.11 *ABL1* Gene Rearrangement in T-ALL

The Philadelphia chromosome is detected in ≤1 % cases of T-ALL [259]. *ABL1* is a ubiquitously expressed cytoplasmic tyrosine kinase that has been shown to play a role in TCR signaling [260]. The *NUP214-ABL1* fusion is specific to T-ALL and found in up to 6 % of cases [261]. The fusion gene is found on amplified episomes, which are not visible cytogenetically, or only exceptionally in homogeneously staining regions [294]. FISH or RT-PCR studies are required to detect the *NUP214-ABL1*. These leukemias are characterized by ectopic expression of *TLX1* (*HOX11*) or *TLX3* (*HOX11L2*) and deletion of CDKN2A locus [261, 263]. Other *ABL* fusion variants have rarely been reported. Like *BCR-ABL*, *ETV6-ABL* resulting from t(9;12)(q34;p13) is found in CML, B-ALL and exceptionally in T-ALL. The t(9;14)(q34;q32) encoding a *EML1-ABL* fusion protein has been described in a single T-ALL case [264].

30.4.4 Other Abnormalities in T-ALL

In T-ALL with a relatively mature immunophenotype (CD2-, CD4+), *HOXA* genes (especially *HOXA10* and *A11*) can be upregulated as a consequence of cryptic inv(7) or t(7;7), which juxtaposes the *TCR-β* enhancer within the *HOXA* locus [265]. FISH analysis disclosed these rearrangements in up to 5 % of cases. Expression-array analysis of *HOXA*+ T-ALL precursor indicates arrest after lineage choice but before β selection [236]. Another recurrent aberration in T-ALL is del(6q). The common deleted region is of variable size but is focused around 6q16. The target gene(s) have not yet been formally identified [266].

To date, T-ALL has received less attention than B-ALL in studies using whole genome sequencing, RNAseq, and other high-throughput methods. T-ALL cases usually have multiple gene mutations, in the range of 5–10 in children and ~20 in adult cases. In addition to genes already mentioned, mutations have been reported in *PHF6* (~40 %), *FBXW7* (~20 %), *DNMT3A* (~18 %), *RUNX1* (~15 %), *CNOT3* (~10 %), *RPL5* (~10 %), *RPL10* (~10 %), and *PTEN* (~10 %). *FLT3* mutations are rare in T-ALL, but more common in neoplasms with stem cell features [267, 268]. Activating mutations of *N-RAS* have been detected in 10 % of a series of pediatric T-ALL [269]. Other studies indicate that *RAS* is highly activated in 50 % of T-ALL [270] suggesting a key role for *RAS* activation in T-ALL pathogenesis.

30.5 Chronic Myelogenous Leukemia

Chronic myelogenous leukemia (CML) primarily affects adults and is distinguished by neutrophilic leukocytosis, basophilia, eosinophilia, anemia, and splenomegaly, among other findings [271]. The bone marrow at diagnosis is usually hypercellular with granulocytic hyperplasia. The disease course is an continuum from more indolent to aggressive disease that frequently entails three phases: (1) an initial chronic phase that lasts 3–4 years; (2) a transitional accelerated phase that lasts approximately 6 months in which there is a progressive left shift in myeloid maturation, often associated with new cytogenetic abnormalities; and (3) blast phase or crisis characterized by a proliferation of myeloid, lymphoid, or less commonly megakaryoblastic or erythroid blasts.

Chronic myelogenous leukemia is a monoclonal neoplasm in which 90–95 % of cases show cytogenetic evidence of a distinct chromosomal abnormality, a small derivative chromosome 22, designated the Philadelphia chromosome (Ph), and subsequently shown to be the t(9;22)(q34;q11) (Fig. 30.15). The t(9;22)(q34;q11) disrupts the *ABL1* and *BCR* genes and forms a novel fusion gene, *BCR-ABL1*. This disease is now defined by the presence of *BCR-ABL1* and, as a result, the definition of CML has been extended to include rare morphologic variants, once not recognized as CML, as well as cases that lack cytogenetic evidence of the Ph, as long as *BCR-ABL1* is present (shown by other methods).

30.5.1 *ABL1*

The *ABL1* gene is a cellular homolog of the transforming sequence of *Abelson murine leukemia virus* (v-*ABL*), located on chromosome 9q34. *ABL1* spans over 230 kb. By convention the exons of *ABL1* are numbered lb, la, and a2-a11 from 5′→3′ (Fig. 30.14). The 5′-exons (1b and 1a) of *ABL1* undergo alternative splicing to exon a2. This normally yields 6 kb and 7 kb mRNA transcripts that encode two alternative proteins, type la and 1b $p145^{abl}$ that differ in their N-terminal amino acid sequence. The normal *ABL1* resides, at least in part, in the nucleus and contains the regulatory *src*-homology domains SH2 and SH3, a tyrosine kinase domain, a DNA-

Fig. 30.15 Karyotype of a case of chronic myelogenous leukemia in chronic phase. Conventional cytogenetic analysis demonstrates the t(9;22). GTG banding technique.

binding domain, and actin-binding domains. In CML, the breakpoint on chromosome 9 can occur over a 300 kb segment of the *ABL1* gene, upstream of exon 1b, between exons lb and la, or between exons 1b and a2.

30.5.2 *BCR*

The *BCR* locus is located on chromosome 22q11 (Fig. 30.16). The breakpoints on chromosome 22 are localized to a 5.8 kb region, originally called the breakpoint-cluster region or *BCR*. It is now referred to as the major breakpoint-cluster region (*M-BCR*) because two additional breakpoint-cluster regions have since been described. The *M-BCR* is part of a larger gene on chromosome 22, known as *BCR*. It encompasses exons e12-e16 of *BCR* that historically are referred to as M-*BCR* exons bl-b5. In its entirety, the *BCR* gene consists of 21 exons that stretch over a region of 130 kb. It encodes a protein ($p160^{bcr}$) with dimerization, phosphoserine/threonine-rich SH2 binding, *DBL*-like (a guanine-nucleotide-releasing factor for the GTP-binding protein CDC24M), and GTPase activating protein for $p21^{RAC}$ (GAP^{RAC}) domains. The subcellular localization of BCR protein shifts from being predominantly cytoplasmic in interphase cells to being largely perichromosomal during mitosis. The overall features suggest that BCR protein may be involved in signal transduction pathways and cytoskeletal/chromatin organization. The *BCR* breakpoints in CML most frequently arise between M-*BCR* exons b2 (e13) and b3 (e14), or between M-*BCR* exons b3 (e14) and b4 (e15). A breakpoint either 5′ or 3′ of M-*BCR* is uncommon, occurring in less than 5 % of cases.

30.5.3 *BCR-ABL1* and $p210^{BCR-ABL1}$

The aforementioned translocations result in an aberrant fusion genes, *BCR-ABL1* located on the derivative chromosome 22 (Ph), and *ABL1-BCR* on the derivative chromosome 9, respectively. Despite the absolute position of the *ABL1*

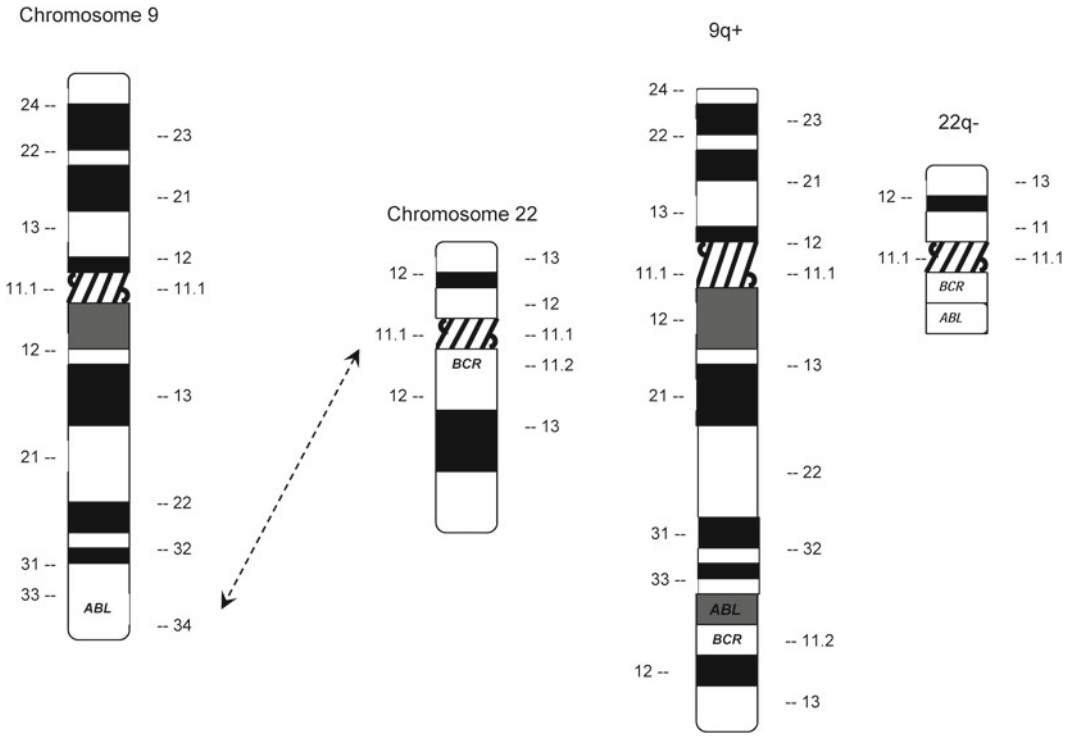

Fig. 30.16 Schematic representation of the t(9;22)(q34;q11) in chronic myelogenous leukemia. Compare the normal chromosomes (*left set*) to the derivative chromosomes (*right set*). The t(9;22) is a balanced and reciprocal translocation involving the *ABL1* gene at 9q34 and the *BCR* gene at 22q11. The derivative 22q- is known as the Philadelphia chromosome.

breakpoint, processing of primary *BCR-ABL1* transcripts generally produces a fusion mRNA with a e13-a2 junction, a e14-a2 junction, or occasionally both types due to alternative splicing [110]. Translation yields two similar $p210^{BCR\text{-}ABL1}$ fusion protein variants that differ only slightly in amino acid sequence without affecting clinical outcome. Regardless of which molecular species is produced, $p210^{BCR\text{-}ABL1}$ is uniformly expressed in CML, aberrantly localizes to the cytoplasm, and possesses enhanced tyrosine kinase activity and transforming capabilities [110]. Moreover, a CML-like syndrome can be induced in irradiated mice reconstituted with BM progenitor cells transfected with a retrovirus containing *BCR-ABL1* constructs [272].

BCR-ABL1 plays a crucial role in the initiation of CML. The *BCR-ABL1* oncogene encodes $p210^{BCR\text{-}ABL1}$ composed of N terminal *BCR* and C-terminal *ABL1* sequences. The *BCR* first exon is a critical component of the transforming capability exerted by *BCL-ABL1*. The serine/threonine kinase domain of BCR protein is able to bind to the SH2 regulatory domain of *ABL1* and other putative signal transduction proteins such as the SH2 domain of the GRB2 (for growth factor receptor binding protein 2) adaptor protein. Its coiled-coil oligomerization domain brings about tetramerization of *BCR-ABL1*. The net effect is to initiate constitutive tyrosine kinase activity and activate the F-actin-binding domain contributed by ABL1. The RAS-related signal-transduction proteins are likely substrates of $p210^{BCR\text{-}ABL1}$, resulting in disruption of these important signaling pathways [273]. For example, $p210^{BCR\text{-}ABL1}$ binds GRB2 and CRKL (CT10 regulator of kinase-like adapter protein), each of which can bind SOS (son of sevenless; a guanine-nucleotide releasing factor) and then activate the RAS signaling pathway [274]. Activation of F-actin binding probably leads to aberrant subcellular localization by promoting attachment to the cytoskeleton, thereby interfering with translocation to the nucleus. MYC protein also has been implicated in BCR-ABL1-induced transformation [275]. Other aspects concerning the pathogenesis of CML are beyond the scope of this chapter and are reviewed elsewhere [274].

30.5.4 Variant *BCR-ABL1* Transcripts

A minor breakpoint cluster region (m-BCR) that occurs upstream of M-*BCR* between exons el and e2 produces an ela2 transcript that encodes a smaller $p190^{BCR\text{-}ABL1}$ fusion protein. The m-BCR is involved in nearly two-thirds of Ph+ ALLs, but only rarely in CML or AML. The rare cases of CML associated with $p190^{BCR\text{-}ABL1}$ share certain characteristics with chronic myelomonocytic leukemia such as an absolute monocytosis and a decreased neutrophil to monocyte ratio.

A micro breakpoint-cluster region (μ-bcr) also has been found at the 3′ end of the *BCR* gene, between exons e19 and e20, that encodes a e1a2 transcript and a larger ($p230^{BCR\text{-}ABL1}$) fusion protein [276]. Rare cases associated with $p230^{BCR\text{-}ABL}$ show a greater degree of myeloid maturation and had been incorrectly characterized as chronic neutrophilic leukemia in the past [276]. It is now clear that $p230^{BCR\text{-}ABL}$ cases are a variant of CML and chronic neutrophilic leukemia is a clinicopathologic distinct entity.

30.5.5 *ABL1-BCR*

In contrast to *BCR-ABL1*, the reciprocal chimeric *ABL1-BCR* on derivative chromosome 9 encodes a product that has no known pathogenic consequence. Although the fusion transcript bas been detected in about 40 % cases of CML by RT-PCR, the ABL1-BCR protein has not been identified. It has been suggested that *ABL1-BCR* expression might account for some differences in presentation or clinical outcome

30.5.6 Accelerated Phase and Blast Crisis of CML

Additional cytogenetic changes often accompany progression of chronic phase CML into accelerated phase and are almost always present in blast crisis [271]. The most frequently observed cytogenetic abnormalities include trisomy 8, isochromosome 17, an additional Ph, or isochromosome 19. The t(3;21)(q26;q22), monosomy 7, and loss of chromosome Y occur less commonly [277]. At the molecular level, a variety of low-frequency acquired events have been reported in association with transformation, suggesting that maturation arrest may occur as a result of the interruption of several pathways. Gene amplification of *MYC* also has been implicated in progression of CML. Alterations of the *TP53* gene have been found in the myeloid and megakaryocytic variants of blast crisis, accounting for progression in approximately 25 % of CML patients. Rarely, translocations associated with specific types of AML, such as t(15;17)(q22;q21), t(8;21)(q22;q22), and inv(16)(p13q22), can occur at time of blast crisis.

Theories regarding the potential role of a second Ph, such as increased gene expression or a new *BCR-ABL1* rearrangement, are intriguing but the evidence is inconclusive. Homozygous deletion of the $p16^{INK4A}$ tumor-suppressor gene has been reported in up to 50 % of CML patients with lymphoid blast crisis [278]. Structural abnormalities of the *RB1* gene with loss of protein expression have been reported with an incidence of 11–29 % in lymphoid blast crisis of CML [279]. The apparent emergence of $p190^{BCR\text{-}ABL1}$ in $p210^{BCR\text{-}ABL1}$-positive CML patients also has been put forth as a putative mechanism of transformation. However, some reports indicate that low-level co-expression of $p190^{BCR\text{-}ABL1}$ with $p210^{BCR\text{-}ABL1}$ can occur due to alternative splicing and both transcripts are detectable by RT-PCR in most cases of CML with M-bcr breakpoints [280, 281].

The clinical course of CML patients was dramatically changed with the introduction of imatinib into clinical practice. Imatinib inhibits the BCR-ABL1 tyrosine kinase by competitive binding at the ATP-binding site [282]. In patients with newly diagnosed chronic-phase CML, treatment with imatinib results in a high complete cytogenetic remission rate and a high molecular remission rate with low or undetectable amounts of *BCR-ABL1* transcripts [283]. The high rates of complete cytogenetic response with imatinib necessitate molecular monitoring by quantitative RT-PCR to measure residual disease [284]. It was demonstrated that the reduction of BCR-ABL1 transcripts was associated with better prognosis.

With the success of imatinib therapy, which has dramatically extended the life of many CML patients, the problem of imatinib resistance has come to the forefront. This can be manifested as primary refractoriness to therapy or relapses after the patients has received therapy for a prolonged interval of time. Mutations in *ABL1*, most often involving the kinase domain, have been identified that explain, in part, imatinib resistance. Second and third generation tyrosine kinase inhibitors have been developed that are valuable in the treatment of CML patients at time of relapse, and upfront for some CML patients with high-risk disease. Dasatinib, nilotinib, and ponatinib are three examples of more recently developed drugs that have a role in managing CML patients. Other causes of imatinib resistance involve genomic amplification of *BCR-ABL1* or may be mediated through mechanisms independent of *BCR-ABL1* such as activation of the mTOR/Akt pathway, loss of functional *TP53*, or *SRC* activation [285, 286]. The utility of detecting mutations before imatinib therapy is not well established [287]. This is an active area of research and the reader referred to reviews discussing imatinib resistance in CML [288].

Sanger sequencing can detect *BCR-ABL1* mutations in approximately 50 % of CML patients resistant to imatinib, but not all mutations have the same effects. Certain mutations in the kinase domain, such as Y253F/H, E255K/V, T315I, or H396P/R, are highly imatinib resistant and usually indicate the need for alternative therapy, whereas patients with other mutations, such as M244V, M351T, or F359V, can benefit from an increased imatinib dose [289]. Various ABL1 mutations are more or less sensitive to either dasatinib or nilotinib; the T315I mutations is resistant to both drugs but sensitive to ponatinib [290].

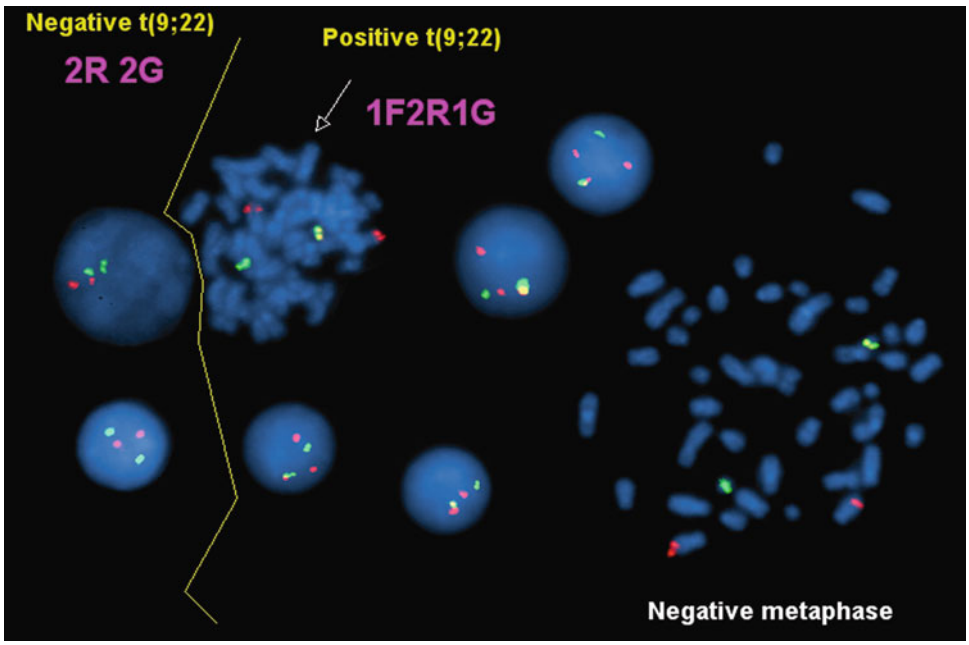

Fig. 30.17 Fluorescence in situ hybridization (FISH) analysis of a case of chronic myelogenous leukemia in chronic phase. *BCR/ABL1 ES* dual color probe (Vysis) in which the BCR probe is *green*. This probe spans approximately 300 kb beginning between *BCR* exons 13 and 14 (M-bcr exons 2 and 3). The *ABL1* probe is *red* and spans an area centromeric of the *ASS* gene to well telomeric of the last *ABL1* exon. In the absence of t(9;22), a cell has two *red* and two *green* signals. In the presence of t(9;22) and preserved *ASS* gene, a cell shows one *green* (native *BCR*), one large *red* (native *ABL1*), one smaller *red* (*ASS*), and one fused (*yellow*) signal pattern (*middle panel*). In a case of *ASS* deletion, an abnormal nucleus shows one *green*, one large *red*, and one *yellow* (fused) signal (not shown).

30.5.7 Molecular Methods for Diagnosis and Detection of Minimal Residual Disease in CML

The diagnosis of CML is most often made by morphologic analysis with conventional cytogenetic analysis showing the presence of a small derivative chromosome 22 (Ph) that is created as a result of t(9;22)(q34.q11). Approximately 95 % of all cases of CML have evidence of the Ph as detected by conventional cytogenetic analysis. Routinely 20 metaphases are examined and therefore the analytic sensitivity is about 5 %. Despite the availability of more sensitive methods, conventional karyotypic results have prognostic as well as diagnostic significance. Karyotypic results after therapy are divided into prognostic groups: complete response (no Ph+ metaphases); major response (1–34 % Ph+ metaphases), and partial response (35–90 % Ph+ metaphases). A complete response correlates with lower levels of BCR-ABL1 by quantitative RT-PCR and longer survival.

More sensitive techniques such as FISH (Fig. 30.17) or RT-PCR (Fig. 30.18) are also very popular because they permit assessment of minimal residual disease following therapy [291]. FISH routinely assesses 200 nuclei and unlike conventional cytogenetics does not require dividing cells. This method allows a semiquantitative determination of the percentage of nuclei positive for *BCR-ABL1* and has an analytical sensitivity of approximately 0.5 %. FISH studies have shown that not all *BCR-ABL1* translocations are identical in that variably sized deletions of chromosome 9 occur and have prognostic significance [292]. However, FISH is highly focused on detecting *BCR-ABL1* and cannot provide information about other chromosomal abnormalities that may be present.

Quantitative RT-PCR is the most sensitive method for detecting *BCR-ABL1* with an analytical sensitivity of at least 0.001 % or 1 positive cell in 100,000 negative cells. Most laboratories also measure a control gene that is present in near constant amounts in the cell and tumor burden is expressed as a *BCR-ABL1*–control ratio. Quantitative RT-PCR for *BCR-ABL1* transcript levels is the best approach to assess for minimal residual disease and assessment of serial specimens over time is an excellent means of assessing risk of relapse, permitting stratification of patients into risk groups.

Great efforts have been made to standardize qRT-PCR techniques by definiting an internal standard for *BCR-ABL1* quantification and an international scale for results [284]. The monitoring of *BCR-ABL1* transcript levels is important for early detection of imatinib resistance at the molecular level. Imatinib resistance is defined as lack or loss of complete molecular response [293]. Complete molecular response is defined as undetectable *BCR-ABL1* transcripts by

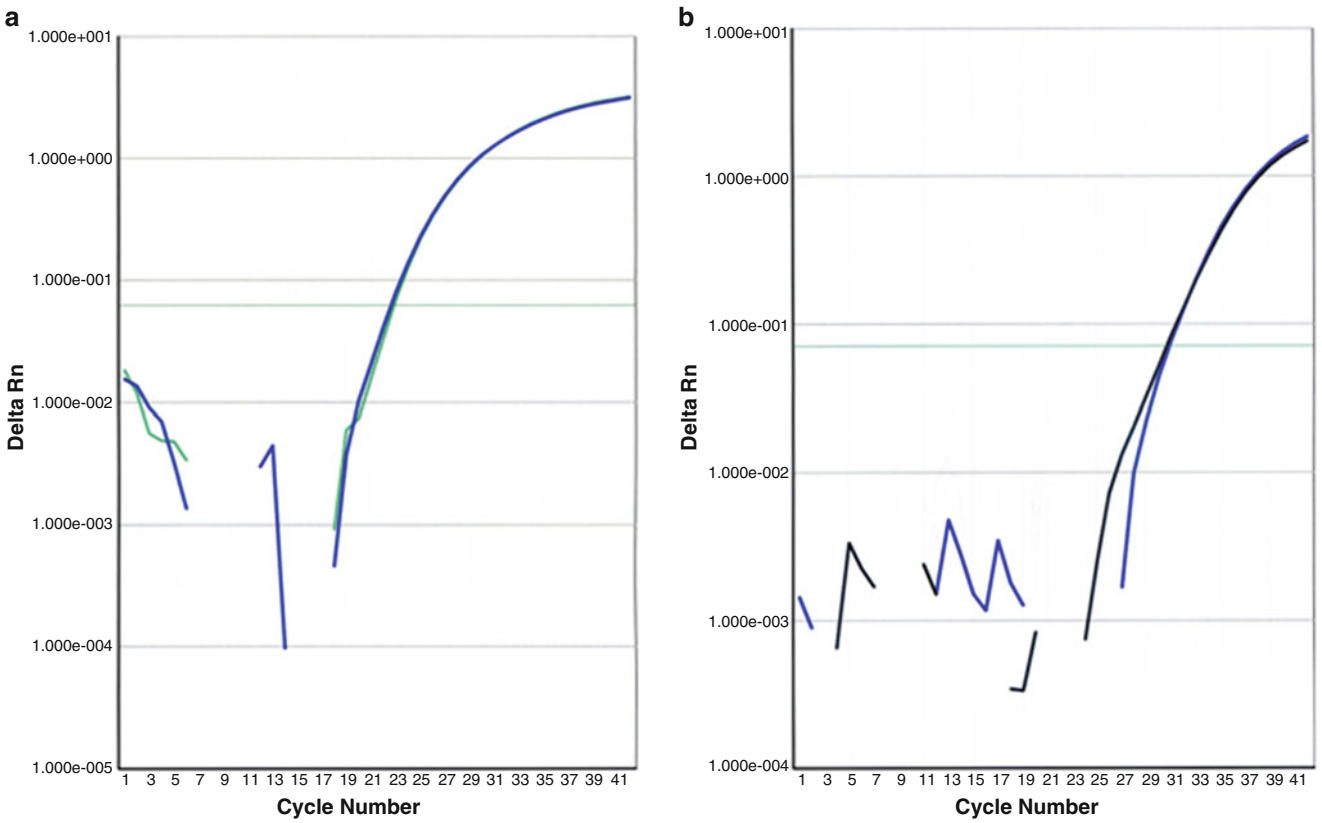

Fig. 30.18 Real-time PCR for BCR/ABL1. In addition to establishing diagnosis, this technique is widely used for monitoring the therapy response. A,B RT-PCR for *BCR/ABL1* in the same patient with CML before (**a**) and 3 months after (**b**) therapy with imatinib. Lower level of *BCR/ABL1* transcript is reflected in large number of cycles (31 versus 23) required to reach the positive threshold (*green line*). Note the different scale of the *y*-axis in two cases.

RT-PCR. Major molecular response is defined quantitatively as a >3 log reduction of *BCR-ABL1* transcripts or a *BCR-ABL1/ABL1* ratio of <0.1 % [294]. Molecular relapse, in complete cytogenetic responders, is considered to be an increase in *BCR-ABL1* transcript levels by a log of 0.5–1 [293]. The current recommendation is to judge the possibility of relapse after therapy based on at least two consecutive samples after more than one negative result [293].

30.6 Other Myeloproliferative Neoplasms and Myelodysplastic/ Myeloproliferative Neoplasms

In addition to CML, the current WHO classification lists a group of myeloproliferative neoplasms (MPN) including polycythemia vera, essential thrombocythemia, chronic idiopathic myelofibrosis, chronic neutrophilic leukemia, and chronic eosinophilic leukemia/hypereosinophilic syndrome. The MDS/MPN category includes chronic myelomonocytic leukemia, atypical chronic myeloid leukemia (*BCR-ABL1* negative), and juvenile myelomonocytic leukemia. These entities are defined based on a constellation of clinicopathologic and laboratory findings, and, unlike CML, some of these diseases lack unifying molecular abnormalities. However, a few important molecular abnormalities in these diseases have been identified.

30.6.1 *JAK2* Mutations

The Janus family of tyrosine kinases (*JAK1, JAK2, JAK3, TYK2*) are cytoplasmic tyrosine kinases that mediate signaling downstream of cytokine receptors [295]. Activation of the JAK-cytokine receptor complex results in JAK-mediated phosphorylation of substrate molecules, including STAT proteins that have critical roles in cellular proliferation, cell survival, and immune responses [296]. *JAK2V617F* is the most common mutation in cases of MPN. This mutation is found in virtually all patients with polycythemia vera (PV) and approximately half of those with essential thrombocythemia (ET) or chronic idiopathic myelofibrosis (CIMF) [297].

V617 resides within the pseudokinase, JH2 domain, a residue that is highly conserved between species [298]. Molecular modeling of JAK2 kinase suggests that the JH2 domain mutation lies adjacent to the site that stabilizes the activation loop of the kinase in its inactive conformation. A mutation at this point conceivably destabilizes this conformation, allowing the loop to flip into active conformation leading to constitutive activity of JAK2-cytokine receptor complex [299]. In addition to point mutations, *JAK2* can be altered by chromosome translocations, including *ETV6-JAK2* via t(9;12)(p24;p13), seen in T-ALL or B-ALL as well as MDS/MPN; *PCM1-JAK2* via t(8;9)(p22;p24) seen in eosinophilia-associated MDS/MPN, ALL, AML, and T-cell lymphoma; and *BCR-JAK2* via t(9;22)(p24;q11.2) seen in MDS/MPN [300, 301].

JAK2V617F is a G to T somatic mutation of *JAK2*, at nucleotide 1849 in exon 14, resulting in substitution of phenylalanine for valine at codon 617 [297]. Initially reported in PV, ET, and CIMF [297, 303–305], *JAK2V617F* mutation also has been described in MDS/MPN and MDS, although at a lower frequency [306, 307]. Some researchers express doubt that *JAK2V617F* is the initiating or even a mandatory event in MPN and MDS/MPN [308, 309]. Those concerns are supported by observations of *JAK2V617F*-negative leukemia clones arising from *JAK2V617F*-positive MPN [310].

Most recently, other *JAK2* mutations have been described in *JAK2V617F*-negative patients with PV and in idiopathic erythrocytosis; most of these cases demonstrate one of four exon 12 *JAK2* mutant alleles and induce cytokine-independent/hypersensitive proliferation in erythropoietin receptor-expressing cell lines and a PV-like phenotype in mice [311]. The four newly described exon 12 mutations, which include both in-frame deletions and tandem point mutations, appear to be specific to either PV or idiopathic erythrocytosis.

30.6.2 *CALR* Mutations

The *CALR* (*calreticulin*) gene, located at chromosome 19p13.3-p13.2, is a multifunctional protein located in the endoplasmic reticulum, cytosol, and cell surface of the cell. Calreticulin is important in calcium homeostasis, has a transport chaperone function, and is involved in cell adhesion. *CALR* mutations have been identified in about 25 % of ET and CIMF cases, in over 50 % of cases negative for *JAK2* mutation [312]. In most but not all studies, *CALR* and *JAK2* mutations have been mutually exclusive. The exact role of *CALR* mutations is not well established, but is likely involved in JAK-STAT signaling. In patients with ET, *CALR* mutations have been associated with a higher platelet count, lower hemoglobin level and leukocyte count, and a lower risk of thrombosis.

30.6.3 *MPL* Mutations

The *MPL* gene, located at chromosome 1p34, encodes a receptor for thrombopoietin, which is essential for megakaryopoiesis. *MPL* mutations have been described in familial thrombocytosis [313] and congenital amegakaryocytic thrombocytopenia [314]. Recently, somatic gain of function mutations involving codon 515 of the *MPL* gene (*MPLW515L* and *MPLW515K*) have been identified in approximately 5 % of CIMF patients and 1 % of ET patients [308]. *MPL* and *JAK2* mutations are not mutually exclusive [308].

30.6.4 *ASXL1* Mutations

The *ASXL1* (*additional sex combs-like transcriptional regulator 1*) gene, located at chromosome 20q11, is involved in regulation of the polycomb repressor complex and other functions. Mutations of *ASXL1* have been reported in about 6 % of cases of essential thrombocythemia (in addition to cases of MDS and AML) [315].

30.6.5 *CSF3R* Mutations

The *colony-stimulating factor 3 receptor (CSF3R)* gene, located on chromosome 1p35-p34.3, is mutated in about 60 % of cases of chronic neutrophilic leukemia and atypical CML. These mutations tend to cluster in distinct regions of the gene and result in downstream JAK activation [316].

30.6.6 *PDGFR* Mutations

Rearrangement of the *platelet-derived growth factor receptor α* (*PDGFRA*) gene, located on chromosome 4q12, most often occurs as a consequence of del(4)(q12) resulting in *FIP1L1-PDGFRA* fusion gene. *FIP1L1-PDGFRA* occurs in a very small subset of patients who present with the phenotypic features of both chronic eosinophilic leukemia (CEL) and systemic mastocytosis and predicts complete hematologic and molecular response to imatinib therapy [317, 318]. *PDGFRA* can also be activated through other mechanisms such as t(4;10)(q12;p11) resulting in an in-frame fusion gene *KIF5B-PDGFRA;* t(4;22)(q12;q11) forming a *BCR-PDGFRA* fusion gene, and ins(9;4)(q33;q12q25) forming *CDK5RAP2-PDGFRA* fusion gene [319, 320]. Clinically, patients with MPN associated with t(4:10)(q12;p11), t(4;22)(q12;q11), or ins(9;4)(q33;q12q25) present as CEL.

Rearrangements of *platelet-derived growth factor receptor α* (*PDGFRα*) gene, located on chromosome 5q31-32, are found in several cases of MPN, most of which are associated with eosinophilia. The examples include t(5;12)(q33;p13)

resulting in *ETV6-PDGFRα* fusion gene; t(5;17)(q33;p13) resulting in *RABAPTIN5-PDGFRβ*; t(5;17)(q33;p11.2) resulting in *HCMOGT-1-PDGFRα*; t(5;14)(q33;q24) resulting in *NIN-PDGFRα*; t(5;14)(q33;q32) resulting in *KIAA1509-PDGFRα*; t(5;15)(q33;q22) resulting in *TP53BP1-PDGFRα*; t(1;5)(q23;q33) resulting in *PDE4DIP-PDGFRα*; t(5;7)(q33;q11.2) resulting in *HIP1-PDGFR α;* t(5;10)(q33;q22) resulting in *H4-PDGFR α* [321–323].

30.6.7 Mutations Involving RAS Signaling Pathway

Mutations involving the RAS signal transduction pathway are most prevalent in juvenile myelomonocytic leukemia (JMML) [324]. JMML is often associated with monosomy 7 [325, 326]. Known hypersensitivity of myeloid progenitors in JMML to granulocyte-macrophage colony-stimulating factor (GM-CSF) [327] has recently been attributed to altered RAS signaling as a result of mutations affecting one of the pathway regulatory molecules such as *RAS*, *PTPN11*, and *NF1* [326, 328]. *PTPN11* mutations are found in approximately 30 % of patients with JMML, whereas NF1293 and RAS29 mutations have lower incidence of approximately 15–20 %; all three mutations appear to be mutually exclusive [326, 328].

RAS mutations are also found in other MPN or MDS/MPN including chronic myelomonocytic leukemia (CMML). *RAS* mutations in JMML often represent single nucleotide substitutions involving the P loop domain of either *KRAS* (approximately 15 %) [326, 329] or *NRAS* (approximately 30 %) [330] and have been shown to cause the disease phenotype in mice [331]. BRAF mutations have been reported in about 40 % of cases of CMML [332].

Neurofibromatosis type 1 (*NF1*) located on chromosome 17q11.2 is a tumor suppressor gene that encodes for a 327-kDa neurofibromin protein that inactivates RAS through acceleration of RAS-associated GTP hydrolysis. *Germ line NF1* mutations cause von Recklinghausen disease. Children with type 1 neurofibromatosis are predisposed to JMML [333] and demonstrate loss of heterozygosity of *NF1* in myeloid progenitor cells [334]. Primary leukemia cells from such patients accumulate RAS in the active GTP-bound state [335]. It was shown that *NF1* knockout mice developed an MPD-like disease with GM-CSF hypersensitivity [335, 336].

PTPN11 (*Protein-Tyrosine Phosphatase, Nonreceptor-type, 11*), located on chromosome 12q24.1, encodes for the nonreceptor protein tyrosine phosphatase, SHP-2, that transmits signals from growth factor receptors to RAS. *Germ line PTPN11* mutations are found in approximately 45 % of patients with Noonan syndrome, and these patients are at risk of developing JMML [336]. On the other hand, more than 30 % of patients with JMML demonstrate *PTPN11* mutations [328, 337]. In mice, retroviral transduction of *PTPN11* mutant alleles in bone marrow cells induces GM-CSF hypersensitivity and an MPD-like disease [338], which suggests an important role of *RAS* mutations in pathogenesis of JMML.

30.7 8p11 Myeloproliferative Syndrome

The 8p11 myeloproliferative syndrome (EMS) is also known as stem cell leukemia/lymphoma syndrome, or as myeloid and lymphoid neoplasms associated with FGFR1 abnormalities in the current WHO classification (Fig. 30.19). Patients with this entity most often present with a MPN or MDS/

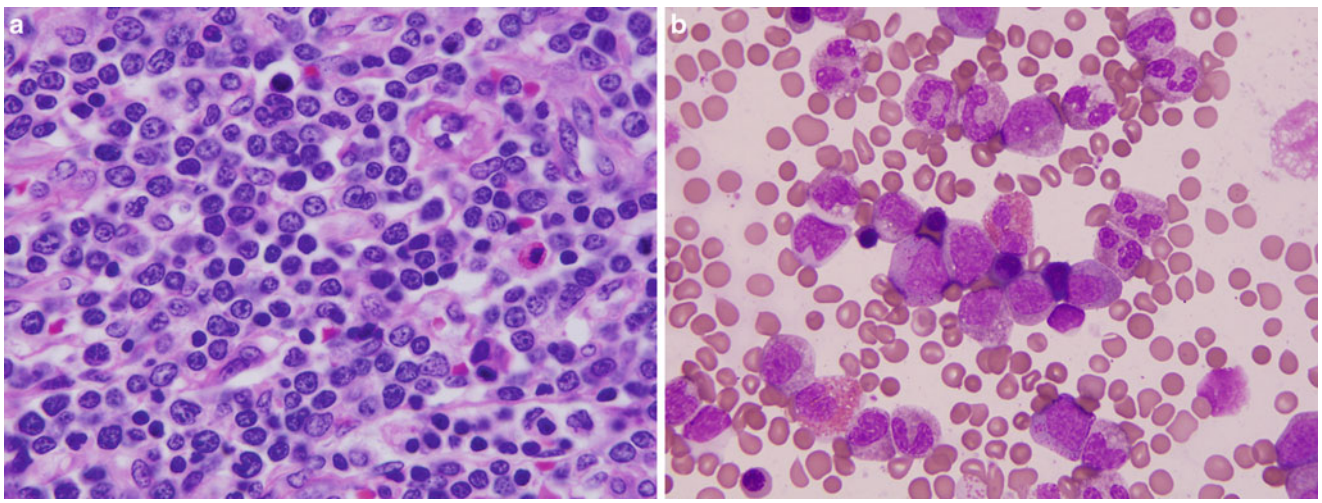

Fig. 30.19 A case of 8p11 myeloproliferative syndrome with t(8;13). (**a**) The lymph node demonstrates involvement by blastic neoplasm that most closely resembles precursor T-cell lymphoblastic lymphoma with minor myeloid foci. (**b**) The bone marrow is hypercellular and is consistent with a myeloproliferative syndrome (**a**, hematoxylin–eosin stains, 1000×; **b**, Wright-Giemsa, 1000×).

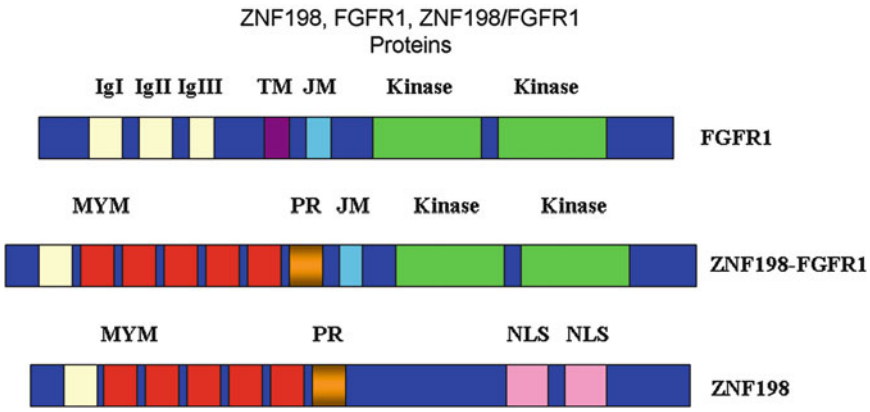

Fig. 30.20 Schematic representation of ZNF198 (ZMYM2), FGFR1, and ZNF198 (ZMYM2)/FGFR1 fusion proteins. The fusion is the result of t(8;13)(p11;q12), the most common translocation in 8p11 myeloproliferative syndrome.

MPN associated with eosinophilia [339]. Many patients develop an immature lymphoid neoplasm, most often classified as T ALL/LBL, although in some of these neoplasms there is evidence of mixed lineage [339]. Patients with EMS have a high risk of subsequent acute myeloid leukemia.

The fibroblast growth factor receptor 1 (*FGFR1*) at chromosome 8p11 is always involved. The most common partner is *ZMYM2* (previously known as *ZNF198)* at 13p11. The t(8;13) results in the joining of *FGFR1* with the novel *ZMYM2* gene on chromosome 13q11 [339]. The *ZMYM2-FGFR1* fusion transcript encodes a 76 kDa protein localized predominantly to the cytoplasm. Conventional cytogenetics is most commonly used to detect the t(8;13), but FISH and RT-PCR methods also can be used.

A number of other partner genes can be involved including *FOR* in the t(6;8)(p17;p11), *FGFR1OP2* in the ins(12;8)(p11;p11p22), *BCR* in the t(8;22)(p12;q11); *TPR* in the t(1;8)(q25;p11.2); *TIF1* in the t(7;8)(q34;p11), *MYO18A* in the t(8;17)(p11;q23), *HERV-K* in the t(8;19)(p11;q13.3), and *CEP110* in the t(8;9)(p12;q33) (Fig. 30.20) [339]. In all translocations, *FGFR1* and the partner gene are disrupted and recombined to form novel fusion genes that constitutively activate *FGFR1*. The different translocations show some clinical correlations. Patients who develop T-ALL/LBL or mixed T-cell/myeloid lymphomas often carry *ZMYM2-FGFR1*. Patients with *BCR-FGFR1* often present with a CML-like disorder. The *ZMYM2-FGFR1* and *BCR-FGFR1* have been shown to induce CMPD in mice [340].

30.8 Chronic Lymphoid Leukemias

30.8.1 Chronic Lymphocytic Leukemia

Virtually all cases of chronic lymphocytic leukemia (CLL) express surface Ig, usually at a low level, and have *IgH* and *Ig light chain* gene rearrangements (k>λ). Surface Ig expression requires a functional Ig protein and two other critical proteins, B29 (Igβ and CD79b) and mb-1 (Igα and CD79a), that are essential components of the B-cell antigen-receptor complex. Mutations in the B29 gene and/or abnormalities of B29 expression (at the mRNA level) are common in CLL [341]. The diminished surface Ig on CLL cells may result in these cells being unresponsive to antigen binding, perhaps preventing initiation of growth signals or apoptosis cascades.

A milestone in understanding of CLL was the observation that somatic mutations of the *IgV* (*immunoglobulin variable region*) genes occur in a subset of CLL cases, and that the absence or presence of these mutations correlates with clinical course [342]. Mutations occur in both the *IgH* and *Ig light chain* genes, but *IgHV* analysis is easier and adequate for prognostic purposes. An arbitrary cutoff of 2 % or more mutations divides CLL into two prognostic groups. Patients with CLL in which the *IgHV* show <2 % somatic mutations (unmutated CLL) have a poorer clinical outcome. It appears that CLL cells in this subset receive continuous anti-apoptotic and/or proliferating microenvironmental stimuli via the BCR leading to more aggressive disease. In contrast, CLL patients in which the *IgHV* show ≥2 % mutations (mutated CLL) have a clinically indolent course [342]. A difference in outcome was also demonstrated in CLL patients receiving an autologous stem-cell transplant (ASCT); all patients with unmutated *IGHV* genes relapsed and progressed after a 4-year follow-up, whereas most patients with mutated *IGHV* genes remained in molecular remission [343].

Initially it was thought that CLL cases with unmutated *IgHV* (U-CLL) were derived from naive B-cells, and that CLL cases with mutated *IgHV* CLL (M-CLL) derived from antigen-experienced B-cells. It is now known that all CLL cells bear the surface membrane immunophenotype of being antigen experienced (CD27) and activated (expression of CD23, CD25, CD69, and CD71). Gene expression profiling has shown that CLL cells have a profile similar to memory

B-cells irrespective of *IgHV* mutational status [344]. These findings suggest that all cases of CLL have a common cellular origin and/or common mechanism of transformation and a continued requirement for antigen after the transformational event [345]. However, comparative analysis of U-CLL and M-CLL suggests that the neoplastic cells, by differing in their *IgHV*, have different antigen encounter histories [345]. It also has been suggested that an antigen-driven process might be critical for determining clinical features and for modulating disease outcome, irrespective of mutation status in B-CLL [346].

Biased use of *Ig* gene variable (V) segments has been described in CLL cases. The *VH1* family of the *IgH* gene and the *VIIIb* family of the *Igk* gene are used in the formation of *Ig* gene rearrangements more often than can be explained by chance alone. DNA sequence analysis of the variable V, diversity (D) and joining (J) segments involved in *IgH* and *Igk* gene rearrangement has shown that a subset of CLL have somatic mutations [346].

The frequency of chromosomal abnormalities detected in CLL depends on the method used. Conventional cytogenetic analysis detects abnormalities in a substantially lower proportion of cases as compared with FISH. The significant false-negative rate of conventional cytogenetic analysis is attributed to the low proliferation rate and therefore poor growth of CLL cells in culture [348]. Using conventional cytogenetic analysis, chromosomal abnormalities have been identified in up to 50 % of cases of CLL, with trisomy 12 being the most common chromosomal abnormality (15–20 % of cases), followed by structural abnormalities of chromosomes 11, 13, and 14. The most common chromosomal abnormality in CLL detected by FISH is deletion of 13q14, followed by deletion of 11q22.3-q23.1 and trisomy 12 (Fig. 30.21) [348].

There is a correlation between genomic aberrations and the *IgHV* mutation status. Unfavorable aberrations, such as del(11q) and del(17p), occur more frequently in *IgHV* unmutated, and del(13q14), a favorable finding, occurs more often in the *IgHV* mutated subgroup [348, 349]. Approximately two thirds of the *IgHV* unmutated CLL cases show no unfavorable genomic aberrations, indicating a differential influence of these factors [349].

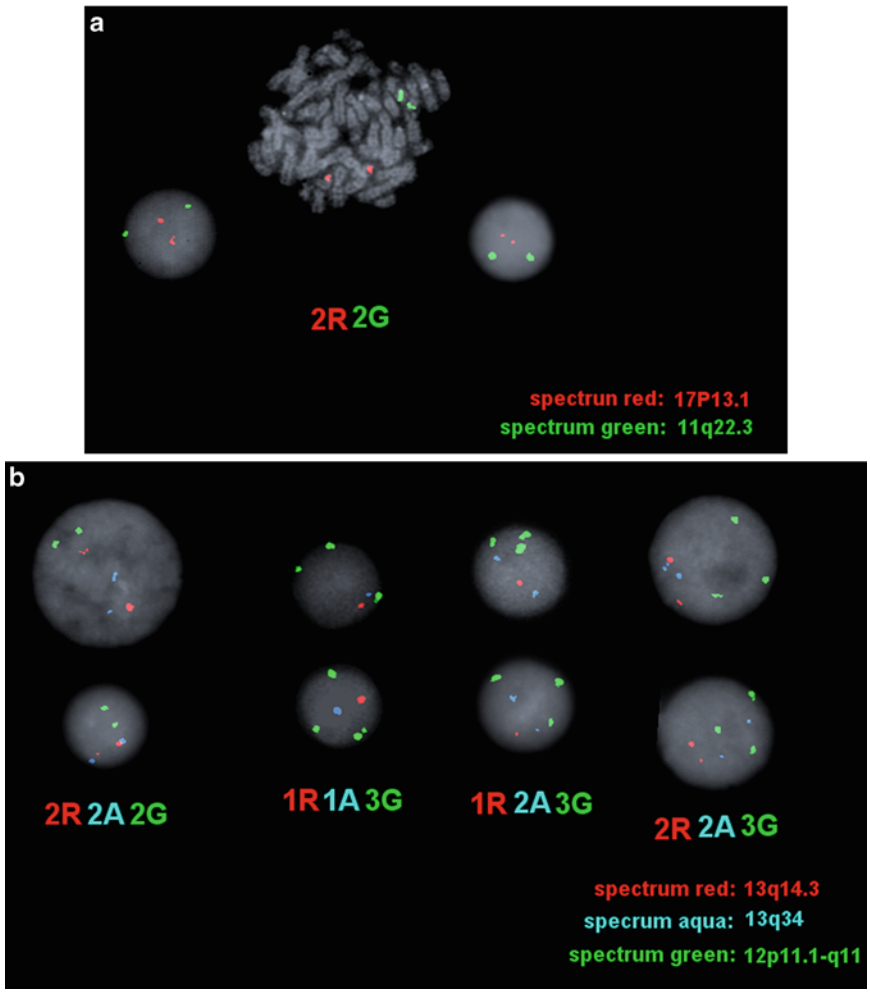

Fig. 30.21 Fluorescence in situ hybridization (FISH) analysis of chronic lymphocytic leukemia. The probes are part of a commercially available panel (Vysis). (**a**) Probe mixture 1 assesses 17p13.1 (p53) and 11q22.3 (ATM). In a normal cell with two intact copies of chromosomes 17 and 11, two *orange*, and two *green* signals will be observed. (**b**) Probe mixture 2 assesses 13q14.3 (D13S319), 13q34, and 12p11.1-q11. In a normal cell with two intact copies of chromosome 13 and chromosome 12, two *orange*, two *aqua*, and two *green* signals are observed. Any deviation of the normal pattern indicates deletion or gain a corresponding chromosomal region.

30.8.2 CLL with 13q14 deletion

13q14 deletions occur in 40–50 % of CLL cases using FISH. Studies using FISH and CGH have frequently shown *RB1* deletion, located at 13q14, as well as 13q deletions. Monoallelic loss of the *RB1* gene was detected in 30 % of CLL patients, but disruption of both alleles is rare. Additional loci D13S25 and D13S319 located distal to band 13q14, which are more frequently deleted in CLL, were identified suggesting a novel tumor suppressor gene located in these regions [350]. Deletion or downregulation of two microRNA genes, *miR15* and *miR16*, has been recently implicated in the pathogenesis of CLL [351].

30.8.3 CLL with Structural Aberrations of Chromosome 11

Structural aberrations of chromosome 11 are reported in 12–25 % of CLL [348, 352]. The 11q22-q23 locus is frequently deleted in CLL and is rich in tumor suppressor and other genes including *FDX*, ataxia telangiectasia mutated (*ATM*), *KMT2A*, *PZLF*, *Mre11*, and *RDX* [352]. The del(11q22.3) group of patients often has a poor prognosis, and acquisition of this abnormality is associated with clonal evolution and disease progression [353]. Tumor cells carrying del(11q22.3) often show upregulation of genes that control cell cycle progression and signaling pathways [354, 355]. The *ATM* gene frequently shows *germ line* as well as somatic mutations in CLL patients. More than two thirds of CLL cases have monoallelic loss of *ATM*. The other nondeleted allele often bears point mutations, most frequently in the PI-3 kinase domain [356]. Recently, three new candidate genes in the 11q22-23 region, *NPAT* (cell-cycle regulation), *CUL5* (ubiquitin-dependent apoptosis regulation), and *PPP2R1B* (component of the cell-cycle and apoptosis regulating *PP2A*) have been shown to be significantly downregulated in CLL cases with 11q deletion [357].

30.8.4 CLL with 17p13 Aberration

The *TP53* gene, located on 17p13, plays a crucial role in apoptosis induction or cell cycle arrest after DNA damage. *TP53* mutations occur in 10–15 % of patients with CLL [358]. Acquisition of *TP53* mutations is a late event in CLL, detected in about 10 % of early CLL cases but in more than 30 % of CLL patients who subsequently develop large B-cell lymphoma [359]. *TP53* abnormalities in CLL are associated with advanced stage at presentation, resistance to purine nucleoside analogues, high incidence of transformation and disease progression in 1–2 years, and poorer clinical outcome [359]. *TP53* deletions are detected by FISH in 10–20 % cases and independently predict poor survival and resistance to chemotherapy in CLL patients [359].

Wild-type *p53* protein is a target of *MDM-2*-mediated ubiquitination and subsequent degradation and, thus, has a short half-life in early-stage tumor cells in CLL [360]. The protein product of mutated *TP53* has a prolonged survival in cells, and it is thus possible to detect *p53* expression by immunocytochemistry [361]. *p53* expression serves as an independent prognostic variable in CLL and is associated with *TP53* gene mutations, advanced disease, resistance to therapy, and poor survival [361].

30.8.5 CLL with Trisomy 12

Trisomy 12 is reported in 10–20 % of CLL patients as assessed by conventional cytogenetic analysis and in 20–40 % of CLL patients as assessed by interphase FISH [362]. The occurrence of trisomy 12 is more common in CLL with atypical morphological and immunophenotypic features [362]. CLL cases with trisomy 12 often have unmutated *IgVH*. The acquisition of trisomy 12 is associated with advanced-stage disease, shorter time to progression, and significantly poorer median survival rates [362]. Detailed structural analyses of chromosome 12 identified a minimally gained region limited to bands 12q13-q15. A number of genes including *CDK2*, *CDK4*, *STAT6*, *APAF-1*, and *MDM-2* are located in this region and play critical roles in the regulation of oncogenesis, cell cycle control, and apoptosis; however, the role of these genes in the pathogenesis of CLL has not been well characterized.

30.8.6 CLL with 6q deletion

Deletions of the long arm of chromosome 6 are detected in 4–6 % of CLL cases by conventional cytogenetics and up to 9 % cases by FISH [363]. Deletions of 6q are often associated with high leukocyte counts, extensive lymphadenopathy, and splenomegaly. Cases with del(6q) often show atypical morphologic features, including large lymphocytes, immunoblast-like cells, prolymphocytoid cells, and cleaved lymphocytes. Usually these neoplasms have a classic immunophenotype with CD38 positivity, and an intermediate frequency of *IGHV* somatic hypermutation.

30.8.7 Chromosomal Translocations in CLL

A small subset of cases of CLL, less than 5 %, are associated with chromosomal translocations that involve the immunoglobulin gene loci. These cases differ somewhat from other CLL cases in that patients may be younger or the tumors show atypical morphologic or immunophenotypic features.

t(14;18)(q32;q21). Conventional cytogenetic studies have rarely identified the t(14;18)(q32;q21) in CLL [348]. In addition, the *BCL2* gene at 18q21 can be involved in t(2;18)(p11;q21) or t(18;22)(q21;q11), involving the *Igk* (chromosome 2p11) or *Igλ* (chromosome 22q11) gene loci [365]. The breakpoint on chromosome 18 usually occurs within the variant cluster region, 5′ to the *BCL2* gene, but may also occur 3′ to the *BCL2* gene, at a location intermediate between the major and minor breakpoint cluster regions [365]. Errors in the VDJ recombination process may be involved in the generation of the t(2;18) and t(18;22), as a heptamer-like recognition sequence is present upstream of the *BCL2* gene [365]. Despite the relative infrequency of chromosomal translocations involving *BCL2* in CLLs, virtually all CLL cases express BCL2 protein. The BCL2 protein is known to inhibit apoptosis (programmed cell death). Because chemotherapeutic drugs act by inducing apoptosis, BCL2 expression in CLL appears to be a major mechanism for drug resistance.

t(14;19)(q32;q13). The t(14;19)(q32;q13) involves the *BCL3* gene at chromosome 19q13. This translocation is rare in CLL. The *BCL3* gene encodes a protein of the IkB family and is involved in regulating the NF-kB family of transcription factor proteins. Cases with the t(14;19) are associated with atypical lymphocyte morphology manifested by a mixture of small and larger lymphocytes, increased prolymphocytes (usually <10 %), and cleaved/indented nuclei. Trisomy 12 is common. In addition, such patients present at a younger age and with rapid disease progression [366].

30.8.7.1 CLL with 8q24/*MYC* Rearrangements

A small subset of CLL cases are associated with translocations involving chromosome locus 8q24 with either the *IgH* (14q32) or the *Ig kappa* (2p12) or *Ig lambda* (22q11) loci. FISH analysis has confirmed *MYC* gene rearrangements in these cases. Clinically, patients with 8q24/*MYC* rearrangements tend to show morphologic evidence suggestive of disease progression including increased (>10 %) prolymphocytes or full blown prolymphocytic transformation (>55 % prolymphocytes) [367].

30.8.7.2 CLL with t(2;14)(p16;q32)

Rare cases of CLL have been associated with t(2;14)(p16;q32) involving the *BCL11A* gene at chromosome 2p16. These tumors are associated with atypical morphologic features and often exhibit plasmacytic differentiation. The *IgHV* are often unmutated in these tumors [368].

30.8.7.3 CLL with t(11;14)(q13;q32)

In older literature, t(11;14)(q13;q32) was reported in a small subset of cases of CLL, up to 5 %. In retrospect, these cases were most likely indolent variants of mantle cell lymphoma in leukemic phase. The translocation involves the *CCND1* (also known as BCL1 and cyclin D1) at chromosome 11q13 and the *IGH* gene at chromosome 14q32. *CCND1* encodes cyclin Dl protein, which is involved in progression of the cell cycle from G_1 to S phase. The t(11;14) is common in mantle cell lymphoma, being present in virtually all cases (Figs. 30.22 and 30.23) [369].

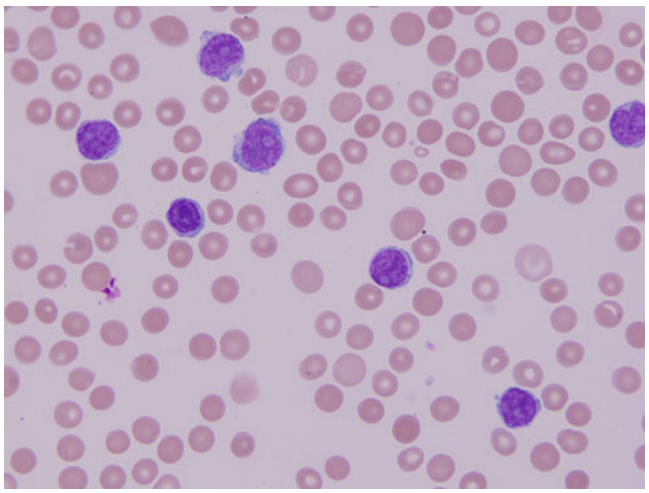

Fig. 30.22 Mantle cell lymphoma with unusual prolymphocyte-like morphology. Wright-Giemsa, 1000×. This case had the t(11;14)(q13;q32).

30.8.8 Gene Mutations in CLL

Using next-generation sequencing approaches, CLL has been shown to be highly heterogeneous. Overall, a number of genes are mutated in CLL, but no specific gene is mutated in greater than ~10 % of cases, with most genes mutated in <5 % of cases. In addition, a subset of CLL cases has very few gene mutations.

The genes most commonly mutated in CLL include *NOTCH1, SF3B1*, *TP53*, *MYD88*, and *BIRC3 (API2). NOTCH1* mutations have been reported in approximately 10 % of CLL cases and have been correlated with unmutated *IGV* and a poorer prognosis. Other genes are mutated in <5 % of cases and involve many different cellular functions. *SF3B1* is involved in mRNA splicing, *TP53* in DNA repair, *MYD88* is an adaptor protein involved in Toll-like receptor and interleukin-1 receptor signaling, and *BIRC3* in apoptosis regulation. *MYD88* mutations are more common in the mutated type of CLL.

30.8.9 Richter Syndrome

A small subset of CLL/SLL patients can subsequently develop diffuse large B-cell lymphoma (DLBCL), so-called

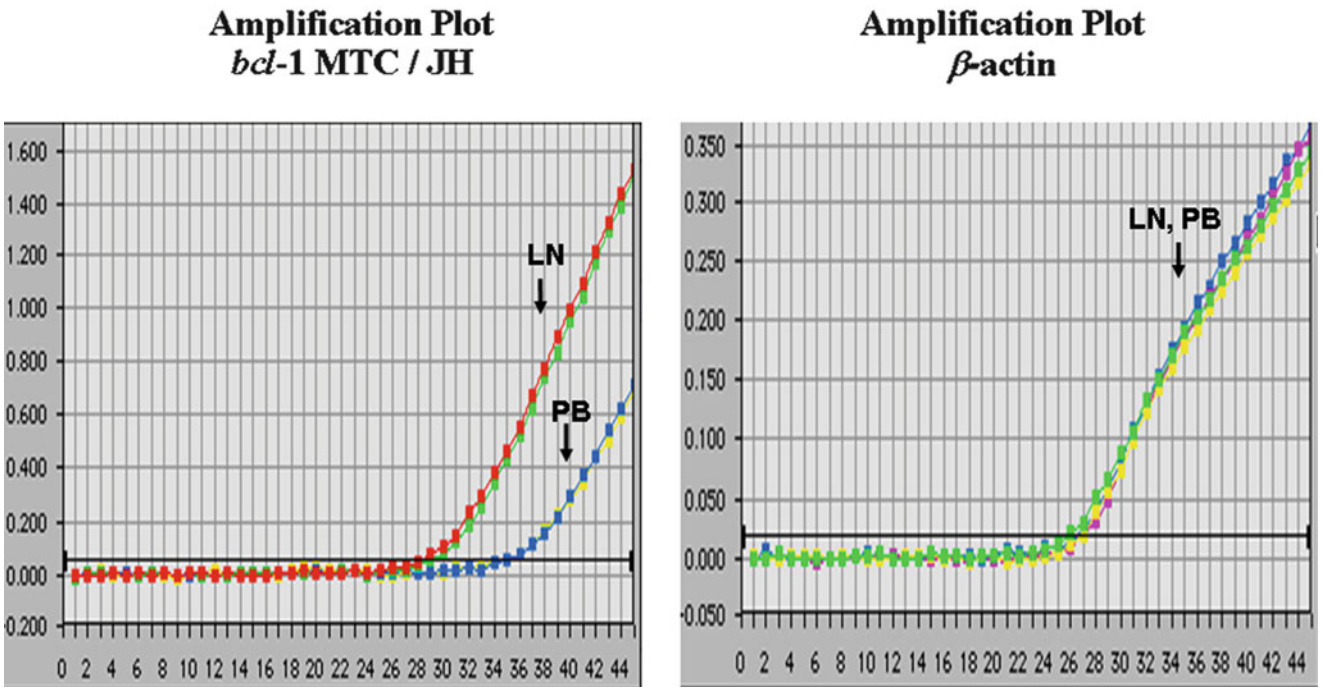

Fig. 30.23 Real-time PCR for BCL1/IgH. *Left* histogram shows DNA level in peripheral blood and lymph node of a patient with mantle cell lymphoma. *Right* histogram shows similar levels of β-actin DNA in both peripheral blood and lymph node used as a control.

Richter syndrome [370]. The overall frequency of this occurrence ranges from 2 to 10 % of patients in various reports, or about 0.5–1 % per year. In 70–80 % of patients, the CLL/SLL and DLBCL are clonally related and therefore the DLBCL is a form of histologic transformation. The risk of Richter transformation is increased in patients with high tumor stage, high-risk cytogenetic abnormalities, unmutated *IGHV* region genes, and expression of ZAP70 and/or CD38. At a genetic level, DLBCL arising as part of Richter syndrome is genetically distinct from de novo DLBCL [371].

30.8.10 Epigenetic Changes

Gene methylation is another mechanism of gene inactivation and with the advent of new methods for assessing DNA methylation, the importance of epigenetic changes in human cancers is well recognized [372].

Genome-wide patterns of DNA methylation in CLL are rather specific for CLL cells and can be reproduced in different patients [373, 374] suggesting that DNA methylation plays a specific role in CLL pathogenesis. Aberrant methylation has been described for specific genes, for example, hypomethylation of BCL2 and TCL1 [375]. Unbiased genome-wide screens of CLL have shown specific methylation of the promoter region of *TWIST2* [376] and of *DAPK1* [377]. When DNA methylation analyses were performed on the promoter region of *ZAP-70*, a specific CpG was methylated in 51 of 53 ZAP70-negative CLL cases. By contrast, no methylation was found in 30 of 32 ZAP70+ CLL cases [378].

Apart from their role in pathogenesis and their potential utility in diagnosis, epigenetic modifications are also an interesting target for therapy as epigenetic modifications are reversible (in contrast with genetic aberrations). Several compounds have been tested on cells in vitro and in clinical studies and shown to be biologically and clinically active. An inhibitor of histone deacetylases (depsipeptide FR901228) was shown to selectively target CLL cells in vitro as compared with normal blood B-cells and BM-derived progenitors [379].

30.8.11 B-Cell Prolymphocytic Leukemia

B-cell prolymphocytic leukemia (B-PLL) is a rare and ill-defined disease of mature B-cells with prolymphocytic morphology. In many studies, a cutoff of 55 % has been suggested for the number of prolymphocytes required for the diagnosis of B-PLL. In retrospect, it seems clear that cases designated as B-PLL in the past included cases of CLL in prolymphocytoid transformation as well as cases of prolymphocytoid variant of mantle cell lymphoma associated with t(11;14)(q13;q32) and cyclin D1 overexpression. In addition, a subset of patients with splenic marginal zone lymphoma can progress into a leukemic phase with >55 % prolymphocytes [380].

Most cases of B-PLL carry monoclonal *IgH* and *Ig light chain* gene rearrangements. The IgHV demonstrate somatic mutations consistent with antigen selection at a higher frequency than occurs in CLL [381]. Cytogenetic data obtained from cases of B-PLL are sparse and conflicting due to rareness of the disease and its poorly defined nature. In a series of 18 B-PLL patients using FISH, del(13q14) was detected in 55 % and monoallelic del (11q23) in 39 % of cases, respectively [382]. Other abnormalities reported include t(6;12), del (6q) structural aberrations of chromosome 1, and trisomy 12 [383]. Other known B-cell oncogenes (such as *BCL2*, *BCL3*, *BCL6*, and *MYC*) are not rearranged. The *TP*53 gene is frequently mutated in B-cell PLL, in approximately 50 % of cases [384].

A recent study of 13 B-PLL cases used gene expression profiling and showed that B-PLL cases cluster with either CLL or mantle cell lymphoma. Not surprisingly, cases with t(11;14)(13;q32) clustered with mantle cell lymphoma. However, a subset of cases without t(11;14) also clustered with cases of mantle cell lymphoma [385].

30.8.12 Hairy Cell Leukemia

Hairy cell leukemia is a rare type of B-cell lymphoma in which patients present with splenomegaly, and bone marrow involvement with abdominal lymphadenopathy in a subset of patients. Patients commonly present with pancytopenia and monocytopenia, and distinctive neoplastic lymphocytes with villous cytoplasmic projects (hairy cells) can be detected in the blood. Hairy cells have a mature B-cell immunophenotype and often express CD11c, CD22, (bright), CD103, and annexin A1.

Conventional cytogenetic studies have not shown recurrent abnormalities. Cases of HCL carry monoclonal *IgH* and *Ig light chain* gene rearrangements. The *IgHV* often show somatic mutations. In 2011, Tiacci and colleagues showed *BRAF* V600E mutation, in which valine (V) is replaced by glutamic acid (E), in virtually all cases of HCL [386]. The mutation occurs within the activation loop of *BRAF* and likely explains activation of the *RAF-MEK-ERK* pathway that is characteristic of HCL [387]. A small subset of HCL cases have *MAP2K1* mutation in the same pathway.

30.8.13 Splenic Marginal Zone Lymphoma/Leukemia

Splenic marginal zone lymphoma (SMZL) is an uncommon mature B-cell neoplasm, representing 1–2 % of all non-Hodgkin lymphomas. Patients tend to be elderly and they present predominantly with subdiaphragmatic disease characterized by massive splenomegaly, BM involvement, intra-abdominal lymphadenopathy, and hepatomegaly. Most patients have circulating lymphoma cells and patients can present an elevated leukocyte count that can be very high. Conventional cytogenetic and array CGH studies have shown del(7q22-36) in up to 50 % of patients and trisomy 3q in about 25 % of cases.

Recent sequencing studies have shown a number of gene mutations. *NOTCH2* mutations are common, in about 25 % or more of cases [388, 389]. Martinez and colleagues have shown a large number of other genes that are mutated in SMZL implicating activation of NF-kB, B-cell receptor signaling, cytoskeletal genes, and chromatin remodeling [390]. Parry et al. have suggested three genes in the minimally deleted region of 7q possibly being involved in pathogenesis: CUL1, EZH2, and FLNC [391].

30.8.14 T-Cell Prolymphocytic Leukemia

T-cell prolymphocytic leukemia (T-PLL) is a disease of prolymphocytes with a mature T-cell immunophenotype. Typical clinical features of T-PLL are splenomegaly, generalized lymphadenopathy, skin infiltration, and serous effusions. The disease usually affects elderly patients with a median age at presentation 63 years (range: 33–91 years).

A unique feature of T-PLL is dysregulation of the T-cell leukemia 1 (*TCL1*) oncogene [392]. TCL1 deregulation is detected in 70–80 % of T-PLL but not in other T-cell neoplasms [393]. In most cases, *TCL1* is insertionally activated by the T-cell receptor α/δ enhancer via inv(14)(q11q32.1) or t(14;14)(q11;q32.1) [394]. Rarely, it can also rearrange with the TCR-β chain locus on chromosome 7 in translocation t(7;14)(q35;q32.1) [392, 395]. In a small subset of T-PLL cases, the TCL1 homolog MTCP1 is dysregulated as a result of t(X;14) [396].

The 14q32.1 breakpoint region has three additional genes, *TCL1b, TNG1* (*TCL1 neighboring gene 1*), and *TNG2*, that have an expression pattern similar to *TCL1* in that they are not expressed in normal T-cells, but are expressed in T-PLL cell lines and cells from T-PLL patients [397]. Activation of *TCL1* through hypomethylation of its promoter also has been described [375].

In non-lymphoid cell line models, dysregulated TCL1 has been shown to bind to the pleckstrin homology (PH) domain of AKT and to regulate its activity, suggesting that TCL1 homodimers may act by promoting AKT dimerization, thus facilitating AKT transphosphorylation [398, 399]. In vitro TCR engagement results in rapid recruitment of TCL1 and AKT to transient membrane activation complexes that include TCR-associated tyrosine kinases [400]. Pharmacologic inhibition of AKT activation alters the localization, stability, and levels of these transient TCL1-AKT complexes and reduces tumor cell growth [400]. Experimental introduction and knockdown of *TCL1* influence the kinetics and strength of TCR-mediated AKT activation [400]. These

data indicate that TCL1 represents a highly regulated modulator of TCR-mediated AKT growth signaling in T-PLL.

Mutations involving *JAK1*, *JAK3*, *STAT5B*, and *IL2RG* are common in T-PLL, in up to 75 % of all cases. Constitutive activation of *STAT5B* is one result of these mutations and offers a potential target for therapy [401].

30.8.15 Adult T-Cell Leukemia/Lymphoma

Approximately 15 million persons in the world carry human T-cell lymphotropic virus 1 (HTLV-I) infection. The virus is common in endemic regions such as Africa, Middle East, the Caribbean basin, coastlines of South America, southwestern Japan, and some southern Pacific Islands. These locations mirror the transport of slaves from Africa in past centuries. The seroprevalence of HTLV-I infection in the USA is very low; 0.01 % of normal blood donors show serologic evidence of infection.

Adult T-cell leukemia/lymphoma is caused by HTLV-I. About 1–5 % of individuals seropositive for the virus eventually develop adult T-cell leukemia/lymphoma (ATLL), usually after many years. The are at least four clinical variants of ATLL: acute, lymphoma-like, chronic, and smoldering. Most patients with leukemic involvement by ATLL have the acute form. These patients commonly exhibit leukemia, lymphadenopathy, hepatosplenomegaly, skin lesions, osteolytic lesions, and hypercalcemia. Adult T-cell leukemia/lymphoma is a neoplasm of mature T-cell lineage, often with a T regulatory cell immunophenotype; CD4+ CD25+, and FOXP3+, and negative for CD1a, CD8, and TdT.

The HTLV-I provirus genome includes *gag*, *pol*, and *env* genes and other genes encoding Tax, Hbz, Rex, p12, p30, and p21 [402]. Transcriptional activation by Tax occurs through its interaction with cellular transcription factors such as NF-kB and the members of the cAMP responsive element binding proteins (CREB)/activating transcription factor (ATF) family [403]. Heterologous promoters of *IL-2 (interleukin-2), IL-13, IL-15, TGF-β (tumor growth factor-β), GM-CSF (granulocyte/macrophage colony-stimulating factor)*, *MYC, TNF-β (tumor necrosis factor-β)*, and others contain NF-kB binding sites and are transactivated through an interaction between Tax protein and NF-kB/Rel proteins [404, 405]. Other genes such as those for *IL-1, IL-6, major histocompatibility complex class I, and PTHrP (parathyroid hormone-related protein)* are activated by Tax through unknown mechanisms [406]. Transcriptional repression of some genes, such as *DNA polymerase-β*, *p18*, and *TP53*, by Tax protein also has been described [407]. Other effects of Tax include interaction with *CDKN2A* resulting in activation of CDK4, interaction with and inhibition of checkpoint kinase-1 (Chk1), and promotion of nuclear translocation of NF-kB through binding its cytoplasmic inhibitor, IKK [408]. The dysregulated expression of these genes with important roles in cell-cycle regulation, apoptosis, and proliferation leads to the development of HTLV-I-related diseases and contributes to their clinical features [409, 410].

In addition to the important role of Tax in pathogenesis, there are many other abnormalities. Conventional cytogenetics often shows complex karyotypes, pointing to numerous gene alterations. Comparative genomic hybridization has shown many gains and losses of chromosomal loci. *TP53* is mutated in 20–40 %. *CDKN2A* can be inactivated by methylation. A number of pathways have been shown to be activated in ATLL including NF-kB, JAK-STAT, mTOR-Akt, NOTCH, and RhoA [411].

30.8.16 Hepatosplenic T-Cell Lymphoma/Leukemia

This disease tends to involve younger adults, more often men, who present with splenomegaly, hepatomegaly, and BM involvement by an aggressive T-cell lymphoma/leukemia. Patients have short survival, often less than 2–3 years. Pathologic examination of tissues involved by HSTCL shows a sinusoidal pattern of involvement in the spleen, liver, and bone marrow. Patients can present with cytopenias and low-level involvement of the blood occurs in a patient subset; however, the total leukocyte count is often in the normal range. The neoplastic cells have an immature cytotoxic immunophenotype (TIA-1+, granzyme B-) and usually express the T-cell receptor (TCR) γ/δ, although ~20 % of cases express TCR α/β.

Conventional cytogenetic analysis has shown isochromosome 7q in 50–60 % of all cases. A variant ring-7 chromosome also has been reported less commonly. Isochromosome 7q results in loss of one copy of 7p and gain of one copy of 7q. Using array CGH, Ferreiro reported that the minimally deleted region as 7p22.1p14.1 and the minimally gained region as 7q22.11q31.1 [412]. Losses involving 7p are thought to be critical driver genetic alterations whereas gains at 7q are thought to provide growth advantages and may be involved in chemoresistance. Genes suggested as important at these loci include *CHN2* (which encodes β-chimerin) at 7p and *ABCB1*, *RUNDC3B*, and *PPPAR9A* at 7q. The *JAK-STAT* pathway also appears to be important in HSTCL; *STAT5B* and *STAT3* mutations have been reported in approximately 40 and 10 % of HSTCL cases, respectively [413].

30.8.17 T/NK Large Granular Lymphocyte Leukemia

Large granular lymphocyte (LGL) leukemias are proliferations of neoplastic LGLs that are further characterized, based on surface CD3 expression and TCR gene rearrangement, as

being of either T or NK cell lineage [414]. The median age of patients at diagnosis of LGL leukemias is 55–60 years, but these tumors has been reported in all age groups [415]. LGL leukemia is characterized by a persistent increase in the number of peripheral blood LGLs and is commonly associated with neutropenia and anemia [415]. Previously, an increase in the peripheral blood LGLs greater than 2.0×10^9/L lasting for more than 6 months was used as the necessary criterion for the diagnosis. However, some authors advocate establishing a diagnosis of T-LGL leukemia at lower level of LGL lymphocytosis, provided a monoclonal *TCR* rearrangement is detected.

The cytopenias characteristic of LGL leukemias are thought to be the result of leukemic cells exerting an inhibitory effect on normal hematopoiesis, rather than as a result of BM infiltration or hypersplenism [415]. Abnormalities in the FAS/FASL pathway resulting in dysregulated apoptosis are thought to play an important role in the pathogenesis of LGL leukemias [416]. Activated cytotoxic lymphocytes are normally eliminated through FAS-mediated apoptosis. However, LGL leukemic cells are resistant to FAS-mediated cell death [416]. Furthermore, leukemic LGLs express high levels of Fas and FasL and high levels of soluble Fas has been reported in the sera of patients with LGL leukemia [416]. These high levels of soluble Fas may block Fas-mediated apoptosis of LGL leukemic cells and contribute to the neoplastic process [417]. Reports have shown a correlation between serum levels of Fas ligand and disease activity and normalization of these levels with successful therapy [416, 418].

Neutropenia in LGL patients may be secondary to neutrophil destruction resulting from FAS-mediated apoptosis by direct contact of LGL cells expressing FAS ligand (FASL) or through paracrine effects of soluble FASL [415, 416].

Recent studies have shown a high frequency of *STAT3* mutations in cases of LGL leukemias. Koskela and colleagues identified *STAT3* mutations in approximately 40 % of cases [419]. The mutations occurred exclusively in exon 21, encoding the Src homology 2 domain, and a number of hotspots were also reported. In <5 % of LGL leukemias *STAT5B* mutations also have been reported and appear to be mutually exclusive with *STAT3* mutations [420].

30.9 Summary

Characterization of the molecular abnormalities in leukemias is important for a number of reasons. From the scientific viewpoint, these studies help to identify the genes and mechanisms involved in normal hematopoiesis and in the pathogenesis of leukemia. Further progress may help to identify targets for rational drug design or gene therapy. From a more immediate clinical perspective, information gleaned from these studies has improved the accuracy of diagnosis, aided in the design of assays to detect minimal residual disease, helped to predict response to therapy, and has provided criteria for selecting high-risk patient groups who may benefit from intensive but highly toxic chemotherapy protocols or stem cell transplantation.

Molecular Mechanisms in Non-Hodgkin Lymphoma

31

John Hunt, Yuri Fedoriw, and William N. Rezuke

31.1 Introduction

Hematologic malignancies are a heterogeneous group of disorders that include neoplasms derived from cells of myeloid and lymphoid lineages. These malignancies can be categorized in many ways, but the most commonly used classification today is the World Health Organization's Classification of Tumours of Haematopoietic and Lymphoid Tissues (WHO classification) [1]. The WHO classification is largely based on the Revised European American (REAL) classification, which divided this diverse group of disorders into what were felt to be distinct or real clinicopathologic entities on the basis of combined morphologic, immunophenotypic, clinical, and genetic features [2]. The lymphoid neoplasms include immature B-cell and T-cell neoplasms (precursor lymphoblastic leukemia/lymphoma), mature B-cell and T-cell neoplasms (including the group of disorders collectively known as non-Hodgkin lymphomas (NHL) and plasma cell myeloma) and Hodgkin lymphoma. A review of Surveillance, Epidemiology, and End Results (SEER) data stated that in 2005 the United States would have approximately 93,420 incident cases of lymphoid neoplasms with approximately 38,000 deaths. Over the 10-year course of SEER data that were reviewed, the B-cell lymphomas showed a modest decrease in incidence (approximately 1 % per year), while T-cell neoplasms increased and Hodgkin lymphoma incidence remained stable [3]. Because lymphomas comprise a significant number of new cancer diagnoses, it is important to understand the pathogenesis of these disorders and how this information can be used for diagnosis, prognosis, and guidance of therapy.

The diagnosis of hematologic malignancies often requires a multi-parameter approach, correlating morphologic evaluation of traditional hematoxylin and eosin-stained tissue sections or Romanowsky-stained smears along with a variety of ancillary studies, including cytochemical and histochemical stains, immunohistochemical studies, flow cytometric analysis, cytogenetic analysis, and molecular genetic techniques. Of these, immunohistochemistry is favored among many pathologists because of the ability to directly correlate with the tissue morphology and convenience in working with readily available paraffin-embedded tissue (PET) (Fig. 31.1). Other methods may be more sensitive and quantitative than immunohistochemistry, but each method has advantages and disadvantages. For instance, flow cytometric analysis can detect small populations of aberrant B-cells and T-cells in a background of normal lymphocytes, a feat that is often not possible with routine immunohistochemical analysis. However, this technique requires viable cells in suspension for analysis and allows only limited correlation with morphologic findings. Molecular studies by polymerase chain reaction (PCR) or Southern blotting are very sensitive in fresh or frozen tissue, but sensitivity may be decreased in some assays using the more commonly available PET. Any of these ancillary studies can produce false positive and false negative results, and the interpretation of results must be made in the context of the traditional morphologic findings and clinical findings.

This chapter will focus on the underlying pathogenesis of lymphoproliferative disorders with some reference on how that information can be used for diagnostic and prognostic purposes. First, there will be an overview of normal B- and T-cell development, noting that the various stages of lymphocyte development can be roughly correlated with different types of lymphoma. A description of immunoglobulin

gene rearrangement and T-cell receptor gene rearrangement is imperative since this process provides the basis for the detection of clonality of B- and T-cells and because it highlights some of the differences in subtypes of lymphomas. Because an in depth discussion of the pathogenesis of lymphoproliferative disorders is enough to fill several textbooks, a select group of non-Hodgkin lymphomas will be reviewed with particular attention to how the pathogenetic mechanisms can be used to classify, diagnose, and in some cases serve as a potential therapeutic targets. Finally, there will be a brief discussion of molecular profiling and microRNAs, two areas in which our understanding of lymphomagenesis stands to grow a great deal in the coming years.

31.2 Physiology of B-Cell and T-Cell Development

31.2.1 Normal B-Cell Development

The B lymphocytes arise from pluripotent stem cells in the bone marrow, which subsequently migrate to secondary lymphoid organs including lymph nodes, spleen, and various mucosal sites (e.g., Waldeyer's ring, Peyer's patches). There are two phases of B-cell development: the antigen-independent phase of B-cell differentiation that occurs in the bone marrow, independent of antigen exposure and giving

rise to naïve B-cells, and the antigen-dependent phase of differentiation that primarily occurs in the extramedullary compartment and secondary lymphoid organs after exposure to antigen [4, 5]. Definable intermediate stages of the antigen-dependent phase have been characterized, ultimately related to the germinal center reaction in secondary lymphoid organs and proliferation of memory B-cells and immunoglobulin-secreting plasma cells.

An orderly progression of morphologic, molecular, and immunophenotypic changes allows recognition of distinct stages of B-cell development from the progenitor B-cells to the terminally differentiated plasma cells. The stages of B-cell development are illustrated in Fig. 31.2. At the molecular level, the genes coding for the immunoglobulin heavy and light chain proteins undergo sequential rearrangements early in B-cell development (Fig. 31.2). Initially, the immunoglobulin mu heavy chain located on chromosome 14q32 undergoes rearrangement, followed by kappa light chain rearrangement on chromosome 2p12 and lambda light chain rearrangement on chromosome 22q11 [6]. Subsequent transcription and translation of the mu heavy chain gene results in the appearance of cytoplasmic mu heavy chain protein, which defines the pre-B-cell stage of development. Antigen-independent differentiation leads to mature, but naïve B-cells that produce intact surface immunoglobulin molecules (surface IgM and IgD), including two heavy and two light chains (Fig. 31.3a). In the lymph node, the primary antigen response leads to development of B-immunoblasts, which are capable of progressing to IgM-secreting mature B-cells. Several days after antigen exposure, the T-cell-dependent germinal center reaction occurs. This complex reaction involves rapid proliferation of surface Ig-negative centroblasts that have switched off the gene encoding the protein bcl-2, rendering them susceptible to death via apoptosis. In addition, expression of bcl-6 protein and somatic mutation of the bcl-6 and immunoglobulin variable region genes (discussed below) occur. As centroblasts mature to centrocytes, mutations in the immunoglobulin variable region (IgV) occur and expression of surface Ig resumes. Centrocytes whose IgV mutations result in immunoglobulins that recognize self-antigens or show decreased antigen affinity undergo programmed cell death. By contrast, centrocytes whose Ig mutations yield immunoglobulins with increased antigen affinity are saved from apoptosis and resume expression of bcl-2. These veterans of the germinal center reaction gives rise to antigen-specific memory B-cells which can subsequently differentiate into plasma cells.

As illustrated in Fig. 31.2, a variety of cellular antigens can be detected at different stages in normal B-cell development. The CD (cluster designation) numbers have been applied to many of these antigens to standardize the nomenclature and allow easier comparison among studies using various antibody clones that recognize the same surface marker. The earliest antigens identified on precursor cells of B lineage are terminal deoxynucleotidyl transferase (TdT), the progenitor cell antigen CD34, the common acute lymphoblastic antigen (CALLA, CD10) and HLA-Dr. However, none of these antigens are B-lineage specific. Specific B-lineage associated antigens, CD19, CD79a, cytoplasmic

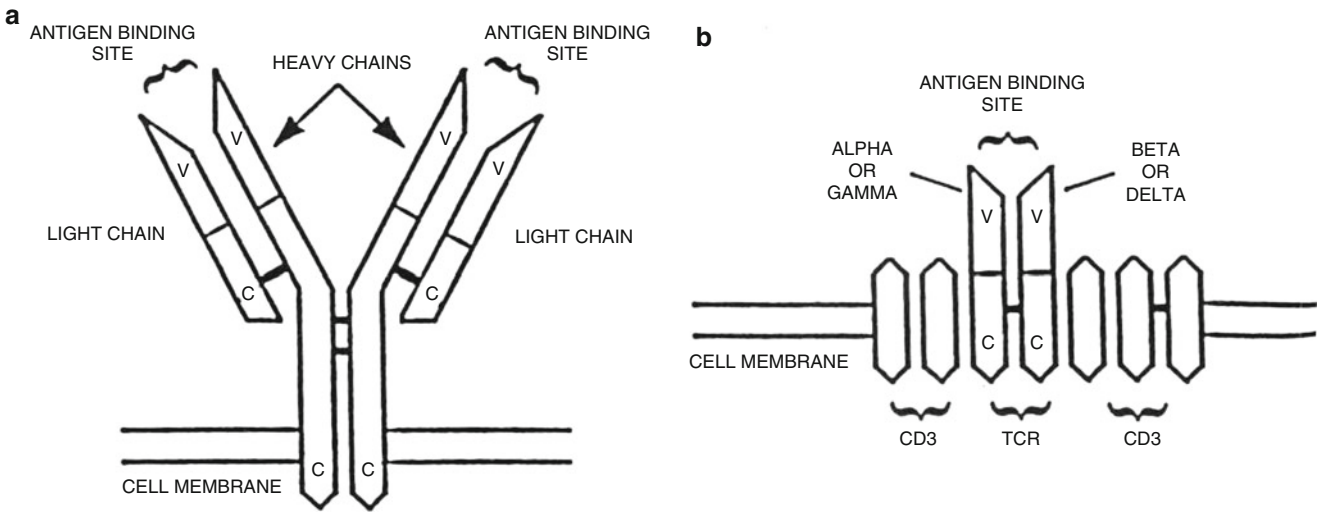

Fig. 31.3 Schematic diagram of immunoglobulin and T-cell receptors. (**a**) The immunoglobulin protein is a heterodimer composed of two heavy and two light chains, each of which has variable (V) and constant (C) regions. (**b**) The T-cell receptor (TCR) is also a heterodimer composed of either one α (alpha) and one β (beta) chain or one γ (gamma) and one δ (delta) chain. Each of the TCR proteins has variable (V) and constant (C) regions. CD3 is a complex of five proteins associated with the TCR.

CD22 and mu heavy chain, and the nuclear transcription factor, B-cell specific activator protein (BSAP, pax-5) are expressed in the pre-B stage of B-cell development [1, 7]. As B-cells mature, there is loss of CD10 and acquisition of the B-cell antigen, CD20 as well as surface immunoglobulin. CD10 is noteworthy in that its expression resumes for the germinal center stage of development, and at the same time, the anti-apoptosis protein, bcl-2 is lost but returns after the germinal center stage. As a B-cell matures to a terminally differentiated plasma cell, the majority of B-cell surface antigens are no longer expressed and CD138 (syndecan-1) appears [8]. The plasma cell is also characterized by presence of abundant cytoplasmic immunoglobulin.

One fundamental theory of lymphoid neoplasia is that disorders of lymphoid cells represent neoplastic transformation of cells at various stages of normal development [9]. This notion has been used in the classification of lymphoid malignancies [1]. For example, precursor B-cell acute lymphoblastic lymphoma/leukemia immunophenotypically mimics normal precursor B-cells by showing expression for TdT, HLA-Dr, CD10, CD19, variable CD20, and (cytoplasmic) mu heavy chain (Fig. 31.2), although the pattern of antigen expression in neoplastic populations differs from that seen in normal precursor B-cells [10]. The mature B-cell neoplasms represent different stages of B-cell development, including mantle cell lymphoma, which represents a neoplasm of CD5-positive naïve B-cells that have not undergone the germinal center reaction [11] and follicular lymphoma, which has an immunophenotype and molecular profile analogous to B-cells at the germinal center stage of development with expression of CD10, bcl-6, and somatic hypermutation of IgH and bcl-6 genes [12]. Plasma cell myeloma is the neoplastic counterpart of the normal plasma cell.

31.2.2 Normal T-Cell Development

T-lymphocytes also arise from pluripotent stem cells in the bone marrow. However, in contrast to B-cell development in which the earliest stages of maturation occur in the bone marrow, progenitor T-cells migrate from the bone marrow to the thymus where the early stages of T-cell development occur [13, 14]. Subsequently, mature T-cells circulate in the peripheral blood and seed peripheral lymphoid tissues, which include paracortical areas of lymph nodes and periarteriolar lymphoid sheaths of the spleen.

Figure 31.4 shows the normal stages of T-cell development in the thymus, which are analogous to B-cell development and occur in an orderly fashion. T-lymphocytes possess a surface membrane protein complex referred to as the T-cell receptor, which is structurally similar to the B-cell surface immunoglobulin receptor (Fig. 31.3b). The T-cell receptor is a heterodimer protein comprised of either one α (alpha) and one β (beta) polypeptide chain, which combine to form the αβ T-cell receptor, or one γ (gamma) and one δ (delta) polypeptide chain, which combine to form the γδ T-cell receptor [15–18]. Approximately 1–5 % of circulating T-cells expresses the γδ T-cell receptor while the remainder expresses the αβ T-cell receptor [18, 19]. T-cells bearing the γδ receptor comprise a greater percentage of T-lymphocytes at mucosal sites and in the spleen. The genes that code for each of the polypeptide chains that make up the T-cell receptor undergo sequential rearrangements early in T-cell development. The first T-cell receptor gene to rearrange is δ, which is followed sequentially by γ, β, and α genes. The genes coding for the α and δ polypeptide chains are located on chromosome 14q11, the β chain gene on chromosome 7q34 and the γ chain gene on chromosome 7p15 [6].

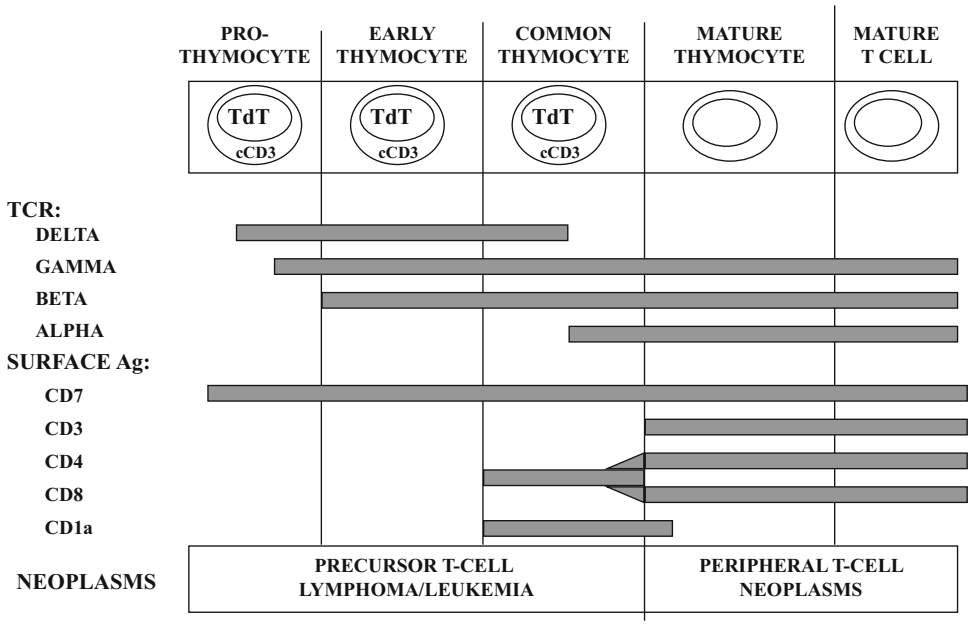

Fig. 31.4 Normal stages of T-cell development with immunological and molecular genetic changes at different stages. See text for discussion. *TdT* terminal deoxynucleotidyl transferase, *cCD3* cytoplasmic CD3, *TCR* T-cell receptor rearrangements, *Ag* antigen.

Analogous to developing B-cells, a variety of cellular antigens can be detected at different stages of normal T-cell development (Fig. 31.4). The earliest antigens expressed are TdT and the T-lineage antigen, CD7. The CD3 antigen, which is a protein complex associated with the T-cell receptor (Fig. 31.3b), is primarily a cytoplasmic antigen early in T-cell development and only appears on the cell surface later in development at the same time as the T-cell receptor β chain. The earliest thymocytes lack expression of CD3, CD4, and CD8, but as development progresses, the developing T-cells acquire CD1a, CD2, and CD5. The common thymocyte stage of T-cell development is characterized by coexpression of the CD4 (helper/inducer) and CD8 (cytotoxic/suppressor) T-cell subset antigens. Phenotypically mature T-cells (also referred to as peripheral T-cells) lack TdT, lack CD1a and express surface CD3 with either CD4 or CD8, but not both. After leaving the thymus, naïve T-cells home to the paracortex of lymph nodes and periarteriolar lymphoid sheaths of the spleen. T-cells undergo antigen-dependent differentiation similar to B-cells with evolution through a T-immunoblast stage, giving rise to antigen-specific T-helper cells (CD4 positive), T-suppressor cells (CD8 positive) which show coexpression of either αβ or γδ T-cell receptor [16].

Similar to B-cell non-Hodgkin lymphoma, the T-cell neoplasms represent neoplastic transformation of cells at various stages of normal T-cell development [9] although the correlation is not quite as well characterized as it is for the mature B-cell neoplasms. For example, precursor T-cell lymphoblastic lymphoma/leukemia may exhibit an immunophenotype which resembles the normal common thymocyte, showing expression for TdT, CD1a, cytoplasmic CD3 and CD7, as well as coexpression for CD4 and CD8 (Fig. 31.4). Examples of T-cell non-Hodgkin lymphoma, which are neoplastic counterparts to relatively mature or peripheral T-lymphocytes, include anaplastic large cell lymphoma, cutaneous T-cell lymphoma (mycosis fungoides), and peripheral T-cell lymphoma [1].

31.2.3 B-Cell Surface Immunoglobulin and T-Cell Receptor Gene Rearrangement

The B-cell surface immunoglobulin receptor and T-cell receptor are involved in the process of antigen recognition by normal B-cells and T-cells, respectively. These receptors are structurally similar being heterodimer proteins linked by disulfide bonds and are composed of both variable (V) and constant (C) regions [6] (Fig. 31.3). The variable regions of these proteins are similarly involved in antigen recognition. The constant region of the immunoglobulin heavy chain protein defines the different immunoglobulin subclasses (IgG1, IgG2, IgG3, IgG4, IgA1, IgA2, IgM, IgD, and IgE) [5]. The genes that code for the B-cell and T-cell receptors are also structurally similar and consist of a large number of exons or coding sequences referred to as a *supergene family*. The exons undergo a process of DNA recombination or rearrangement leading eventually to transcription and translation and the production of functional receptor proteins [5, 6, 15, 18, 20].

A general scheme illustrating the process of B-cell surface immunoglobulin and T-cell receptor gene rearrangement is shown in Fig. 31.5. The *germline configuration* refers to non-rearranged DNA. The exons which code for the variable regions of the immunoglobulin and T-cell receptors are referred to as variable (V) segments, diversity (D) segments, and junctional (J) segments, and those which code for the constant regions are referred to as (C) segments. The process of gene rearrangement first involves the selective apposition

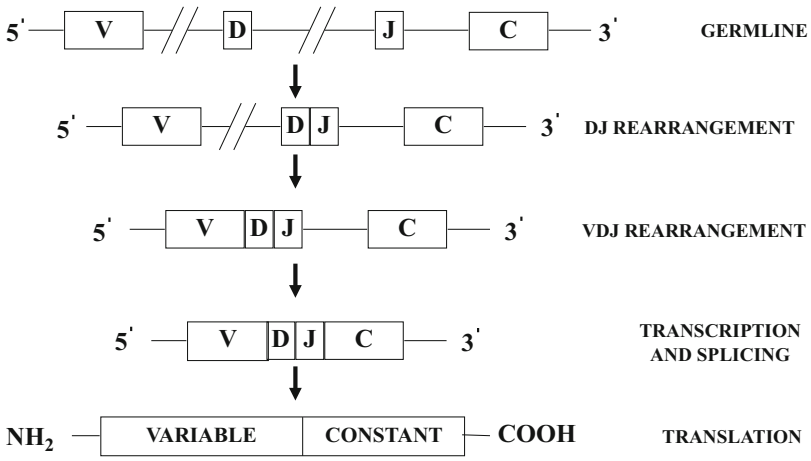

Fig. 31.5 Schematic diagram illustrating the sequential steps involved in immunoglobulin and T-cell receptor gene rearrangements. See text for discussion. *V* variable segments, *D* diversity segments, *J* junctional segments, *C* constant segments.

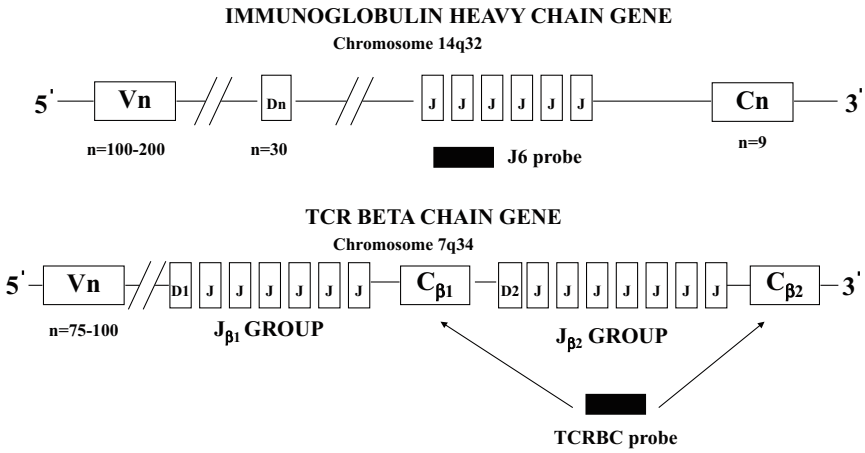

Fig. 31.6 Schematic diagram of the immunoglobulin heavy chain and the T-cell receptor beta chain supergene families. The specific sites of recognition for probes used for Southern blotting are typically associated with consensus sequences in the joining (J_6 probe) and constant regions (TCRBC probe).

of one D segment with one J segment by deletion of the intervening coding and noncoding DNA sequences resulting in a DJ rearrangement. A similar process of rearrangement opposes a V segment, located in the 5′ direction to D and J to form a VDJ rearrangement. Transcription to messenger RNA (mRNA) then occurs even though the rearranged VDJ segments are not yet directly opposed to C segments, which are remotely located in the 3′ direction. Subsequent splicing of the mRNA with deletion of noncoding sequences results in apposition of VDJ with C to form a VDJC mRNA, which can then be translated into a surface immunoglobulin or T-cell receptor protein.

The genes coding for the immunoglobulin heavy chain proteins and T-cell receptor beta and delta chain proteins include V, D, J, and C segments. The genes coding for the kappa and lambda light chain proteins and the T-cell receptor alpha and gamma proteins include only V, J, and C segments without D segments [5, 6, 20]. A schematic diagram of the immunoglobulin heavy chain and the T-cell receptor beta chain supergene families is shown in Fig. 31.6. The immunoglobulin heavy chain locus contains 123 V_H segments, 27 D segments, 6 J_H segments [21]. The V_H segments, which include 79 pseudogenes and 44 segments that have an open reading frame, can be further divided into 7 families based on the presence of conserved or homologous DNA sequences, which are common to each member of a family. The V_H families are designated V_H1 to V_H7. The T-cell receptor beta chain gene includes 75–100 V_β segments, which can be further divided into several families, and two tandem DJC complexes referred to as D1J1C1 and D2J2C2. Each DJC complex contains one D segment and one C segment. The first DJC complex contains six J_β segments ($J_{\beta1}$ group) and the second DJC complex contains seven J_β segments ($J_{\beta2}$ group) [6, 15, 20].

The humoral (B-cell) and cell mediated (T-cell) systems must be able to recognize a wide variety of environmental antigens even though only a finite quantity of DNA is present in each cell. The complex process of DNA recombination or rearrangement involving the surface immunoglobulin and T-cell receptor allows for tremendous diversity of both the humoral and cell mediated systems, and hence, the ability of these systems to detect a wide variety of antigens [5, 6, 15, 18, 20]. The large number of V, D, J, and C segments results in many combinations, which can be transcribed and translated to millions of different antigen receptors.

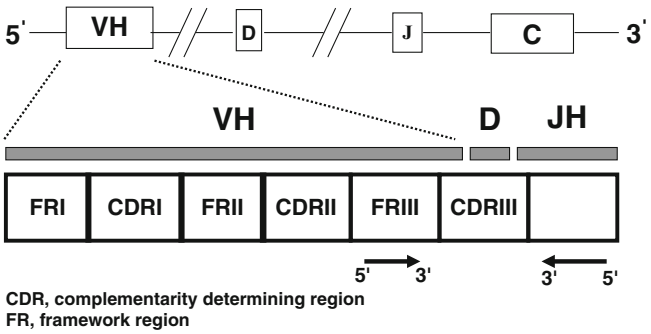

Fig. 31.7 Schematic diagram illustrating the rearranged immunoglobulin heavy chain region. Variable primer sets targeting the complementarity-determining regions or framework regions are used for polymerase chain reaction and southern blot studies to determine B-cell clonality. *Arrowheads* identify restriction enzyme cleavage sites.

Further diversification of the immunoglobulin receptor genes is achieved through a process of *somatic hypermutation*, which occurs normally within germinal center B-cells. In addition to conserved or homologous DNA sequences within V segments referred to as *framework regions* (FR), individual immunoglobulin heavy and light chain V segments contain *complementarity-determining regions* (CDR), which contain nucleotide sequences that encode for the antigen-binding site (Fig. 31.7). The CDRs contain hypervariable nucleotide sequences, which tend to undergo somatic hypermutation. This process results in a series of DNA point mutations with consequent amino acid substitutions within the antigen-binding site. The end product of somatic hypermutation involving the CDRs is enhanced antibody diversity, affinity, and specificity for target antigens [5, 6, 15, 18, 20].

31.3 Molecular Mechanisms in Non-Hodgkin Lymphoma

31.3.1 Background

Non-Hodgkin lymphoma comprises a heterogeneous group of lymphoid neoplasms, which occur because of neoplastic transformation of lymphocytes at different stages of B-cell and T-cell development [4, 13]. The wide variety of B-cell and T-cell non-Hodgkin lymphomas reflects the varying stages of lymphocyte development and the complexity of the immune system. The clinical and pathological characteristics of the non-Hodgkin lymphomas are summarized in a comprehensive manner in the World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues (WHO Classification) [1].

Centrally important to establishing a diagnosis of non-Hodgkin lymphoma is the identification of an abnormal clonal lymphoid population since B-cell and T-cell non-Hodgkin lymphomas represent monoclonal proliferations of B-cells and T-cells, respectively. A major application of molecular genetic methods (e.g., PCR, Southern blot) in the evaluation of non-Hodgkin lymphoma involves the determination of B-cell and T-cell clonality. These methods are considered to be the gold standard for determining clonality but are utilized primarily when a definitive diagnosis (malignant or benign) cannot be determined by morphologic or immunopathologic methods. For B-cell neoplasms, clonality can often be determined immunopathologically by demonstrating the presence of monoclonal surface immunoglobulin [22]. In contrast, for T-cell malignancies, there is no immunopathological equivalent to monoclonal surface immunoglobulin, although qualitative or quantitative loss of normal T-cell antigen expression is considered to be presumptive evidence of T-cell neoplasia [22]. Thus, molecular genetic approaches for the determination of clonality in T-cell non-Hodgkin lymphoma are especially important.

Other uses for molecular genetic techniques in the assessment of lymphoid malignancies include determination of B-cell or T-cell lineage, detection of chromosomal translocations, and detection of minimal residual disease. The latter application has become increasingly useful in evaluating patients before and after bone marrow transplantation particularly in acute lymphoblastic leukemias [23]. The clinical significance of minimal residual disease detection in chronic lymphoproliferative disorders remains a matter of debate and warrants more study [24, 25]. The detection of a specific chromosomal translocation may be very useful in the subclassification of non-Hodgkin lymphoma. For example, in a lymph node with suspected follicular lymphoma, the detection of a translocation, t(14;18), involving the *BCL2* proto-oncogene, would confirm this diagnosis. Similarly, in the appropriate context, the detection of a translocation, t(11;14), involving the *CCND1* proto-oncogene, would confirm a diagnosis of mantle cell lymphoma or a t(8;14) involving the c-*MYC* oncogene would support a diagnosis of Burkitt lymphoma [26].

There are many potential mechanisms of carcinogenesis and lymphomagenesis. In some instances, the details of the pathways involved in the transformation of a benign cell to a malignant one are generally well understood, but in most the pathogenesis is a matter of ongoing study. Some diseases can almost be defined by a single, recurrent cytogenetic or molecular alteration that leads to dysregulation of the cell cycle and proliferation of abnormal cells. For example, in mantle cell lymphoma and Burkitt lymphoma, the alteration involves placement of a normally carefully regulated gene that promotes cell growth and division (*CCND1* and *MYC*, respectively) under the regulatory control of the constitutively active immunoglobulin heavy chain gene. In a similar fashion, the common molecular rearrangement in follicular lymphoma puts the normally tightly controlled expression of

the *BCL2* gene under the control of the immunoglobulin heavy chain gene. However, in this case, the product of the upregulated *BCL2* gene does not lead to cell proliferation but rather a blockade of apoptosis, again culminating in an uncontrolled overgrowth of cells. Marginal zone B-cell lymphoma is associated with multiple different translocations that all lead to dysregulation of the NF-kB pathway which plays many roles in cell proliferation and differentiation. The mechanisms involved in the production of functional immunoglobulins (e.g., VDJ recombination, somatic hypermutation, immunoglobulin class switching) provide the molecular milieu for development of many of the familiar translocations in B-cell lymphomas [27].

In contrast, relatively few of the T-cell lymphoproliferative disorders have recognizable recurrent genetic abnormalities. One that does is T-cell prolymphocytic leukemia, which has a mechanism similar to the B-cell lymphoproliferative disorders listed above, placing an oncogene under control of the promoters of the T-cell receptor α/β locus. In the case of anaplastic large cell lymphoma (ALCL), the creation of a novel fusion protein (derived from a translocation involving nucleophosmin (*NPM*) and anaplastic lymphoma kinase (*ALK*) genes) with a constitutively active tyrosine kinase domain drives cell proliferation. Another T-cell lymphoma, adult T-cell leukemia/lymphoma (ATLL) has a different mechanism of oncogenesis, being caused by a human retrovirus, HTLV-1.

One thing that has become clear with our understanding of these molecular hallmarks of disease (e.g., *IGH/BCL2* rearrangement in follicular lymphoma, *NPM/ALK* rearrangement in ALCL, HTLV-1 infection in ATLL) is that the presence of the t(14;18), t(2;5), or HTLV-1 infection should be regarded as "required but not sufficient" for malignant transformation. This conclusion must be reached, as many normal subjects can be shown to have molecular evidence of these rearrangements while never manifesting signs of the disease. The discussion of these lymphoproliferative disorders will examine how these molecular alterations can lead to cell cycle disruption and some possible additional hits that may help produce a clinical lymphoma, as well as touch on how the use of molecular diagnostic tests can be used to diagnose and follow these disorders.

31.3.2 Mantle Cell Lymphoma (t(11;14)(q13;q32), *GH-CCND1*)

Mantle cell lymphoma (MCL) is a pathologically distinct B-cell lymphoproliferative disorder [28] that is characterized by upregulation of cyclin D1, most often due to the presence of a translocation involving the *BCL1* (B-cell leukemia/lymphoma-1) region on chromosome 11q13 and the *IGH* gene on chromosome 14q32. MCL makes up between 5 and 10 % of all B-cell NHL and shows a male predominance. MCL occurs over a wide age range, but is more prominent in older patients with a median age of approximately 60 years. Compared to other B-cell non-Hodgkin lymphomas composed of small lymphocytes, MCL has a poor prognosis with a median survival time of 3–5 years even with aggressive therapy.

Classic cases show effacement of lymph node architecture by a population of small to medium-sized lymphocytes with irregular nuclear contours, evenly dispersed chromatin and scant cytoplasm. A population of nucleolated cells is distinctly absent in typical cases. Scattered mitotic figures and solitary epithelioid macrophages are identified (Fig. 31.8a, b). The neoplastic cells can be distributed in a variety of patterns, including nodular pattern, diffuse pattern, and a mantle zone pattern. Several studies have reported an association between the growth pattern and prognosis [29–31]. Occasional cases of otherwise typical mantle cell lymphoma show moderate to abundant cytoplasm, resembling marginal zone B-cells. Plasma cell differentiation is not typical of mantle cell lymphoma, but has been reported. A more aggressive blastoid variant is characterized by larger cells with more open chromatin, scant cytoplasm, and variably prominent nucleoli (Fig. 31.8c). Leukemic presentations of mantle cell lymphomas also occur, and may present with a marked peripheral blood leukocytosis, raising a differential diagnosis with prolymphocytic leukemia.

Flow cytometric immunophenotyping shows that the neoplastic cells in MCL express the B-cell associated antigens CD19, CD20, CD22, and FMC-7. Because this is a lymphoma of mature B-cells, the neoplastic cells express surface immunoglobulins, often IgM and IgD heavy chains and moderate to bright kappa or lambda light chains. One of the phenotypic hallmarks of MCL is coexpression of the T-cell associated antigen, CD5 without coexpression of CD23, CD10, or bcl-6. This immunophenotypic profile supports the notion that mantle cell lymphomas are derived from a population of CD5-positive naïve pre-germinal center B-cells.

Recognition of t(11;14)(q13;q32) as the genetic hallmark of MCL has greatly improved reproducibility in diagnosis and allowed greater study of this disorder [32]. This translocation involves the *BCL1* locus on chromosome 11 and the immunoglobulin heavy chain locus on chromosome 14, with the result that the *CCND1* gene (formerly known as *PRAD1* because of its association with parathyroid adenoma), which encodes for the protein cyclin D1, comes under regulatory control of the immunoglobulin heavy chain enhancer. This translocation leads to overexpression of the cyclin D1 protein, which is not typically expressed at high levels in B lymphocytes [33]. The cyclin D1 mRNA produced as a result of this translocation has two main forms, each of which contains the complete coding region for a 36 kDa form of cyclin D1: a 4.5 kb form with a long 3′ untranslated region and a 1.5 kb form that lacks the long 3′ untranslated region. Cyclin D1 promotes the transition of cells from the G1 phase into the S phase of the cell cycle by binding to cyclin-dependent kinases 4 and 6 (CDK4 and

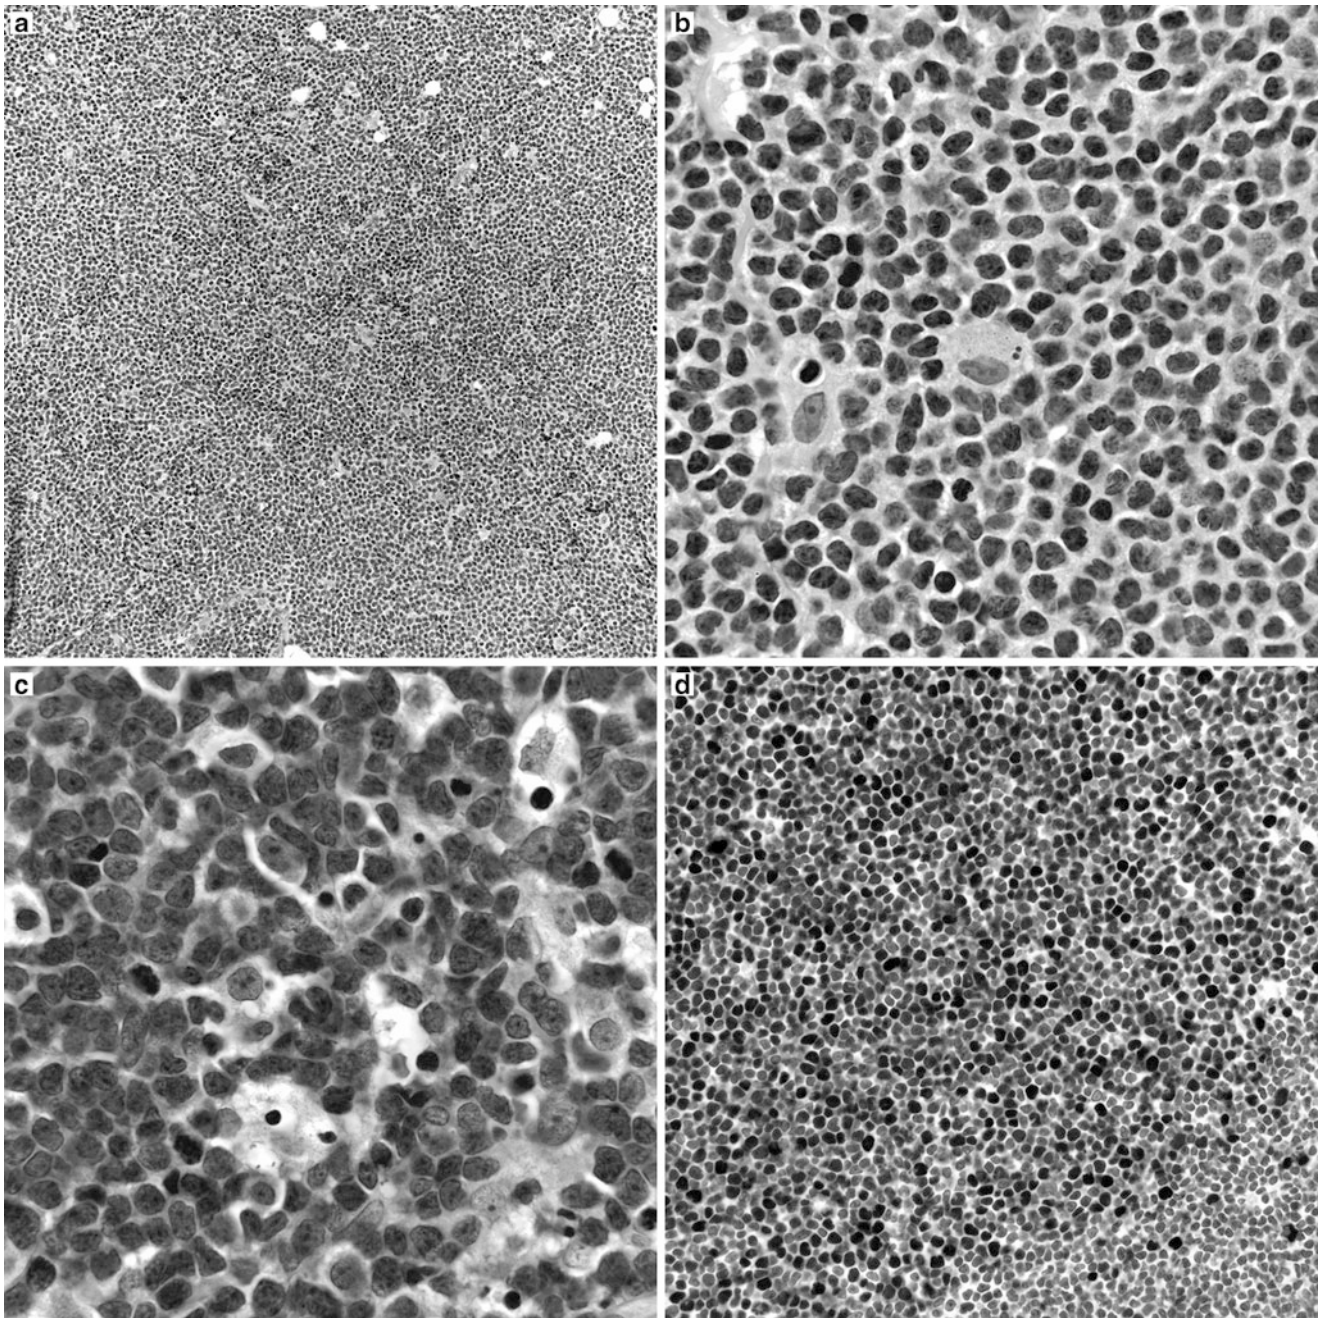

Fig. 31.8 Morpohologic features of mantle cell lymphoma. (**a**) Low magnification image showing a vaguely nodular pattern of growth. (**b**) Classical mantle cell lymphoma cytology with small to medium cells showing slightly irregular nuclear contours, inconspicuous nucleoli, and scant cytoplasm. Scattered epithelioid macrophages are present. (**c**) Blastoid variant of mantle cell lymphoma with larger, nucleolated nuclei and more open chromatin. (**d**) Cyclin D1 immunohistochemistry highlighting nuclear immunoreactivity in the neoplastic cells.

CDK6). These complexes of cyclin D1 and CDK4 or CDK6 lead to phosphorylation of retinoblastoma 1 (Rb1), eliminating its suppressive effects on the cell cycle by leading to the release of the transcription factor E2F and progression into the S phase. Other molecular pathways are affected including downregulation of the *TP53* tumor suppressor gene [34]. Because the t(11;14) with cyclin D1 overexpression is found in virtually all cases, it is felt to be one of the early events in the development of mantle cell lymphoma [35]. However, since it can be seen in normal individuals without MCL and since mouse models with the classic t(11;14) do not develop mantle cell lymphoma without other genes also being affected, it is also felt that this is not sufficient for full transformation. Additional genetic hits are common in MCL, and cytogenetic studies have demonstrated that MCL has one of the highest levels of genetic instability among lymphoproliferative disorders. Many of the additional genetic abnormalities seen in mantle cell lymphoma seem to target either cell cycle regulation (e.g., through deletions of

chromosome 9p21 resulting in the loss of two genes, the CDK inhibitor $p16^{INK4a}$ (interferes with Rb1 function) and $p14^{ARF}$ (downregulates the p53 pathway)) or the DNA damage response (mutations of the *ATM* (ataxia-telangiectasia mutated) gene, which has a role in the cellular response to DNA damage) [33, 34] (Fig. 31.9). Better understanding of the molecular mechanisms leading to mantle cell lymphoma may lead to therapeutic agents that directly target these various pathways [36].

Some groups have asserted that cyclin D1 positivity should be a part of the definition of mantle cell lymphoma [37]. However, by gene expression profiling, a small subset of cyclin D1-negative mantle cell lymphomas has been identified, which have the usual morphologic features and unique gene expression signature of mantle cell lymphoma [38]. This report suggests that other cyclin D proteins may substitute for cyclin D1 in lymphomagenesis in such cases. Like cyclin D1, other members of the cyclin D family of proteins are involved in cell cycle control, particularly as regulators of progression from the G1 to S phase of the cell cycle.

The diagnosis of MCL is based on a combination of morphologic immunophenotypic, cytogenetic, and clinical data. Identification of cyclin D1 overexpression by immunohistochemical analysis (Fig. 31.8d) has been shown to be a specific and sensitive marker for MCL [39]. Immunohistochemical markers for proliferation (especially Ki-67) have been shown to be of prognostic value [29, 40], a finding shown to be associated with a distinct genetic signature [41]. Classical cytogenetic studies allow identification of the t(11;14) (Fig. 31.10a). Since the specific breakpoints in the *BCL1* region are spread over a wide area (Fig. 31.10b), PCR analysis for a specific breakpoint is not as sensitive as other techniques in detecting the rearrangements. FISH analysis has been shown to be a very sensitive marker for detection of the t(11;14) in MCL [42]. Again, it should be borne in mind that while detection of cyclin D1 abnormalities is quite sensitive for mantle cell lymphomas, there seems to be a subset of MCL cases that lack a t(11;14) and cyclin D1 overexpression [38]. It should also be noted that these findings are not entirely specific to MCL). For example, cyclin D1 overexpression by immunohistochemical analysis is seen in hairy cell leukemia, and some cases of plasma cell myeloma not only show overexpression of cyclin D1 by immunohistochemical analysis but even exhibit an identical t(11;14).

31.3.3 Follicular Lymphoma (t(14;18)(q32;q21), *IGH-BCL2*)

Follicular lymphoma (FL) is the second most common NHL seen in the United States, after diffuse large B-cell lymphoma, accounting for greater than 20 % of NHL [43]. Similar to MCL, there is a hallmark cytogenetic abnormality that involves placing a gene whose expression is normally tightly regulated under the control of the immunoglobulin heavy chain promoters. This translocation involves the *BCL2* region located at chromosome 18q23. Unlike cyclin D1 in MCL, this gene does not regulate cell proliferation, but rather serves as an inhibitor of programmed cell death (apoptosis). Follicular lymphoma is a disease predominantly of adults, with a median age in the sixth decade and uncommonly occurring in patients under the age of 20. Morphologic grading of follicular lymphoma allows separation

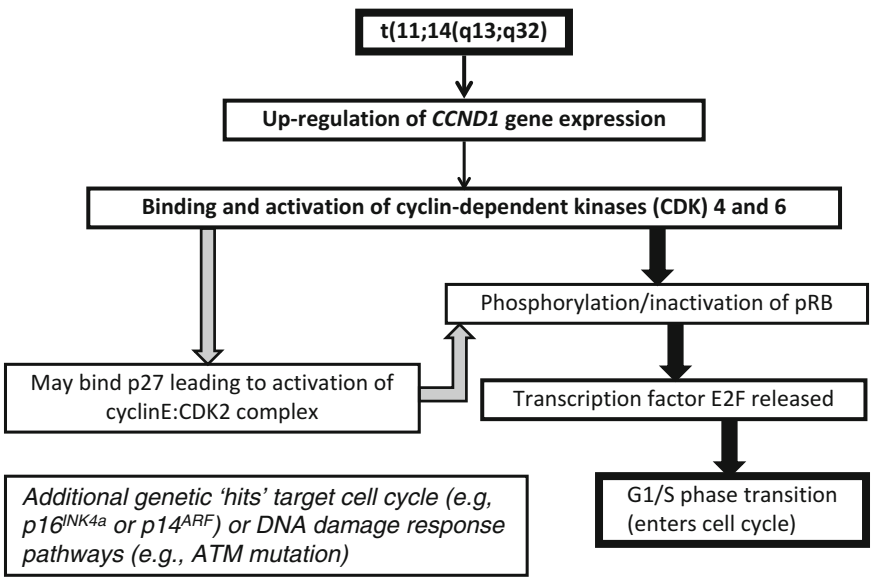

Fig. 31.9 Molecular mechanism in mantle cell lymphoma. The t(11;14)(q13;q32) leads to overexpression of cyclin D1 (*CCND1*), which binds to cyclin-dependent kinases (CDK) 4 and 6. This leads to over-phosphorylation of pRB, releasing the transcription of E2F and progression from the G1 to S phases of the cell cycle. Deregulation of pRB via other cyclins is also possible. Subsequent genetic abnormalities target the cell cycle and DNA repair pathways.

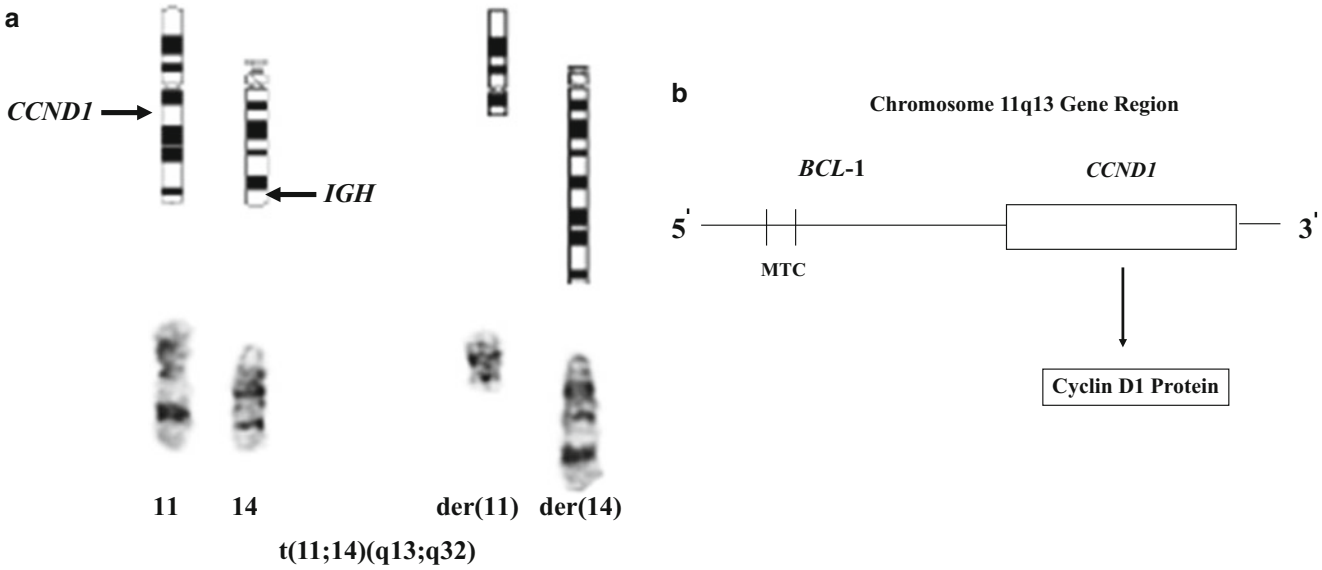

Fig. 31.10 Cytogenetics of mantle cell lymphoma. (**a**) Derivative chromosomes produced by the t(11;14) translocation (Giemsa-stained chromosomes and ideogram). (**b**) Schematic diagram of the chromosome 11q13 gene region, which includes the *BCL1* locus and the *CCND1* gene. The breaks in the 11q13 gene region are widely scattered within the *BCL1* locus; however, approximately 30–40 % of breaks occur within the MTC (major translocation cluster) region of the *BCL1* locus. The *CCND1* gene encodes for the cyclin D1 protein.

into more indolent forms (grades 1 and 2), which have a median survival of up to 10 years and more aggressive forms (grades 3A and 3B) which have a median survival of less than 5 years.

Follicular lymphoma commonly presents as lymphadenopathy and excised lymph nodes show effacement of normal lymph node architecture by closely packed follicles with attenuated or absent mantle zones. At low magnification, neoplastic follicles lack the normal light zone/dark zone polarization seen in reactive germinal centers (Fig. 31.11a). The cytologic features in follicular lymphomas vary considerably, but the most common finding is a predominant population of small to medium-sized lymphocytes with angulated or cleaved nuclei having clumped chromatin and inconspicuous nucleoli. These small cleaved cells are called centrocytes and have scant cytoplasm, although they occasionally have monocytoid differentiation with more abundant cytoplasm or exceptionally exhibit a signet ring appearance (Fig. 31.11b). Also present in follicular lymphomas are scattered large cells with vesicular chromatin, one or multiple nucleoli often adjacent to the coarse, thickened nuclear envelope, and moderate amounts of amphophilic cytoplasm. It is important to recognize these large centroblasts because the number of centroblasts per high power field forms the basis for morphologic grading. Cases with fewer than 15 centroblasts per high power field are considered grade 1–2 (Fig. 31.11c) and those with greater than 15 centroblasts per high power field is classified as grade 3 [44] (Fig. 31.11d). Grade 3 follicular lymphomas are further subdivided into grade 3A, which shows admixed small centrocytes, and Grade 3B which is composed of sheets of centroblasts without admixed centrocytes. Although the predominant pattern of growth is often follicular, some cases have areas with a diffuse pattern of growth. Even in otherwise typical cases of FL, areas with large sheets of centroblasts present in a diffuse pattern should be diagnosed as diffuse large B-cell lymphoma. Admixed follicular dendritic cells and T-cells are present in varying numbers, a finding that has received a lot of recent attention since molecular studies show that benign components of lymphoma may be associated with outcome [45].

Morphologically and immunophenotypically, the cells of follicular lymphoma resemble those of the normal follicle center. These are mature B-cells that show expression of CD19, CD20, and CD22 along with coexpression of CD10. Also like their normal follicle center cell counterparts, they show expression of bcl-6. Follicle center cells do express surface immunoglobulin, although this may be downregulated to very low levels. Mitotic activity in low-grade follicular lymphomas is usually decreased relative to that in normal reactive follicles.

Follicular lymphomas are characterized by a recurrent translocation involving the *BCL2* gene located at chromosome 18q21 and the immunoglobulin heavy chain locus at chromosome 14q32 (Fig. 31.12). This places production of the anti-apoptotic gene, *BCL2* under the regulation of *IGH* enhancers, resulting in overproduction of a structurally intact and functional bcl-2 protein. Physiologically, bcl-2 expression is present in naïve B-cells but is downregulated as these cells enter the germinal center. If somatic immunoglobulin hypermutation in the germinal center results in antibodies with poor antigen affinity or avidity or antibodies that recognize self-antigens, the lack of bcl-2 permits the cell to undergo apoptosis. However, if the process leads to increased

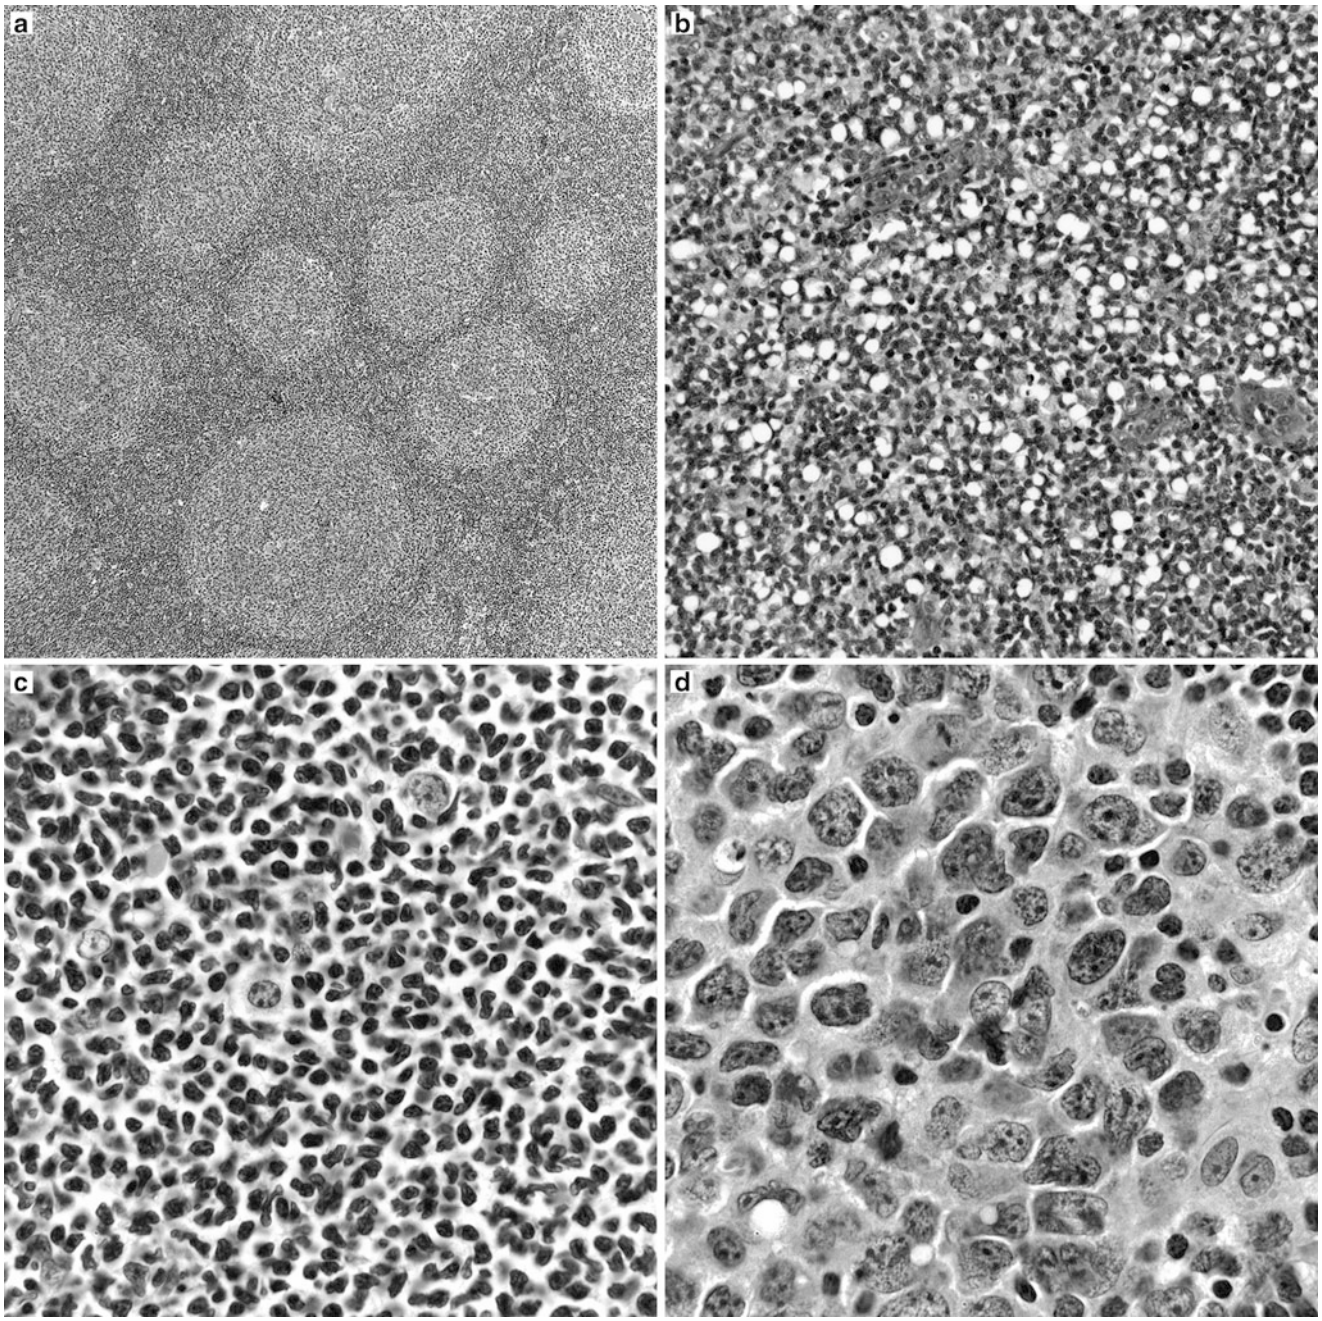

Fig. 31.11 Follicular lymphoma. (**a**) Low-magnification image showing closely packed neoplastic follicles. (**b**) Signet-ring cell forms containing cytoplasmic immunoglobulin are seen in an unusual morphologic variant of follicular lymphoma. (**c**) Cytologic findings including numerous cleaved cells within the neoplastic follicles and rare large cells with multiple peripherally arrayed nucleoli (centroblasts) (grade 1). (**d**) Cytologic features in grade 3 follicular lymphoma with numerous centroblasts.

antibody affinity for non-self-antigens, the cell will reactivate bcl-2 and escape programmed cell death.

The constitutive overexpression of bcl-2 protein in abnormal follicle center cells due to the t(14;18) represents an early and important step in the development of follicular lymphoma. The translocation occurs during V(D)J rearrangement at the pre-B-cell stage of development [46], but the cells ultimately mature and expand in germinal centers [47]. However, t(14;18) is not the sole abnormality required for transformation. This assertion is supported by the fact that a high percentage of normal individuals who never develop follicular lymphoma can be shown to harbor this translocation in low numbers of cells [48]. In addition, experimental mouse models with this same translocation first develop follicular hyperplasia but only later, presumably after additional genetic changes, progress to follicular lymphoma [49].

These t(14;18) positive cells in normal individuals do have a survival advantage over other follicle center cells and

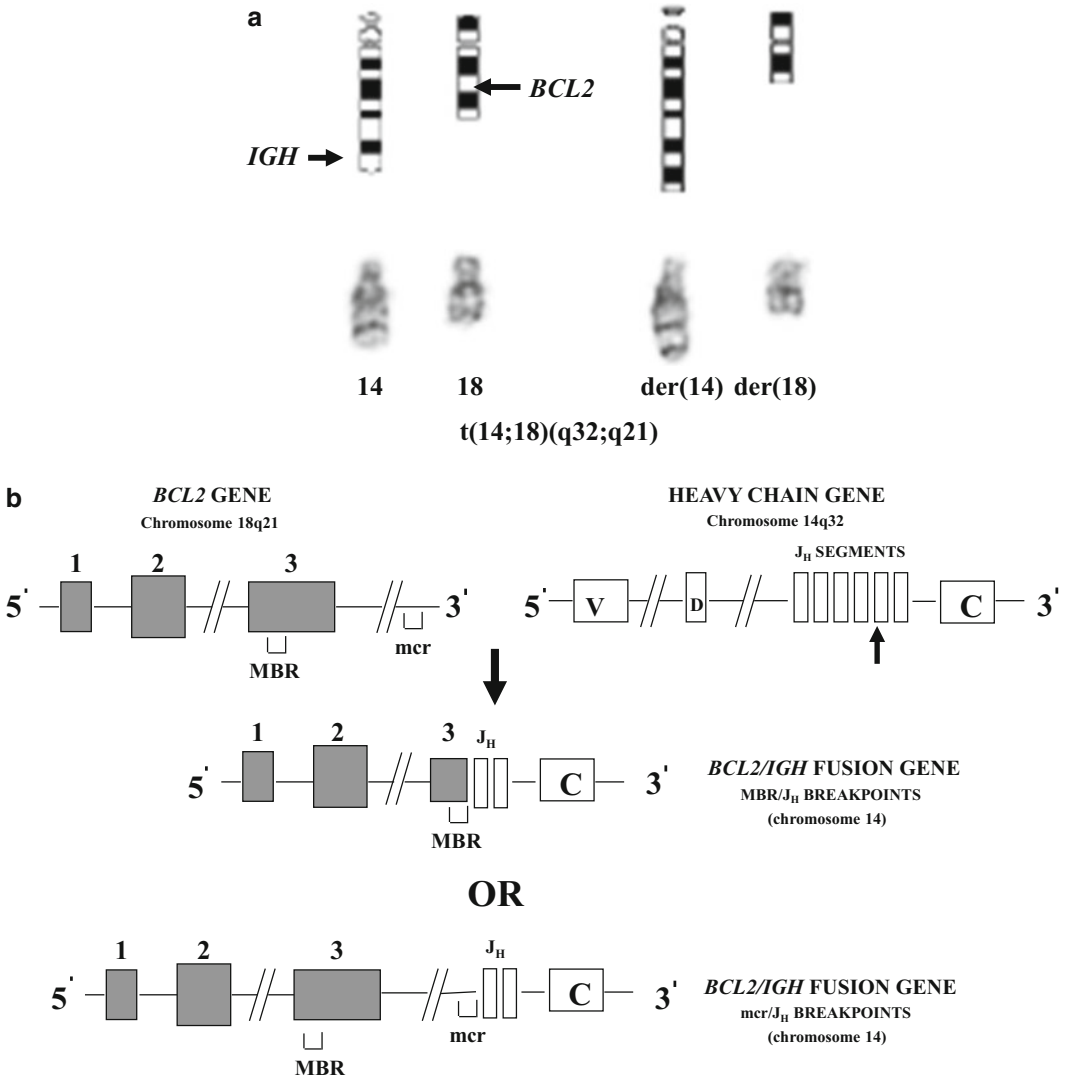

Fig. 31.12 Cytogenetics of follicular lymphoma. (**a**) Derivative chromosomes produced by the t(14;18) translocation (Giemsa-stained chromosomes and ideogram). (**b**) Schematic diagram showing the translocation of *BCL2* from chromosome 18 (*shaded boxes*) to the heavy chain gene (IgH) on chromosome 14 (*open boxes*) resulting in a *BCL2*/*IGH* fusion gene. For *BCL2*, most breaks occur in either the MBR or mcr regions. Breakpoints in the heavy chain gene involve J_H segments (*arrowhead*). The translocation may involve MBR and J_H breakpoints (*middle panel*) or mcr and J_H breakpoints (*lower panel*).

can undergo multiple rounds of rearrangement and somatic mutation in the germinal center. It is tempting to speculate that the additional time in the follicle center predisposes those cells to accumulation of additional genetic damage. Although these further genetic steps are thought to be required to complete transformation to follicular lymphoma, there are few secondary genetic alterations that occur in a significant proportion of follicular lymphomas, and this stepwise progression is currently ill-defined [50]. Several chromosome abnormalities were seen in FL in greater than 20 % of cases in one series (loss of 1p32-36, loss of 6q11-27, +7, +12, and + X) [51], but the specific genes involved have not been elucidated. It is noteworthy that a small number of follicular lymphomas (especially among those with grade 3B morphology) do not show a t(14;18) but rather have alterations in *BCL6* on chromosome 3q27. Histological and clinical progression of FL can be associated with a variety of molecular alterations including some that are also seen in mantle cell lymphoma via *CDKN2A* ($p16^{INK4a}$-ARF), *MYC* rearrangements, or mutations of *BCL6* or *TP53* [50].

Recent studies investigating the role of the microenvironment in the development and progression of FL have shown that the neoplastic cells have close interactions with T-cells, follicular dendritic cells (FDCs), macrophages, and other stromal cells. The stromal cells in some FL have a phenotype typical of FDCs in normal germinal centers, while in others, there is an absence of most FDC markers. This phenotype did not correlate with nodularity or architectural pattern, but it did correlate with the density of T-cells within neoplastic follicles. Those cases in which FDCs expressed normal germinal

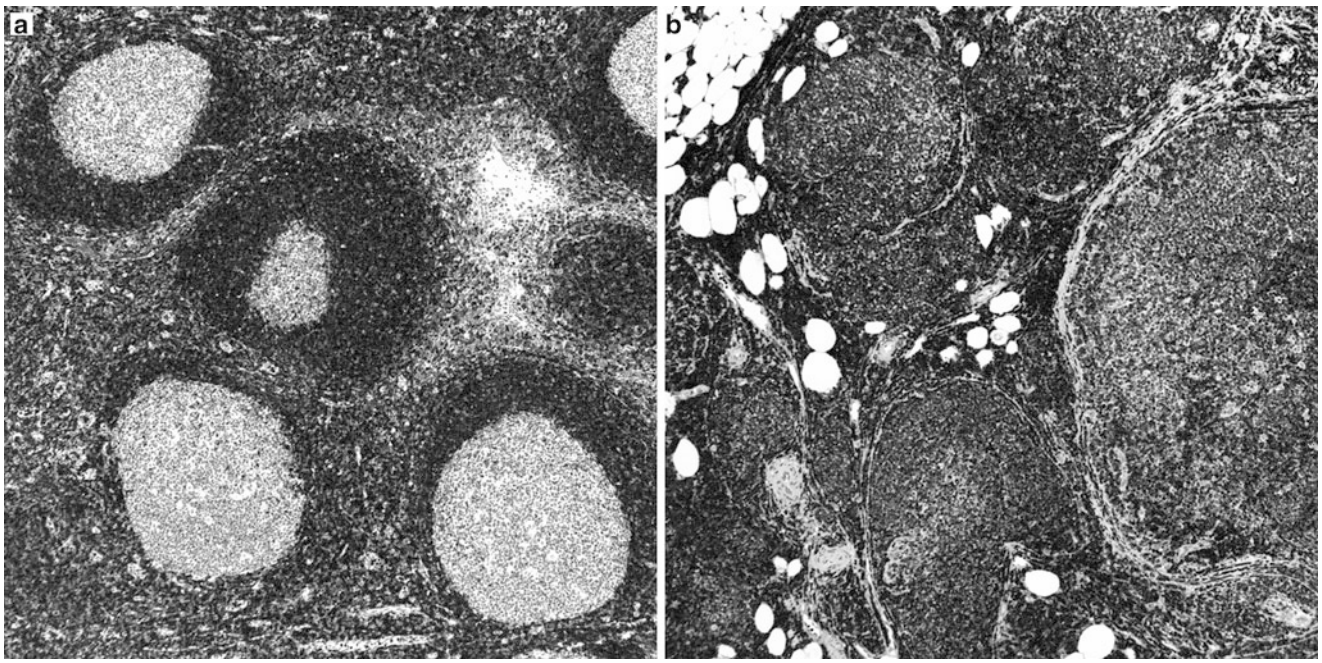

Fig. 31.13 BCL-2 expression in normal and neoplastic follicles. (**a**) Bcl-2 immunohistochemical study on a reactive lymph node showing absence of BCL-2 in reactive follicle centers. (**b**) Bcl-2 immunohistochemical study shows that virtually all cells, including those in follicle centers, are immunoreactive in this case of follicular lymphoma.

center type FDC markers had higher numbers of intrafollicular T-cells. It is speculated that follicular lymphomas with extranodal spread, which have few FDCs, may have lost their requirement for mature FDC or germinal center T-cell signals for growth. The loss of these features in a patient with follicular lymphoma may herald early disease progression [52]. In addition, molecular profiling studies of follicular lymphoma patients showed that survival in follicular lymphoma patients was correlated with molecular features at diagnosis and had little to do with subsequent acquisition of oncogenic abnormalities. Instead, the gene expression profile that best predicted survival was derived from non-malignant cells in the tumors [45]. Other studies have suggested that increased numbers of lymphoma associated macrophages were associated with a worse prognosis [53] although the predictive value of this parameter may not hold true in the setting of rituximab (monoclonal anti-CD20) therapy [54].

The diagnosis of FL can be made solely on morphologic grounds, although correlation with immunophenotypic and immunohistochemical findings is often employed. The expression of bcl-2 in follicle centers helps distinguish benign and malignant follicles (Fig. 31.13a, b). Expression of bcl-2 protein is not specific for follicular lymphoma, since bcl-2 is also expressed in normal T-cells, in non-germinal center B-cells and in other types of lymphoproliferative disorders. This marker is expressed only in about 90 % of FL cases and in the appropriate morphologic or immunophenotypic setting, lack of bcl-2 expression does not exclude a diagnosis of FL. FISH analysis for a *BCL2* rearrangement can be useful and is more sensitive than PCR in detecting the rearrangement [55, 56]. PCR analysis for immunoglobulin gene rearrangements can yield false negative results in FL, depending on the primer sets used. This is in part due to the high degree of somatic hypermutation present in cases of FL. Using more comprehensive BIOMED-2 primer sets and protocols yielded improved sensitivity by assessing IgH as well as Igk and Igλ probes. Of note, analysis for T-cell receptor gene rearrangements also highlighted a clonal T-cell gene rearrangement in 13 % of 109 cases tested [57]!

31.3.4 Extranodal Marginal Zone B-Cell Lymphoma, MALT type (t(11;18)(q21;q21), *API2-MALT1*; t(14;18)(q32;q21), *IGH-MALT1*; t(1;14)(p22;q32), *IGH-BCL10*; t(3;14)(p14.1;q32), *IGH-FOXP1*)

Marginal zone B-cell lymphomas (MZBCL) comprise a heterogeneous group of typically indolent B-cell lymphomas that make up approximately 7–8 % of all cases of NHL. Although there is morphologic overlap between the various forms of MZBCL, there are significant differences in clinical presentation, cytogenetic findings, and to a degree in immunophenotype that warrant their separation in the WHO classification [1]. The most commonly encountered forms of marginal zone B-cell lymphomas are those associated with mucosa-associated lymphoid tissue (MALT). Splenic

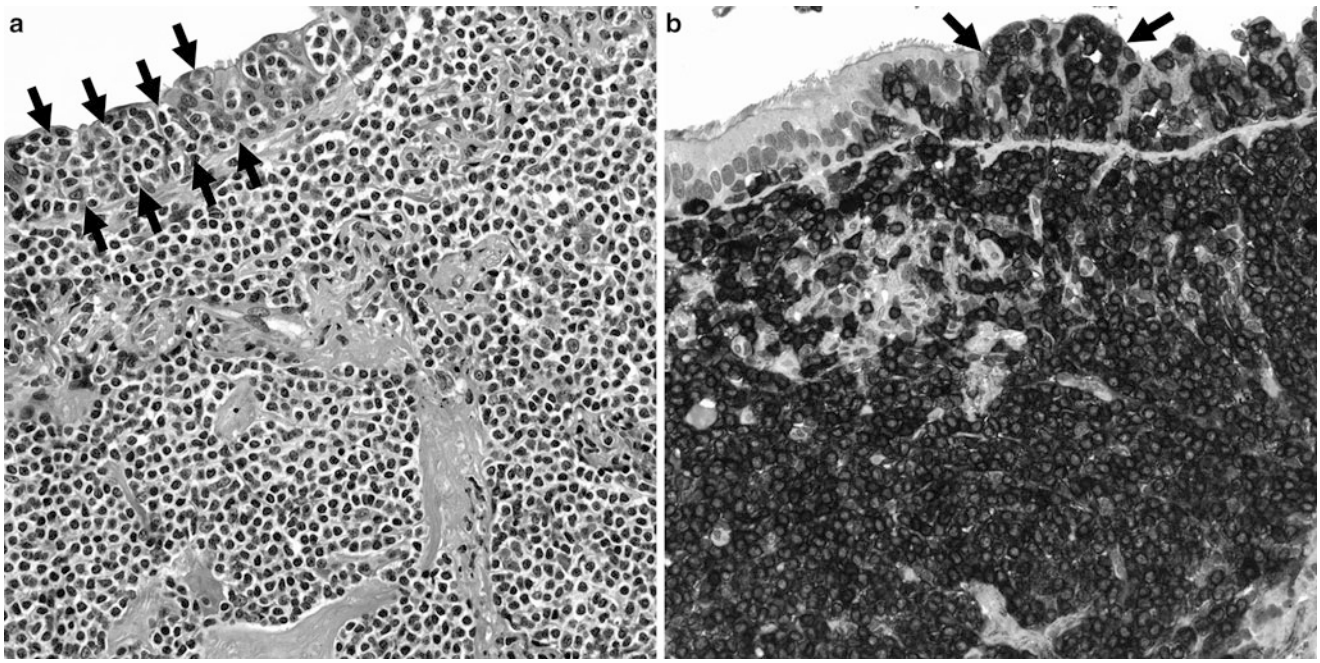

Fig. 31.14 Histology of extranodal marginal zone B-cell lymphoma, MALT type. (**a**) Lung biopsy with infiltrate of small lymphocytes with abundant cytoplasm with infiltration of bronchial epithelium (*arrows*). (**b**) Immunohistochemical study for CD79a shows predominance of B-cells and highlights the lymphoepithelial lesion (*arrows*).

marginal zone B-cell lymphoma with or without circulating villous lymphocytes and nodal marginal zone lymphoma are much less common.

The marginal zone is seen as a layer of small lymphocytes with moderate amounts of pale cytoplasm that surround the mantle zone and germinal center. Marginal zones are commonly found in Peyer's patches and other MALT sites, mesenteric lymph nodes, the spleen and occasionally in peripheral lymph nodes [58]. In extranodal MZBCL of MALT tissues (MALT lymphomas), the neoplastic cells frequently surround reactive follicle centers mimicking the normal marginal zone [59]. Similar morphologic findings are seen in splenic and primary nodal MZBCL. The marginal zones are expanded and sometimes fuse to form large sheets of the pale-staining cells. In MALT lymphoma, there is often infiltration of the epithelium by small groups of neoplastic cells, forming lymphoepithelial lesions (Fig. 31.14a). The neoplastic cells of MZBCL are usually small to medium-sized lymphocytes with abundant cytoplasm (classically described as monocytoid), although cytologic variability is common, even within a given case. Plasma cell differentiation is common [60].

By immunohistochemical analysis the neoplastic cells are shown to be mature B-cells with expression of CD19, CD20, CD22, and CD79a (Fig. 31.14b). Although exceptions occur, MZBCL is typically regarded as negative for CD5 and CD10. A subset of cases will show coexpression of the T-cell/macrophage associated marker, CD43. These lymphomas do not express cyclin D1 and usually lack expression of bcl-2 [61]. Molecular studies show that MZBCL are derived from post-germinal center B-cells with evidence of ongoing somatic mutation.

MZBCL are usually associated with chronic immune stimulation, either from exogenous (typically infectious) or endogenous (auto-antigen) exposure. Examples of this connection include the association that of *H. pylori* (Fig. 31.15) infection and gastric MALT lymphomas, hepatitis C and splenic marginal zone B-cell lymphoma, and MALT lymphomas involving the salivary gland and thyroid in patients with Sjögren syndrome and Hashimoto thyroiditis, respectively. Evidence of the association between infection and the gastric MALT lymphoma is the most clearly defined, and includes the fact that up to 90 % of patients with gastric MALT have the infection, the fact that eradication of the infection leads to regression of the lymphoproliferative disorder in a significant number of patients, and the fact that infection with *H. pylori* leads to similar lymphoid proliferations in animal models. There is increasing evidence of an association between *C. jejuni* and immunoproliferative small intestinal disease (IPSID), *B. burgdorferi* and cutaneous MZBCL, and *C. psittaci* and ocular adnexal MALT lymphoma [62]. In patients with hepatitis C (HCV), there is a question of whether the chronic infection leads to an increase in lymphoproliferative disorders in general or to an increase in specific subtypes such as splenic MZBCL [63]. Supportive evidence of a causative relationship between HCV and some cases of NHL (particularly MZBCL) includes series of patients who show a response to antiviral therapy with interferon and ribavirin [64, 65]. It has been suggested that the chronic immunologic response in patients with these infections or autoimmune disease leads to DNA damage. This damage is likely related in part to the effects of associated acute inflammation (particularly

Fig. 31.15 Infection with *H. pylori*. Gastric biopsy with encircled area showing *H. pylori*, which has been shown to be the major causative agent in the development of gastric MALT lymphomas.

the release of reactive oxygen species) and in part to the process of proliferation and differentiation of B-cells associated with chronic inflammation [66].

Several recurrent balanced translocations have been described in association with MALT lymphomas, the most common of which are t(11;18)(q21;q21) (Fig. 31.16a) involving the *API2* and *MALT1* genes, t(14;18)(q32;q21) involving *IGH* and *MALT1* genes, and t(1;14)(p22;q32) (Fig. 31.16b) involving the *BCL10* and *IGH* genes. The translocations involving chromosome 14 share a common theme with MCL and FL with upregulation of a gene by placing it under regulatory control of the IgH promoters. The t(11;18) is different in that it involves the formation of a novel protein, which fuses parts of the *API2* gene product and *MALT1* gene product with the result that the MALT1 activity is constitutively expressed. Despite the various genes and mechanisms involved in these translocations, they ultimately result in activation of the necrosis factor kappa B (NF-κB) pathway. Other genetic alterations are known to occur with MALT lymphoma, including the recently described t(3;14)(p13;q32), involving the *FOXP1* gene on chromosome 3 and the *IGH* gene [67]. This translocation was shown to be present in 10 % of 91 MALT lymphomas evaluated, with a predilection for the thyroid, ocular adnexae, and skin. There appears to be potential for a geographic influence on distribution of these translocations related to sites of involvement of lymphoma as a large study from the US showed discrepancies with what was found in European and Japanese studies of distribution [68]. The t(11;18) and t(1;14) are most commonly associated with GI tract and pulmonary MALT lymphomas, while the t(14;18) is typically seen in other sites [66]. The reasons for the site predilections are not well-understood, but may in part be related to the types of antigenic stimulation that drives the lymphoid proliferation.

The t(11;18), t(14;18), and t(1;14) share a common theme in cases of MZBCL. Each ultimately leads to constitutive upregulation of the NFkB (Fig. 31.17). In the resting state, NFkB is sequestered in the cytoplasm because of the inhibitory effects of the IkB protein. In stimulated cells, IkB is phosphorylated and targeted for elimination by ubiquitin. In the absence of the inhibitory protein, NFkB can enter the nucleus, where it activates transcription of genes involved in inflammation, immunity, apoptosis, and cell survival. The gene for *BCL10* is located on chromosome 1p22, and expressed in many normal tissues. This protein binds to MALT1 to activate NFkB in the normal state. The *MALT1* gene at chromosome 18q21 encodes a paracaspase that does not activate NFkB without interacting with other proteins. BCL10 and MALT1 can bind together, leading to oligomerization of the caspase-like domain of MALT1 and physiologic activation of the NFkB pathway. The *API2* gene on chromosome 11q21 (also called cIAP2) is an inhibitor of apoptosis protein that inhibits active caspases that promote apoptosis. In each of the three translocations, there is upregulation of this system. In two translocations, there is upregulation of one of the partners in this activation pathway (BCL10 is overexpressed in t(1;14) and MALT1 is overexpressed in t(14;18)), leading to constitutive upregulation of the NFkB pathway. In t(11;18), there is a novel fusion protein, which allows for self-oligomerization of MALT1 and the upregulation of NFkB pathway without the participation of BCL10. In each case, the changes lead to activation of NFkB essential modulator (NEMO or IKKγ) resulting in phosphorylation and degradation of inhibitory kB proteins (IkB). The end result is that movement of NFkB to the nucleus is uncontrolled and leads to enhanced cell survival and proliferation [62, 66]. It is interesting to note that in MALT lymphoma cases, the t(1;14) and t(14;18) are often present with additional chromosomal abnormalities, while the t(11;18) is often the sole abnormality. It is also noteworthy that cases with the t(11;18) translocation rarely undergo transformation [69].

Because of the sites of involvement and the mechanisms of sampling those sites, the diagnosis of marginal zone B-cell lymphoma of MALT type is frequently made on small fragments of tissue. Morphologic and immunohistochemical findings are important; however, isolation of a B-cell clone by immunohistochemistry alone can be challenging. The lack of a specific aberrant immunophenotype in most cases can also render diagnosis difficult. In many cases, establishing clonality of the associated plasma cell population can serve as a surrogate for clonality in the lymphoid population [70]. In some instances, PCR analysis is required to establish clonality. FISH studies can also be performed looking for specific translocations, as listed above. The finding of a

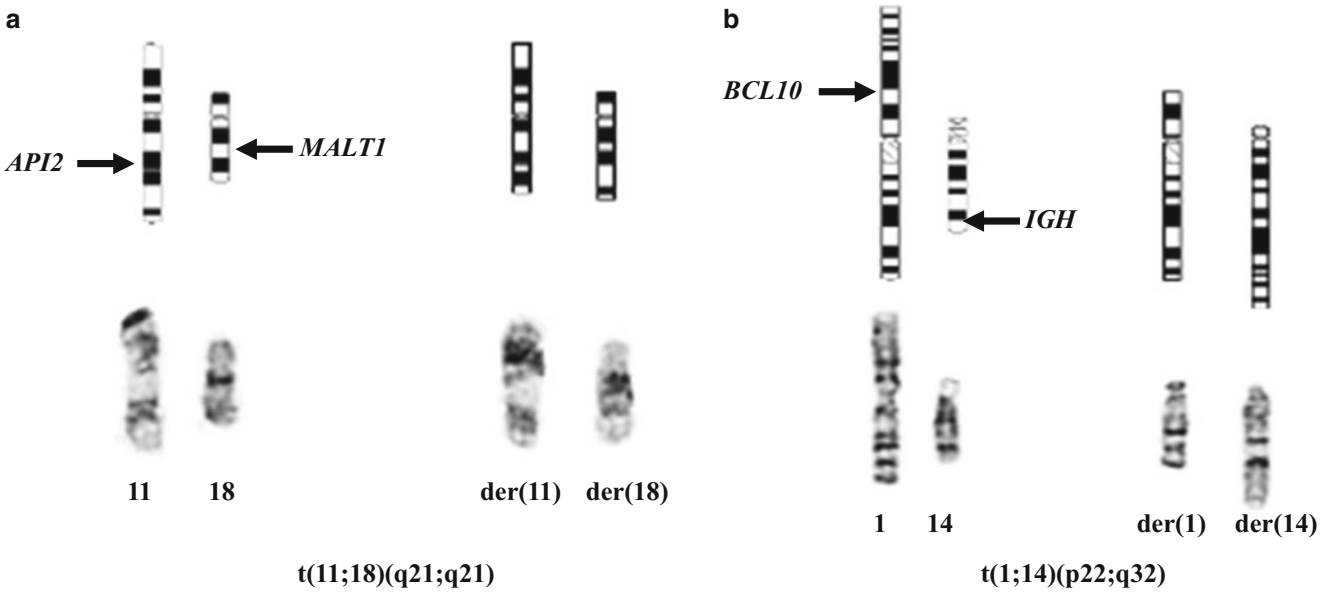

Fig. 31.16 Translocations in MALT lymphoma. (**a**) Translocation involving *API2* on chromosome 11 and *MALT1* gene on chromosome 18 that produces a novel API2-MALT1 fusion product that is capable of self-oligomerization and constitutive activation. (**b**) Translocation involving the *BCL10* gene on chromosome 1 and the *IGH* gene on chromosome 14 leads to overexpression of *BCL10*.

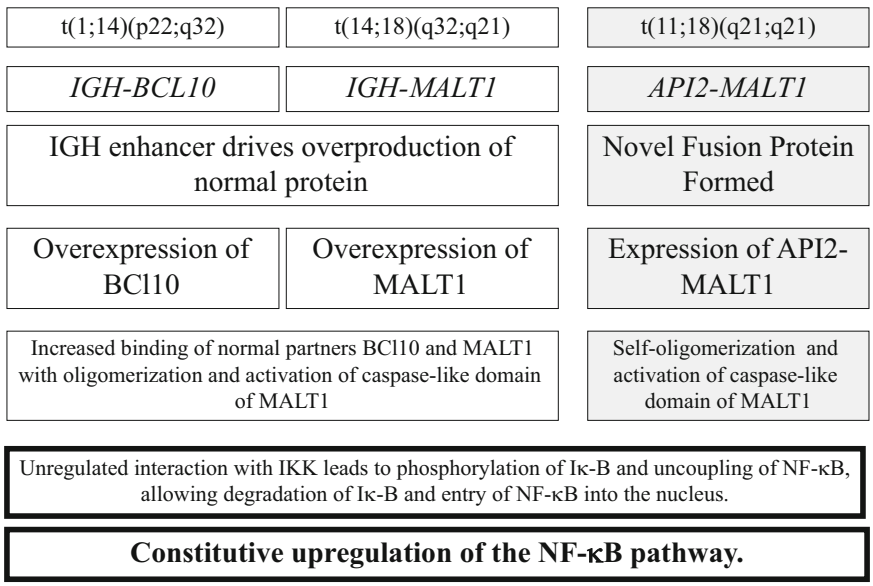

Fig. 31.17 Mechanisms by which NF-kB is upregulated in marginal zone B-cell lymphoma. The three common translocations, t(11;18), t(1;14), and t(14;18) in MALT lymphomas lead to increased activity of MALT1 and BCL10, which upregulates function of NF-kB pathway and leads to cell proliferation.

t(11;18) in a gastric MALT lymphoma by FISH can be of value clinically, since patients with this translocation are unlikely to respond to antibiotic therapy for *H. pylori* [71].

31.3.5 Anaplastic Large Cell Lymphoma (t(2;5)(p23;q35), *NPM-ALK*

The term anaplastic large cell lymphoma (ALCL) was first used in 1985 to describe a group of lymphoproliferative disorders that showed immunoreactivity for the Ki-1 antibody raised against Hodgkin lymphoma but that had distinctive morphologic features [72]. This lymphoma accounts for approximately 2 % of NHL [73], with a predilection for young patients and shows a striking male predominance [1]. The disease comprises a heterogeneous group that can be largely divided by the presence or absence of expression of anaplastic lymphoma kinase (ALK) which is caused by certain translocations. Patients with ALK overexpression have a remarkably good prognosis, while those that lack it have a poor prognosis, similar to patients with peripheral T-cell lymphoma, unclassified. This difference is so striking that it has led to the suggestions that the ALK-positive (ALK+) and ALK-negative (ALK−) forms be separated into two distinct entities.

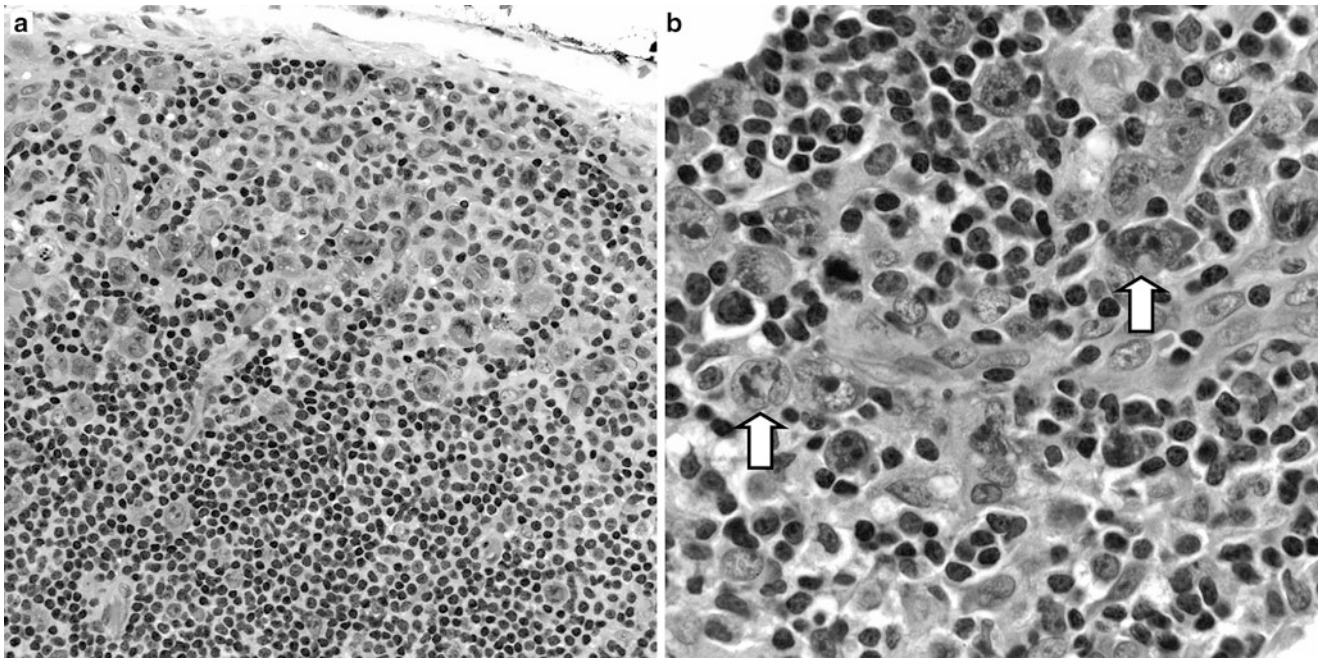

Fig. 31.18 Morphology of anaplastic large cell lymphoma. (**a**) Lymph node with predominantly sinusoidal and perisinusoidal infiltration by atypical lymphoid cells. (**b**) "Hallmark" cells of ALCL (*arrows*) with large, reniform/embryoid nuclei and prominent paranuclear clearing.

Lymph nodes involved by ALCL often show preservation of lymph node architecture with the population of abnormal cells showing a peculiar sinusoidal pattern of distribution (Fig. 31.18a). In other cases, there may be diffuse effacement of the lymph node architecture. The so-called hallmark cell is a cell classically described as having a reniform, embryoid or horseshoe-shaped nucleus, and moderate to abundant cytoplasm often with a distinct perinuclear eosinophilic region which may represent a prominent Golgi apparatus (Fig. 31.18b). There are several morphologic variants of ALCL, including the common variant, small cell variant, lymphohistiocytic variant, and a sarcomatoid variant. Despite the variation in the overall morphology, the hallmark cells remain a constant finding, which can be very useful in establishing the diagnosis [74]. Morphologically, the ALK+ and ALK− variants do not show substantial differences, although it has been suggested that the t(2;5), which is the most common translocation leading to ALK positivity is more frequent in the monomorphic and small cell variants [75]. A group of Ki-1 (CD30) positive cutaneous lymphoid proliferations with similar cytologic features is also recognized. The clinical features of the CD30-positive cutaneous lymphoproliferative disorders are quite variable, and they rarely express ALK by immunohistochemistry.

Aside from the uniform expression of CD30, the immunologic features in ALCL are variable. Most cases show immunophenotypic evidence of T-cell differentiation with expression of one or more T-cell markers including CD2, CD3, CD5, and CD7. ALCL is somewhat more frequently immunoreactive for CD4 than for CD8. The null cell type expresses no lineage-specific antigens. Whether or not the neoplastic cells express T-cell markers, the majority show evidence of clonal T-cell receptor gene rearrangement [73]. Curiously, the neoplastic cells express the epithelial membrane antigen, which along with the tendency for the neoplastic cells to cluster and involve lymph node sinuses can cause confusion with carcinoma at the time of diagnosis. Most cases express one or more cytotoxic molecules such as granzyme B, perforin, TIA-1. In contrast to some cases of Hodgkin lymphoma, there is no expression of EBV and no expression of the B-cell specific activator protein (BSAP, *PAX5*) [1]. Rare cases show expression of CD15 [74].

Anaplastic large cell lymphoma has been shown to be associated with a variety of translocations. The first described was the t(2;5)(p23;q35) [76, 77] which was later shown to involve the nucleophosmin gene (*NPM*) located at chromosome 5q35 and a previously uncharacterized receptor tyrosine kinase dubbed anaplastic lymphoma kinase (ALK) located at chromosome 2p23 [78] (Fig. 31.19). NPM is a ubiquitously expressed nuclear shuttling protein that carries proteins to the nucleolus. Its function depends on an N-terminal oligomerization motif and nuclear localizing domains at the C-terminus. ALK is a transmembrane receptor tyrosine kinase most closely related to leukocyte tyrosine kinase and is a member of the insulin receptor superfamily. It carries an intracytoplasmic tyrosine kinase catalytic domain that is activated by forming homodimers after ligand binding [79]. The ALK protein shows relatively limited expression in

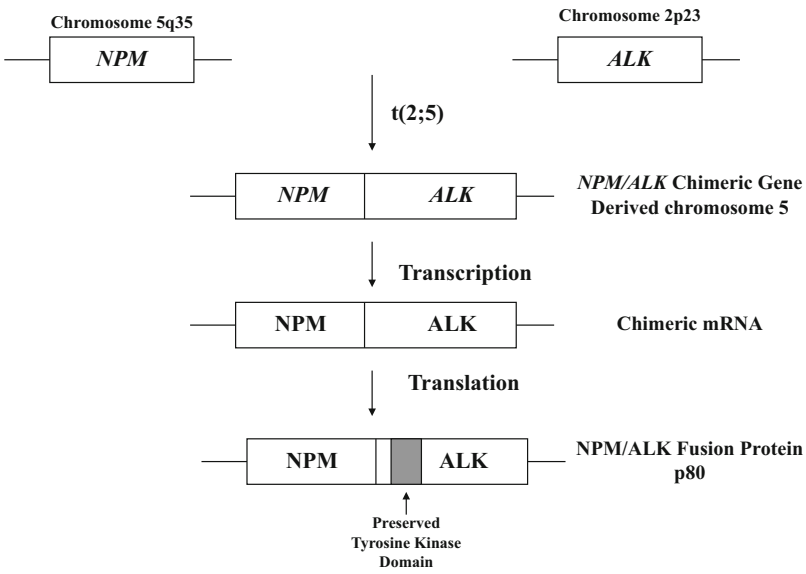

Fig. 31.19 Schematic diagram of the t(2;5)(p23;q35). This translocation juxtaposes the *NPM* and *ALK* genes on the derived chromosome 5 resulting in a *NPM/ALK* chimeric gene, which codes for an 80-kd, NPM/ALK fusion protein (designated p80). The NPM/ALK fusion protein includes a preserved tyrosine kinase domain (*shaded area*).

cells of neural origin and is not expressed in normal hematopoietic cells. The t(2;5) leads to the production of a novel chimeric protein that carries the 5′ oligomerization motif of NPM that allows homodimerization of the fusion protein leading to constitutive activation of the 3′ tyrosine kinase domain derived from ALK. Numerous genes can be the 5′ partner for *ALK* in ALCL (including clathrin heavy chain-like 1 on chromosome 17, tropomyosin 3 on chromosome 1, *TRK*-fused gene on chromosome 3, and others) and most supply domains that lead to spontaneous oligomerization allowing the ALK fusion kinases to auto-phosphorylate and activate downstream pathways [80]. ALK overexpression has been associated with other tumors including inflammatory myofibroblastic tumors, neuroblastoma, and some solid tumors. The oncogenic potential of NPM-ALK fusion has been demonstrated in mouse models, with development various tumor types including B-cell lineage lymphomas [81] and/or T-cell lineage lymphomas [82]. It is also important to note that similar to with the t(11;14) of MCL and t(14;18) of FL, normal patients can be demonstrated to carry NPM-ALK fusion transcripts can be demonstrated in non-neoplastic cells, suggesting that this is an important but not sufficient step in the development of ALCL [83].

Constitutive activation of the ALK tyrosine kinase interacts with numerous cellular pathways involved in cell-cycle progression, survival, and proliferation. For instance, constitutive activation of signal transducers and activators of transcription (STATs) by tyrosine kinases leads to their translocation to the nucleus where they regulate transcription of genes involved in apoptosis, the cell cycle, and cell growth. Constitutive activation of the STAT3 pathway is consistently present in ALK-positive ALCL. Other proteins, including JAK2 and STAT5 can also play a role in ALCL pathogenesis [84]. Two other relevant and relatively well-characterized pathways affected by ALK fusions include the Ras-extracellular signal-regulated kinase (ERK) pathway and the phosphatidylinositol 3-kinase (PI3-K)-Akt pathway. The Ras-ERK, JAK3/STAT3, and PI3-K-Akt pathways interact at multiple points in mediating the effects of ALK activity, with the first playing a major role in cell proliferation and the latter two involved with anti-apoptotic effects and cell survival [80]. The role of CD30 in the pathogenesis is unclear, but its consistent expression in these tumors suggests it may have a role.

Although the presence of ALK overexpression in ALCL defines a relatively discrete population, they do not seem to have much in common with ALK-negative ALCL cases. Indeed, there is some debate about considering ALK+ ALCL a discrete entity and classifying the ALK− lymphomas otherwise typical of ALCL with the group of peripheral T-cell lymphoma, unspecified because of differences in clinical presentation and outcome. Gene profiling studies show that ALK+ ALCL and ALK− ALCL hold some mechanisms in common (expression of anti-apoptotic molecules and certain kinases) but differ in other ways (such as level of expression of signal transduction molecules (greater in ALK+ cases) and transcription factors (less in ALK+ cases)) [85]. Another gene expression profile study confirmed the discrepancy between ALK+ and ALK− subgroups and showed subgroups even among the ALK+ ALCL cases. The common type clustered together with increased expression of genes associated with inflammatory/immune response and stress responses, while the morphologic variants were in a different group showing increased expression of genes involved in cell adhesion and cell migration. The authors postulated that this clustering among ALK+ cases may reflect expression of different genes during the course of the disease [86].

Diagnosis of ALCL hinges on recognition of morphologically abnormal cells showing CD30 expression (Fig. 31.20a).

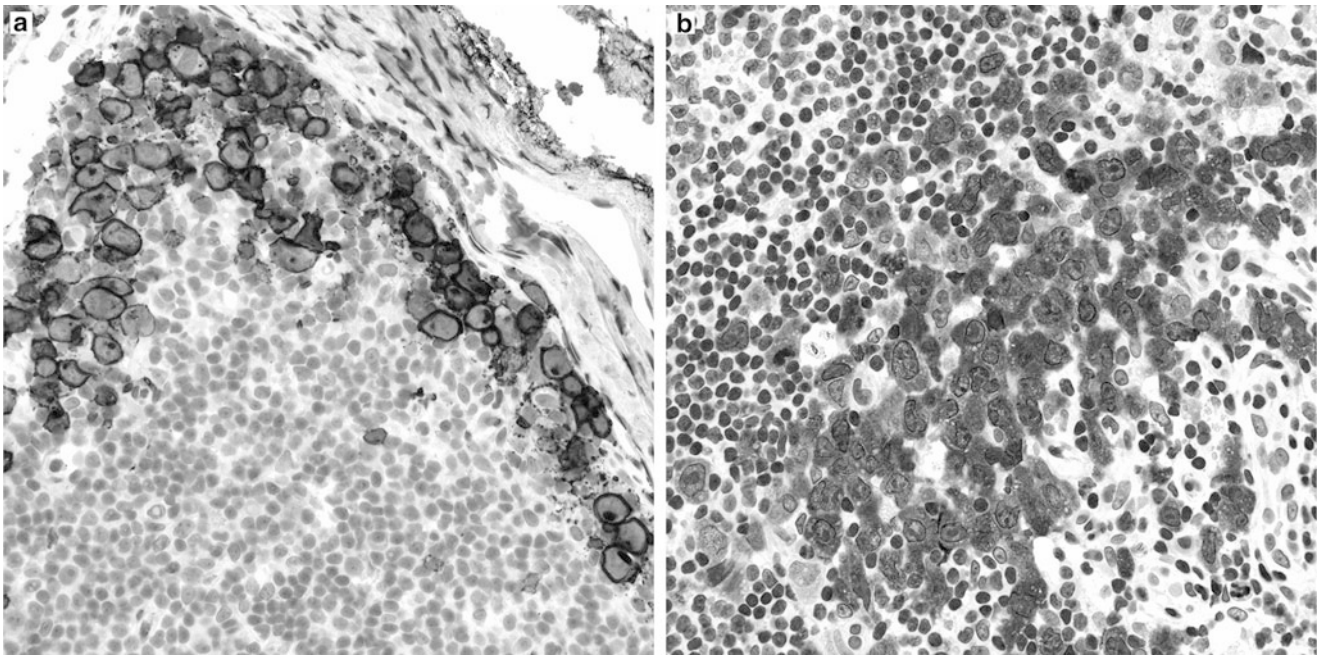

Fig. 31.20 Immunohistochemistry in the diagnosis of ALCL. (**a**) CD30 highlights the sinusoidal infiltration of the lymph node. (**b**) Immunohistochemical study for antibody to anaplastic lymphoma kinase (ALK) showing only cytoplasmic immunoreactivity, suggesting an *ALK* translocation involving a partner gene other than nucleophosmin (*NPM*), which would show nuclear and cytoplasmic immunoreactivity.

Discrimination from cases of Hodgkin lymphoma is aided by the expression of other markers such as *PAX5*, ALK, and T-cell markers in many cases. The presence of ALK expression is an important prognostic variable that can be demonstrated by immunohistochemical analysis and the pattern of immunoreactivity to ALK can provide some insight into the translocation partners involved [79] (Fig. 31.20b). Cytogenetics and FISH studies can be useful in demonstrating the characteristic translocations and additional genetic abnormalities. Finally, although T-cell markers are not expressed all cases, the large majority will exhibit clonal T-cell receptor gene rearrangements, including those that are of null cell phenotype.

31.3.6 Adult T-Cell Leukemia/lymphoma (Integrated, Clonal HTLV-1)

Unlike the chronic inflammation and infection-associated MALT lymphomas, another group of lymphomas can be directly caused by viruses. The main transforming viruses implicated in lymphomagenesis include Epstein-Barr Virus (EBV), Human Herpesvirus-8 (HHV8), and Human T Lymphotropic Virus-1 (HTLV-1). EBV is consistently linked with the endemic form of Burkitt lymphoma and the consistent presence of EBV DNA and proteins in the cells in such cases is a strong argument for an etiologic role of the virus. Other evidence includes serologic evidence of infection preceding the development of lymphoma and the fact that the EBV itself is monoclonal in the lymphoma cells. This virus is also found in the vast majority of extranodal NK/T-cell lymphomas (nasal type), most post-transplant lymphoproliferative disorders, and a subset of Hodgkin lymphoma. Another virus more recently associated with non-Hodgkin lymphoma, particularly in the setting of infection with the human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) is HHV8 (also known as Kaposi sarcoma-associated herpesvirus (KSHV)). This virus is closely associated with the primary effusion lymphomas, which are clinically aggressive lymphomas. The exact mechanism of oncogenesis in such cases is under investigation, but pathways involving p53, the retinoblastoma gene product, cyclin-dependent kinase 6, and NFkB have been implicated [87]. A viral etiology has been established for greater than 20 years in adult T-cell leukemia/lymphoma (ATLL), which is caused by infection with a retrovirus known as HTLV-1 [88].

ATLL is a disease of mature CD4+ T-cells and shows distinctive geographical clustering in areas with high seroprevalence for HTLV-1. The clinical manifestations of ATLL vary with acute, lymphomatous, chronic, and smoldering forms recognized by the WHO [1]. Most patients with ATLL present with lymphadenopathy and many have organomegaly. The presence of hypercalcemia and lytic bone lesions is common, which is likely caused by increased numbers of osteoclasts and accelerated bone resorption [89]. The peripheral blood of involved patients shows varying numbers of

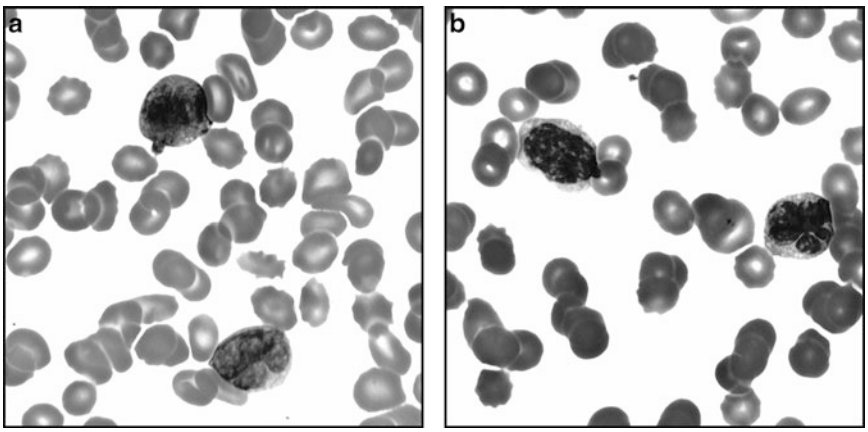

Fig. 31.21 Adult T-cell leukemia/lymphoma. (**a**, **b**) Flower cells in the peripheral blood of a patient with adult T-lymphocytic leukemia/lymphoma.

abnormal lymphocytes including those with markedly convoluted nuclear contours (so-called flower cells) (Fig. 31.21). The neoplastic cells have a mature T-cell phenotype and show expression of T-cell antigens including CD2, CD3, CD5, and CD4 and typically lack expression of CD7 and CD8. The malignant cells also show expression of CD25. There is not a specific karyotypic abnormality associated with development of ATLL, but multiple chromosomal abnormalities may be seen [90], including loss of heterozygosity on chromosome 6q, which has been reported in up to 40 % of cases [91]. The genetic hallmark of ATLL is the integration of HTLV-1 at a random site in the genome. The viral genome and the site of integration are clonal within a given patient's neoplastic population.

HTLV-1 is a type C human retrovirus with a positive single-stranded RNA genome. The encapsulated virion contains the viral RNA, a protease, reverse transcriptase, and integrase. Upon entering the cell, possibly via a ubiquitous glucose transporter [92], the virus is converted into double-stranded DNA and is integrated randomly into the DNA of the host cell as a provirus. The infection is lifelong, and preferentially infects CD4-positive T-cells. The virus optimizes its RNA by using RNA ribosomal frameshifts, transcript splicing patterns, and even makes use of the negative strand for encoding functional proteins [93]. Given that the virus replicates with the cells it infects (as an integrated provirus) using cellular polymerases, the genome of the virus is quite stable and viral loads are low. Based on the low level of genetic variability, and low incidence (2–6 %) of ATLL among infected populations, it is presumed that development of leukemia is related to host factors [90]. The variation in host factors may also help explain the various clinical manifestations of infection with HTLV-1, including HTLV-1-associated myelopathy/tropical spastic paraparesis and the associations with infective dermatitis, Sjögren syndrome, etc.

The molecular pathways involved in development of lymphoma revolve around the viral Tax protein and a recently discovered gene encoded on the minus strand of the viral RNA that encodes for HTLV-1 bZIP factor, also called HBZ [94]. Tax increases expression of viral genes and stimulates expression of cellular genes via cell signaling pathways of NFkB, cyclic AMP response element-binding protein (CREB) among others. The Tax protein affects these pathways by interacting with cellular transcription factors or other modulators of cell function. It has also been shown to inactivate the tumor suppressors p53, $p16^{INK4a}$, and others [89]. Because of its activities in promoting transcription of its own genome, cytokines, and receptors, anti-apoptosis genes and its inhibition proteins involved in tumor suppression and DNA repair, Tax seems a likely candidate for the transforming factor in ATLL. However, it also serves as a target for the host cytotoxic T-cell response and its overexpression leads to destruction of infected cells. The ATLL cells can lose expression of Tax protein by several mechanisms, including deletion or hypermethylation of the promoter for production of viral Tax, which is a 5′LTR, or various missense or nonsense mutations leading to loss of production of functional Tax. The loss of Tax via these mechanisms allows the cells to evade the host immune system [95]. Another way of downregulating the expression of Tax was found in the form of *HBZ*. This protein was expressed in all ATLL cells and no cases with abortive mutations were found, suggesting that this gene is important in oncogenesis. The *HBZ* gene seems to function in perpetuating the infected cell line in the protein form by suppressing Tax expression and evasion of the immune response, and in the mRNA form by increasing expression of E2F1, a gene pivotal in control of the G1 to S phase transition in the cell cycle [96]. Ultimately, these mechanisms of immune system surveillance and proliferation are important in driving the process of ATLL, but more complex interactions with host immunologic and genetic factors must play a role in the development of neoplasia since the large majority of patients infected with HTLV-1 do not develop this fatal complication.

Diagnosis of ATLL is made by correlating the clinical, morphologic, immunophenotypic, and genetic findings. Patient demographic data may be a key feature in leading one to consider the diagnosis. The presence of atypical circulating lymphocytes (flower cells) confirmed by immunophenotyping, and serologic data to confirm the presence of HTLV-1 infection are also invaluable. PCR analysis, directed at detecting the presence of integrated proviral sequences is a sensitive technique for identifying ATLL and T-cell receptor studies show clonal rearrangements, although molecular analysis for ATLL is not usually necessary for diagnosis [97]. The presence of hypercalcemia and lytic bone lesions is a helpful but not specific finding as these are also characteristic of plasma cell myeloma.

31.4 Future Directions in Understanding the Molecular Basis of Lymphoma

31.4.1 Molecular Profiling

Morphologic and immunohistochemical methods of analysis have improved our classification of lymphomas in the past 20 years. However, there are still large groups of NHL that are not further classifiable with routinely used methodologies. Two of the major groups include diffuse large B-cell lymphoma and peripheral T-cell lymphoma, unspecified. There are morphologic, immunohistochemical, genetic, and clinical differences among these groups of lymphomas, but their subclassification with routine methods is poorly reproducible. A recent trend in tumor analysis is gene expression profiling using DNA or RNA libraries and applying these to tissue microarrays composed of samples from a host of different cases. This process allows one to examine genes that are upregulated or downregulated on a case by case basis and then group cases based on similarities and differences in how those genes are expressed [98].

The seminal article in gene expression profiling details a study that examined thousands of genes expressed in normal cells as well as chronic lymphocytic leukemia/small lymphocytic lymphoma, follicular lymphoma, and diffuse large B-cell lymphoma [99]. The expression of genes expressed in subsets of normal cells was compared to that in neoplastic cases. Hierarchical clustering was used to compare samples and to group cases with similar profiles. It was found that among the heterogeneous category of diffuse large B-cell lymphomas, two major groups were present—a group with a an pattern of gene expression that resembled germinal center B-cells (germinal center B-cell-like) and a second group with a profile more akin to activated peripheral blood B-cells (activated B-cell-like). These groups were shown to have significantly different outcomes when treated with similar therapeutic regimens. It was further noted that although these two groups were distinct, there was heterogeneity within each group. The possibility that the differences in molecular signatures and clinical outcomes were sufficient to consider the ABC type and GCB type as two distinct entities was raised. Subsequent gene profiling studies of DLBCL have largely substantiated this initial work, although differences exist, including the presence of a third subgroup by some authors [100, 101]. In addition to substantiating the findings of the original study, other groups have applied various technologies including self-organizing maps to simplify and organize the vast amounts of data generated [102]. Another group applied fuzzy neural networks to aid in sorting data and found that the number of genes evaluated can be reduced from several thousand to less than 10 with reasonable predictive value [103]. Because gene expression profiling is not yet readily available for such distinction, several groups have proposed immunohistochemical algorithms for distinguishing the ABC from GCB types of large B-cell lymphoma [104, 105] (Fig. 31.22).

Along with value in subclassification and prognostication, the use of gene expression profiling can be helpful in further defining existing disease entities. For instance, it is a well-known issue that distinction of Burkitt lymphoma from other forms of B-cell lymphoma, which is extremely important for optimal therapy, can be difficult or impossible on a pure histologic basis [106] (Fig. 31.23). With the judicious use of immunohistochemical analysis, cytogenetics and FISH, the classification of these cases can frequently be made, but there is a subset of cases that defies precise classification [107]. Molecular studies of cases of Burkitt lymphoma, Burkitt-like lymphoma, and diffuse large B-cell lymphoma show distinctly different gene expression profiles, emphasizing the fact that the current tools used for classification of these lymphomas is not ideal. One group identified a molecular signature for Burkitt lymphoma using eight cases that met all WHO criteria for that diagnosis. Using that signature in an analysis of numerous cases of mature, aggressive B-cell lymphomas, the authors found that among cases with the molecular signature of Burkitt lymphoma, 25 % had morphologic features that were more typical of diffuse large B-cell lymphoma and only 65 % had classical or atypical Burkitt morphology [108]. Another study published at the same time analyzed over 300 cases of aggressive lymphoma and found that all 25 cases of pathologically confirmed Burkitt lymphoma were correctly identified and distinguished from DLBCL. However, some cases originally diagnosed as DLBCL had the molecular signature of Burkitt lymphoma and vice versa. The findings underscore the difficulties in diagnosis of BL using currently accepted criteria. Because of significant differences in therapeutic regimens and clinical outcome between cases of DLBCL and Burkitt lymphoma, molecular profiling studies may be the best way to ensure correct therapy, although such testing methods are not currently available in clinical laboratories [109].

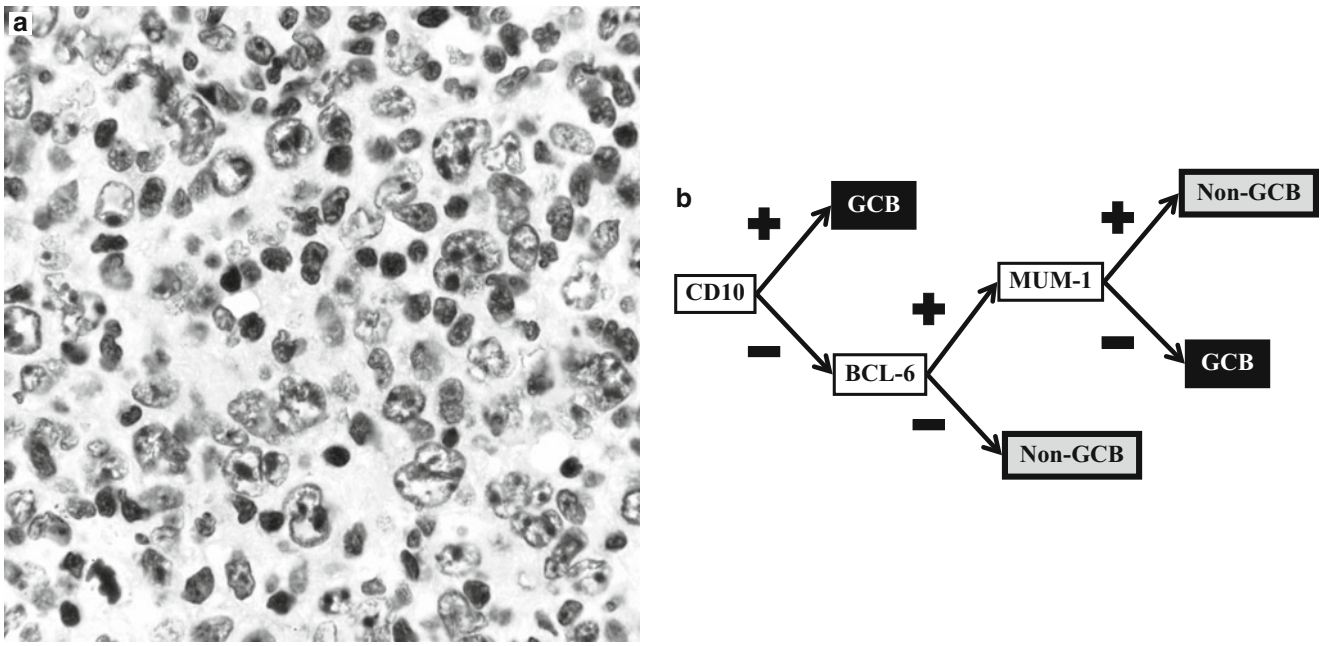

Fig. 31.22 Diffuse large B-cell lymphoma. (**a**) Diffuse large B-cell lymphoma with large atypical cells showing multiple nuclei, vesicular chromatin, and thickened nuclear contours (centroblastic morphology). (**b**) A suggested algorithm is the Hans algorithm, which uses a small number of immunohistochemical studies as a surrogate for gene profiling studies in the separation of non-germinal center B-cell type (non-GCB) from the germinal center B-cell (GCB) types of DLBCL.

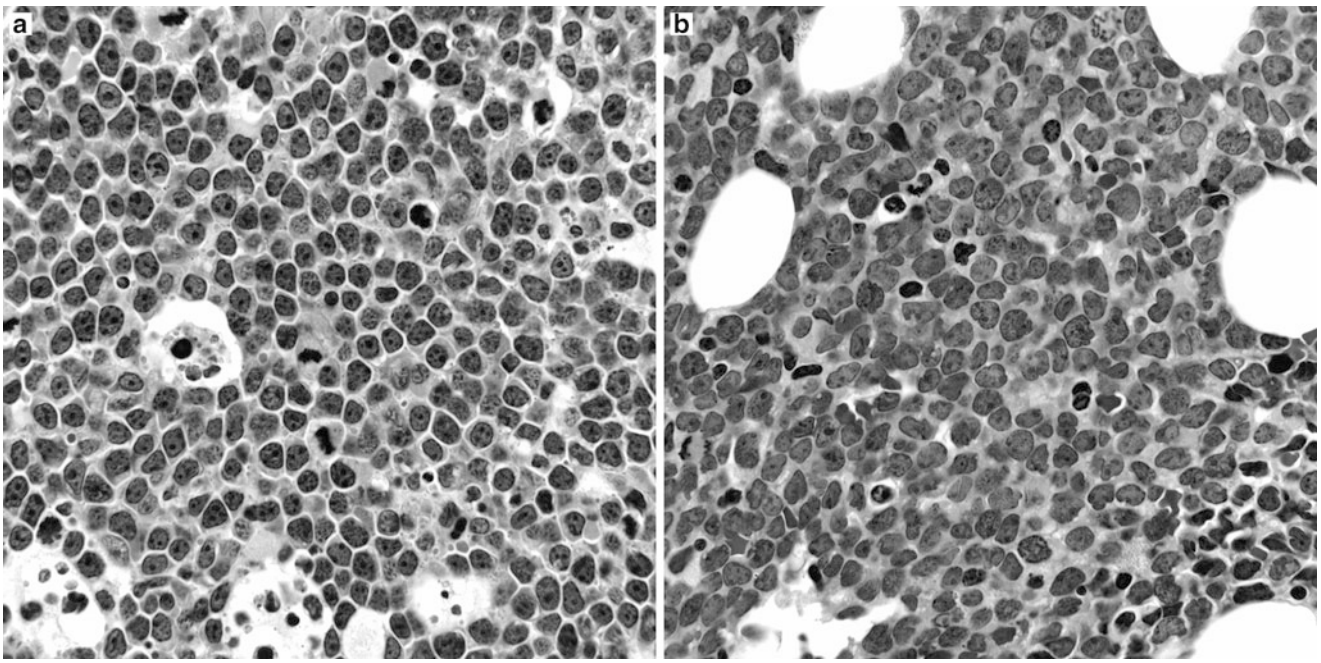

Fig. 31.23 Aggressive B-cell lymphomas. (**a**) Aggressive B-cell lymphoma immunophenotypic findings and morphologic findings that would be compatible with double hit lymphoma. Despite a *MYC* rearrangement in the form of a t(8;14), the presence of an additional t(14;18) argues against classification as Burkitt lymphoma. (**b**) Burkitt lymphoma with classic morphology and isolated t(8;14). There is often morphologic and immunophenotypic overlap among aggressive B-cell lymphomas; however gene expression profiling has been shown to be a reproducible method of discriminating Burkitt lymphoma, which requires more aggressive therapy from others that might be better treated with more conventional DLBCL therapy.

These and other findings and others are exciting and may lead to further subclassification of DLBCL, and may help lead to more precise classification of existing entities. However, this use of this data is a work in evolution. It is noted, for instance, that as therapies have evolved and with the addition of anti-CD20-directed rituximab, the differences in outcome related to various prognostic factors, including those noted at the time of Alizadeh's original study may be somewhat lessened [110]. Utilization of molecular profiling could be of great value in ensuring that patients with aggressive disease receive appropriate therapy. In addition, the use of these techniques to further delineate the pathogenetic mechanisms of lymphomas may lead to novel therapies more precisely directed at disrupted molecular pathways, such as specific inhibitors of cyclin-dependent kinases in mantle cell lymphoma or inhibitors of the NFkB pathway in various lymphomas with deregulation of this pathway.

31.4.2 MicroRNAs

A relatively new player in the understanding of molecular mechanisms of disease is the microRNA. These small molecules, first characterized in *C. elegans* in 1993 [111] were not well-appreciated for their widespread function in physiologic and pathologic processes until years later [112]. The term microRNA was coined by Lee and Ambros in 2001 [113]. Study of microRNA structure and function has been extensive, and several hundred microRNAs have been described and cloned in humans [112]. MicroRNAs are conserved across various organisms, and play important roles in many cellular and developmental processes. A single microRNA can influence large numbers of genes, and can serve as tumor suppressors or as oncogenes [114]. Their expression has been shown to be dysregulated across the spectrum of epithelial, mesenchymal, and hematopoietic malignancies.

The molecular profiling studies involving DNA libraries and proteomics have been shown to be effective in distinguishing various tumor types. Similarly, it has been shown that there are unique microRNA fingerprints that distinguish normal cells from tumor cells and tumors from one another. Among lymphoid neoplasms, the use of a microRNA-microchip to analyze chronic lymphocytic leukemia found that microRNA profiles were associated with expression of ZAP-70, with the mutational status of the immunoglobulin heavy chain variable region and with the length of time from diagnosis treatment [115]. Although many microRNAs were found to be dysregulated, there were two microRNAs that were abnormal in cases of CLL, *miR-15a* and *miR-16-1* that were felt to behave as tumor suppressors. The ability to distinguish accurately between patients with CLL into good prognosis and bad prognosis groups is only one of the many useful pieces of information that can be gleaned from the study of microRNAs. Another study showed that microRNA expression profiles were able to distinguish accurately between acute lymphoblastic leukemia and acute myeloid leukemia. It was found that using expression patterns of just two to four microRNAs, one could accurately distinguish ALL from AML in greater than 97 % of case analyzed [116].

Other recent studies have shown interactions between microRNAs and other oncogenes, supporting their role in cancer development. For instance, it has been shown that Myc activation in tumor cells results in widespread changes in the expression of microRNAs, predominantly in the form of downregulation, a finding that suggests that microRNA expression plays a role in Myc-mediated tumorigenesis [117].

Like the gene expression profiling that relies on DNA, microRNA gene expression profiling has identified patterns that can be used in the classification and prognosis of various tumors. They can be upregulated or downregulated and can serve as oncogenes or tumor suppressors [118]. The study of these small molecules has some advantages over the study of mRNA, particularly that they are stable in routinely available tissue (including paraffin-embedded tissue), and that it seems that a limited number of microRNAs may be sufficient for classification of tumors. It is hoped that these small molecules will have a big impact on understanding the biology of cancer and in either serving as a target for novel therapies or at least helping illuminate other mechanisms of tumorigenesis that can be targeted.

31.5 Conclusion

Our understanding of the molecular basis of tumors continues to grow, but there is much yet to learn. It has been known for many years that cancer is not a single disease but many, and that neoplasia is a multi-step process. As we have seen, many of the molecular hallmarks of common diseases are simply markers, but do not cause the disease *per se*. For this reason, in the realm of clinical diagnostics it is important to not equate clone with malignant. The detection of low levels of aberrant transcripts by highly sensitive methods similarly does not translate to the presence of early malignancy. The principles of classification espoused in the WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues [1] are highly applicable. There needs to be correlation of morphologic, immunophenotypic, clinical, and molecular data. It is through this integration that we are able to advance our understanding of these disorders and further study them. At this point, the use of tools like cytogenetics, FISH, and PCR can help us to diagnose, classify, and prognosticate lymphoproliferative disorders. It is hoped that the use of powerful molecular techniques like molecular profiling to study disease and the discovery of novel ways in which gene expression is con-

trolled will lead to better characterization and understanding of disease processes. This understanding should lead to development of novel therapies, and ideally improve clinical outcome in patients suffering from these disorders.

The Molecular Pathology of Head and Neck Squamous Cell Carcinoma

32

Laura J. Tafe

32.1 Introduction

In the United States, there were an estimated 49,000 new cases of head and neck cancer diagnosed in 2010, the majority of which were squamous cell carcinomas [1]. Head and neck squamous cell carcinoma (HNSCC) is the sixth leading cancer worldwide by incidence [2]. HNSCC arises in the oral cavity, oropharynx, larynx, or hypopharynx. The overall 5-year survival for all stages and races is approximately 63 %, but this varies from 30 to 80 % for patients with distant metastases versus localized disease, respectively [1].

The pathogenesis of HNSCC has been associated with environmental risk factors such as alcohol, tobacco, and regional/ethnical substance chewing which may act synergistically. During the past decade there has been a decreasing incidence of HNSCC in several sites which has been attributed to a decrease in tobacco use [3]. However, there has been an increase in oral tongue and especially oropharyngeal tumors which is speculated to be because of increasing high-risk Human Papilloma Virus (HPV) infections [4]. In addition, patients with certain inherited disorders, such as Fanconi anemia and Li-Fraumeni syndrome, and genetic susceptibility have a predisposition for HNSCC. There is growing evidence that HNSCC associated with HPV infection is a unique clinical and biologic subset of HNSCC. Currently, there are two models of pathogenesis in HNSCC. One, in so-called conventional HNSCC, is associated with environmental substance use and the second driven by oncogenic HPV infection.

32.2 Etiology and Biology of Conventional HNSCC Associated with Environmental Substance Use

Tobacco, alcohol, and regional/ethnical substance, such as the betel quid (a combination of betel leaf, areca nut, and slaked lime; when combined with tobacco this is called gutka), use are classical risk factors for development of HNSCC. Exposure to these carcinogenic substances over time leads to multiple opportunities for DNA damage and often a stepwise accumulation of genetic events leads to carcinogenesis. In a simplified approach, carcinogenesis develops from overexpression of oncogenes and or suppression of tumor suppressor genes. A number of genetic alterations have been described in HNSCC and the interplay among all of these changes that lead to carcinogenesis are not yet completely understood.

Conventional HNSCC is thought to evolve through a multistep process of genetic, epigenetic, and metabolic changes secondary to exposures to the above carcinogens. Clinically, this is reflected through the progression from normal mucosa to precancerous and dysplastic lesions to eventual carcinoma. However, not all precancerous lesions develop into carcinoma. Oral leukoplakias have an approximate 1–2 % rate of transformation into cancer [4]. Histologically, conventional HNSCC usually have some degree of keratinization and are classified as well to poorly differentiate based on the amount of keratin produced (Fig. 32.1a). It appears that an accumulation of changes are necessary for progression. Alterations in chromosomal region 9p21 are seen in 70–80 % of oral dysplastic lesions. This region, known as the *CDKN2A* locus encodes the p16 and $p14^{arf}$ tumor suppressors, which are frequently inactivated by promoter hypermethylation [5]. Loss of 3p is another common alteration in early carcinogenesis; this region includes the *FHIT* (fragile histidine triad) and *RSSFIA* tumor suppressor genes which are commonly inactivated by promoter methylation or exonic deletion. Loss of heterozygosity (LOH) at chromosomal regions 4q, 8p, 11q, 13q, 14q, and 17p are common in dysplastic lesions,

(**a**) A well differentiated conventional type HNSCC with keratinization (hematoxylin-eosin, 100×). (**b**) HPV-associated HNSCC which lacks keratin and has a poorly differentiated basaloid histology (hematoxylin-eosin, 200×). (**c**) The same tumor in part **b** with diffuse and strong nuclear and cytoplasmic p16 staining (p16 immunohistochemistry, 200×).

p53 mutations or deletions and LOH at 13p and 18q are associated with increased genomic instability and aneuploidy are commonly seen in carcinomas [5]. Additional events important to the events in carcinogenesis include the activation of telomerase, and overexpression of epidermal growth factor receptor (EGFR), cyclooxygenase-2 (COX-2), and cyclin D1 (11q13) [6]. Loss of heterozygosity (LOH), promoter methylation, and somatic mutations are all mechanisms of genetic alterations that play a role in the multistep progression model of HNSCC carcinogenesis. Below is further discussion on several of the molecular alterations that seem to play an important role in tumorigenesis.

32.2.1 Field Cancerization/Precursor Lesions

The study of pre-malignant lesions and the concept of field cancerization have been best studied and described in oral squamous cell carcinomas (OSCCs) in part because of the accessibility of these lesions for clinical observation and biopsy. The term field cancerization was proposed in 1953 by Slaughter et al. to explain the high incidence of local recurrences of HNSCC after treatment and the high likelihood of multiple independent tumors arising in the oral mucosa [4, 7]. Oral leukoplakias are precursor lesions that are visible to the naked eye. However, evidence suggests that there are precursor lesions that cannot be seen on a macroscopic level. Initially histologic studies and now molecular studies have shown that dysplasia and genetic changes are frequently seen in the grossly normal appearing tissues surrounding carcinomas [4]. This is significant because of the real potential that if these areas of genetically abnormal epithelium are not resected at the time of surgical excision of the tumor they are likely an important source of local recurrences and secondary primary tumors. Approximately 10–30 % of resected cancers recur despite negative surgical margins [4, 8]. Studies have shown that the carcinoma and their adjacent fields are often clonally related, supporting the

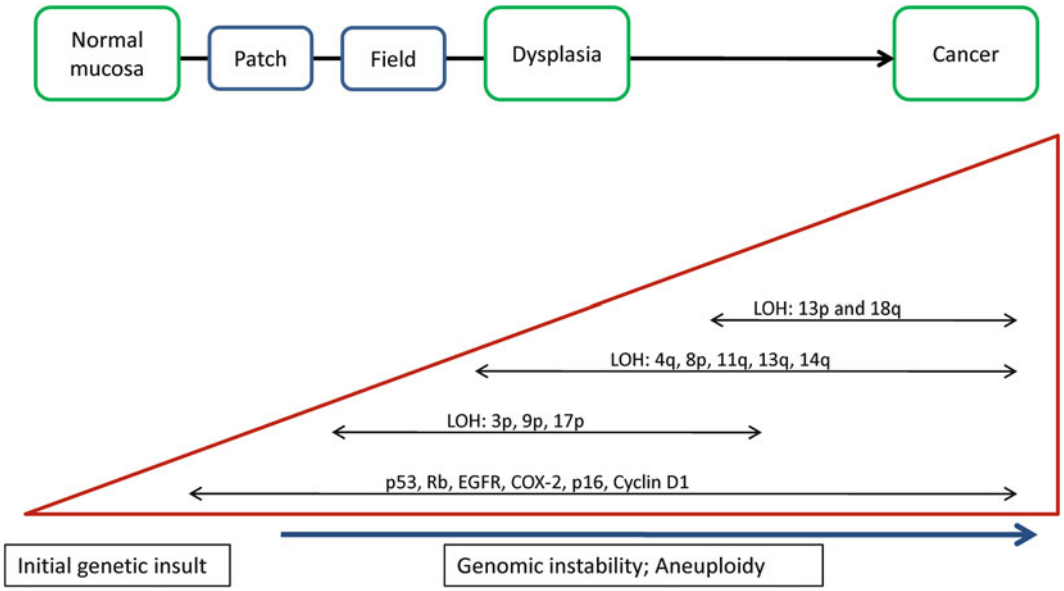

Fig. 32.2 The multistep genetic progression model of conventional head and neck squamous cell carcinoma (HNSCC) carcinogenesis [4–6, 71]. An initial genetic insult occurs (e.g. exposure to mutagenic tobacco products) which leads to a series of genetic events along the pathway to carcinogenesis. Histologically, this manifests as normal mucosa transitioning to dysplasia and eventually frank carcinoma. Events associated with dysplasia and early phases of carcinogenesis include loss of heterozygosity (LOH) at 3p, 9p, and 17p. Accumulated genetic changes lead to genetic instability and aneuploidy characteristic of carcinoma. This also includes mutations and epigenetic silencing of genes as well as upregulation and overexpression of genes all leading to deregulation of the cell cycle and uncontrolled proliferation.

hypothesis that the field precedes the invasive carcinoma [9]. It is hypothesized that a stem cell acquires the genetic alteration and passes it onto it progeny eventually evolving into a field that develops a cancer. In addition, van Houten et al. have shown that the mucosa of patients with carcinoma may harbor focal patches with *TP53* mutations that are not identical to the tumor (i.e. not clonally related), these *TP53* mutated patches or clonal units are considered to represent the first oncogenic changes in the mucosa and these findings suggest that exposure to carcinogens, such as tobacco and alcohol, leads to multiple unrelated clonal patches [8]. These findings are the basis of the patch-field-tumor-metastasis progression model for the development of HNSCC (Fig. 32.2) [4, 9].

32.2.2 Alterations in Signaling Pathways

32.2.2.1 p53 and Rb Pathways

One of the first genetic changes in HNSCC is disruption of the p53 pathway. *TP53* is a tumor suppressor gene which induces apoptosis and is an important regulator of the cell cycle. Disruption of p53, through *TP53* mutations, LOH at 17p or the interaction with viral proteins, is one of the most common genetic alterations seen in HNSCC. Somatic *TP53* mutations have been identified in 60–80 % of HNSCC [4]. In a multicenter study of 560 patients with HNSCC, Poeta et al. screened the tumors for *TP53* mutations using the Affymextix GeneChip p53 assay for high-throughput detection of mutations in exons 2-11 of *TP53* with sequencing for confirmation. They defined two categories of mutations based on the location of the mutation and the predicted amino acid alterations. Disruptive mutations were defined as stop codons in any region or non-conservative mutations located inside the key DNA-binding domain, and non-disruptive mutations are non-conservative or conservative mutations outside the DNA-binding domain. The results of their study showed that the presence of a disruptive *TP53* mutation was strongly associated with a decreased overall survival ($P<0.001$) [10].

Studies have shown that p53 immunohistochemistry (IHC), looking specifically for protein overexpression, does not correlate with *TP53* mutation status for several reasons: (1) *TP53* mutations at splice sites, frame shifts, or nonsense mutations would produce a truncated p53 protein that may not be detectable by IHC; (2) other causes of overexpression such as retention and secondary stabilization of wild-type p53; and (3) poor tissue processing (i.e. over fixation, delayed fixation, or inadequate tissue processing) which would result in p53 degradation [11].

P53, when activated by DNA damage, is an important intracellular regulator of apoptosis by affecting regulation of expression of apoptosis-regulatory proteins. These regulatory molecules include the Bcl-2 family of proteins which have either anti-apoptotic (Bcl-2, Bcl-XL) or pro-apoptotic (Bax, Bak) effects. Thus, alterations in p53 expression can change the ratio of anti-apoptotic to pro-apoptotic regulatory proteins which can promote tumor cell survival and resistance to chemo and radiation therapies [5]. For example, Nichols et al. reported that in a subset of patients with oropharyngeal squamous cell

carcinoma (OPSCC), pretreatment Bcl-2 expression was an independent risk factor (independent from HPV status) for treatment failure and distant metastasis after therapy [12].

The retinoblastoma (Rb) pathway (p16-cyclin D-CDK4/6-Rb axis) can be deregulated at a number of points. Inactivation of the *CDKN2A* gene (region 9p21), which encodes for p16, a key regulatory molecule, by mutation, deletion, LOH or a combination of these is another frequent occurrence in HNSCC [4]. Humans have three cyclin D proteins referred to as cyclin D1-3 which are present in most proliferating cells. *CCND1*, which encodes cyclin D1 (region 11q13), a key activator of the Rb pathway, shows gain or amplification in more than 80 % of HPV-negative HNSCCs [13]. The Rb protein itself can be inactivated by HPV oncoproteins, as discussed below. Taken together, disruption of the p53 and Rb pathways lead to disordered cell cycle regulation and immortalization of the neoplastic cells.

32.2.2.2 Tyrosine Kinase Receptors: The EGFR and MET Pathways

Epidermal growth factor receptor (EGFR) is a member of the Erb family of four tyrosine kinase receptors that form homo- or heterodimers upon ligand binding and initiate signaling cascades through the Ras-MAPK, PI3K-PTEN-AKT, and phospholipase C pathways. Studies have shown that EGFR is overexpressed in many HNSCCs. However, these were based on immunohistochemistry studies with variations in antibodies and techniques; therefore, the reported prevalence rates of overexpression are widely variable. Overexpression may be a result of receptor cross phosphorylation (autocrine activation) or gene amplification; rates of EGFR amplification are reported to be 10–30 % [4]. EGFR copy number alterations have been associated with a poor prognosis and this observation did lead to a clinical trial that showed improved locoregional control and progression-free survival with radiotherapy in combination with the EGFR-specific antibody cetuximab (Erbitux) versus radiotherapy alone [14, 15].

EGFR has multiple tyrosine phosphorylation sites that interact with different partner proteins with different intracellular signaling, thus the real role of EGFR in HNSCC is not clear and maybe different for different tumors. In addition, Epidermal Growth Factor (EGF)-bound EGFR is able to translocate to the nucleus and function as a transcription factor or coactivator of genes involved in cell proliferation. *CCND1*, the gene for Cyclin D1, appears to be one of the targets induced by intranuclear EGFR, linking the mitogenic stimulation of EGF-EGFR to cell cycle promotion [16].

Few activating *EGFR* mutations have been found in HNSCC, which is not entirely surprising when taken in the context of the lung carcinoma data which have shown that activating *EGFR* mutations are essentially exclusive to adenocarcinoma histology [17]. The most common EGFR alteration, seen in up to 42 % of the HNSCCs analyzed, is the *EGFR* variant III (EGFRvIII) truncation mutation, which has also been observed in gliomas and non-small-cell lung carcinomas [5, 16]. EGFRvIII leads to constitutive activation of the receptor in the absence of ligand or receptor overexpression. These mutants also seem to show resistance to chemotherapy and targeted EGFR monoclonal antibody treatments, but on univariate analysis was associated with better disease control [18, 19].

MET (the receptor for hepatocyte growth factor (HGF); also known as scatter factor) is another receptor tyrosine kinase that is also able to activate the AKT and Raf-MAPK pathways. MET and its ligand HGF play a role in invasion and metastasis through up regulation of the expression of matrix metalloproteinases MMP-1 and MMP-9 [5]. *MET* (region 7q31) mutations and gene amplification have been identified in HNSCC, but biomarkers to predict response to anti-MET treatment have not yet been identified [4].

32.2.2.3 NOTCH1 Pathway

One unexpected finding from whole exome sequencing of a set of HNSCC was the identification of *NOTCH1* mutations. While *NOTCH1* has been implicated in the tumorigenesis of several lymphomas and, *NOTCH1* mutations have also been identified in lung SCC, they are not frequent in other solid tumors [20, 21]. *NOTCH1* inactivating mutations are seen in approximately 10–19 % of HNSCC making it second only to TP53 as most frequently mutated gene in HNSCC [20, 22, 23]. NOTCH1 is a transmembrane receptor with extracellular and intracellular domains. The intracellular domain is cleaved and translocation to the nucleus is necessary to turn on target genes which are necessary for cell differentiation (including keratinocytes) and embryonic development [22, 24]. In the setting of HNSCC *NOTCH1* appears to act as a tumor suppressor gene where *NOTCH1* mutations lead to silencing of the pathway. However, in a study by Sun et al. in about 30 % of tumors, there was an increase in gene copy number and expression of the NOTCH1 receptor or ligands and subsequent downstream pathway activation. These findings suggest a bimodal pattern of alterations in the NOTCH pathway in HNSCC and this may lend itself to the use of NOTCH pathway targeted therapeutics [22].

32.2.2.4 PI3K-PTEN-AKT Pathway

The PIK3-PTEN-AKT pathway is also important in HNSCC. The class Ia PIK3s, form heterodimers with a receptor tyrosine kinases, such as EGFR, or adaptor molecules, are activated by phosphorylation and lead to downstream activation of AKT, a serine/threonine kinase. Activated AKT subsequently activates a number of downstream proteins including apoptosis inhibitors, cell cycle inhibitors, and transcription factors which promote cell proliferation and survival. PTEN is a tumor suppressor that counteracts the activation of AKT. This pathway can be deregulated at a number of points. Homozygous deletions or inactivating mutations in *PTEN* (region 10q23) have been

reported in 10 % of HNSCC; in these tumors, the AKT pathway cannot be turned off so the cells proliferate uncontrollably [25]. One of the PIK3 subunits, the p110α catalytic peptide, is encoded for by *PIK3CA*, located on the 3q26 locus which is frequently gained in HNSCC. *PIK3CA* somatic mutations have also been reported in 10–20 % of HNSCC [4]. In one study, *PIK3CA* mutations were more frequently seen in HPV-positive tumors versus HPV-negative tumors, and were associated with activation of mTOR suggesting a possible role for PI3K/mTOR inhibitors in *PIK3CA* mutant HNSCC [26].

32.2.3 Immortalization

Human telomeres, repetitive tandem DNA repeats at the ends of the chromosomes, naturally shorten after each cell division which purposefully limits the life span of cells. In tumor cells, this process likely needs to be overcome to maintain proliferation. The enzyme telomerase elongates telomeric DNA by reverse transcription via its catalytic subunit TERT (telomerase reverse transcriptase). Telomerase or TERT activity is detected in up to 80 % of HNSCC, allowing for the potential of limitless replication of the tumor cells [4, 5]. Recurrent mutations in the *TERT* promoter have been described in several tumor types; in laryngeal squamous cell carcinomas, univariate survival analysis showed that *TERT* promoter mutations were significantly associated with poor survival with a hazard ratio (HR) of 1.52 (95 % CI, 1.05–2.20; *p* 0.03) [27].

32.2.4 Angiogenesis

Angiogenesis is very important in the development of cancer; tumors require a new blood supply in order to invade and metastasize. This is achieved through a shift in the balance between pro-angiogenic and anti-angiogenic factors. Solid tumors induce neo-angiogenesis by producing angiogenic factors, such as vascular endothelial growth factor (VEGF) [5]. In one meta-analysis, VEGF expression seemed to be associated with worse overall survival in HNSCC patients [28]. More studies are needed to further elucidate the role of VEGF and its potential as a therapeutic target in HNSCC.

32.2.5 Invasion and Metastases

HNSCCs classically invade locally and metastasize primarily to cervical lymph nodes. Steps involved in invasion and metastasis involve a complex process of: (1) alterations in cellular adhesion and the cytoskeleton, (2) cellular migration and dissolution of the basement membrane and extracellular matrix, (3) movement into and survival in the blood stream, (4) extravagation at the metastatic site with (5) subsequent growth and neovascularization [5]. Epithelial-to-mesenchymal transition (EMT) is a process associated with invasion and metastases where cells shift from an epithelial to a mesenchymal phenotype such that their shape changes and they become more motile. Alterations in e-cadherin, a cell surface molecule, are associated with EMT. Integrin that mediate cell-cell and cell-matrix interactions play a role in the motility and invasion of tumor cells. Enzymes, secreted by the tumor cells such as matrix metalloproteinases (MMP) are likely involved with the remodeling of the extracellular matrix around invasive and metastatic tumor cells [5].

32.2.6 Gene Expression Profiles

Messenger RNA (mRNA) expression analysis has been used to categorize HNSCC into subtypes based on expression profiles. Unsupervised hierarchical clustering is a powerful discovery tool that is often used for this purpose and heatmaps of mRNA expression values of a large number of classifier genes are used to visualize the clustering into subtypes. Walter et al. mRNA expression microarrays on 138 tumor samples using an 840 gene classifier and The Cancer Genome Atlas (TCGA's) preliminary data on HNSCC have resulted in consistent classification of HNSCC into four molecular subtypes: basal (BA), mesenchymal (MS), atypical (AT), and classical (CL) based on the characteristics of the genes that are highly expressed in each subtype [29, 30]. These studies also confirm the finding of four gene expression subtypes reported by Chung et al. in 2004 [31]. When comparing the HNSCC subtypes to those reported in lung SCC by Wilkerson et al and the TCGA, there is a striking correlation with the HNSCC BA, MS, and CL subtypes with lung SCC basal, secretory, and classical subtypes, respectively [21, 32].

The BA signature is similar to that seen in basal cells of human airway epithelium; MS tumors had elevated expression of epithelial-to-mesenchymal transition (EMT) associated genes. The AT tumors have a strong HPV-positive signature (although only 14 HPV-positive cases where included in the study) and lacked either *EGFR* amplification or deletion of 9p; and, the CL subtype showed high expression of genes associated with cigarette smoke exposure as well as deletion of 3p and 9p, amplification of 3q, *EGFR*, and *CCND1*. Each subtype is associated with distinct expression patterns and chromosomal gains and losses. For example, gain of 3q, a common alteration in SCC, contains *TP63*, *PIK3CA*, and *SOX2* was associated with variable expression of these genes in the different subtypes. The CL and AT subtypes show higher SOX2 expression relative to the MS and BA subtypes, whereas, BA subtype showed the highest level of p63 expression of all. Interestingly, while MS had 3q copy number gains, the target genes above did not show expression levels any higher than normal tonsil [29]. These findings

suggest that there is likely differential usage of transcription factors (i.e. *SOX2* and *TP63*) and oncogenes (i.e. *PIK3CA*) that may contribute to the heterogeneity seen in HNSCC and help define the expression subtypes [29].

32.2.7 miRNA

MicroRNAs (miRNAs) are a class of noncoding regulator RNA molecules that are expressed in a tissue-specific manner and are believed to control the expression of up to 30 % of genes via a negative regulation on their target messenger RNA (mRNA) by either targeting the mRNA for degradation or blocking translation. Several excellent reviews on the role of miRNAs in human cancers have recently been published and the discovery of miRNAs is changing how we understand the molecular pathways)associated with carcinogenesis [33, 34].

Within HNSCC, researchers have confirmed deregulation of a number of miRNAs in tumor cells versus corresponding normal tissues but, with considerable variation across studies. However, there does appear to be at least a core set of miRNAs comprising miR-21, miR-31, miR-115, miR-155, and miR-205 which are consistently up-regulated and let-7b, miR-26b, miR-107, miR-133a/b, miR-138, and miR-139 which are consistently down regulated in HNSCC [35, 36]. Because a single miRNA may have hundreds or more potential gene targets, the causal role played by any individual miRNA in the carcinogenesis transformation is difficult to define and the relationship of miRNAs to different etiologies of HNSCC (e.g. HPV-positive cases versus conventional) is not entirely clear. HPV infection, by disrupting the p53 and pRb pathways, may lead to a signature increase of miR-16, miR-25, miR-92a, and miR-378 and the decrease of miR-22, miR-27a, miR-29a, and miR-100 [37]. Recent studies have reported progression of leukoplakia to squamous cell carcinoma associated with miRNA-345, miRNA-21, and miRNA181b; higher rates of locoregional occurrences and sorter survival associated with low expression levels of miRNA-205 and Let-7d; and, miRNA-451 expression a strong predictor for relapse [38–40]. We can anticipate many future studies evaluating the role of miRNAs in HNSCC for their potential as markers of prediction, prognosis, monitoring of disease, and targeted therapeutics.

32.3 Etiology and Biology of HPV in HPV-Associated HNSCCs

HPV-positive HNSCC tumors are different from conventional HNSCC in their clinicopathologic features and molecular pathogenesis (Table 32.1). While the incidence of HPV-unrelated HNSCC is decreasing, the incidence of HPV-related HNSCC has risen by about 11 % in the last two decades [3]. HPV type-16 (HPV-16) was discovered in the 1970s and since then, its role as an oncogenic virus has been well established and particularly well characterized in cervical cancer [41, 42].

Low-risk HPV has long been known to be associated with respiratory papillomas. The role of high-risk HPV in HNSCC has been studied since the 1980s and it was found that the same *E6* and *E7* viral oncogenes that were carcinogenic in cervical cancer were also involved in development of squamous cell carcinoma in the upper aerodigestive tract, especially in the oropharynx [43]. The majority (~90 %) of these cancers are associated with HPV-16 [44]. A case-control study in 1998 showed that the presence of HPV in the oral cavity was associated with an increased risk of oropharyngeal cancer independent of tobacco or alcohol exposure [45]. In 2000, Gillison et al. showed for the first time that HPV-positive HNSCC is most commonly associated with HPV-16, oropharyngeal sites, high grade non-keratinizing or minimally keratinizing morphology (Fig. 32.1b) and a more favorable clinical outcome than HPV-negative tumors. Overall, their patients with HPV-positive tumor had a 59 % reduction in risk of death from cancer in comparison to patients with HPV-negative tumors [46].

Table 32.1 Differences in the clinical and biologic features between HPV-negative and HPV-positive HNSCC

Characteristic	HPV-negative HNSCC (approximately 80 %)	HPV-positive HNSCC (approximately 20 %)	References
Incidence	Decreasing	Increasing	[3]
Etiology	Smoking, alcohol abuse	Multiple sexual partners	[66, 78]
Patient age	Greater than 60	Less than 60	[79]
Site of origin predilection	None	Oropharynx	[46]
Field cancerization	Yes	Unknown	[8]
Precursor lesions	Step-wise progression of dysplasia	None identified	[59]
Histology	Keratinizing	Non-keratinizing or minimally keratinizing	[59, 66]
TP53 mutations	Frequent	Infrequent	[51]
P16 protein overexpression	Infrequent	Frequent—detectable by IHC	[64]
Chromosomal instability (CIN)	Frequent (65 %)	Infrequent	[4, 51]
Prognosis	Poor	Favorable	[46, 69]

Adapted in part from Leemans et al. [4]

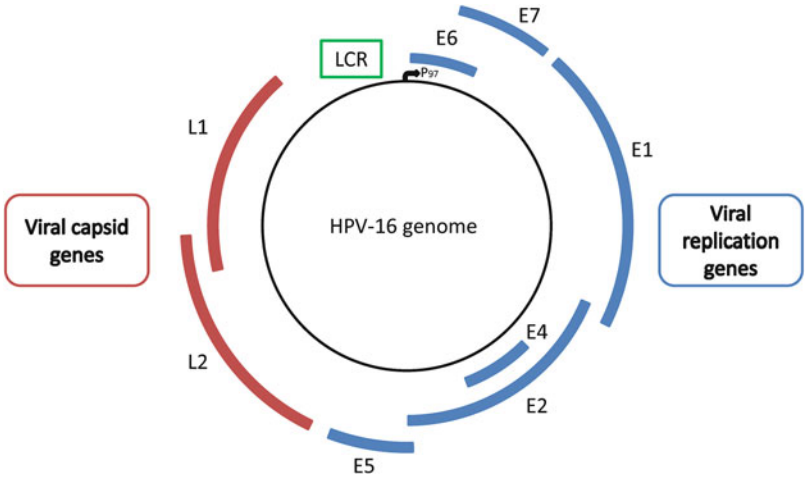

Fig. 32.3 HPV 16 genome. HPV 16, the major type of high risk HPV seen in HNSCC, has a 7904 base pair, double-stranded circular DNA genome which encodes a set of early (E1, E2, E4, E5, E6, and E7) and late genes (L1, L2) on one of the DNA strands. The viral Long Control Region (LCR) contains elements that regulate transcription and replication. P_{97} is the transcriptional promoter. The early genes are involved in viral replication while the late genes encode for the major and minor capsid proteins. E6 and E7 play a role in carcinogenesis by binding to p53 and retinoblastoma protein (pRb), respectively. Adapted from Lin et al. [48].

HPV is a circular, non-enveloped double-stranded DNA virus that is strictly epitheliotropic (preferentially infecting squamous epithelial cells). There are greater than 100 known viral subtypes and the ones known to be associated with cervical carcinogenesis have been designated as high-risk HPVs (most notably HPV-16 and HPV-18) [47]. The HPV genome is around 8000 base pairs and is organized into three regions: early region, late region, and the Long Control Region (LCR). The genome encodes at least six early genes (*E1*, *E2*, *E4*, *E5*, *E6*, and *E7*) and two late genes (*L1* and *L2*) on one strand. The early genes are responsible for regulation of viral DNA replication and the late genes encode the viral capsid [48]. The LCR does not code for viral proteins but contains replication and transcriptional control sequences that interact with viral (E1 and E2) and host proteins (Fig. 32.3) [49].

HPV infection is presumed to be via microtrauma and infection of the basal epithelial cells and in the majority of instances, infection is transient and self-limiting by the host's immune response [48]. The immature epithelial basal cells allow for expression of the early HPV genes whereas in more mature and terminally differentiated cells viral transcription shifts to the late genes which allows for release of newly formed virions away from the host's immune surveillance in the submucosa. Most often HPV remains episomal but, in some persistent infections, high risk HPVs may integrate into the host genome. With integration there is often deletion of *E2*, *E4*, *E5*, *L1*, and *L2* genes. The loss of E2, a transcriptional repressor of E6 and E7, allows upregulation of the viral oncogenes *E6* and *E7*, and their expression causes inactivation of p53 and retinoblastoma (Rb) pathways, respectively [48]. The E6 oncoprotein targets the p53 protein for ubiquitination and degradation thus disrupting the p53 pathway, which plays a role in the host's response to DNA damage (Fig. 32.4). E6 also activates telomerase which allows cells to regenerate chromosomal telomers after cell division [50]. The E7 oncoprotein inactivates pRb, an important cell cycle regulatory protein, through direct interaction (Fig. 32.5). Integration leads to disordered cell cycle regulation (genomic instability and repression of apoptosis) in the infected cells which is considered to be the mechanism of carcinogenesis [42].

Data support that HPV-positive HNSCCs form a distinct molecular entity within HNSCC based on different genetic profiles. In a case- control study of the genetic patterns found in tumors positive for HPV DNA and E6 and E7 mRNA versus tumors negative for HPV DNA and E6 and E7 mRNA, Braakhuis et al. found that the HPV DNA—E6/E7 mRNA positive tumors had less LOH than the HPV-negative tumors (14 % versus 81 %) which was statistically significant for the markers tested specifically on 3p, 9p, and 17p ($P < 0.05$). In addition, none of the HPV-positive tumors harbored mutations in *TP53* but, mutations were found in 75 % of the HPV-negative tumors ($P < 0.001$). Interestingly, cases that were HPV DNA positive but negative for E6 or E7 mRNA had similar LOH pattern and presence of *TP53* mutations as the HPV-negative group. This suggests that the E6 and E7 transcriptional activity is driving these tumors [51]. This group has shown that 77 % of dysplastic lesions (early in the carcinogenesis pathway of conventional HNSCC) exhibited LOH at 3p, 9p, and/or 17p, therefore the lack of LOH in the HPV DNA and E6 and E7 mRNA positive cases is a significant finding which supports the concept that HPV infection with E6 and E7 integration is an early and likely initiating oncogenic event [51]. In addition, the disruption of these oncoproteins

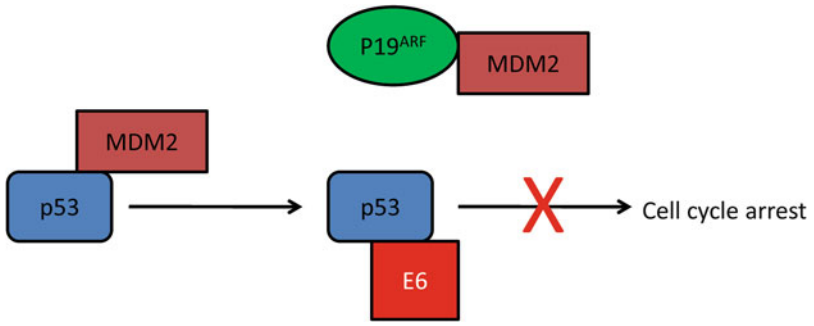

Fig. 32.4 Simplified p53 pathway [76]. p53 is a tumor suppressor which acts as a transcription factor. When bound to Mdm2, p53 in inactive and unstable. P19ARF binds Mdm2, decreasing its affinity for p53. Unbound p53 is stable and active and induces cell cycle arrest for DNA repair and if necessary, apoptosis. The E2F transcription factor in the pRb pathway binds to the promoter region of p19ARF and is a potent inducer of apoptosis through the p53 pathway. Therefore, inactivation of pRb leads to activation of p53 in the cells. The HVP oncoprotein E6 directly binds p53 and targets it for ubiquination and degradation. Thus the E7 and E6 proteins inactivate pRb and p53 pathways leading to genomic instability and repression of apoptosis.

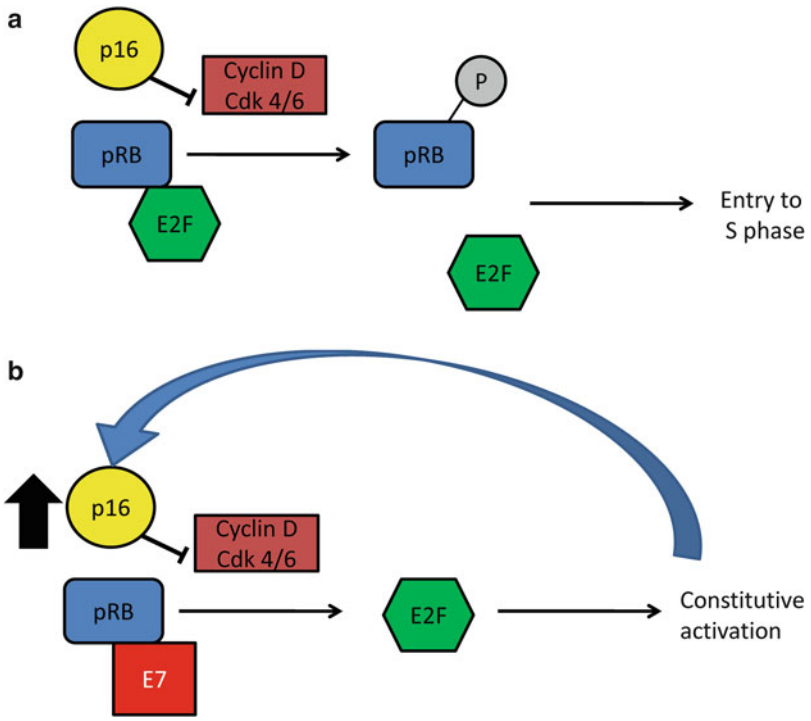

Fig. 32.5 p16-pRB pathway. (**a**) In a normal cell, p16 acts as a tumor suppressor to block the activity of the CDK4/6 Cyclin D kinase complex. This complex is responsible for increasing the phosphorylation of pRB. In the hypophosphorylated form (early G1) pRB binds the E2F transcription factor and inactivates it. In the phosphorylated state, pRb releases E2F which leads to transcription and progression into the S phase of the cell cycle. (**b**) In an HPV infected cell that has undergone viral DNA integration into the host genome, E7 binds to the E2F site on pRb, thus blocking the regulatory control of pRb leading to constitutive activation of E2F transcription. The expression of p16 is greatly increased in a futile attempt to provide negative feedback to the pathway. Adapted from Munger et al. [77].

in squamous cell carcinoma cell lines via short hairpin RNAs have resulted in increased levels of p53 and pRb and induction of apoptosis, supporting that these pathways remain intact within HPV infected tumor cells [52]. The absence of *TP53* mutations in HPV-positive tumors has also been seen by others [46, 53]. A number of other studies have demonstrated differences in gene expression between HPV-positive and HPV-negative tumors with the use of microarray comparative genomic hybridization (CGH) [13, 54, 55].

In recent years the spectrum of HPV-associated HNSCC has expanded beyond the oropharynx to include sinonasal squamous cell carcinoma and a fraction of EBV negative nasopharyngeal carcinomas. As in OPSCC, the HPV-associated sinonasal carcinomas have a favorable prognosis;

Table 32.2 Common HPV detection methods

Testing method	Targeted molecule	Tissue type	Advantages	Disadvantages	Detects biologically relevant infection	Detection method
P16 IHC	Cellular protein	FFPE	High sensitivity (100 %) Easy to assess	Low specificity (79 %)	Yes—a surrogate marker for E7 integration	SA
HPV-16 in situ hybridization	DNA	FFPE	Visualization of nuclear localization of HPV DNA Easy to assess	Lower sensitivity than TA methods	Not directly but, a punctuate signal is suggestive of viral integration	SA
RT-PCR E6 or E7	mRNA	Fresh or frozen	High sensitivity and specificity	Poor performance in FFPE Not practical for most labs	Yes—considered the "gold standard" for identifying biologically relevant infection	TA
Consensus- or type-specific PCR and genotyping	DNA	Fresh, frozen, FFPE	High sensitivity	Inter assay variation	No—cannot determine biologically relevant from transient infection or contamination	TA
Real-time PCR	DNA	Fresh, frozen, FFPE	High sensitivity and specificity	Requires tissue microdissection	No but gives an estimate of viral load. Copy number >1 viral genome per cell is highly specific for biologically relevant HPV infection	TA

Adapted from Robinson et al. [62]
IHC immunohistochemistry, *FFPE* formalin-fixed paraffin-embedded tissue, *SA* signal amplification, *TA* target amplification, *PCR* polymerase chain reaction, *RT-PCR* reverse transcriptase PCR

the clinical significance of HPV in nasopharyngeal carcinomas is not yet known [56–59].

The 2005 World Health Organization (WHO) classification of HNSCC is principally based on histologic pattern and degree of differentiation [60]. Lewis and Chernock make the compelling argument that because much has changed in our understanding of HNSCC this should be reflected in the anticipated revised WHO classification. In particular, HPV-associated OPSCC have a different etiology and prognosis than conventional HNSCC, and deserve to be considered separately [59].

32.3.1 Detection of HPV in HNSCC

A number of methods have been used to detect HPV in HNSCCs (Table 32.2) and studies reporting on the prevalence of HPV-positive tumors ranges from 14 to 72 %, most likely because of differences in the sites of origin and in HPV detection methods used in various studies [61]. More likely, approximately 20 % of HNSCCs contain transcriptionally active (i.e. integrated) HPV [4]. The choice of detection method is dependent on the type of specimen available (fresh/frozen, formalin-fixed, paraffin-embedded (FFPE), fine needle aspiration (FNA), or cytology), the preservation of the target molecule (protein, DNA, RNA), the desire to detect a broad group of DNA types or target a specific genotype. The detection methods are based on either target amplification techniques (PCR based) or signal amplification using chemical or colorimetric indicators [62]. For an HPV test to be useful in routine clinical diagnostic practice it needs to be reliable at classifying HPV-driven tumors (clinically sensitive and specific), reproducible, subject to standardization and quality assurance and be economically feasible for the laboratory [62].

Polymerase chain reaction (PCR) is a technique that is able to amplify specific rare DNA sequences in a background of diverse DNA molecules. It is a qualitative technique and therefore provides no quantitative information about the target DNA. Because of its high analytical sensitivity it may provide false-positive results. In the case of HPV testing in HNSCC, a positive result does not distinguish among DNA integrated into the host genome (i.e. biologically significant), a transient infection or a contaminated specimen. Consensus PCR using GP5+/6+ primer sets, directed to the L1 gene which encodes the major capsid protein, is commonly used [63]. Consensus PCR products can then be genotyped by a variety of methods including a linear array assay and reverse line blotting [64, 65].

Real-time PCR can amplify HPV genotype-specific sequences, compare them to the amplification of an endogenous control gene such as β-globulin and provide quantitative measurement of the viral copy number per cell number analyzed. Smeets et al. have found that a copy number of >1 viral genome per cell is highly specific for biologically relevant infection [64].

In situ hybridization (ISH) for high risk HPV is performed on glass slides with bright-field microscopy and provides a visual determination of the signal localization to the infected cell nucleus. A punctuate nuclear staining pattern is highly suggestive of viral integration into the host genome as opposed to a more diffuse pattern seen with episomal (non-integrated) virus [66]. Two ISH testing strategies are available using either genotype-specific probes (HPV-16 or HPV16/18) or a high-risk HPV probe cocktail [63].

It has been proposed that p16 overexpression, which is detectable by IHC, can be used as a surrogate marker for HPV

DNA integration into the host genome (Fig. 32.1c) [67]. In one study, this method had 100 % sensitivity in screening for transcriptionally active infection. However, there are HPV independent pathways that can drive oncogenesis and lead to increased p16 expression so the specificity was only 79 % [64]. A significant benefit of the p16 IHC is that, unlike some in situ assays, it is not specific to HPV type.

The National Comprehensive Cancer Network (NCCN) and the College of American Pathologists (CAP) recommend routine HPV testing for all oropharyngeal squamous cell carcinomas (OPSCCs). At this time there are no guidelines for the best testing strategy for determination of HPV status in HNSCCs. However, the College of American Pathologists has developed a work group with this focus. Two diagnostic algorithms have recently been proposed. The first utilizes p16 IHC followed by HPV DNA (using the GP5+/6+ primers) detection with a polymerase chain reaction (PCR) amplification technique. This method was validated for formalin-fixed paraffin-embedded (FFPE) biopsy samples by comparing with HPV E6/E7 mRNA in matched frozen tissue samples [64]. HPV E6/E7 mRNA is considered the reference test of choice or the gold standard for transcriptionally active and biologically significant HPV infection. Although more reliable than standard PCR for HPV DNA (which can have false-positives), reverse transcriptase (RT)-PCR assays for E6 and E7 transcripts do not work well in FFPE tissue specimens.

The second algorithm utilizes p16 IHC followed by in situ hybridization (ISH) for HPV DNA [68]. This algorithm has been clinically validated as an independent prognostic marker through its use in clinical trials and epidemiological studies [63, 69].

Most pathologists and oncologists agree on the importance of testing OPSCCs for high-risk oncogenic HPV because this provides prognostic information and in the future may be used in treatment decision making. In addition, in patients with metastatic HNSCC of unknown origin, a positive HPV status could direct the search for the primary tumor to the oropharynx [62].

32.4 Standard Treatment and Targeted Therapeutics

A majority of patients with HNSCC present with locally advances stage III or IV cancer that is usually treated with a combination of chemotherapy, radiation, or surgery. In general, two approaches are taken: either (1) induction chemotherapy (cisplatin is the first choice) followed by radiation therapy or (2) concurrent chemo-radiotherapy [70]. Patients who present with earlier stage I or II disease are most often treated with radiation or surgery and have an excellent prognosis although they are still at risk for local recurrence or second primary tumors [71].

Anti-EGFR monoclonal antibodies (mABs), which specifically recognize the extracellular ligand-binding domain of EGFR, are clinically being used in patients with HNSCC. But, there are currently no validated testing methods for selecting patients likely to respond to EGFR targeted therapies. Bonner et al. demonstrated in a phase III study, significant survival benefit (from 29.3 to 49.0 months) and local-regional control (from 14.9 to 24.4 months) with the addition of cetuximab (Erbitux) to radiation therapy in patients with stage III and IV HNSCC [14]. Based on these result, additional monoclonal antibodies (panitumumab and matuzumab) are being used in clinical trials. In 2006, the U.S. Food and Drug Administration (FDA) approved cetuximab for use in combination with radiation therapy (RT) for the treatment of locally or regionally advanced HNSCC or as a single agent in patients with recurrent or metastatic HNSCC who had failed platinum-based therapies.

The small-molecule EGFR tyrosine kinase inhibitor (TKI) erlotinib (Tarceva) bind to the receptor's intracellular ATP-binding site, thus inhibiting autophosphorylation. In lung cancer, TKIs have been shown to have higher affinity for the TK domains in mutated EGFR, thus in HNSCCs, which rarely have EGFR activating mutations, and TKIs may be less effective than mABs [72]. However, TKIs are actively being studied as targeted therapies in HNSCC and phase I and II trials have demonstrated a modest increase in progression-free and overall survival [51, 52]. A phase III trial of gefitinib compared to methotrexate for recurrent HNSCC did not show improved survival compared to methotrexate [72]. Additional clinical trials are needed to further elucidate the therapeutic prospects of TKIs in HNSCC.

The EGFRvIII variant is another possible target for therapy. EGFRvIII is the result of the deletion of amino acids 6-273 in the EGFR extracellular domain which leads to a reduced affinity to mABs. Targeted immunotherapy for the EGFRvIII is currently in development for glioblastomas. If immunotherapy is shown to be applicable to HNSCC, this would be a promising therapeutic target for cetuximab-refractory tumors that express EGFRvIII [72].

The anti-VEFF mAb, bevacizumab is another agent being evaluated in clinical trials that has shown some efficacy in HNSCC. Phase I and II trials of bevacizumab in combination with anti-EGFR agents, pemetrexed and chemoradiation have shown some promising results and phase III trials are underway [73, 74]. Additional promising targeted therapeutic agents include lapatinib (a selective dual inhibitor of both EGFR and HER2 TKs), sunitinib (a TKI that targets RET, VEGFR, PDGFR, and KIT), cediranib (selective inhibitor of VEGF signaling), bortezomib (the first proteasome inhibitor selected for development as an anti-cancer agent), figitumumab, and cixutumumab (insulin growth factor receptor (IGF-1R) mAbs) [73].

TP53 gene therapy is another fascinating treatment modality that is being investigated in HNSCC. Advexin, which is an adenovirus that enters the cell via a cytomegalovirus promoter, delivers a functional wild-type *TP53* gene into the tumor cells, thus triggering growth arrest and/or apoptosis leading to tumor inhibition and necrosis. The therapy is delivered via injection to the tumor site and is well tolerated with flu-like symptoms being the most common side effect. Although this form of gene therapy is associated with tumor response, it has not yet been shown to improve patient survival [73]. Studies of the use of such agents combined with other targeted therapies and chemoradiation therapy are ongoing.

Currently, despite the prognostic benefit of HPV-positive tumors, there are not different treatment regimens being utilized for HPV-positive versus HPV-negative tumors. Ang et al. in a retrospective study of patients with stage III or IV oropharyngeal squamous cell carcinoma (SCC) treated with radiation and combined cisplatin, were able to classify these patients into low, intermediate, or high risk of death based on tobacco use, stage, and HPV status. HPV status was an independent prognostic factor for survival in these patients [69]. Several current de-escalation clinical trials are underway trying to evaluate if current treatment paradigms need to be altered based on HPV status to reduce the acute and chronic treatment related morbidity. Several approaches are currently being evaluated including replacing cisplatin with cetuximab to reduce toxicity. RTOG 1016 (NCT01302834) is one such phase III trial involving p16 positive OPSCC patients randomized to weekly cetuximab or cisplatin with concurrent accelerated intensity-modulated radiation therapy. The trial enrolment has been completed but provisional data will not be available for several years. Another approach is induction chemotherapy followed by decreased chemo-radiotherapy dose in good responders. ECOG-1308 (NCT01084083) is a phase II trial that includes induction chemotherapy (cisplatin, paclitaxel, and 90 cetuximab) followed by low dose (54 Gy) or standard dose (70 Gy) radiation therapy with cetuximab, dependent on response to induction chemotherapy. Preliminary results for this trial show that a favorable response to induction chemotherapy may identify a group of HPV+ patients with a low 1-year failure rate with the lower radiation dose. The third approach to de-escalation therapy includes surgical resection with or without adjuvant chemo-radiotherapy randomized based on histopathology features (such as extra nodal extension). The excellent article by Masterson et al. provides a more extensive review of current de-escalation protocols for HPV-associated OPSCC [75].

In the next several years, we can expect that clinical trials, epidemiologic observations about tumor HPV status and smoking history and ongoing genomic research will lead to a more molecular-based classification of HNSCC and a better understanding of targeted therapies and biomarkers that will drive more individualized therapies for HNSCC patients.

Ovarian Cancer

33

Amy D. Brockmeyer and Louis Dubeau

33.1 Introduction

Ovarian carcinomas account for more deaths annually than any other gynecological cancer in the US. More than twice as many women die of ovarian cancer than endometrial cancer in spite of the fact that cancer of the endometrium is more frequent than that of the ovary. The 5 years survival of patients affected by these tumors has improved only modestly, from 45.4 to 48.6 % during the last two decades [1]. The high mortality associated with ovarian carcinomas is due largely to the hidden anatomical location of the ovaries, which complicates the detection of abnormalities on physical examination, and the fact that these tumors typically remain asymptomatic until they spread outside the ovary, at which time they are difficult to eradicate. Hopefully, advances in our understanding of the histogenesis of ovarian epithelial tumors as well as of their underlying molecular mechanisms will lead to more effective strategies aimed at their early detection and prevention. This, in turn, should have a major impact on the morbidity and mortality associated with these tumors.

The majority of ovarian tumors are epithelial (carcinomas). Tumors of this organ that are derived from other cell types, such as germ cell tumors, stromal tumors, and others, share little in common with those of epithelial origin and will not be addressed in this chapter.

33.2 Classification of Ovarian Epithelial Tumors

Ovarian epithelial tumors are a heterogeneous group that comprises several histological subtypes. Basic knowledge of the most common subtypes is essential to understand issues related to their cell of origin, risk factors, and other biological characteristics.

33.2.1 Histological Classification

The four most frequent subtypes of ovarian carcinomas as well as their distinctive morphological features and are shown in Table 33.1. The question of whether or not these different lesions share a common cell of origin has been the subject of debate among pathologists for several decades. Differences in the risk factors, clinicopathological characteristics, and molecular genetic features of individual subtypes suggest that they are distinct disease entities. However, the fact that different subtypes occasionally co-exist, resulting in mixed lesions that show features of two or more subtypes adjacent to each other within the same tumor mass, provides a strong argument that they are related.

An intriguing characteristic shared by the major subtypes of ovarian epithelial tumors is their resemblance to tumors that originate in other organs of the reproductive tract (Table 33.1). Serous ovarian carcinomas are morphologically similar to tumors arising in the fallopian tubes. This resemblance is so striking that pathologists have agreed several decades ago not to attempt to determine the exact origin of large serous tumors involving both the ovary and the fallopian tubes. It is by pure convention that these tumors are labeled as ovarian, except in rare cases where an origin from the tubes can unequivocally be demonstrated. Endometrioid ovarian carcinomas are morphologically identical to carcinomas arising in the endometrium. Here again, the striking resemblance has led to diagnostic dilemmas related to the fact that when an endometrioid ovarian tumor coexists with

Table 33.1 Most common subtypes of ovarian carcinomas

Name	Frequency (%)	Morphological features of well differentiated lesions	Segment of the reproductive tract with similar features
Serous	50	Columnar cells with a prominent ciliated border that often form finger-like projections around a fibro-vascular core (papillae) within the inner lining of cysts filled with serous fluid	Fallopian tube and other extra-uterine Müllerian tissues
Endometrioid	25–30	Glandular structures lined by low columnar cells that may be filled with bloody material	Endometrium
Mucinous	10–15	Columnar cells filled with clear mucus pushing cell nucleus toward the basal pole; typically forming complex cystic structures	Endocervix
Clear cell	5	Low columnar to cuboidal cells with clear cytoplasm and hobmail appearance; often forms small glandular structure or solid nests	NA
Others	<5	Heterogeneous group that includes tumors so poorly differentiated that their exact lineage cannot be determined as well as rare subtypes such as tumors showing features of transitional epithelium (malignant Brenner tumor) and others	NA

an endometrial tumor in the same patient, it is not possible to determine whether the ovarian tumor represents a primary lesion or a metastasis from the endometrial lesion. Mucinous ovarian carcinomas are identical to endocervical carcinoma. Clear cell carcinomas are identical to the clear cell variant of endometrial carcinomas. The observation that ovarian carcinomas are similar to tumors arising in these other sites of the reproductive tract is not based solely on morphological arguments, as recent studies have shown that the profile of homeobox genes expressed in serous, endometrioid, and mucinous ovarian carcinomas is similar to that expressed in tumors of the fallopian tubes, endometrium, and endocervix, respectively [2]. This phenomenon has implications regarding the site of origin of ovarian epithelial tumors.

33.2.2 Toward a Molecular Classification of Ovarian Carcinoma Subtypes

There are several examples of molecular genetic alterations in ovarian epithelial tumors that are strongly associated with specific tumor histological subtypes. For example, genetic factors associated with familial ovarian carcinoma predisposition are subtype-specific. Indeed, mutations in BRCA1 or BRCA2 are associated with strong predisposition to serous ovarian carcinomas but not with any of the other tumor subtypes. Germline mutations in DNA repair enzymes leading to microsatellite instability are associated with endometrioid ovarian carcinomas. In addition, specific somatic mutations are more common in certain subtypes of ovarian carcinomas than others. The association of PTEN mutations with endometrioid tumors [3, 4] and the more frequent (although not exclusive) presence of K-RAS or B-RAF mutations in mucinous and serous tumors [5–9] are additional examples. Mutations in ARID1A, a gene encoding a key component of the SWI–SNF chromatin remodeling complex called BAF250a, are associated with endometrioid and clear cell ovarian carcinomas but not with serous ovarian carcinomas [10]. These differences underscore the importance of not lumping different ovarian carcinoma subtypes as if they represented a single entity in research studies.

The development of analytical tools to examine global expression profiles over the last decade has allowed investigators to compare the spectrum of gene expression in different subtypes of ovarian epithelial tumors. Not surprisingly, the current data suggests fundamental differences in the expression profile of each major ovarian epithelial tumor subtype [11–14]. As more data accumulates, it might be possible to identify panels of markers specific for individual subtypes that might assist pathologists in the diagnosis of poorly differentiated ovarian tumors. This could be valuable in ruling out, for example, tumor subtypes associated with a less favorable prognosis such as clear cell carcinomas. In addition, profiling studies comparing tumors from patients with rapid clinical course to those from patients with more favorable outcomes suggest that panels of markers could be developed and used as predictors of clinical aggressiveness or therapeutic response independent of classical predictors such as tumor stage or grade [15, 16]. Finally, these studies could provide important clues about cell lineage derivation and histogenesis. For example, the expression profile of clear cell carcinoma of either the endometrium or the ovary was reported to be remarkably similar to that of clear cell carcinomas of the kidney [14]. This is interesting in light of the fact that the embryological origin of much of the reproductive tract is related to renal development.

33.3 Risk Factors for Ovarian Epithelial Tumors

Knowledge of genetic and environmental factors associated with predisposition to a specific cancer type can provide insight into the mechanisms underlying its development. This is particularly true of ovarian epithelial tumors, where strong predisposing factors have been well established.

33.3.1 Reproductive Factors

Most ovarian cancers occur sporadically, without evidence of genetic predisposition. Ovulation is the most well established risk factor for the sporadic form of these cancers [17, 18]. Interruption of ovulatory activity protects against the development of this disease independently of whether such interruption is achieved through pregnancy or oral contraceptives, although there is evidence of late pregnancies being more protective than earlier ones. For example, use of oral contraceptives for 5 years results in an approximately 40 % decrease in lifetime ovarian cancer risk, which is similar to the protective effect of five pregnancies after the first [19].

An initial explanation for the association between ovulation and ovarian cancer predisposition was based on the notion that these tumors originate in the coelomic epithelium lining the ovarian surface. Fatallah [20] reasoned over four decades ago that the chronic breakage and repair of the ovarian surface epithelium that results from monthly releases of the egg might lead to predisposition to malignant transformation of this epithelium (the incessant ovulation hypothesis). This hypothesis seemed attractive given the known association between cancer predisposition and cellular proliferation, one of the consequences of chronic repair. However, it fails to provide a comprehensive explanation for the current epidemiological data. For example, the disproportionately increased protective effect of late pregnancies compared to early pregnancies, as well as the progressive rise in ovarian cancer incidence after menopause, cannot be readily accounted for by the incessant ovulation hypothesis [17, 18]. Although the incessant ovulation theory is still widely quoted, a currently more favored hypothesis stipulates that it is the hormonal changes associated with the normal menstrual cycle that may have a lasting effect on predisposition of the cell of origin of ovarian epithelial tumors to neoplastic transformation. Estradiol, which is unopposed during the first half (follicular phase) of the menstrual cycle, stimulates growth of benign and malignant ovarian epithelial tumor cells in vitro, while progesterone, which is elevated during the second half (luteal phase) of the cycle, inhibits the growth of the same cells [21]. The fact that pituitary gonadotropins, which have high circulating levels around menopause, stimulate the growth of ovarian epithelial tumors in vitro suggests that hormonal changes associated with menopause may also play a role [21]

It is possible that each follicular phase of the menstrual cycle, characterized by unopposed estrogen stimulation and by elevated levels of follicular stimulating hormone, favors growth stimulation. Such stimulation may be accentuated at the end of the follicular phase due to the rapid surge in levels of luteinizing hormone that triggers ovulation. Each luteal phase, in contrast, is characterized by growth inhibition due to increased levels of progestins. This scenario of growth stimulation followed by growth inhibition might contribute to the increased risk of tumor development in women with uninterrupted menstrual cycles. The protective role of either pregnancy or oral contraceptive could, in turn, be partly due to the interruption of such a scenario. Alternatively, a study examining the long-term effects of oral contraceptives in macaques suggested that the direct action of progestins is primarily responsible for the protective effects of oral contraceptives [22].

Another explanation for the association between ovulation and ovarian cancer risk is known as the stromal hyperactivity hypothesis, which stipulates that although most ovarian follicular cells undergo apoptosis following release of the egg and the ensuing luteinization period, some may persist and retain their hormone-producing ability [23]. This would result in accumulation of steroid producing cells proportionate to the number of lifetime ovulations. Indeed, the basal levels of circulating estradiol were higher in premenopausal women with a greater lifetime number of ovulatory cycles in a longitudinal study [23].

In a recent population-based case-control study involving 477 patients with ovarian epithelial tumors and 660 controls, there was a 51 % reduction in risk of developing ovarian cancer in women who had given birth after the age of 35 compared to nulliparous women. Although prior births further reduced the risk, the magnitude of the protective effect of an early pregnancy was less than that of a pregnancy occurring after age 35 [17]. These observations underscore the complexity of the link between ovulatory activity and risk of sporadic ovarian cancer, which may in fact be the net result of several factors. In that regard, a role for androstenedione, which is the major ovarian hormone after the menopause and is suppressed by oral contraceptives, has also been suggested [24]. A role for this hormone is further supported by the fact that its circulating levels were found to be higher in the serum of patients with ovarian cancer compared to that of matched controls [25].

33.3.2 Inflammatory Factors

Although reproductive factors associated with the menstrual cycle are by far the strongest risk determinants of ovarian cancer, a role for inflammation has also been suggested [26]. Application of talc on the perineal area has consistently been associated with increased risk of ovarian cancer. Inflammatory conditions such as pelvic inflammatory disease have also been associated with such increase [27–32]. The association between endometriosis and endometrioid ovarian carcinoma [26, 33–38] is often regarded as further support for a role of inflammation in ovarian cancer predisposition, but this association can also be explained by the hypothesis that ovarian epithelial tumors arise in components of the secondary

Müllerian system. However, the apparent association between pelvic inflammatory diseases not involving endometriosis and ovarian cancer risk [39, 40], as well as the evidence for a protective effect of anti-inflammatory drugs [41–44] provide further support for the notion that inflammation can influence the risk of ovarian cancer.

33.3.3 Smoking

Multiple studies have linked cigarette smoking with risk of mucinous ovarian cancer, but not of other ovarian cancer subtypes [45–47]. This parallels the reported effect of smoking on histologically similar cancers of both the gastrointestinal tract and cervix. The proposed mechanism of carcinogenesis is a combination of direct DNA damage by carcinogens in cigarette smoke and the ability of these carcinogens to accumulate in mucin-secreting cells. Interestingly, not only is smoking not shown to increase serous or endometrioid cancer rates, but also it has been shown to decrease the relative risk of clear cell ovarian cancer. This suggests that the mechanism of carcinogenesis may be different for mucinous cancer than for other ovarian epithelial tumor types and may be more related to environmental carcinogens than to hormonal influences, as smoking is known to lower circulating estrogen levels.

33.3.4 Diet

The influence of diet has also been studied as it pertains to ovarian cancer. Data regarding the role of dietary saturated fat is controversial. One retrospective study showed an increased risk of mucinous tumors in women with diets high in saturated fats [48] while another large study found only a weakly positive, non-linear association between ovarian cancers of all subtypes and no difference for the mucinous subtype [49]. Although milk consumption and, more precisely, consumption of galactose, which is high in countries with elevated risks of ovarian carcinoma, has been proposed as a risk factor for this disease, recent data could not confirm this association, including in individuals with a functional polymorphism in an enzyme involved in galactose metabolism [50–52].

33.3.5 Genetic Factors

Approximately 15 % of all ovarian carcinomas are familial [53]. Almost all of these cases are due to germline mutations in the BRCA1 or BRCA2 genes, which are also associated with hereditary breast cancer. Approximately 40 % of women carrying a germline BRCA1 mutation will develop ovarian cancer in their lifetime while the risk for BRCA2 mutation carriers is about 20 % [54–60]. Given that the risk of ovarian cancer in the general population is only 1.7 %, cancer-causing mutations in either one of these two genes are highly penetrant. The only major subtype of ovarian epithelial tumors that has a well-defined familial component other than serous tumors is endometrioid. These tumors, which are often associated with microsatellite instability due to replication error repair deficiencies, are the fourth most common cancer type associated with the HNPCC syndrome [61].

Although the isolation of the BRCA1 gene more than a decade ago [62] raised hopes that elucidation of its biological function would shed light on the mechanisms underlying ovarian (as well as breast) cancer development, little progress has been made to date in spite of extensive data on the cellular function(s) of this gene. Part of the difficulty comes from the fact that although BRCA1 influences a large number of cellular functions potentially important in controlling cancer development, there is little insight into which function is most closely associated with familial cancer. The fact that the *BRCA1* locus is associated with several splice variants, with at least one, IRIS, possibly showing effects that are opposite to those of the full-length BRCA1 protein, complicates this issue further [63].

Individuals with germline BRCA1 mutations are predisposed almost exclusively to cancers of the breast and ovaries in spite of the fact that this gene product is expressed ubiquitously in most cell types. Cellular processes associated with the full-length BRCA1 nuclear protein that are often invoked as potentially underlying the alleged tumor suppressor function of this protein include cell cycle regulation, regulation of apoptosis, DNA repair, chromatin remodeling, transcriptional regulation, X chromosome inactivation, and post-translational modification [64–68]. These are global processes important in most cells. Thus, if any of these processes were primarily responsible for cancer predisposition in mutation carriers, the resulting cancers would be expected to affect a large number of cell types. Thus, current knowledge of the normal function of BRCA1 is difficult to reconcile with the site specificity of the tumors that develop in mutation carriers. This, plus the fact that BRCA1 mutations are rare in the sporadic form of ovarian cancer, suggests that this gene may act indirectly, perhaps by controlling cells that are not direct precursors, but that nevertheless influence the cells of origin of ovarian tumors.

It is with this idea in mind that Chodankar et al. [69] hypothesized that loss of BRCA1 function could influence ovarian tumorigenesis cell non-autonomously, by disrupting interactions between cells that control the menstrual cycle, the most important risk factor for sporadic ovarian carcinoma, and cells from which ovarian epithelial tumors originate. Given the central role of granulosa cells in regulating progression through the normal menstrual cycle, plus the fact that these cells secrete a variety of hormones such as estradiol,

Müllerian inhibiting substance, and others that are known to influence ovarian cancer cell growth in vitro, these authors used the *cre-lox* system to inactivate the *Brca1* gene in mouse granulosa cells specifically. The mice indeed developed benign tumors that were clearly of epithelial origin (as opposed to an origin from granulosa cells) in strong support of a cell non-autonomous mechanism. Although it is not clear whether a similar mechanism is also applicable to humans, these results strongly suggest that ovarian cancer predisposition in BRCA1 mutation carriers is due, at least in part, to decreased BRCA1 expression in ovarian granulosa cells, thereby disrupting control mechanisms that these cells exert on the cells from which ovarian epithelial tumors originate. The finding by Hu et al. [70] that down-regulation of BRCA1 in primary cultures of human granulosa cells results in increased expression of aromatase, the rate-limiting enzyme in estradiol biosynthesis, is well in line with this hypothesis. It is not clear whether the same mechanism is also responsible for breast cancer predisposition in BRCA1 mutation carriers. The fact that ovulatory activity, which is largely controlled by ovarian granulosa cells, has a strong influence on sporadic breast cancer predisposition in addition to ovarian cancers suggests that the mechanisms of predisposition to breast cancer in mutation carriers could indeed be similar. This idea is further strengthened by the demonstration that oophorectomy can protect against breast cancer in BRCA1 mutation carriers [71].

33.3.6 Potential Link Between Genetic and Reproductive Risk Factors

Another intriguing aspect of the genetic risk factors for ovarian carcinoma is that BRCA1 and BRCA2 are rarely abnormal in the sporadic form of this disease. A possible explanation that would also account for the site specificity of the tumors that develop in BRCA1 and BRCA2 mutation carriers is that inactivation of either one of these two genes might amplify the effects of risk factors for sporadic ovarian carcinoma. It is possible, for example, that such mutations could result in slight alterations in the dynamics of the menstrual cycle by increasing the length of the follicular phase resulting in increased estrogen stimulation unopposed by progesterone. The net result would be an amplification of the consequences of the menstrual cycle on ovarian cancer risk. The fact that pregnancy or oral contraceptive use, both of which have a strong protective effect against sporadic ovarian cancer, are also protective in BRCA1-2 mutation carriers [72, 73] is supportive of this idea. Hong et al. [74] tested this hypothesis by measuring the relative lengths of the different phases of the estrus cycle in mice harboring a Brca1 mutation in their ovarian granulosa cells and showed that indeed, the average length of the proestrus phase, which corresponds to the follicular phase of the human menstrual cycle, was longer than in wild type littermates. In addition, circulating levels of estradiol were higher in mutant mice than in wild type following inoculation of gonadotropins. They concluded that mice carrying a Brca1 mutation had both increased and prolonged estrogen stimulation unopposed by estrogen, raising the possibility that similar changes are also present in human BRCA1 mutation carriers [74].

33.4 Origin of Ovarian Epithelial Tumors

A fascinating aspect of ovarian cancer research is the persisting debate among scientists as to where and from which cell type these tumors actually originate. An answer to this fundamental question is essential to the understanding of the biology of the normal counterpart of these tumors, of the risk factors for this disease, and to the development of effective protective measures. This is also important for the identification and characterization of ovarian carcinoma precursor lesions and for the development of strategies aimed at their early detection.

33.4.1 Origin of the Theory That Ovarian Epithelial Tumors Arise in the Coelomic Epithelium

It has been widely accepted for the most part of the last century that ovarian epithelial tumors arise from the single mesothelial cell layer that lines the ovarian surface, which is also called ovarian surface epithelium [75]. This cell layer is also called coelomic epithelium because it is continuous with and identical to the mesothelial cell layer that lines all pelvic and abdominal surfaces. It was once believed, in the early part of the last century, that various cell types present in the normal mature ovary, including follicular and germ cells, were embryologically derived from the portion of the coelomic epithelium that lines the ovarian surface. It is for this reason that this cell layer was named germinal epithelium, a name that continues to be used today. The idea that ovarian epithelial tumors arose from this cell layer was attractive given such an alleged role in ovarian development. It is now well established that germ cells do not form from the coelomic epithelium and although the exact origin of ovarian follicular cells continues to be debated, there are strong morphological, functional, and molecular arguments that they are of mesonephric origin [76]. It is intriguing that although the original embryological arguments that led to the development of the theory that ovarian carcinomas originated in the overlying coelomic epithelium are no longer valid, this theory persisted, probably due to delays in the formulation of an alternative hypothesis.

33.4.2 Issues Relevant to the Identification of the Cell of Origin of Ovarian Epithelial Tumors

33.4.2.1 Morphological Arguments

Several histological observations cannot be readily accounted for by the idea that ovarian epithelial tumors are derived from the coelomic epithelium. First, this cell layer rarely, if ever, shows pre-neoplastic changes. Although a handful of microscopic cancers have been described in the coelomic epithelium lining the ovarian surface, these are extremely rare and an origin from the fallopian tubes or other components of the Müllerian tract is difficult to rule out. Second, and even more compelling, ovarian epithelial tumors do not resemble mesotheliomas, which is what would be expected if they originated from the coelomic epithelium, but are similar to epithelial tumors arising from other organs of the female reproductive tract as already pointed out (Fig. 33.1, Table 33.1). The fact that the most common ovarian epithelial tumor subtypes resemble tumors originating in either fallopian tubes, endometrium, or endocervix is intriguing because not only do these other components of the reproductive tract share a common embryological origin that is different than that of the ovary, but there are also no normal cells resembling either fallopian tubes, endometrium, or endocervix within normal ovaries. If ovarian carcinomas indeed arose from the ovarian surface, they would be the only example of somatic tumors that are better differentiated than their cell of origin.

33.4.2.2 Embryological Arguments

The fallopian tubes, endometrium, and endocervix all share a common embryological origin that is distinct from that of the ovaries. They are derived from two ducts, called Müllerian ducts, which are completely separate from each other initially as they develop adjacent to the ureters of the mesonephros, which is the functioning kidney of the embryo. It is because of the close association with this renal system that the Müllerian ducts are also called paramesonephric. The distal portions of the two Müllerian ducts converge and eventually fuse in the midline during fetal development. It is this fused segment that develops into the upper third of the vagina,

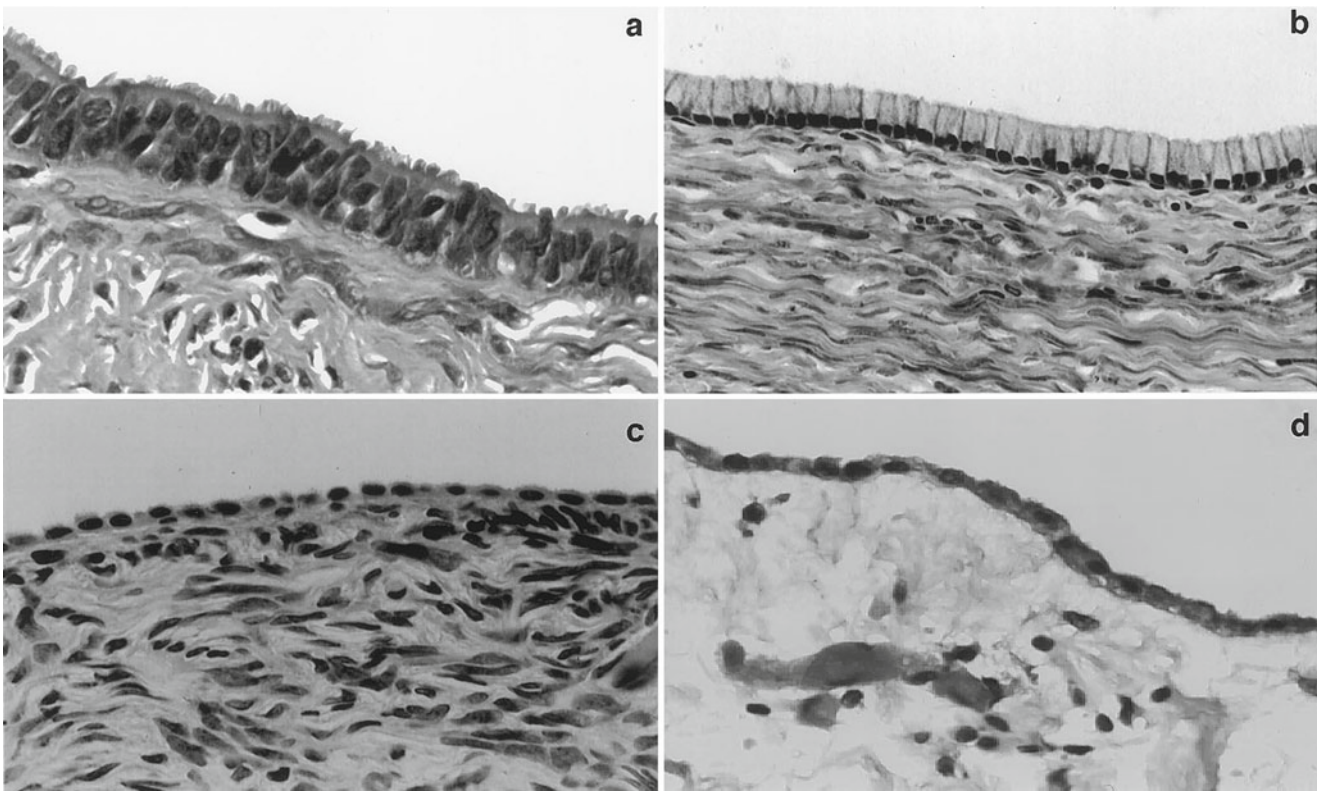

Fig. 33.1 Morphological comparison between the ovarian surface epithelium, serous or mucinous cystadenomas and peritoneal mesothelium. Photographs of benign tumors are shown because they better illustrate the morphological features of interest due to better differentiation. (**a**) Serous cystadenoma characterized by tall columnar cells with prominent cilia. Such cells are reminiscent of the epithelial cells lining normal fallopian tubes. The mucin-secreting cells lining the mucinous cystadenoma shown in (**b**) are reminiscent of cells lining normal endocervix. The differences between the epithelial lining of these two cystadenoma subtypes and that of the ovarian surface (**c**) are readily apparent. The morphological characteristics of cells lining normal ovarian surface epithelium, which are flat to low cuboidal, are much closer to those of the cells lining the abdominal peritoneum shown in (**d**). (Reproduced from Gynecol Oncol vol 72, p. 438, 1999 with permission).

the exocervix and endocervix, and the body of the uterus. The proximal portions of the Müllerian ducts remains unfused, giving rise to the fallopian tubes. In the adult, the epithelial lining of the exocervix and upper vagina is replaced by squamous epithelium derived from the lower vagina. The epithelial linings of the endocervix, endometrium, and fallopian tubes form a continuum, with gradual transitions but no sharp boundaries between those different organs. It is puzzling how the ovary, which is not derived from the Müllerian ducts, could give rise to tumors identical to tumors of Müllerian origin.

33.4.2.3 Molecular Biological Arguments

The notion that ovarian epithelial tumors resemble tumors derived from the Müllerian tract is not only supported by morphological arguments. Cheng et al. [2] studied the expression status of genes involved in body segmentation and morphogenesis in different components of the female reproductive tract. Expression of individual members of this gene family, called HOX genes, is highly specific for different body segments. These authors showed that ovarian surface mesothelium, fallopian tube epithelium, endometrium, and endocervix each expressed a different set of HOX genes. When they examined the expression status of these genes in different subtypes of ovarian epithelial tumors, they found that serous ovarian carcinomas expressed the same set of HOX genes expressed in normal fallopian tube epithelium. Likewise, endometrioid ovarian carcinomas expressed the same set of HOX genes as normal endometrium and mucinous ovarian carcinomas had a HOX gene expression profile similar to that of the endocervix. These results are highly supportive of the idea that these different ovarian tumor subtypes originate in Müllerian epithelium as opposed to the coelomic epithelium.

33.4.2.4 Primary Peritoneal Tumors

Hypotheses about the origin of ovarian epithelial tumors must take into account the fact that tumors that are histologically and clinically indistinguishable from ovarian carcinomas can arise outside the ovary. Such tumors, which are often referred to as primary peritoneal carcinomas, are confined to women and may be seen in individuals in whom the ovaries were removed several years ago for reasons other than cancer.

33.4.3 The Coelomic Epithelium Hypothesis

The idea that ovarian epithelial tumors arise from the portion of the coelomic epithelium that lines the ovarian surface is still favored by many in spite of the arguments discussed. Proponents of this theory account for the fact that these tumors have morphological and molecular features characteristic of Müllerian tumors by stipulating that the coelomic epithelium is not the direct precursor of ovarian tumors, but must first change into Müllerian-like epithelium through a process known as metaplasia. According to this theory, it is the rich hormonal environment of the ovary that triggers such changes. It is further hypothesized that this is most likely to happen in portions of the coelomic epithelium that have invaginated within the ovarian parenchyma, resulting in the formation of small cystic structures referred to as inclusion cysts. This readily accounts for the fact that benign ovarian epithelial tumors as well as most carcinomas are cystic in nature. This theory also accounts for the observation that small cysts within the ovary are often lined by cells with features suggestive of Müllerian differentiation while such features are extremely rare on the ovarian surface itself. Finally, proponents of this theory account for the presence of primary peritoneal tumors by stipulating that the hormonal environment in fertile women can trigger Müllerian metaplasia in coelomic epithelial cells away from the ovary in addition to cells on or within the ovary.

33.4.4 The Müllerian Hypothesis

There is little evidence that hormonal stimuli can trigger metaplastic changes within the coelomic epithelium although such changes are central to the notion that this epithelium is the site of origin of these tumors. Because of the various arguments raised so far, it was proposed by the author nearly two decades ago that this theory, in spite of its wide acceptance, should be revisited and that the notion that ovarian epithelial tumors arise directly from Müllerian elements should be given due consideration [77]. An obvious site in the Müllerian tract that might contribute to tumors likely to be diagnosed as ovarian carcinomas is the fallopian tubes. Indeed, pathologists have acknowledged for several decades that many lesions diagnosed as primary serous ovarian tumors are in fact of fallopian tube origin because these two organs are so close to each other and the morphology of the tumors is so similar that it is usually impossible to tell them apart. It is by pure convention that serous tumors from this area are categorized as ovarian unless morphological features are present that clearly reveal an origin from fallopian tubes. Strong support for this notion comes from reports from several groups that the fimbriated end of the fallopian tubes is a frequent site of pre-neoplastic changes such as dysplasia in surgical specimens from women undergoing prophylactic procedures due to familial predisposition to ovarian cancer [78–81]. These dysplastic lesions also showed differences in expression of regulators of cell cycle progression and of apoptosis such as p53, p21, and p27 [80].

It is clear that the fallopian tubes are not the only site of origin of serous carcinomas arising in the tubo-ovarian region because some tumors do not involve the tubes and

because benign serous cysts that are lined by the same cell type present in ovarian carcinomas are frequently seen within the ovary as well as in the para-tubal region with no connection to the tubes. In addition, a tubal origin is unlikely for endometrioid and mucinous ovarian carcinomas. It was proposed that these lesions could originate in other derivatives of the Müllerian ducts, which are common in the tubo-ovarian region and often impinge on the ovary [77]. Such derivatives are often referred to as the secondary Müllerian system [82] and include structures such as endosalpingiosis, which are lined by cells similar to those lining the fallopian tubes, endometriosis, which are lined by cells similar to endometrial glands, and endocervicosis, which are lined by cells similar to those lining the endocervix. In fact, small cysts lined by serous or mucinous epithelium and morphologically indistinguishable from ovarian serous or mucinous cystadenomas are frequent outside the ovaries (para-ovarian and para-tubal cystadenomas). The frequency of such extra-ovarian cysts is so high that pathologists often do not mention them in surgical pathology reports unless they are large enough to be clinically relevant. Such extra-ovarian cysts, when they increase in size, usually engulf the ovary within their wall because of their close proximity to this organ, at which point they would be categorized as ovarian cystadenomas.

Further support for the notion that endometrioid carcinomas arise in endometriosis is available from epidemiological [26, 33, 35, 38], histopathological [34, 36], as well as molecular biological evidence [37]. Additional evidence that primary peritoneal tumors arise in Müllerian tissues comes from a statistical argument made by Quddis et al. [83]. These authors reviewed all cases of endosalpingiosis and endometriosis of the omentum seen at their institution over a 12-year period. They reported that the endosalpingiosis to endometriosis ratio in this cohort was similar to the ratio of primary peritoneal serous to endometrioid carcinomas, [84] supporting the view that these two malignant tumor types arise from these two benign lesions, respectively.

Dubeau used these arguments to suggest that ovarian epithelial tumors develop exclusively in derivatives of the Müllerian ducts [77, 85]. Many serous ovarian carcinomas originate in fallopian tubes, a notion that has been accepted by pathologists for several decades. Serous tumors that do not originate in the tubes arise in endosalpingiosis, which is defined as tubal epithelium outside the tubes. Most serous carcinomas from the tubo-ovarian area, even if they originate outside the ovary, have reached a large enough size to involve the ovary by the time they come to medical attention and are thus categorized as ovarian. Those that arise in foci of endosalpingiosis that are far enough from the ovaries or tubes to spare both of these organs are categorized as primary peritoneal. Thus, the 3 serous tumor types currently categorized to as ovarian, tubal, or primary peritoneal all originate in serous Müllerian epithelium according to this hypothesis and are regarded as a single disease entity. With regard to the other histological subtypes of ovarian epithelial tumors, it is proposed that mucinous tumors arise in endocervicosis (defined as endocervical tissue outside the cervix) while endometrioid tumors arise in endometriosis (defined as endometrial tissues outside the uterus). Endosalpingiosis, endometriosis, and endocervicosis, which are the most important components of what is referred to as the secondary Müllerian system, can also give rise to intra- and extra-ovarian cystadenomas, which are the benign counterparts of ovarian carcinomas. This theory provides a straightforward explanation for the otherwise unaccounted finding that either tubal ligation or hysterectomy, which undoubtedly result in the destruction of components of the secondary Müllerian system, is protective against ovarian cancer based on numerous epidemiological studies [86–95].

The main differences between the classical theory invoking the ovarian surface epithelium as the site of origin of ovarian epithelial tumors and the Müllerian hypothesis are illustrated diagrammatically in Fig. 33.2. The Müllerian hypothesis implies that the term ovarian in ovarian carcinomas is somewhat of a misnomer given that most of these tumors arise outside the ovary. Dubeau suggested the term extra-uterine Müllerian carcinomas, further subdivided into serous, endometrioid, mucinous, and clear cell, as being more appropriate [85].

33.5 Animal Models of Ovarian Cancer

33.5.1 Spontaneous Ovarian Tumor Development in Animals

Until recently, the development of a suitable animal model for spontaneous ovarian carcinoma has been complicated by the fact that these tumors are rare in most animals including lower mammals. Knowledge of the reasons for the relatively low incidence of spontaneous ovarian epithelial tumors in lower mammals compared to humans could provide important clues about the origin and risk factors of the human tumors. Tumors resembling human ovarian carcinomas are frequently present in the domestic hen [84]. The high frequency of ovarian tumors in those animals has been linked to the activity of incessant egg production, similar to the relationship between incessant ovulation and ovarian cancer risk in humans. Wild hens or other wild birds, in which continuous egg production is not artificially induced, do not develop ovarian tumors. These observations raise the possibility that ovarian carcinomas result from an artifact of civilization, that of incessant ovulation, as chronic menstrual cycling was unlikely in early humans due to more frequent pregnancies and longer lactation periods.

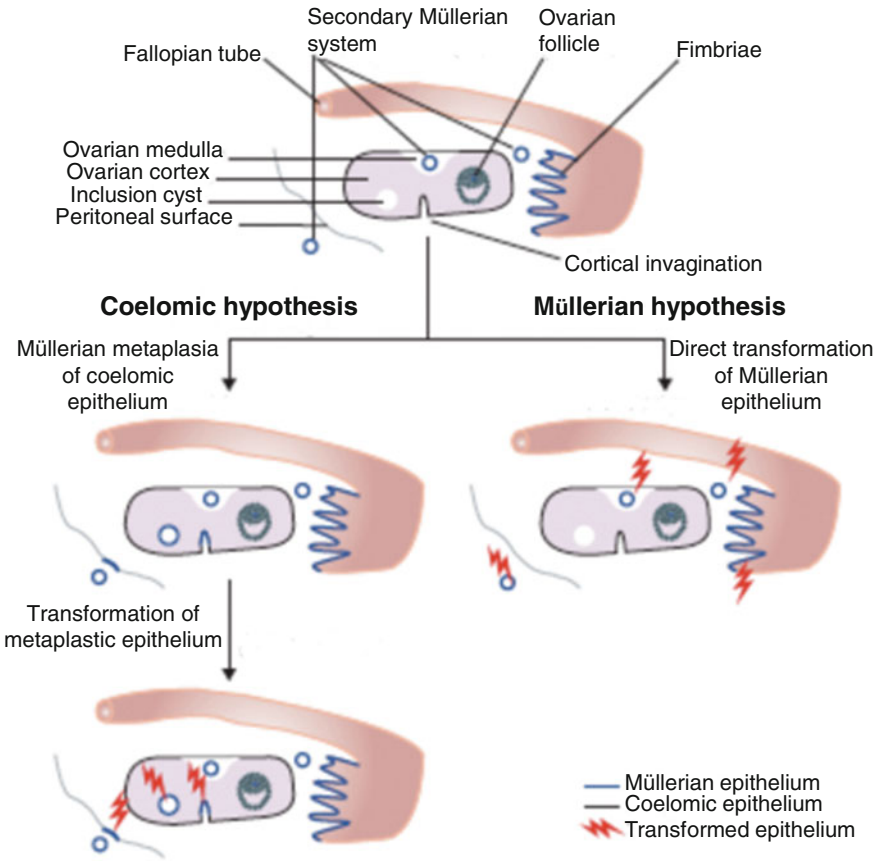

Fig. 33.2 Coelomic versus Müllerian hypotheses for the origin of ovarian, tubal, and primary peritoneal carcinomas. According to the coelomic hypothesis, cortical invaginations and cortical inclusion cysts, which are initially lined by coelomic epithelium (*thin black line*), undergo metaplasia, and change to Müllerian-like epithelium (*thicker blue lines*) before undergoing malignant transformation (lightning signs). The coelomic epithelium covering peritoneal surfaces outside the ovary can give rise to primary peritoneal tumors only after undergoing metaplasia to acquire characteristics of Müllerian epithelium. No intermediary metaplastic step is necessary with the Müllerian hypothesis, which stipulates that Müllerian-like tumors arise directly and exclusively from Müllerian epithelium that is already present, either in the fimbriae or in components of the secondary Müllerian system. (Reproduced with minor modifications from Lancet Oncol vol 9, p. 1193, 2008 with permission).

33.5.2 Models Based on Targeted or Conditional Manipulations of the Mouse Genome

The isolation of BRCA1 and BRCA2, the main genetic determinants of familial ovarian carcinoma, first raised the hopes that inactivating the genes encoding the analogous proteins in mice would lead to the creation of animal models for ovarian cancer based on genetic manipulations relevant to the human disease. These approaches initially failed because mice lacking a functional Brca1 die during early embryological development. Also disappointing was the fact that none of the mice carrying heterozygous inactivation of any of these two genes were prone to cancer development. Although mutants encoding the Brca1-delta11 splice variant of Brca1, which lacks the nuclear localization signal of the full-length protein, are viable, most of the tumors that developed in these animals were lymphomas or sarcomas [96]. Models of Brca2 knockout compatible with survival were likewise associated with predisposition to lymphomas predominantly [97–99].

Models based on conditional Brca1 and Brca2 alleles have mostly been targeted to mammary epithelium. A model where Brca1 inactivation was targeted to the ovary was developed by Chodankar et al. [69], who used a truncated form of the Fshr promoter, which is expressed in granulosa cells specifically, to create a conditional Brca1 knockout. The embryos were viable and fertile. A majority of Brca1 knockout mice had grossly visible cystic tumors either attached to the ovary, to the uterine horns, or with no demonstrable attachment to either of these organs. All tumors except one resembled human serous cystadenomas, the benign counterparts of ovarian serous carcinomas. Strikingly, these tumors carried only the non-recombined (wild type) form of the floxed Brca1 allele; the recombined (mutant) form was present only in granulosa cells. These findings provide strong support to the notion that tumor predisposition in BRCA1 mutation carriers is mediated, at least in part, via a cell non-autonomous

mechanism where granulosa cells control from a distance, in a BRCA1-dependent manner, neoplastic transformation in the tissue from which ovarian epithelial tumors originate. Elucidation of the mediator(s) of such transformation in this mouse model could lead to the development of better strategies for the prevention of these tumors in human populations at risk. The fact that the tumors that developed in this model were not confined to the ovary, but were seen along the entire Müllerian tract including in tissues from the para-ovarian and para-uterine areas, is supportive of the hypothesis that ovarian epithelial tumors are of Müllerian origin.

Several authors have succeeded in inducing tumors in mouse ovarian surface epithelium using conditional manipulations of the mouse genome targeted to ovarian surface epithelial cells. Orsulic et al. [100] demonstrated that the superimposition of a p53 mutation on any two of the oncogenes c-Myc, k-Ras, or Akt in targeted ovarian surface epithelial cells was sufficient to induce tumors in those cells. Flesken-Nikitin et al. [101] performed intrabursal administration of a vector expressing Cre recombinase in mice carrying floxed alleles of both p53 and Rb1, resulting in malignant transformation of the ovarian surface epithelium. Dinulescu et al. [102] similarly used intrabursal inoculations of a vector expressing Cre recombinase to induce expression of a conditional oncogenic allele of K-ras in the ovarian surface epithelium. The authors argued that the epithelial cells expressing this allele resembled the endometrial lining, providing us with an experimental model for endometriosis. Endometrial stroma, an important diagnostic feature of human endometriosis, was absent in these lesions. When inactivation of the Pten tumor suppressor was superimposed on the oncogenic K-ras allele, invasive tumors were obtained that were morphologically similar to the endometrioid subtype of ovarian carcinoma. Wu et al. [103] targeted the ovarian surface epithelium for dysregulation of the PI3K/Pten and Wnt/beta-catenin pathways, both of which are constitutively active in human endometrioid carcinomas, by conditional inactivation of Pten and Apc. Mice carrying those mutations developed carcinomas morphologically similar to human endometrioid carcinomas. These models are all based on the assumption that the targeted tissue, the ovarian coelomic epithelium, is the site of origin of ovarian epithelial tumors, a hypothesis that was favored by a majority of scientists.

Conditional inactivation of Brca1 in mouse ovarian surface epithelium resulted in hyperplasia, epithelial invaginations, and inclusion cysts [104]. This model could be valuable in understanding the potential relationship between such changes and ovarian carcinoma development. Epithelial ovarian inclusion cysts were also observed in Cd1 and Smad2 dominant negative mice after chronic superovulation from inoculations of gonadotropin hormones [105].

A transgenic model for ovarian cancer was developed by Connolly et al. [106], who used the mouse homolog of the human mullerian inhibitory substance type two receptor to drive expression of SV40 large T antigen. This receptor, which has a highly restricted tissue distribution, is expressed in a large majority of human ovarian epithelial tumors. The resulting transgenic mice developed highly invasive and metastatic tumors at a young age in the tubo-ovarian areas. A specific area where this model can be particularly attractive is for investigating the merit of targeting the Müllerian inhibitory substance type two receptor for the treatment of ovarian cancer [107, 108].

33.6 Ovarian Epithelial Tumors as Models of Cancer Progression

33.6.1 Classification of Ovarian Epithelial Tumors Based on Their Malignant Potential

Serous, mucinous, and endometrioid ovarian epithelial tumors can be further subdivided based on their malignant potential (Fig. 33.3). At one end of the spectrum are benign tumors lacking the ability to infiltrate into adjacent tissues and lacking metastatic ability. These tumors are often fluid-filled cysts (hence their designation as cystadenomas) lined by a single layer of epithelial cells resembling the lining of either fallopian tubes (serous cystadenomas) or endocervix (mucinous cystadenomas). Benign tumors of the endometrioid subtype (endometriomas) are usually filled with bloody material because they respond to the cyclic hormonal events of the normal menstrual cycle resulting in bleeding at the time of menses. At the opposite end of the spectrum are fully malignant lesions, which can be further subdivided based on histological grade. Increasing the attractiveness of ovarian epithelial tumors as a model for cancer progression is the existence of an additional category, called tumors of low malignant potential (LMP) or tumors of borderline malignancy, which are regarded as intermediate between the clearly benign and fully malignant lesions. This concept of semi-malignant tumors, which is not a feature of most other cancer models, was first advanced by Howard Taylor in 1929 [109]. It took an additional 40 years before such ovarian tumors, which are associated with a more favorable prognosis than their frankly malignant counterparts regardless of stage of presentation, became accepted as a clinical entity [110, 111]. Both the International Federation of Gynecology and Obstetrics (FIGO) and the World Health Organization (WHO) have classified ovarian epithelial tumors as benign, malignant, and low malignant potential [112].

Ovarian tumors of low malignant potential are characterized by absent or minimal invasive potential, although they can spread outside the ovary and implant onto peritoneal surfaces. Since they are distinguished from carcinomas

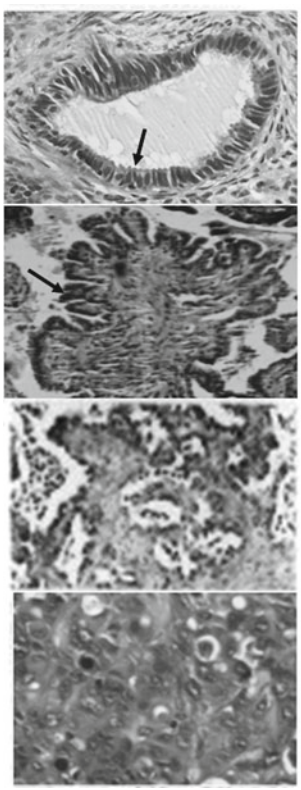

Fig. 33.3 Classification of ovarian epithelial tumors based on their malignant potential.

primarily based on differences in their invasive ability, progress in understanding their molecular determinants and in elucidating the basic molecular differences between these tumors and ovarian carcinomas could shed light on the mechanisms underlying this hallmark of the malignant phenotype. Unfortunately, the data so far have not been telling in that regard.

A fundamental molecular genetic difference between tumors of low malignant potential and carcinomas seems to be that mitotic errors leading to somatic losses of heterozygosity, a hallmark of malignancy, are rare in LMP tumors [113]. Although such losses can be demonstrated in these tumors, it is clear that these events are not frequent enough to play an important role in their development. On the other hand, some of the molecular features associated with the malignant phenotype are present in LMP tumors. For example, these tumors usually express telomerase [114], a feature of the malignant phenotype, and global DNA methylation levels or levels of DNA methylation status in centromeric and juxtacentromeric sequences in these tumors are closer to those seen in carcinomas than in cystadenomas [115, 116]. Although these results strengthen the notion that LMP tumors are intermediate between benign and frankly malignant ovarian epithelial tumors, they shed little light on their underlying mechanisms. Studies at the individual gene level have likewise been unrevealing. Although mutations in specific protein kinases have been associated with LMP tumors and may be more frequent in these tumors than in carcinomas [6, 117–119], such mutations are nevertheless seen in a large number of cancers of various types as well as in some ovarian cystadenomas and their presence in LMP tumors sheds little light on the distinguishing molecular features responsible for the phenotypic differences between these tumors and either ovarian cystadenomas or carcinomas. Along the same lines, expression profiling studies have suggested that although a panel of genes or specific pathways may be more frequently associated with LMP tumors [11, 16, 120], there are so far no clues as to the molecular determinants of the fundamental difference between these tumors and carcinomas, the ability of the latter to infiltrate into adjacent tissues.

33.6.2 Insights from Work with In Vitro Systems

Scientists have attempted to obtain further insight into the biology and molecular mechanisms of ovarian cystadenomas, tumors of low malignant potential, and carcinomas by studying the behavior of these cells in tissue culture. Several authors succeeded in culturing the mesothelial cell layer lining the ovarian surface [121–124]. Cultures of epithelial cells derived from rete ovarii, which could be of Müllerian origin and play a role in ovarian tumorigenesis although this structure is usually regarded as of mesonephric origin [76, 77], were also reported [125]. Godwin et al. [126] reported a high transformation rate in cultured ovarian surface mesothelial

cells, suggesting that they may indeed be prone to malignant development.

One of the difficulties in investigating the molecular mechanisms underlying the development of ovarian tumors of low malignant potential has been the inability to culture these tumors beyond primary explants [127]. The same problem also applies to benign tumors (cystadenomas). It is possible to extend the in vitro life span of either cystadenomas or LMP tumors by introducing viral oncoproteins such as SV40 large T antigen [128], but studies based on such models are complicated by the consequences of such oncoproteins on the malignant phenotype. Nevertheless, these approaches have led to a number of observations with potentially important implications. Although these tumors clearly show continuous growth in vivo and, like carcinomas, almost always express telomerase, expression of this enzyme is not detected in cultures of LMP tumors transfected with SV40 large T antigen. Also, these cells are not immortal in culture despite the fact that this antigen prolongs their in vitro life span to about 50 population doublings [129, 130]. It is therefore possible that only a small fraction of tumor cells, perhaps with stem cell features, are primarily responsible for sustained proliferation in vivo.

Work with in vitro cultures of cystadenomas and tumors of low malignant potential transfected with SV40 large T antigen also led to the observation that although ovarian cystadenomas typically undergo severe numerical chromosomal alterations resulting in aneuploidy when they reach the phenomenon of in vitro crisis toward the end of their in vitro lifespan, cultures of tumors of low malignant potential remain remarkably stable through the crisis period [129, 130]. It is tempting to relate such chromosome stability in culture to the fact that these tumors are typically diploid and genetically stable in vivo [131, 132]. In fact, aneuploid LMP tumors are associated with a more aggressive clinical course and their response to chemotherapeutic agents may be more typical of ovarian carcinomas, raising the possibility that at least some of those tumors are carcinomas incorrectly diagnosed as LMP tumors [132–135]. Indeed, the possibility of using ploidy status as a diagnostic tool to help distinguish ovarian LMP tumors from carcinomas has been suggested [131]. Further understanding of the mechanisms underlying the apparent protection against chromosomal instability that appear to be present in LMP tumors should further increase our understanding of the development of aneuploidy, one of the hallmarks of cancer.

33.6.3 Molecular Genetic Model for Ovarian Carcinoma Development

Table 33.2 lists a number of abnormalities that have been associated with the development of these tumors, none of which are specific for ovarian cancer. A diagram illustrating global as well as selected specific abnormalities distinguishing ovarian cystadenomas, LMP tumors, and carcinomas is shown in Fig. 33.4. This diagram is primarily applicable to the serous subtype of ovarian tumors, as K-RAS, H-RAS, and B-RAF mutations are not common in all subtypes and PTEN mutations, which are frequent in endometrioid carcinomas, are not featured in this illustration. Mutations in BAF250a [10], which are frequent only in the endometrioid and clear cell subtypes (Table 33.2), are likewise not mentioned in the Fig. 33.4. The complexity of molecular genetic changes present in ovarian carcinomas clearly increases with

Table 33.2 Molecular genetic alterations associated with sporadic (non-familial) ovarian carcinomas

Category	Gene or locus	Comment
Oncogenes	*Her-2/neu*	Receptor tyrosine kinase; over-expression is associated with poor prognosis and therapeutic response
	K-RAS, H-RAS, B-RAF	Mutations are frequent in serous and mucinous low grade carcinomas and tumors of low malignant potential
	AKT-2	Member of a subfamily of protein-serine/threonine kinases
	Cyclin E	Over-expression in ovarian carcinomas has been associated with poor clinical outcome
Tumor suppressor genes	*P53*	Regulator of cell cycle progression and apoptosis
	PTEN *BAF250a*	Phosphatase that results, in part, in inhibition of cell death; it is mutated in a significant proportion of endometrioid ovarian carcinomas Component of the SWI–SNF chromatin remodeling complex
	NOEY2	Induces p21 and down-regulates cyclin D
	SPARC2	Encodes a calcium binding matrix protein that contributes to cell adhesion
	DOC-2	Binds GRB-2 upstream of RAS
Chromosomes with frequent losses of heterozygosity	*3p, 6p, 6q, 7q, 9p, 11p, 11q, 13q, 17p, 17q, 19q, 22q, Xp, Xq*	Multiple candidate tumor suppressor genes have been reported on these chromosomes, but their role in ovarian tumorigenesis remains unclear
Altered signal transduction pathways	*PI3K/PTEN*	
	Wnt/beta-catenin	
	EGF-R	

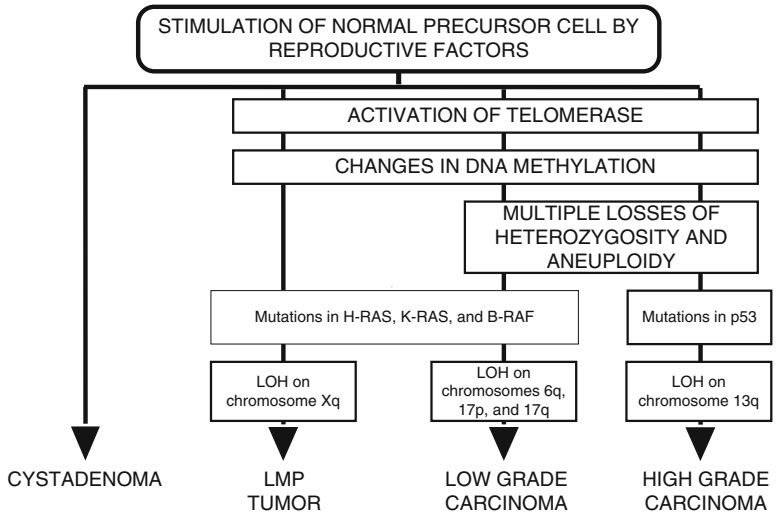

Fig. 33.4 A genetic model for ovarian epithelial tumor development. This diagram is not meant to feature all molecular genetic changes that have been associated with the development of ovarian epithelial tumors. It emphasizes the global genetic mechanisms as well as the most important locus-specific differences that distinguish ovarian cystadenomas, tumors of low malignant potential, and carcinomas. It is mostly applicable to serous tumors.

increasing tumor histological grades, which can be regarded as a measure of a tumor's biological aggressiveness [113, 136–138]. However, as is apparent from Fig. 33.4, the grade of ovarian carcinomas is not only a function of the mere number of molecular genetic abnormalities present in a given tumor genome, as specific molecular abnormalities appear strongly associated with high histological grades [113, 136–139]. For example, losses of heterozygosity in certain chromosomal regions, such as 6q, 17p, and 17q, appear frequent in ovarian tumors of all histological grades [113] while losses in chromosome 13 are frequent only in those of high histological grades [139, 140]. It may be that the gene(s) targeted by losses of heterozygosity in chromosome 13 control(s) cellular pathways associated perhaps not with cell cycle regulation, but with differentiation or other determinants of tumor grade. Another point illustrated in Fig. 33.4 is that although loss of heterozygosity, which is an important mechanism of inactivation of tumor suppressor genes in most human cancers, is frequent in ovarian carcinomas, this abnormality is rare in the biologically less aggressive ovarian epithelial tumors. Perhaps tumor suppressor gene inactivation, which is an important consequence of such losses, is not a feature of cystadenoma or low malignant potential tumor development. Mutations in the p53 gene, which are among the most frequent tumor suppressor gene alterations in all cancers, are present in nearly 100 % of high grade serous ovarian carcinomas but are very rare in low grade carcinomas as well as in ovarian low malignant potential tumors and cystadenomas [141]. Alterations in DNA methylation are associated with tumors of low malignant potential as well as carcinomas but not with cystadenomas, suggesting fundamental differences in the mechanisms underlying the development of these benign ovarian tumors [115, 116]. This conclusion is further strengthened by the fact that telomerase is usually not detected in cystadenomas while it is expressed in most tumors of low malignant potential and carcinomas [114]. Given that this enzyme is regarded as necessary for continuous cell growth, its absence in most cystadenomas suggests that these tumors may have a limited life span in vivo, an idea consistent with the observation that benign ovarian cysts frequently regress or remain unchanged in post-menopausal women [142].

The only exception to the rarity of losses of heterozygosity in LMP tumors is losses affecting the X chromosome, which are present in about 50 % of the cases [113]. However, these losses appear to arise through a different mechanism than that responsible for most losses occurring in carcinomas because they are small interstitial chromosomal deletions as opposed to losses involving large segments such as entire chromosomes or chromosomal arms, which usually result from mitotic errors. The gene(s) targeted by the interstitial allelic losses in LMP tumors is/are still not known. The fact that the reduced allele invariably affects the inactive copy of the chromosome suggests that the targeted gene(s) escape(s) X chromosome inactivation. This suggestion is attractive because individuals born with a single X chromosome (Turner syndrome) show abnormal ovarian development (gonadal dysgenesis). Thus, the presence of the inactive X chromosome is necessary for normal ovarian development. It is conceivable that abnormalities in the same gene during adult life may lead to tumorigenesis. In that regard, it is intriguing that BRCA1, a protein involved in the control of

familial ovarian carcinoma, is thought to interact with the X chromosome and has been suggested to play a role in X chromosome inactivation [143–146].

33.6.4 Relationship Between Ovarian Cystadenomas, Tumors of Low Malignant Potential, and Carcinomas

The fact that ovarian epithelial tumors are subdivided into benign, low malignant potential, and malignant lesions raises the question of whether these represent distinct disease processes or are part of a single disease continuum where tumors first develop as cystadenomas and later progress to more aggressive lesions. The answer is not only important for our understanding of ovarian tumor development, but is also relevant to the clinical management of cystadenomas and tumors of low malignant potential, which often occur in women of reproductive ages. Arguments in favor of a continuum come from morphological observations that areas histologically indistinguishable from typical ovarian cystadenomas are sometimes found contiguous to carcinomas. The most straightforward interpretation for these lesions, which are sometimes called cystadenocarcinomas, is that the histologically malignant areas arose from the pre-existing morphologically benign areas. This interpretation implies that any molecular genetic change associated with carcinomas, but normally not present in solitary cystadenomas, should be confined to the histologically malignant portions of cystadenocarcinomas. However, losses of heterozygosity and p53 mutations, which are both frequent in carcinomas and absent or at least very rare in solitary cystadenomas, are usually concordant in all portions of ovarian cystadenocarcinomas including the morphologically benign areas [147, 148]. Concordance for aneuploidy was likewise shown in different regions of cystadenocarcinomas using interphase cytogenetic approaches [149]. It seems clear, based on these observations, that the histologically benign portions of cystadenocarcinomas are genetically different from typical (solitary) cystadenomas. This conclusion supports the idea that cystadenomas do not generally progress to malignancy unless they carry a genetic predisposition to such progression such as, for example, a mutation in the p53 gene.

Another argument against the notion of a disease continuum is the presence of specific genetic abnormalities that are more frequent in tumors of low malignant potential than in carcinomas. Interstitial deletions of a small region of the X chromosome are a feature of LMP tumors but not of carcinomas [113]. In addition, mutations in the K-RAS and B-RAF genes appear to be more frequent in LMP tumors. Since mutations in these genes are also seen in low grade carcinomas [5–9], Shih and Kurman [150] suggested a dual mechanism for carcinoma development where high grade tumors develop de novo while low grade lesions arise in pre-existing LMP tumors. The fact that LMP tumors appear to be intrinsically more stable than either cystadenomas or carcinomas also argues against the notion that they are precursors of high grade ovarian carcinomas, which are typically highly aneuploid [130].

33.7 Strategies for Early Detection of Ovarian Carcinoma

33.7.1 Screening Strategies for Early Detection in Populations at Risk

The ability to detect ovarian carcinoma precursor lesions before they develop into fully mature cancers would undoubtedly have a profound effect on morbidity and mortality. The poor prognosis currently associated with these lesions is largely due to the fact that they are most often detected after they spread outside the ovary, at which time they are difficult to eradicate. All cancer screening tests that have had a significant impact on disease morbidity and mortality allow detection of pre-cancerous or pre-invasive lesions in addition to localized cancers. This is true of the PAP test used for the detection of pre-invasive cervical cancers (cervical dysplasia), of mammography for the detection of pre-invasive breast cancer (detection of microcalcifications associated with atypical ductal hyperplasia and ductal carcinoma in situ), of prostate biopsy for the detection of prostatic epithelial neoplasia in individuals with elevated PSA, etc. Although this has not been fully established, it is perhaps not the ability to detect localized cancers, but the ability to detect pre-malignant lesions that accounts for the bulk of the impact that these various screening methods have had on disease mortality. Although it is clear that localized cancers (stage I) generally have a better prognosis than disseminated cancers, these cancers could be inherently less aggressive biologically, implying that they are less likely to metastasize. Their prognosis could therefore remain more favorable even if they are not detected until they become clinically manifest. This view is supported in the ovarian model by expression profiling studies comparing localized versus metastatic ovarian cancers, which suggest that they indeed could be regarded as distinct disease entities [151].

One of the problems with developing a sensitive screening protocol for precursors of ovarian carcinomas is that not only the nature of the precursor lesion itself is unclear, but also there is still debate as to where these tumors actually originate. There is therefore a great deal of effort focused on the development of alternate approaches with enough sensitivity and specificity for ovarian carcinomas to allow detection of early disease in populations at risk. Given that transabdominal and transvaginal ultrasound is commonly

used in the evaluation of pelvic masses, the potential of this technique as a screening tool was extensively investigated. However, current data suggest that this approach alone not only lacks specificity, but may be of little value to diagnose ovarian carcinomas before they metastasize [152]. Measurement of serum CA125, a glycoprotein encoded by the *MUC16* gene that has been used extensively as a marker of disease recurrence following adjuvant chemotherapy for ovarian carcinoma, is not specific for this disease and is elevated in only 50–60 % of patients with stage I ovarian carcinomas. Although measurements of rate of change in serial CA-125 measurements can increase the sensitivity of this marker based on the fact that it tends to gradually increase in women with cancer while it remains stable in those with benign conditions, the sensitivity of this approach falls short of meeting the needs of a practical screening tool [153]. Combining serial measurements of CA-125 with transvaginal ultrasound was evaluated as a means of further increasing both sensitivity and specificity. However, there was no difference in overall incidence of ovarian cancer or stage at diagnosis in women screened by this method compared to matched controls in a study of 21,935 women [154]. We are still awaiting data from an ongoing trial based on utilizing rate of rise of CA-125 as an adjunct to ultrasound as a mode of increasing positive predictive value [155].

More recently, investigators have used gene expression profiling technologies and proteomic tools in an effort to identify novel markers associated with ovarian cancer. Lu et al. [156] were able to distinguish normal from malignant ovarian epithelial cells based on expression levels of 5 markers identified from gene expression profiling analyses. In another study, proteomic approaches based on a panel of three markers, combined with CA-125 measurements, distinguished patients with stage I/II ovarian cancer from healthy controls with a specificity of 94 % [157]. Similarly, Gorelik et al. [158] used multianalyte profiling to compare the amounts of multiple cytokines in women with stage I/II ovarian carcinoma and healthy controls. These authors showed strong correlation between marker levels and early stage disease. It is hoped that further progress with these approaches will lead to the development of a panel of markers which, when used alone or in combination with CA-125 measurements or transvaginal sonography, will increase our ability to detect early ovarian carcinomas in populations at risk.

33.7.2 Early Detection of Residual or Recurrent Disease

Patients diagnosed with advanced ovarian carcinoma are usually first treated with surgical debulking of all visible disease greater than 1 cm, followed by adjuvant chemotherapy. Although most patients show good initial therapeutic responses, a large proportion with no evidence of residual disease after completion of the initial chemotherapeutic regimen undergo later recurrences. The development of sensitive methods for the detection of minimal residual disease in treated patients should therefore enhance our ability to identify those at higher risk of recurrence. In addition, it is possible that further therapeutic interventions may be most effective for small, subclinical tumors. Of all current surveillance modalities, second-look procedures provide the most accurate assessment of response to chemotherapy in patients with advanced epithelial ovarian cancer [159–161]. These procedures refer to laparotomies or laparoscopies, performed usually 6 weeks after completion of chemotherapy, in patients who display no clinical evidence of residual disease. These procedures were widely used to aid physicians in deciding whether to stop, change, or continue chemotherapy in patients undergoing treatment until recently. However, the fact that up to 50 % of patients in whom no residual carcinoma was detected during such procedures subsequently developed disease recurrence [160] has prompted most centers to abandon these procedures except when mandated by research protocols. Currently, most patients are followed up with serial measurements of CA-125 and CT scan. Although rising CA-125 levels constitute a good indicator of disease recurrence, this approach is not sensitive enough to allow detection of residual disease immediately after adjuvant chemotherapy.

Recent progress in our understanding of the molecular genetic changes associated with cancer development may provide us with novel sensitive approaches to better evaluate the presence or absence of residual disease in patients treated for advanced ovarian carcinoma. In that regard, the presence of detectable telomerase activity in abdominal washings may be of some value. Duggan et al. [162] showed that the presence of such activity is a more sensitive indicator of the presence of disease than cytological examination. Half of patients with negative second-look procedures tested positive for telomerase in a subsequent study [163]. A follow up study of these patients is not yet completed, but preliminary results show that patients with negative second-look procedures have a shorter survival if they test positive for telomerase (unpublished results from the author's laboratory), raising the possibility that this marker could identify a subset of patients for whom further chemotherapy could be beneficial.

33.8 Concluding Remarks

Although progress in decreasing the incidence and improving mortality rates associated with ovarian carcinoma has lagged behind progress made with other gynecological cancers, it is hoped that current efforts will have a significant impact in the foreseeable future. A better understanding of the precursor lesion for these tumors, combined with efforts

aimed at the identification of specific serum markers expressed early in disease development, should lead to better screening strategies applicable to the general population. In addition, further progress in understanding the biology of these tumors as well as of their underlying genetic mechanisms should lead to more effective therapeutic protocols based on specific molecular profiles.

Molecular Pathology of Bone and Soft Tissue Tumors

34

José Luis Ordóñez, Daniel Osuna, Juan Madoz-Gúrpide, and Enrique de Álava

34.1 Introduction

Bone and soft tissue sarcomas are a heterogeneous and infrequent group of tumors. They make up roughly less than 5 % of neoplasms in adult patients and 10 % of childhood tumors. Despite this difference in the proportion, they are, in absolute numbers, more frequent in the adult age [1]. Some of these tumors, such as synovial sarcoma, ES, and osteosarcoma, are more usual in children, adolescents, and young adults, while some neoplasms such as leiomyosarcoma or liposarcoma are more frequent in patients over 55 years of age.

They are classified according to its specific type of cellular differentiation. Many of them exhibit similar features to those from healthy cells of the mesenchymal tissue, such as cartilage, adipose tissue, or muscle, in chondrosarcoma, liposarcoma, and rhabdomyosarcoma (RMS), respectively; others, though, lack a differentiation program reminiscent of any given normal tissue, for example synovial sarcoma or ES. It is unknown which is the cell type that originates sarcomas, especially considering that there are hardly ever any precursory lesions, quite the opposite than in the case of carcinoma. It is believed that some of the molecular alterations which are described later on affect the mesenchymal stem cell (or cells) to induce them to a neoplastic differentiation program (phenotype). That is why the recent WHO classification on sarcomas has dropped the histogenesis concepts to focus on a combination of parameters that include morphology, phenotype, and genotype. We know very little of the origin of sarcomas. However, some studies point to mesenchymal stem cells (MSC) as the possible origin for some types of sarcomas, such as ES [2–4]. We know some environmental risk factors are associated to some specific types of sarcoma, such as vinyl chloride and hepatic angiosarcoma; or ionizing radiation, which is associated to various types of sarcomas. There are four syndromes of family cancers that are associated to sarcomas, but pathogenesis is based in most of them on the presence of acquired mutations.

Sarcoma diagnosis did not need to be particularly precise 40 years ago, when we lacked highly effective treatments for sarcomas, they were lethal tumors. Current development of therapies is consistent with that of pathology; a timely diagnosis should integrate histopathology, immunophenotype, and molecular techniques.

34.2 Which Cells Give Rise to Sarcomas?

The genesis of most types of sarcomas is unknown, and the elucidation of the cell of origin is a key for discovering the early molecular mechanisms involved in the genesis of the different types of sarcomas as well as the identification of reliable molecular markers and possible therapeutic targets. The cellular context contributes to the phenotype; for example, the transfection of *EWS-ets* fusions into different cellular models resulted in diverse outcomes ranging from the induction of cell cycle arrest or apoptosis to dedifferentiation [5–8].

Recently, Pan Q et al. showed that MSC derived from bone marrow and liver suffers spontaneous transformation. Interestingly, these transformed cells implanted into imunodeficient mice induced sarcoma-like tumors [9]. Moreover, the tissue source of MSC does not seem to be relevant with regard to development of a particular type of sarcoma [10, 11]. However, the MSC differentiation state seems to play a main role in order to define the sarcoma phenotype [11].

34.2.1 Chondrosarcoma

Several theories about the histogenesis of dedifferentiated chondrosarcoma have been proposed: (1) Originally, it was thought that a well-differentiated cartilaginous tumor cell dedifferentiates into a primitive undifferentiated tumor cell [12]. (2) The two components (anaplastic and cartilaginous) are derived from two separate clones of primitive spindle cells (collision tumor), one of which differentiates into a low-grade chondrosarcoma, while the other fails to differentiate and displays features of high-grade sarcoma [13–15]. (3) Both components of dedifferentiated chondrosarcoma display numerical aberrations of chromosome 7 [16], suggesting that both components are derived from a single abnormal clone or cell (common primitive mesenchymal progenitor). (4) Bovée et al. [17] analyzed a case of a dedifferentiated chondrosarcoma and showed compelling evidence for a monoclonal origin (common primitive mesenchymal progenitor), since both components have specific genetic alterations in common. Combination of comparative genomic hybridization (CGH) and loss of heterozygosity (LOH) results revealed that both components share an identical p53 mutation (somatic 6 bp deletion in exon 7) and deletion of the same copies of chromosome 13. However, the presence of many additional different genetic alterations suggests that the separation of the two clones was a relatively early event. The p53 alteration being an early event in chondrosarcomas is in contrast with the literature, since p53 overexpression and mutation were mainly found in high-grade chondrosarcomas [18–20].

34.2.2 Ewing Sarcoma (ES)

ES is a group of pediatric or young adult sarcomas characterized by EWS-ETS gene fusions, mainly EWS-FLI-1 [2, 3]. The expression of neural markers in ES points to a potential mesenchymal or neuroectodermal origin. Recently, Neural Crest Stem Cells (NCSC) have been shown permissive to EWS fusion. However, MSC remains as the most acceptable candidate to be the origin cell in this neoplasia [10].

Bone marrow-derived human mesenchymal stem cells (hMSCs), which are classic mesodermal derivatives, express an extensive assortment of neural genes, and therefore, are predisposed to differentiate to neural and glial lineages [21]. Considering that most ES occur in bone and soft tissue, hMSCs serve as one possible source of cells prone to EWS-FLI1 transformation. Simulation of the expression of EWS-ETS in hMSCs from healthy donors would likely recapitulate the early signaling events underlying in oncogenic transformation. In fact, the development of ES from primary BM-derived mesenchymal cells (MPCs) has been already described in mice [22] and the profiles of different *EWS-FLI1*-silenced Ewing cell lines converge toward that of mesenchymal stem cells [23]. Riggi et al. found out that the EWS-FLI1 fusion protein, can transform MPCs to form ES-like tumors in mice [22]. Moreover, EWS-FLI1 expression in the absence of other pro-oncogenic events is sufficient to induce MPC transformation, suggesting that, in the appropriate cellular microenvironment, it may constitute the initiating event in ES pathogenesis. MPCs display a high degree of plasticity and can differentiate into osteocytes, adipocytes, neurons, and chondrocytes [24]. Despite their bone marrow origin, MPCs can migrate to a broad range of tissues, including soft tissues, where most sarcomas develop [25]. Based on these observations and the hypothesis that sarcomas arise from pluripotent mesenchymal cells, the possibility is that MPC whose developmental program is deranged and blocked in differentiation at an early stage, might provide insights on the origin of other translocation-related sarcomas. However, EWS-FLI1 does not transform hMSC, suggesting the involvement of secondary events to the fusion [26]. This highlights the need of research on MSC or even earlier precursor cells. Recent studies show that some MSC could originate from the neuroepithelium, neural crest stem cells, and from hematopoietic stem cells. Based on this and other data, the Stamenkovic group suggested an hMSC of hematopoietic or neuroectodermal origin as the possible origin cell for ES [27]. Additionally, the some authors also found that pediatric hMSCs transduced with EWS-FLI1 showed ES features of cancer stem cells (CSCs) in vitro but the ability of the CSCs to generate tumors in immunosuppressed mice was not shown [28].

More recently, our group also characterized MSCS obtained from sarcoma patients (hMSC-P). These cells are more similar to hMSC derived from healthy donors than to ES cells. hMSC-P lacked EWS gene rearrangements but showed a few immunophenotypical features also, present in ES cells, such as CD99 expression. Interestingly, ES were sensitive to anti-CD99 therapy while MSCs were not [10].

34.2.3 Leiomyosarcoma

Sanerkin postulated that primary leiomyosarcoma of the bone does not necessarily arise from the media of blood vessels; it might also conceivably develop through advanced myogenic metaplasia of a sarcoma originating from fibroblastic tissue [29]. Yamashina described a case of a primary

leiomyosarcoma in the breast and from the analysis of ultrastructural features of this case led to suggest a tumor of pluripotent mesenchymal cell nature rather than of vascular smooth muscle cell origin [30]. Leiomyosarcoma can also take part into a carcinosarcoma [31] and the establishment of a leiomyosarcoma cell line (HTMMT) derived from human uterine carcinosarcoma was described by Ishiwata et al. [32]. The findings of a monoclonal origin of carcinosarcomas support the hypothesis of a single totipotential stem cell divergence [33]. The divergence hypothesis proposes the differentiation of a single totipotential stem cell into separate epithelial and mesenchymal directions. Jin et al. described that most uterine and ovarian carcinosarcomas are monoclonal [34]. Hernando et al. generated a Tagln-cre/Pten$^{loxP/loxP}$ mice and sarcomas developed responded to rapamycin (an mTOR inhibitor used as an immunosuppressor), showing that *Pten* genetic inactivation in the mouse smooth muscle lineage predisposed smooth muscle cells to transformation and led to mTOR constitutive activation, which was strongly associated with sarcomagenesis in their model [35]. Although required, *Pten* inactivation seemed insufficient to completely promote leiomyosarcoma formation. In humans, *PTEN* loss may not be the only molecular alteration in this pathway responsible for leiomyosarcoma genesis. Interestingly, Rubio et al. reported that adipose-derived MSCs and also Bone marrow MSCS both lacking p53 alone or in combination with Rb induces leiomyosarcoma-like tumors when implanted into immunodeficient mice [11, 36].

34.2.4 Liposarcoma

Regarding the origin cell of liposarcoma, it is known that these tumors can arise in any location, and have an unusual pattern of metastases to the soft tissues, bone, visceral surfaces, and lung. Myxoid liposarcomas (M-LPS) are associated with specific chromosomal translocations that give rise to fusion genes. Embryonic fibroblasts from double-transgenic FUS-CHOP animals showed a similar phenotype to that of human liposarcomas, including the presence of lipoblasts with round nuclei, accumulation of intracellular lipid, induction of adipocyte-specific genes, and a concordant block in the differentiation program [37]. Riggi et al. suggested that expression of FUS-CHOP may be the initiating event in myxoid liposarcoma pathogenesis, and that MPCs may constitute one cell type from which these tumors originate [38]. Domoto et al. identified the *TLS/FUS-CHOP* target gene *DOL54* of the M-LPS and round cell liposarcoma oncogene (RC-LPS). The *DOL54* gene product is closely associated with adipogenic differentiation [39]. They examined *TLS-CHOP* and *DOL54* expressions in M-LPS/RC-LPS, well-differentiated liposarcoma, observing *DOL54* expression in 50 % of M-LPS/RC-LPS cases (in which *TLS-CHOP* was also expressed). Rodriguez et al. reported recently that FUS-CHOP expression in mouse but not in human adipose-derived mesenchymal stem/stromal cells lacking p53, induced liposarcoma [40].

34.2.5 Malignant Fibrous Histiocytoma (MFH)

The so-called malignant fibrous histiocytoma (MFH), now termed high-grade undifferentiated pleomorphic sarcoma, has been postulated that represents a transformed adult hMSC [41]. A stem cell-specific gene expression pattern revealed that the profile of hMSCs was significantly associated with that of MFH. Wnt2 mediates commitment to differentiation while Wnt5a mediates a viability checkpoint in hMSCs. They showed that the tumor suppressor function for specific Wnt2 signaling in hMSCs may mediate differentiation of β-catenin in conjunction with Wnt5a/JNK. Nevertheless, other authors have reported that Wnt3a signaling is inhibitory to hMSC differentiation [42]. The differences in these results suggest that interactions between specific Wnts and Wnt receptors (i.e., frizzled family) may result in potential activation of different downstream pathways [43].

34.2.6 Osteosarcoma

The genesis of the different types of osteosarcoma remains speculative. Several research groups are working on characterizing cancer stem cells, and functional studies are being carried out to assess the tumorigenic potential of these cells. In primary osteosarcoma of the breast, an origin from totipotent mesenchymal cells of the breast stroma or the transformation from a preexisting fibroadenoma or phyllodes tumor has been suggested [44, 45]. The origin of osteosarcoma in testis from undifferentiated mesenchymal cells or from a malignant transformation of preexisting teratomatous elements is still unclear [46].

Recently, Rubio et al. reported osteogenic progenitors derived from bone marrow-MSC defective in Rb and p53 are the cell of origin for osteosarcoma [11]. The same authors showed that intra-bone or periosteal inoculation of MSCs derived from bone marrow or adipose tissue both of them deficient in p53(−/−) or p53 (−/−) and Rb (−/−), induced metastatic osteoblastic osteosarcoma (OS) in immunosuppressed mice. They also showed the main role played by bone microenvironment in osteosarcoma development [47].

34.2.7 Rhabdomyosarcoma

RMS is a common pediatric soft tissue sarcoma that resembles developing fetal skeletal muscle. Keller et al. generated a Cre-mediated conditional knock-in of *PAX3-FKHR* into

the mouse *Pax3* locus, suggesting that terminally differentiating skeletal muscle myofibers have the capacity to give rise to alveolar RMS, which can express early myogenic markers (e.g., myogenin, MyoD, and Pax7), known *PAX3-FKHR* targets (e.g., c-Met, Bcl-XL), and markers of proliferation (e.g., C-Myc and Cyclin D1) [48, 49]. *Pax3-Fkhr* activation was restricted to a target pool of terminally differentiating Myf6-expressing skeletal muscle. *PAX3-FKHR* homozygosity and *Ink4a/ARF* or *Trp53* pathway loss of function significantly accelerates alveolar RMS formation, raising the possibility that some or most alveolar RMS arise from postnatal, terminally differentiating, Myf6-expressing myofibers. Odelberg et al. demonstrated that fully differentiated mature skeletal muscle is able to dedifferentiate into earlier precursor myogenic forms or even into different lineages [50]. These findings reconsider the widely held assumption that only muscle stem cells give rise to RMS. The embryonal subtype of RMS is not associated with these fusion genes. Tiffin et al. suggested that myogenic satellite cells are the origin of these tumors [51]. The pattern of *PAX7* and *MET* (*c*-met) expression (a marker for the myogenic satellite cell lineage), corroborated this hypothesis.

34.2.8 Synovial Sarcoma

Synovial sarcomas are divided into biphasic, monophasic, and poorly differentiated sarcomas on the basis of histopathology. Biphasic synovial sarcoma expresses generally *SYT-SSX1* gene fusion which it is associated with a worse prognosis, and the monophasic subtype shows predominantly, but not exclusively, the expression of *SYT-SSX2* fusion genes [52]. The relationship between fusion gene and the histological subtype suggests that *SYT-SSX1* facilitates the acquisition of epithelial features by undifferentiated tumor cells [53]. De Torres et al. suggested that *SYT-SSX1* fusion transcript collaborates in the epithelial differentiation of mesenchymal tumors [54]. The differences in the degree of transcriptional derepression of E-cadherin by SYT-SSX1 and SYT-SSX2 result in different propensities for epithelial differentiation [55]. These findings strengthen the concept that the protein interactions with Snail or Slug are important in the modulation of mesenchymal to epithelial transition and vice versa in mesenchymal differentiation and neoplasia. The ultrastructural features together with the common epithelial (cytokeratin) and mesenchymal (vimentin) immunophenotype suggest that both epithelioid and synovial sarcoma probably share a similar histogenetic background. Araki et al. suggested a lineage relationship between synovial sarcoma cells and smooth muscle-like mesenchymal cells in a subset of synovial sarcomas expressing the basic calponin gene [56]. Capecchi and colleagues reported a mouse model of synovial sarcoma based on conditional expression of the human SYT-SSX2. Tumors were generated within Myf5 lineage, pointing out the cell of origin to myoblasts [57]. Since they suspected tumor origin in their model to be postnatal, the best cellular candidate was Myf5-expressing myoblasts arising from activated satellite cells (muscle stem cells). However, quiescent satellite cells themselves, postnatally, could also be a potential source of synovial sarcoma. Recently, some authors also suggested a non-myoblast origin for synovial sarcoma [58].

34.2.9 Technologies Applied to Classification and Discovery of Early Events in the Genesis of Sarcomas

Genome-wide expression profiling leads to an improved classification of bone and soft tissue tumors [59, 60], and its combination to light/electron microscopy and immunohistochemical techniques contributes to a better understanding of the genesis of sarcomas. It could also allow a better understanding of poorly described normal connective-tissue counterparts of these tumors, such as fibroblasts, myofibroblasts, and pericytes, because some of the highly expressed genes are implicated in the pathogenesis of these type of tumors.

Once the possible origin cell of a given sarcoma type would be discovered, a major challenge would be to gain insights into the origin of the genetic alterations taking place in that particular cell type. Emerging technologies allow us to analyze posttranslational histone modifications and their roles in regulating chromatin structure and function. Epigenetic regulation of gene expression is mediated in part by posttranslational modifications of histone proteins, which in turn modulate chromatin structure [61, 62]. The core histones H2A, H2B, H3, and H4 are subject to dozens of different modifications, including acetylation, methylation, and phosphorylation.

It is known that embryonic stem (ES) cell differentiation is accompanied by changes in chromatin accessibility to several key developmental genes, including a large-scale opening of the HoxB locus [63, 64]. Furthermore, Polycomb-group proteins play an essential role in maintaining the pluripotent state of ES cells and show markedly reduced expression upon differentiation [65–67]. However, little is known about the overall structure of ES cell chromatin, how it is established, or how it contributes to the maintenance of pluripotency [68].

Exciting findings can be obtained from genome-wide maps of chromatin state. Because the cellular state may be closely related to chromatin state, ChIP-Seq studies by using Solexa® Technology could reveal the mechanisms triggering genetics instabilities. ChIP-Seq is a sequencing-based alternative to ChIP-chip assays. For ChIP-chip studies, DNA fragments that interact with a protein of interest are identified by

hybridization of DNA to the array. Mikkelsen et al. reported the development of ChIP-Seq method for mapping ChIP (chromatin immunoprecipitation) enrichment by sequencing, and described its application to create chromatin state maps for pluripotent and lineage-committed mouse cells [69]. They generated genome-wide chromatin state maps of mouse embryonic stem cells, neural progenitor cells, and embryonic fibroblasts and the resulting data defined three broad categories of promoters based on their chromatin state. Cancer cells are the most obvious targets, as they are frequently associated with epigenetic defects and many appear to have acquired characteristics of earlier developmental stages. Kwon et al. described a sensitive ChIP-DSL technology to detecting in vivo DNA-protein interactions by coupling ChIP with a DNA selection and ligation strategy, permitting analysis of many fewer cells than required by the conventional ChIP-on-chip method [70]. Recently, Riggi et al. reported that EWS-FLI1 acts directly on reprogramming genes by both activating new enhancers and inactivating conserved enhancers. The chimeric fusion acts on the chromatin remodeling which, in turn, induces repression of tumor suppressors and activation of oncogenes [71].

34.3 Molecular Alterations

34.3.1 Acquired Somatic Mutations

Five major types of acquired mutations are detected in sarcomas. *Deletion*: Any loss of genetic material smaller than a chromosome. It may affect a chromosome's arm, a gene, or a small number of base pairs. *Amplification:* The presence of various copies of a single gene whose structure is otherwise normal. *Translocation:* The interchange of genetic material between two non-homologous chromosomes. Frequently, there is no material loss but it simply moves to another place; in this case, we refer to balanced translocations. *Inversion:* This is the result of two ruptures in a chromosome that are followed by reinsertion of the original fragment in reverse order. *Point mutation:* In this type of mutation, one base is substituted by another.

34.3.2 Family Syndromes

Although most cases of mutations turn up sporadically, there are, however, four well-characterized syndromes of family cancer associated to sarcoma. Firstly, patients with RB mutations in the germ-line have a frequency of developing osteosarcomas higher than the general population [72]. Patients with Li-Fraumeni syndrome, showing p53 gene germ-line mutations [73], have a higher incidence for a wide group of sarcomas, and typically earlier than 40 years of age. Another type of sarcoma, malignant peripheral nerves sheath tumor, is frequently observed as a consequence of a neurofibromatosis type 1 (NF-1) associated to the loss of NF-1 gene in the germ-line [74].

34.3.3 Types of Sarcomas Regarding the Complexity of Molecular Alterations

There are two types of sarcomas with regard to the complexity of molecular alterations. On the one hand, there is a group of sarcomas that is more frequent in children and adolescents, their cytogenetic alterations are relatively simple, balanced translocation in general [75]. From the molecular point of view, they are characterized by translocations or punctual mutations which suppose the beginning of the process of carcinogenesis.

A second group of sarcomas, such as the osteosarcoma or malignant fibrous histiocytoma [76], are characterized by a very complex karyotype and lack of gene fusions. In fact, they show a clear chromosome and genomic instability.

The mutations of tumor-suppressing genes p53, INK4A, or RB are found on both subtypes of tumors and are related with tumor progression. Therefore, it is worth mentioning that they have no diagnostic interest, but may determine the prognosis of some sarcomas [77].

34.3.4 Mutations in Sarcomas

There are two types of mutations of clinical value in sarcomas: (1) translocations and (2) point mutations.

34.3.4.1 Translocation

Various types of sarcomas show characteristic translocations [2] In fact, the deepest advances in the knowledge of its pathogenesis have been carried out in these types of tumors [75]. Gene fusions generated from these translocations are the initiating events of many sarcomas and are probably essential in some subtypes of these tumors. These translocations break up certain genes, recombine them, and create gene fusions with new structures and functions by combining functional domains that are usually found in separate molecules. Most chimeric proteins are transcription factors, namely, proteins that have the capacity for union to regions regulating the transcription of some genes. These genes are usually involved in certain key functions of the cell, such as cell proliferation or survival. As a result of translocations, gene fusions represent almost always aberrant transcription factors. Two noteworthy exceptions are: COL1A1-PDGFB in dermatofibrosarcoma protuberans, a growth factor; and ETV6-NTRK3 in congenital fibrosarcomas, a protein with

tyrosine kinase activity [75]. As gene fusions and their products are specific to each tumor type, and they are practically seen in all cases of a large group of sarcomas, their characterization is not only important from the pathogenesis point of view, but it offers great diagnostic and therapeutic opportunities.

34.3.4.2 Point Mutations

Mutations are another type of specific findings in sarcomas, usually beyond the bone-soft tissue location for example, c-*kit* activating mutations in GIST, or inactivating mutations on hSNF5/INI1 in rhabdoid tumors.

34.4 More Relevant Translocations and Their Tumor Type

EWS-FLI1 fusions are detected in roughly 90–95 of Ewing sarcomas [3]; EWS-ERG are present in 5–10 % of cases, while 1 % stand for some other type of fusion of EWS with a member of the ETS family of the transcription factor group [3]. It is specific to this neoplasia, as PCR studies of other tumors that could be included in differential diagnosis, such as central primitive neuroectodermal tumors, neuroblastomas, RMS, adamantinoma and giant cell tumors, have repeatedly yielded negative results [78].

In addition to the usual prognostic factors of this neoplasia (stage, localization/volume of the primary tumor, age, and response to treatment), recent studies have assessed the contribution of molecular heterogeneity (Table 34.1) toward prognosis in ES. There are at least 18 structural chances of gene fusions in this neoplasia. There are two sources of variability. On the one hand, *EWS* fusion companion (*FLI1*, *ERG*, *ETV1*, *E1A,* or *FEV*), and on the other hand, the localization of the translocation rupture point within each gene involved. It has been reported that patients with localized ES expressing the most common chimeric transcript (EWS exon 7 united to FLI1 exon 6; 63 %) have a better prognosis than those with some other type of fusion [79, 80]. However, prognostic differences based on this have not been found in the EuroEwing99 prospective multicentric trial [81].

In the case of the *desmoplastic small round cell tumor* (SRCDT), the *EWS* gene is bound to the *WT1* gene. At first, *WT1* was known to be an altered tumor suppressor gene in Wilms tumor (nephroblastoma); in fact, *EWS-WT1* is the first example of a constant rearrangement of a tumor suppressor gene. The chimeric transcript EWS-WT1 has been found in 97 % of cases that were studied. This is very helpful for diagnosis [82]; it also suggests the chimeric protein is important for the tumor development. It is, as in many other sarcomas, an aberrant transcription factor that regulates the expression of genes that partially coincide with usual WT1 targets. One of them is PDGFA, a fibroblastic growth factor, which is probably involved in the characteristic fibrosis of this neoplasia [83]. BAIAP3 is another factor that regulates the exocytosis process, and thus the secretion of growing factors [84].

EWS binds to *ATF1* in the *clear cell sarcoma* (soft tissue malignant melanoma) [85] and in the *angiomatoid fibrous histiocytoma* [86]. EWS binds to a DNA-binding domain of a transcription factor, as in the Ewing tumor. Contrary to ATF1, EWS-ATF1 fusion works as a transcriptional activator, probably altering the regulation of genes usually controlled by ATF1. The chimeric RNA is detected both in fragments of frozen tumor and formalin-fixed paraffin-embedded material [87].

EWS-CHN fusion, generated from a t(9;22), is observed in the extraskeletal myxoid chondrosarcoma, curiously, not from myxoid chondrosarcoma of osseous origin [88]. CHN codifies a nuclear receptor having a binding domain to DNA. The fusion protein has an EWS amino-terminal domain bound to the whole CHN reading frame; this yields a nuclear receptor more active than the native one. This receptor is involved in the control of cellular proliferation by modulating the response to diverse growth factors. There are some infrequent variants of this fusion. Genomics studies have shown that this tumor has a high expression on PPARG. There are some specific inhibitors against this molecule, which could become a therapeutic target [89].

In addition, a gene analogous to *EWS*, *FUS*, is involved with *CHOP (DDIT3)* in gene fusion in 90 % of cases comprising *round cell/myxoid liposarcoma* (*FUS-CHOP*) [90]. CHOP (DDIT3) is a transcription factor. In TLS-CHOP (FUS-DDIT3), TLS binding domain to RNA is replaced by CHOP binding domain to DNA. The relation between myxoid liposarcoma and round cells is confirmed by detecting FUS-CHOP fusions in tumors made up, as a whole or in part, of round cells [90]. Approximately 5 % of cases show EWS-CHOP fusions, wherein EWS has an analogous role to FUS. Thus, proteins having the ability to bind to RNA, FUS, and EWS seem to be functionally similar, while the component providing the binding domain to DNA, CHOP, is specific in this neoplasia.

34.4.1 Alveolar Rhabdomyosarcoma

Alveolar rhabdomyosarcoma is associated to a characteristic translocation, t(2;13), and another less common one, t(1;13). This is the result of *PAX3* and *PAX7* gene fusion, respectively, with forkhead in RMS (*FKHR*) localized in 13q14 [91]. *PAX* genes are transcription factors regulated during the embryo development; they are essential for the genesis of some organs. PAX3 and PAX7, in particular, are expressed in the neural tube and are fundamental for its correct formation, and for the migration of myoblasts to upper and lower

Table 34.1 Chromosomic translocations and the molecular findings described in sarcomas

(**EWSR1** is also named as EWS); (**FLI-1** is also named as EWSR2, SIC-1) (**ETV4** is also known as E1AF, E1A-F, PEA3,PEAS3); (**DDIT3** is also named as CHOP; CEBPZ, CHOP10; GADD153; MGC4154); (**NR4A3** is also named as CHN, TEC, CSMF, MINOR, NOR1); (**FOXO1** is also named as FKHR, FKH1 y FOXO1A); (**SS18** is also named as SYT, SSXT, MGC116875). (SUZ12 is also name as JJAZF1)

[a]These fusions are also present in other tumors (carcinomas, leukemias or lymphomas) (reviewed in Ordonez et al. [3])

[b] More information can be obtained from Lee et al. [281]

extremities. PAX3 could suppress myoblast differentiation; this could lead to the undifferentiated phenotype of this tumor. Some amplification has been detected concerning gene fusions in some tumors with *PAX7-FKHR* fusions; this suggests that translocation and amplification may be sequential mechanisms in the oncogenesis of this neoplasia. As for PAX3-FKHR fusion, an overexpression of transcriptional origin was detected on PAX3 non-associated to gene amplification [92]. These differences concerning PAX3 and PAX7 overexpression mechanisms are analogous to those observed at clinic level. PAX7-FKHR tumors tend to turn up in younger patients and are associated to a lower rate of metastasis and a better survival than those with PAX3-FKHR, even though they have a similar morphology [93].

34.4.2 Synovial Sarcoma

Synovial sarcoma is characterized due to t(X;18); it generates a fusion between *SS18* (*SYT*) gene on chromosome 18 with one *SSX* gene: *SSX1* and *SSX2*. They are located in two subregions of chromosome Xp11 (23 and 21, respectively); there are, though, rarer fusions. This fusion codifies an abnormal nuclear transcription factor which alters chromatin remodeling; this may induce some changes in the gene expression patterns. Transcripts are detected in almost all synovial sarcomas through RT-CPR. The synovial sarcoma is a clear example of correlation tumor phenotype and transcript type. Biphasic synovial sarcoma is associated with SYT-SSX1 fusions, which are present both in epithelial and fusocellular elements, while monophasic synovial sarcoma is usually present with SYT-SSX2. In addition, patients at clinic level with SYT-SSX2 show a relatively low risk of relapses, while tumors with SYT-SSX1 variant show a high proliferative rate and a worse prognosis [52, 94]. However, the prognostic value of these fusions is still under discussion [95].

Translocation t(17;22) in *dermatofibrosarcoma protuberans* and giant cell fibroblastoma generates a fusion involving *COL1A1*, a collagen gene and *PDGFB*, a protein-modifying gene with growing factor function. This fusion sets *PDGFB* under the control of *COL1A1* promoter, thus removing all elements repressing *PDGFB* transcription. In the case of congenital fibrosarcoma, t(12;15) translocation unites *ETV6 (TEL)* gene with neurotrophin 3 receptor (*NTRK3*) [96]. Curiously, this fusion is also specifically seen in mesoblastic nephroma, acute myeloblastic leukemia, and secretory carcinoma of the breast, a rare variant of the infiltrating ductal carcinoma of the breast [97]. This phenomenon suggests that the same gene fusion may cause different neoplasms, and depends on the characteristics of the cell where this occurs. These two examples represent the exception confirming the general rule that gene fusions generate new ETV6-NTRK3 transcription factors in a chimeric kinase tyrosine, which may contribute to oncogenesis by deregulation of transduction pathways of signals generated by NTRK3, while PDGFB-COL1A1 probably acts as an autocrine growing factor.

34.5 Chimeric Proteins Resulting from Translocations: Structure and Function

34.5.1 Chimeric Protein Structure: ES Oncoprotein as an Example

Sarcomas are paradoxical examples of how a disease with a relatively low prevalence can bear prominent biological significance because of their molecular mechanisms of generation and progression. Fusion genes resulting from chromosomal translocations can be transcribed and translated into chimerical proteins. Let us first take Ewing sarcoma oncoproteins as an example [3, 98].

The ES family of tumors (ES) comprises morphologically heterogeneous tumors that are characterized by nonrandom chromosomal translocations involving the EWS gene and one of the several members of the ETS family of transcription factors [99]. The translocation t(11;22)(q24;q12) is the most common one, associated to 90 % of cases, and this high specificity suggests that the product of this rearrangement is involved in the formation of these malignancies. This translocation leads to in-frame fusion of EWS at 22q12 to FLI1 at 11q24 and the formation of EWS-FLI1 on der[22] comprising the 5' end of EWS and the 3' end of FLI1 [100]. The fusion gene encodes an oncoprotein consisting of the N-terminal domain of EWS and the C-terminal DNA-binding domain of transcription factors such as ETS family, activating transcription factor-1, Wilms' tumor 1, and nuclear orphan receptors [101].

EWS protein is predicted to be an RNA-binding protein containing the transcriptional activation domain(s) in the N-terminal domain and the RNA recognition motif and three arginine-glycine-glycine repeats (RGG boxes 1–3) in its C-terminal domain [102, 103]. The transcriptional potency of the N-terminal domain of EWS observed in its various tumorigenic fusion proteins suggests that EWS may function as a transcription factor. In the EWS-FLI1 fusion protein, the RNA-binding motif containing the C-terminal half of EWS is replaced by the DNA-binding domain (DBD) of the FLI1 protein. EWS belongs to a subgroup of RNA-binding proteins called the TET family, which also includes liposarcoma/fusion protein (TLS/FUS) and human TATA-binding protein-associated factor (hTAFII68) [90, 104]. They all contain a distinctive conserved 87-amino-acid RNA recognition motif/ribonucleoprotein consensus sequence (RRM/RNP-CS) motif commonly found in most RNA-binding proteins and possess a number of R-G-G (arginine-glycine-glycine)

repeats that also seem to facilitate binding to RNA. A zinc finger domain with four cysteines is present in their C-terminal domain. In addition, mammalian TET family members share glutamine-rich N-terminal domains consisting of a series of degenerate repeats. In Fig. 34.1, we present a schematic view of EWS protein domains.

Three key features indicate that the EWS protein is encoded by a housekeeping gene; it is expressed ubiquitously, its expression is stable throughout the cell cycle, and its mRNA has a long half-life [90]. Although more remains to be known about the role of native EWS, it is a nuclear protein that appears to be recruited to promoter regions where it associates with other factors to act as a promoter-specific transactivator [105, 106]. It also functions as a transcriptional coactivator in a cell type-specific and promoter-specific manner. It requires CBP/p300 for hepatocyte nuclear factor 4 (HNF4)-mediated transcriptional activation [107, 108]. Although EWS fusion proteins function as sequence-specific transcription factors, the role of native EWS protein and the regulatory mechanism controlling the coactivator function of EWS are largely unknown.

FLI1 is a member of the ETS family of transcription factors which activate specific target genes by binding to their cognate DNA sequences through their DNA-binding regions, usually located at their carboxyl termini [109, 110]. The replacement of the native transcription activation domain(s)

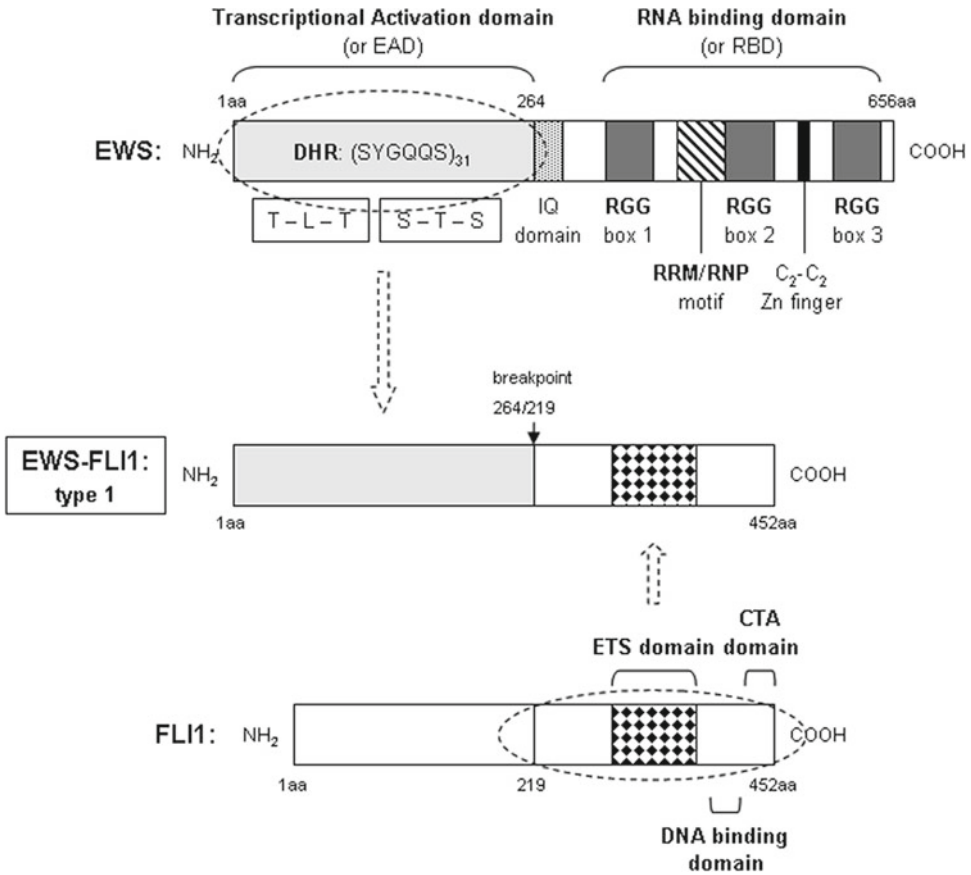

Fig. 34.1 Schematic view of the structural features of a prototypic sarcoma chimeric protein, and the native proteins it arises from. EWS-FLI1 type 1 protein is associated with ES. Primary and secondary structures, as well as functional regions of native EWS, FLI1, their breakpoints, and the resulting fusion protein are depicted. EWS N-terminal domain contain amino acid residues 1–264, referred to as the EWS-activation domain (EAD). It contains 31 degenerate hexapeptide repeats (DHR) with the consensus sequence SYGQQS and 7 other Tyr residues. The C-terminal domain begins with the IQ domain, a region susceptible of binding calmodulin and being phosphorylated. Next, it has a distinctive conserved 87-amino-acid RNA recognition motif/ ribonucleoprotein consensus sequence motif (RRM/RNP domain) commonly found in most RNA-binding proteins, and possess a number of RGG (arginine-glycine-glycine) repeats that also seem to facilitate binding to RNA. A zinc finger domain with four cysteines (C_2-C_2 Zn finger-like) is also present close to the C-terminal end. FLI1 is a transcription factor, with a naturally occurring transactivating region in the N-terminal end. It encloses a highly conserved, sequence-specific, ETS-type DNA-binding domain. FLI1 also has contains a C-terminal end transactivating domain (CTA). The chromosomal t(11;22)(q24;q22) translocation in ES results in the fusion of the N-terminal domain of EWS and the DNA-binding domain of FLI1, generating the oncoprotein EWS-FLI1. The transactivating domain of EWS is retained, while the RNA-binding domain is lost, replaced by the sequence-specific DNA-binding domain of the FLI1 protein. The type 1 chimeric protein is represented entirely schematically. Types 2 or 3 can be deduced from type 1 by the insertion of 84 or 22 additional amino acids from EWS or FLI1, respectively.

of FLI1 by the N-terminal region of EWS converts the non-transforming activator, FLI1, into a transforming protein with new transcriptional activation potential. The ETS family of transcription factors is defined by a conserved ETS domain that recognizes a core DNA motif of GGAA/T [111]. This family of approximately 30 genes including FLI1, ERG, ETV1, E1AF, FEV, and ZSG controls a variety of cellular functions in cooperation with other transcription factors and cofactors. Target genes include oncogenes, tumor suppressor genes, and genes related to apoptosis, differentiation, angiogenesis, and invasion [111, 112]. Recently, Riggi et al. reported that EWS-FLI1 acts on chromatin remodeling playing a main role in Ewing sarcoma biology [71].

34.5.2 Protein–Protein Interactions Studies Provide Structural and Functional Insights into the Mechanisms of Action of Native Proteins in Sarcomas

We can next take a look inside the archetypical case of the ES chimera protein. In the EWS-FLI1 fusion protein, both the N-terminal domain of EWS and the DBD of FLI1 are necessary for the transforming activity of Ewing cells [101, 102]. To assess the contribution of the N-terminal domain of the EWS protein to the formation of human solid tumors, it is important to understand the normal function(s) of EWS. Although much is known about the oncogenic functions of chimeric EWS fusion proteins that result from chromosomal translocations, the cellular role of the normal EWS protein is not well characterized.

Bertolotti et al. investigated the putative role of EWS in RNA polymerase II (Pol II) transcription by comparing its activity with that of its structural homolog, hTAFII68 [105]. The structural homology between EWS and the transcription factor hTAFII68 (70 % similarity among the full-length proteins) strongly suggested that there may be a functional homology between these proteins. The authors demonstrated that a portion of EWS is able to associate with the basal transcription factor TFIID, which is composed of the TATA-binding protein (TBP) and TBP-associated factors (TAFIIs). In vitro binding studies revealed that both EWS and hTAFII68 interact with the same TFIID subunits, suggesting that the presence of EWS and that of hTAFII68 in the same TFIID complex may be mutually exclusive. Moreover, EWS is not exclusively associated with TFIID but, similarly to hTAFII68, is also associated with the Pol II complex. The subunits of Pol II that interact with EWS and hTAFII68 were identified, confirming the association with the polymerase. On the other hand, using Ewing cell nuclear extracts, they studied the association of EWS and the oncogenic fusion protein, EWS-FLI1, with different multiprotein complexes. These experiments suggest that EWS and EWS-FLI1 behave differently since EWS-FLI1 cannot stably associate with either TFIID or Pol II in Ewing cell nuclear extracts. These observations suggested that EWS and EWS-FLI1 may play different roles in Pol II transcription.

Employing yeast two-hybrid cloning to study protein–protein interactions, Petermann et al. isolated the seventh largest subunit of human RNA polymerase II (hsRPB7) as a protein that specifically interacts with the amino terminus of EWS [113]. This association was confirmed in nuclear extracts, where hsRPB7 was found to co-purify with EWS-FLI1 but not with FLI1. Overexpression of recombinant hsRPB7 specifically increased gene activation by EWS-chimeric transcription factors, whereas replacement of the EWS portion by hsRPB7 in the oncogenic fusion protein restored the transactivating potential of the chimera. Those results suggested that fusion to FLI1 causes as structural change of the amino-terminal EWS domain, making it accessible for interaction with hsRPB7. Presumably, the physical interaction of the amino terminus of EWS with hsRPB7 contributes to the transactivation function of EWS-FLI1 and, since hsRPB7 has characteristics of a regulatory subunit of Pol II, may influence promoter selectivity.

Most chimeric proteins in many sarcoma types function as aberrant transcription factors. One step further in the characterization of the RNA-binding capabilities of such proteins was the revelation by proteomics techniques of the association of EWS protein to the IRES of central proteins in some pathogenic processes. This was the case in hepatitis C virus-infected cells [114]. The authors used shotgun peptide sequencing to identify proteins in quadruplicate protein affinity extracts of lysed cells, obtained using a biotinylated IRES. EWS protein contains an RRM RNA recognition motif and a zinc finger RNA-binding region, through which interaction occurs. From a mechanistic point of view, protein binding to the IRES is an indication of the importance of that protein, both for its functional value as well as a potential drug target. In particular, EWS may shuttle from the nucleus to the cell surface [115] and function as a transcriptional cofactor with CBP/p300 [106]. This interpretation is particularly interesting in view of the proposed role of the nucleolus as a gateway for viral infection and site of replication for many viruses. Although to our knowledge this point has not been studied in sarcomas, the evidences gathered to date indicate that it might be interesting to investigate the potential role of EWS as an IRES-binding protein.

Despite the numerous reports aiming at the function of TET proteins as a partner of fusion proteins in different sarcoma translocation types, little evidence has been collected about the cellular function of the normal proteins, let alone from proteomic approaches. Anumanthan et al. reported the interaction between a WD domain-containing protein, serine-threonine kinase receptor-associated protein (STRAP) and EWS, using matrix-assisted laser desorption/ionization,

time-of-flight and tandem mass spectrometry (MALDI-ToF MS/MS) [116]. STRAP interacts with EWS in the nucleus and induces inhibition of EWS transactivation function. Their research found that normal EWS protein is upregulated in human cancers, suggesting a cooperative role of these two proteins in tumorigenesis. Results suggested that STRAP inhibits the transactivation function of EWS by displacing p300 from the functional transcriptional complex. In consequence, this study provided a novel TGF-ß-independent function of STRAP and described a mechanism by which STRAP regulates the physiologic function of oncogenic EWS protein in the nucleus.

Gaining insight into the role of TET proteins in RNA metabolism, Guipaud et al. characterized one of the precise cellular functions of these multifunctional proteins, DNA pairing [117]. Conservation across species suggests that TET proteins have important physiological roles. TET proteins are thought to be involved in RNA transcription and/or processing [118, 119]. Besides these functions, several lines of evidence suggested a new role for TLS/FUS in DNA transaction and in DNA double-stranded break rejoining [120, 121]. Particularly, they addressed the question whether EWS displays pairing on membrane (POM) activities. Since EWS share similar features with TLS/FUS (structure, partners, and affinities), they raised the question whether it also exhibits POM activities. Accordingly, they applied the assay to 2-DE coupled to MS analysis for a global screening of catalysis of homologous DNA POM activities. This test allowed them to identify EWS, in addition to hTAF(II)68, TLS/FUS, but no other proteins, indicating a feature specific to a protein family whose members share extensive structural similarities.

This common activity suggests a role for TET proteins in genome plasticity control. The results suggest for TET proteins a role in DNA metabolism in addition to their role in pre-mRNA splicing and transcription regulation. Proteins that function at the interface between transcription and RNA metabolism affect genetic stability by regulating transcription-associated recombination. Significantly, the homologous DNA pairing activity of TLS/FUS is supported by the phenotypes of TLS/FUS-deficient mice [122, 123]. Based on these findings and on their DNA pairing activities, it is thus tempting to speculate on a role for POM proteins in genome plasticity control. This common enzymatic feature could also be of importance in understanding tumor development involving these proteins.

34.5.3 The Role of Chimeric Proteins in Sarcoma Molecular Mechanisms

Much of the understanding about the function of sarcoma genes is derived from studies of oncogenic fusions that arise from gene rearrangement after chromosomal translocation. And, obviously, even more research has been devoted to understand the mechanisms of action of the chimera proteins themselves, as necessary (but not sufficient?) effector of the tumorigenic cascade of events that ultimately cause the onset of tumoral alterations. However, although extensive work has been performed on cellular, molecular, and genomic lines of attack, little knowledge has been reported so far related to proteomics approaches (Fig. 34.2).

An alternative proteomic approach has been recently developed in our laboratory, aiming at identifying differences in protein expression and posttranslational modifications attributable to the loss of EWS-ETS protein activity: an interference shRNAi model for EWS-FLI1 was constructed in the TC71 ES cell line [124]. Protein expression levels were analyzed in cell extracts of the shRNAi clone model to gain insights into the differential changes associated with the interference of the EWS-FLI1 transcript [125]. Two-dimensional PAGE analyses were performed to visualize differences in a plethora of different conditions. Most of the changes associated with the shRNAi clone were presented as an overexpression of their protein levels (Fig. 34.2). In contrast, about one third of the proteins showed a clear reduction of their expression amounts. Further examination of those results by a MALDI-ToF MS analysis enabled the identification of significant protein changes. Interestingly, many of the identified proteins with the highest scores were molecules directly involved in RNA and DNA processing and functioning. Given the fact that the protein chimera EWS-FLI1 acts as an aberrant transcriptional factor, this evidences suggest that the interference model is altering several protein regulations, in pathways directly and indirectly related to EWS-FLI1, which in consequence brings about changes in expression patterns for molecules involved in nucleic acid activities.

Proteomic expression pattern showed differences for nuclear proteins. For instance, a component of the RNA polymerase II holoenzyme complex that is involved in DNA recombination, DNA repair, and protein folding, in agreement with previously commented reports about the involvement of TET-ETS fusion proteins in direct regulation of RNA polymerase II. Similarly, we have observed alterations in a structural constituent of the ribosome, which binds RNA during translation. An aminoacyl-tRNA synthetase was also selected; through the regulation of Akt, and therefore, modulation of the HSP90 stress-responsive activity, the biological function of this tRNA synthetase may play a role in the response of *ES* cell machinery to stress conditions [126]. Another factor engaged in protein translation is a component of the polyribosome, whose molecular function is the binding of mRNA. This protein has been reported to participate in Wnt signaling, which, in turn, has been proven to play an important role in the development of some types of sarcoma [41, 127]. The list includes more proteins involved in DNA/RNA metabolisms, as well as some others implicated in RNA translation and protein synthesis.

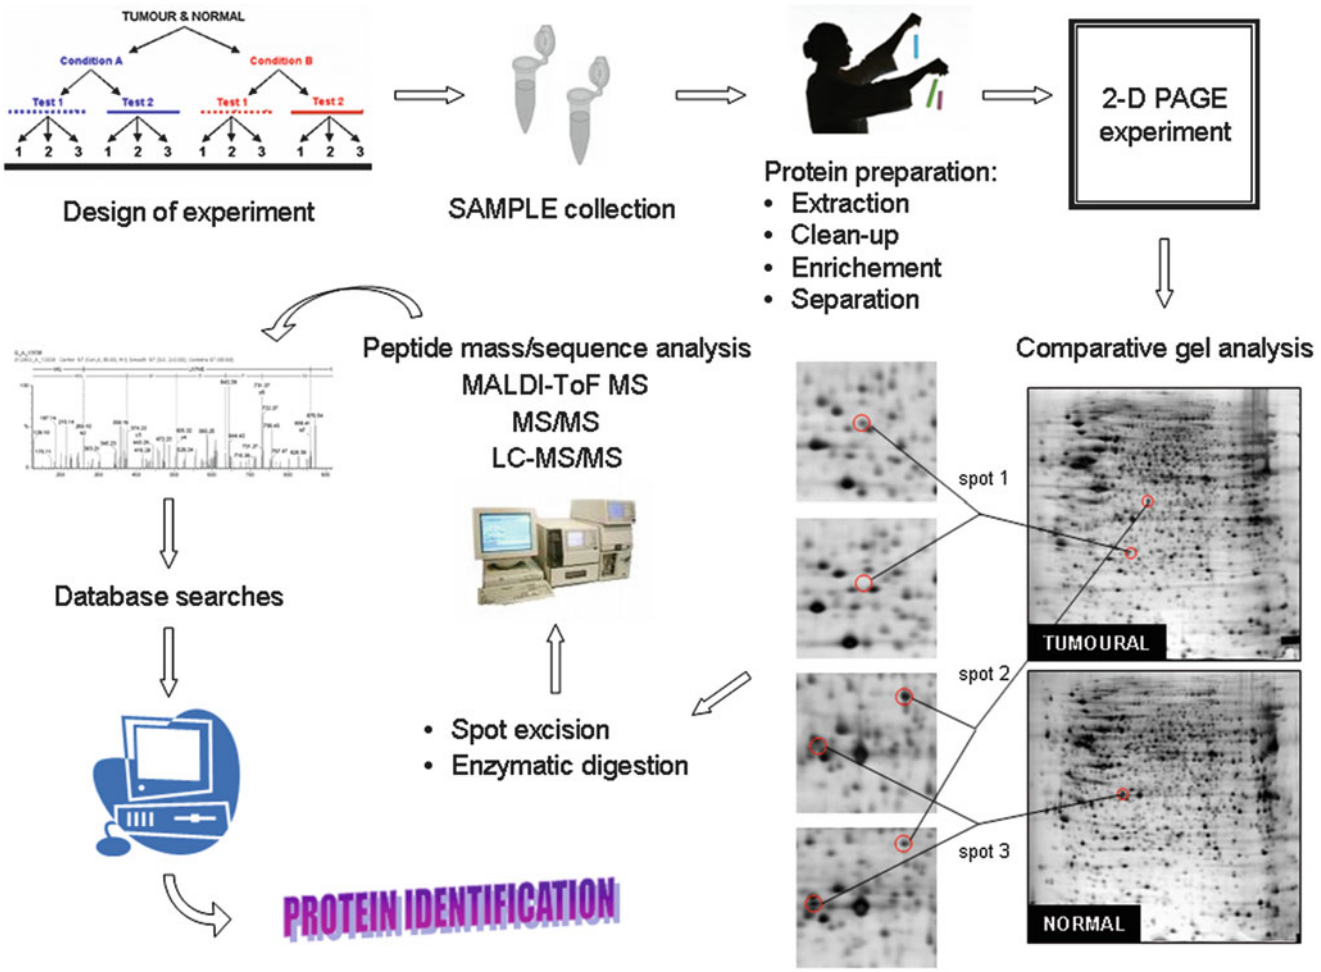

Fig. 34.2 Flow-chart diagram illustrating the experimental steps taken in a proteomics approach to characterize and identify the protein(s) present in a clinical sample. (1) Samples are collected following the recommendations from the donor tumor bank, (2) protein extracts are separated from the cellular debris, and (3) prepared for the proteomic analysis through two-dimensional electrophoresis (2-D PAGE). After isoelectric focusing in a pH gradient the electrophoretic separation is completed in a second polyacrylamide gel dimension. Proteins can be then visualized after staining (chemically or radioactively). A close-up 2-D PAGE image of an assay showing protein expression differences in an experimental ES cell line TC71 versus a control illustrates the proceeding of the comparison, that eventually renders information that can be linked with the pathogenesis of the studied disease; (4) proteins are digested by proteolytic enzymes to smaller peptides and their precise identity is achieved using mass spectrometry (generally performed in two ways); (5) either, precise molecular weights are measured using MALDI-ToF instruments, and the results compared with protein sequences from available databases. Or, (6) tandem mass spectrometry gives information about protein)sequence that is subjected to the search in databases; (7) finally, the identification of the protein(s) in the initial sample can be solved with almost full certainty in 90 % of the cases.

Besides that aspect of chimeric protein regulation, there is another group of proteins altered in sarcoma cells, whose functions are associated to cell cycle and cell division activities. Another protein involved in cell cycle is a serine/threonine phosphatase, essential for cell division. From previous analysis (immunohistochemistry, flow cytometry), it has been suggested that this phosphatase is involved in the accelerated growth of malignant tumor cells in sarcoma.

Finally, we identified in the shRNAi clone a group of targets related to cellular protein metabolic processes. In particular, several of them are molecules engaged in protein binding, folding, or rearranging of polypeptide bonds and structures in specific protein species. It seems that the chimera protein inhibits, in some way, several effectors that have to do with the assembling of tertiary structures of certain proteins. The overexpression of these or similar proteins in the RNA-interfered model may provide some clues about the molecular changes accompanying the redifferentiation program of cells after inhibition of the fusion gene induction. Alternatively, other candidates in this group are connected with proteolytic degradation processes. This is the case of a proteasome subunit. It has been recently pointed that EWS-FLI1 plays an important role in the prevention of senescence, leading to the unlimited growth and oncogenesis of ES cells through a decrease in the stability of p27 protein, due to increased action of Skp2-mediated 26S proteasomal degradation [128].

These results partly correlate with data from a gene expression microarray experiment, where transcript levels from the shRNAi clone and controls were registered by qRT-PCR. Further and deeper studies are currently being accomplished in our group to characterize the effect of another variables, such as the stability of the RNA inhibition with time progression, posttranslational modifications (e.g., phosphorylation, acetylation, etc.), and to quantitate the magnitude of these changes, both at the protein level, and at the translational level.

34.5.4 Functional Studies of Proteins Determining the Tumorigenicity of Sarcomas: An Overview of Protein Targets Identified

The depiction of cellular functionality that explains and corroborates the mechanisms by which cancer originates and eventually propagates has traditionally been entrusted to genomic and post-genomic strategies. For example, microarray analyses have identified differentially expressed genes from many classes that might contribute to the different steps of cancer generation and progression [129, 130], but these expression changes only suggest functional importance. RNA-mediated interference (RNAi) screens in mammalian cells can functionally assess the genome in high throughput, and these screens for cancer phenotypes have identified new gene targets [131]. However, such screens are limited because RNAi knockdown occurs over many hours, and because proteins that turn over slowly cannot be efficiently depleted. The alternative would be to develop a high-throughput approach that directly addresses protein function and is temporally restricted. Such an approach could identify new and different targets for tumor invasion or other disease-relevant processes.

Jay and colleagues exploited a previously developed technology for functional proteomics to identify and validate proteins required for cancer invasion in fibrosarcoma cells [132]. This technique, known as fluorophore-assisted light inactivation (FALI), affords the possibility of targeting a particular surface protein for destruction using the specificity of an antibody [133]. The authors revealed that the molecular chaperone heat shock protein 90 (HSP90) plays a crucial role in the invasion of fibrosarcoma cells. HSP90 was shown to promote maturation of the extracellular metalloprotease MMP2, and therefore, was identified as an important extracellular mediator of invasion.

Making also use of the FALI technology and libraries of monoclonal antibodies and phage-expressed single-chain antibodies, the same group identified CD155/PVR as a key protein in cell motility during cell invasion and migration in fibrosarcoma [134]. CD155 was found to be highly expressed in multiple cancer cell lines and primary tumors including glioblastoma. They showed that CD155 is recruited to the leading edge of migrating cells where it co-localizes with actin and alpha v-integrin, known mediators of motility and adhesion.

34.6 Cellular Signaling Pathway Categories

The cell signaling pathways (Fig. 34.3), cell surface adhesion molecules, receptor tyrosine kinases, growth factors, transcription factors, and early developmental genes expressed in these tumors identify potential candidates for therapeutic intervention and diagnostic development.

A tight clustering has been observed analyzing the gene expression data from 181 tumor types, representing 16 classes of human bone and soft tissue sarcomas on a 12,601-feature cDNA microarray [59]. On one hand, the dendrogram is populated primarily by the more poorly differentiated or dedifferentiated tumors and the typically adult sarcomas with the major branches being formed by the malignant fibrous histiocytoma tumors, leiomyosarcoma, dermatofibrosarcoma, hemangiopericytoma, and liposarcoma. On the other hand, the tightly clustered groups are assigned to the pediatric sarcomas, Ewing sarcoma, synovial sarcoma, osteosarcoma, and RMS. This could denote the existence of common signaling pathways for each branch.

34.6.1 Tyrosine Kinases

ES proliferation and survival is also determined by autocrine and paracrine activation of growth factor receptors and their ligands as insulin-like growth factor 1 [135]. EWS-FLI1 shRNA interference affects IGF-1/IGF-1R survival pathway and its downstream targets (Fig. 34.4) [136]. shRNAi clone showed a marked decrease in IGF-1 transcript and protein levels, both early and late stages (Fig. 34.4a, b), but there were no significant changes in IGF-1R protein level (Fig. 34.4b). shRNAi clone was more sensitive to the action of IGF-1R signaling pathway inhibitors (Fig. 34.4c). A higher apoptotic index was detected, as analyzed by FACS for apoptosis using annexin V (Fig. 34.4d) as well as the reduction of proteins involved in the activation of IGF-1R signaling pathway after treatment with AEW571 combined with inhibitors LY294002 and PD98059 (Fig. 34.4e).

Benini et al. analyzed the contribution of the 2 major pathways of the intracellular IGF-1R signaling cascade to the overall effects elicited by IGF-1 in Ewing sarcoma [137] Both the mitogen-activated protein kinase (MAPK) and phosphatidylinositol-3-kinase (PI3-K) signaling pathways appeared to be constitutively activated in Ewing sarcoma, likely due to the presence of the IGF-1R-mediated autocrine

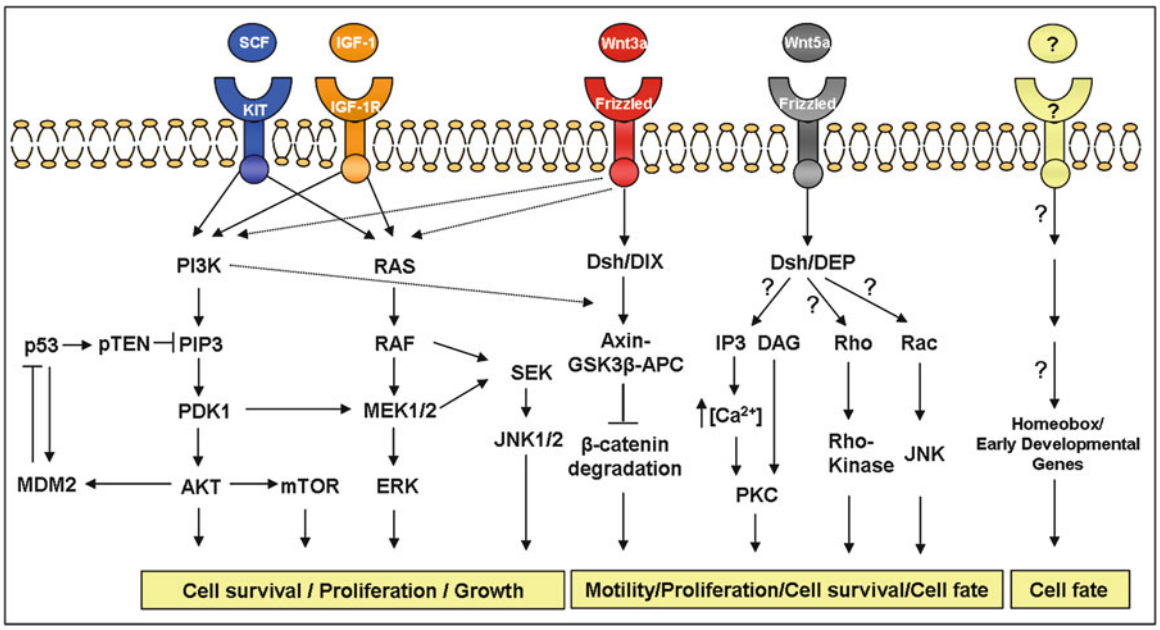

Fig. 34.3 Main cell signaling pathways described in sarcomas. This figure shows the importance of certain specific pathways in sarcomas. The Wnt-frizzled signaling pathway has been found in both, ES and synovial sarcoma. The MEK/MAPK and PI3-K signaling pathways contribute to the malignant behaviour of ES cells and gastrointestinal stromal tumor. The AKT-mTOR pathway plays a critical role in the development of leiomyosarcomas. In dashed lines are shown possible pathways interactions.

loop. Exogenous IGF-1 completely reverted LY294002-induced growth inhibition by abrogating anti-proliferative and pro-apoptotic effects of the PI3-K inhibitor. By contrast, IGF-1 could not rescue cells from growth inhibition induced by PD98059. MEK/MAPK blockade also significantly reduced the migratory ability of ES cells, both in basal and IGF-1-induced conditions, and increased chemosensitivity to doxorubicin, a leader drug in the treatment of ES patients.

Hernando et al. analyzed the PI3K-AKT signaling cascade in a cohort of sarcomas and found a new and critical role for the AKT-mTOR pathway in smooth muscle transformation and leiomyosarcoma genesis [35]. PTEN is a dual–function lipid and protein phosphatase originally identified as a protein encoded by a tumor suppressor gene, found to be frequently mutated in sporadic cancers and hereditary disorders. The main substrate of PTEN is phosphatidylinositol-3,4,5-triphosphate (PIP3), a second-messenger molecule generated by the action of PI3Ks. PIP3 activates the serine-threonine kinase AKT, involved in cell survival, proliferation, and growth. Other alterations, such as IGF-1 or IGF-1R overexpression, also frequently observed in leiomyosarcoma [138], could ultimately account for the observed upregulation of this pathway.

The putative aberrant signaling provided by c-*kit* overexpression may be dispensable for Ewing sarcoma development and is unlikely to constitute a critical therapeutic target [139, 140] Baird et al. found highly expressed tyrosine kinases or receptor tyrosine kinases associating with half of the tumor groups [59] Along with known highly expressed kinases, such as *KIT* in gastrointestinal stromal tumor and *PDGFRB* in dermatofibrosarcoma protuberans, they additionally found *JAK1* in Ewing sarcoma, *FLT1* in hemangiopericytoma, *EGFR* and *PDGFRA* in synovial sarcoma, and several *FGFR* in osteosarcoma.

34.6.2 WNT Signaling Pathway

The *WNT* signaling pathway (Fig. 34.3), involved in the development of brain and the peripheral nervous system, has been found to play a critical role in the formation of several cancers [141], including synovial sarcoma [142–144], Ewing sarcoma [145], and malignant fibrous histiocytoma [41]. Wnts activate a canonical pathway that is characterized by accumulation of β-catenin in the cytoplasm. In the absence of Wnt signaling, cytoplasmic b-catenin forms a complex with Axin, adenomatous polyposis coli (APC) gene product, glycogen synthase kinase-3b (GSK-3b), and casein kinase I-a (CKIa). Phosphorylation of β-catenin by CKIa and GSK-3b results in its ubiquitination and rapid degradation [146–148]. Wnt binding to Fz and LRP5 or LRP6 disrupts this degradation machinery by a process that involves Disheveled (Dvl)-dependent recruitment of Axin to the plasma membrane [147]. As a result, unphosphorylated

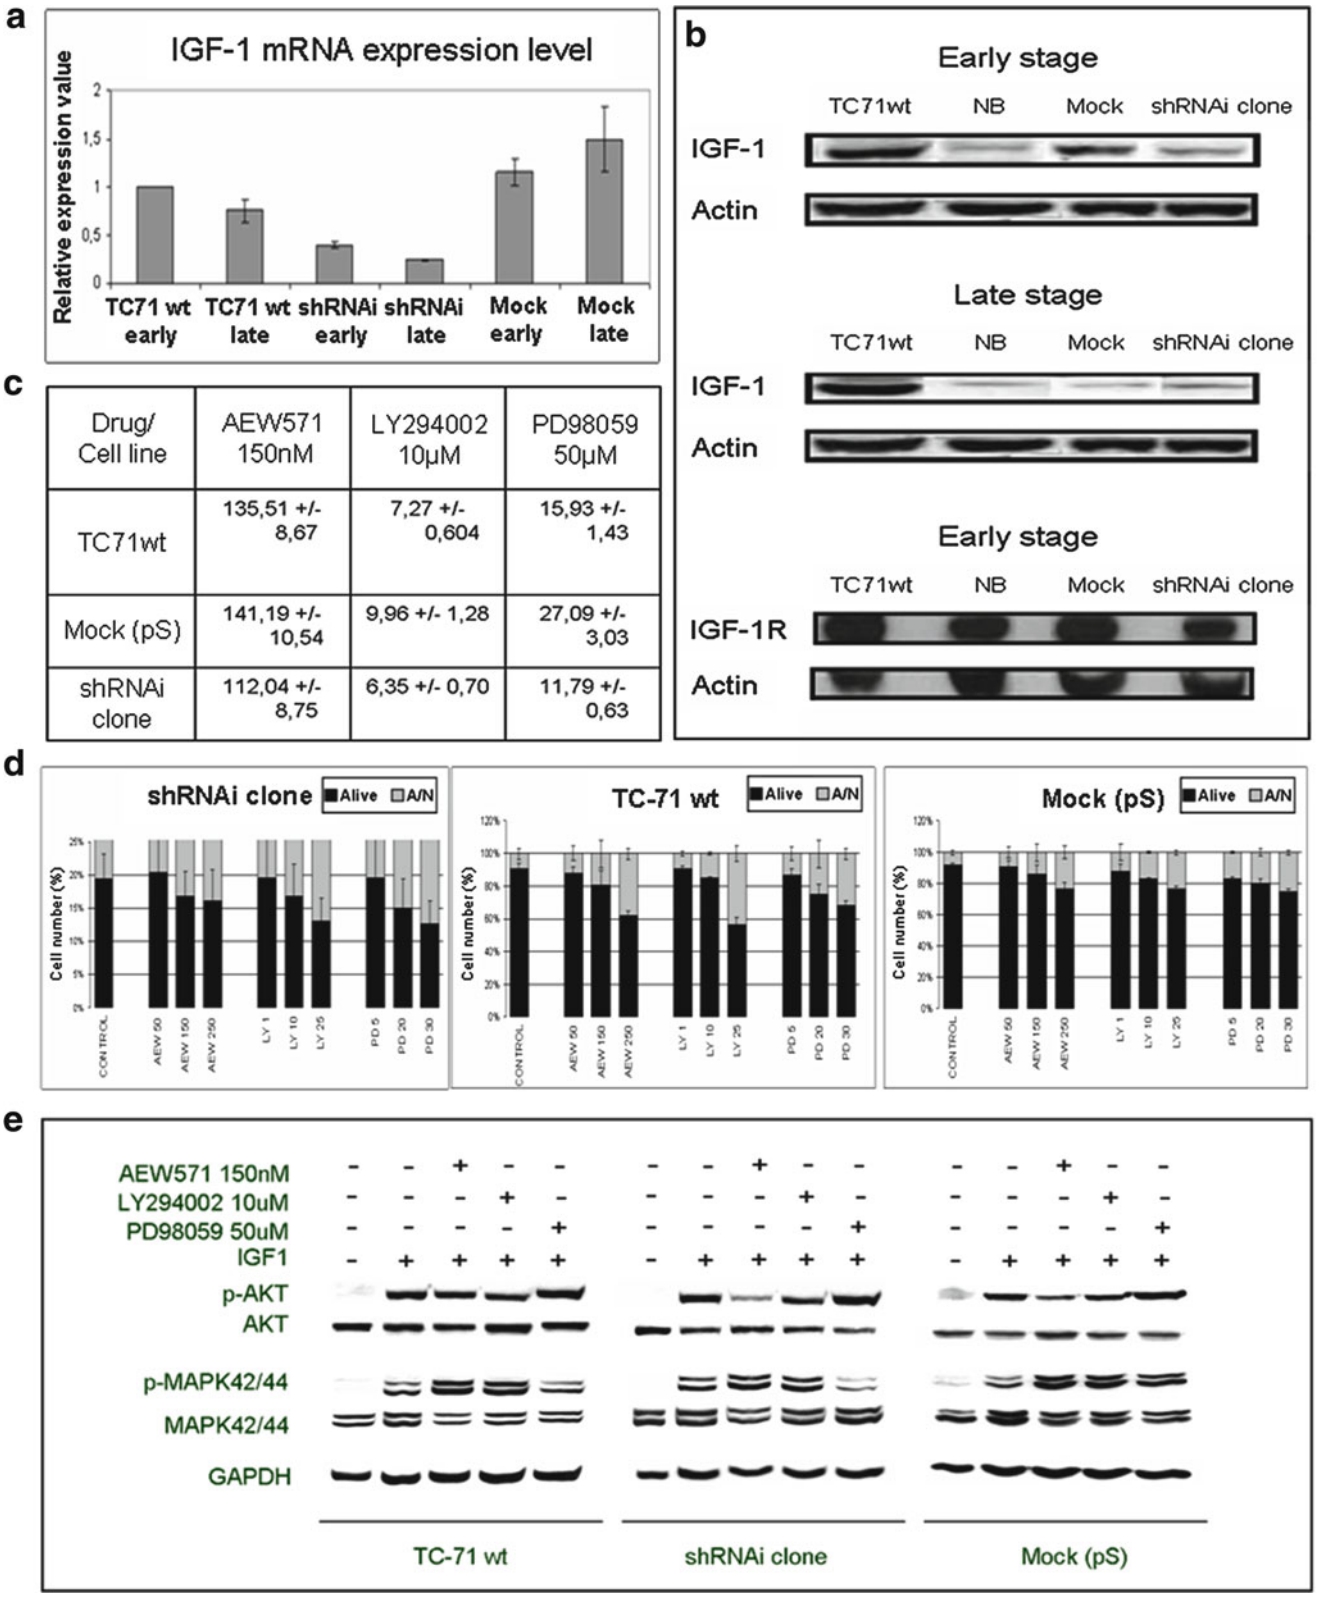

Fig. 34.4 EWS-FLI1 shRNA interference affects IGF1/IGF1R survival pathway and its downstream targets. (**a**) IGF1 mRNA expression level in TC71wt, shRNAi and mock (early and late stages) determined by qRT-PCR. (**b**) IGF1 and IGF1R protein levels as assessed by Western Blot. (**c**) IC50 of proliferation after AEW571, LY294002 or PD98059 treatment at 72 h of incubation measured by MTT assay. shRNAi clone is more sensible to the action of drug and inhibitors. (**d**) Apoptotic index after AEW571, LY294002 or PD98059 treatment at 72 h of incubation cells were seeded on 24 well plates, 72 h after cells were analyzed by FACS for apoptosis using an annexin V detection kit assay. The means ± standard deviations (error bars) of 4 independent experiments are shown. (**e**) Effects of AEW571 combined with inhibitors LY294002 and PD98059 on the activation of IGF1R signaling pathway. All conditions were treated with AEW571 during 15 min and with the inhibitors for 2 h, before IGF1 stimulation (50 ng/ml) during 15 min (serum-free conditions). Data obtained from Herrero et al. 2010. Permission applied [136].

β-catenin accumulates in the cytoplasm and nucleus, forming a complex with members of the TCF/LEF-1 family of transcription factors that activates transcription of target genes such as c-myc and cyclin-D1 [149–151]. Mutations of Axin, APC, and β-catenin have been characterized in numerous human malignancies including colon cancer, malignant melanoma, hepatocellular carcinoma, endometrial carcinoma, ovarian carcinoma, and prostate cancer [152, 153]. A common outcome of these mutations is the accumulation of free β-catenin, mimicking constitutive Wnt activation. Saito et al. showed that APC mutations also occur in sarcomas, especially in synovial sarcoma, and the possible inactivation of the APC gene by missense mutations was thought to contribute to the accumulation of b-catenin in synovial sarcoma [154]. Baird et al. also found evidence implicating this pathway in synovial sarcoma [59]. *WNT5A* expression was pronounced, as was the expression of the *WNT* signaling targets *FZD1, CDH4, EN2, TLE4*, and *TLE1*. *TLE1, WNT5A, FZD1*, and *TLE4* were ranked among the top 50 discriminating genes for the synovial sarcoma, and both *WNT5A* and *FZD1* showed heavy staining on the tissue microarray as well. Uren et al. showed evidence that Wnt/Frizzled signaling is functional in Ewing sarcoma cell lines [145]. They observed a marked stimulation of the β-catenin/canonical Wnt pathway in ES cells treated with Wnt-3a. Wnt-3a induced morphologic changes characterized by the formation of long cytoplasmic extensions in ES cells. β-catenin/canonical Wnt signaling enhanced ES motility, contributing to metastasis, and it could occur through either autocrine or paracrine modes of Wnts since they are expressed in bone, muscle, and soft tissues. They also observed chemotaxis of ES cells in response to Wnt-3a. Both canonical and non-canonical Wnt pathways have been shown to modulate cell motility and tumor metastasis, but non-canonical Wnt pathway is pending of demonstration in ES.

34.6.3 Homeobox and Early Developmental Genes

The homeobox genes are involved in early embryonic development and in the determination of cell fate. There is interest in defining the relationship between deviant expression of these early developmental genes and their role in cancer. Specifically, aberrant homeobox gene expression has been linked to the development of leukemia, testicular cancer, breast carcinoma, as well as several other tumors [155]. Several homeobox genes have been identified in the gene expression profiles of various sarcomas: *MEOX2* in synovial sarcoma [144], *HOXA5* in liposarcoma [60], and *MEOX1* in dermatofibrosarcoma protuberans [156].

34.6.4 Study of Cell Regulation by Proteomics: Proteomic Analysis of Responses to Gene Regulation, Chemicals, Viral Infections, or Therapeutic Treatment in Sarcoma

Alternative proteomics approaches can also combine the disciplines of protein chemistry, molecular biology, and histopathology to paint a portrait of the protein circuitry in diseased cells. It allows the identification of the molecular circuitry of various proteins in a tumor by noting their state of activation (translocation and phosphorylation) and correlative expressions. So far, this approach has been only utilized to depict the mTOR pathway in mesenchymal chondrosarcoma [157].

The combination of 2-DE, MALDI-ToF MS, and bioinformatics offers to the biomedical researcher an opportunity to study the profile of changes in protein levels. Taking advantage of such combination of proteomic tools, and to better understand the mechanisms by which ascochlorin (ASC) regulates physiological or pathological events and induces responses in the pharmacological treatment of cancer, Chang and collaborators performed differential analysis of the proteome of the human osteosarcoma cells U2-OS in response to ASC [158]. In addition, the authors established the first two-dimensional map of the U2-OS proteome. They identified 117 proteins whose expression showed consistent differences in their expression patterns with ASC treatment. Most of the proteins downregulated in U2-OS cells treated with ASC are associated with tumor growth, suggesting that ASC may be useful as a potent clinical suppressor of tumor invasion, a topic of considerable interest in the biological chemistry of chemotherapeutic agents.

In many cases, as seen in the previous examples, sarcoma cell lines are employed as model systems wherein mechanistic molecular schemes are studied. Control of cell-cycle progression, mediation of invasion and migration, evasion of apoptosis, etc. constitute checkpoints that are usually investigated in cell line models of different types of tumors in response to different agents. E2F1, for example, is an essential transcription factor that regulates cell-cycle progression and apoptosis. Overexpression of E2F1 sensitizes neoplastic cells to apoptosis and leads to tumor growth suppression, making it an interesting target for anticancer therapy. Li et al. performed a differential proteome analysis to identify proteins associated with E2F1 activity in inducible p53-deficient Saos-2ERE2F1 osteosarcoma cells [159]. Thirty-three proteins were reproducibly identified, and most of them were the products of genes known to be cancer related. Proteome analysis provided, in this case, new information that may be considered when using E2F1 as a drug.

Using different models of sarcoma xenografts (SK-N-MC and IMR32 (neuroblastoma), RH1 and RH30 (RMS), and KHOS/NP (osteosarcoma), Izbicka et al. evaluated and compared the effects of docetaxel and paclitaxel [160]. The approach used immunoblotting and surface-enhanced laser desorption/ionization (SELDI) MS to assess the drug effects on the expression of the beta-tubulin isotypes and apoptotic markers (Bcl-2, Bax, Bcl-XL). However, the results of this anticancer activity showed no apparent correlation with drug effects on those proteins. The drugs had significantly different, yet highly heterogeneous effects on the tumor levels of the proteins. In contrast, six protein species identified by proteomic profiling were consistently and differentially regulated by docetaxel and paclitaxel in all xenografts.

The mechanisms underlying the clinical outcome of interferon alpha (IFNalpha) treatment of pleomorphic sarcoma (PS) were also investigated using proteomic approaches. A proteomic analysis of 120 signaling components in growth arrested, apoptotic PS cells showed that the relative endogenous expression levels of the IFNAR2 (the IFNalpha/beta receptor) isoforms influence the cytostatic and pro-apoptotic effect of IFNalpha on PS cells [161]. The levels of the receptors may dictate the signaling pathways triggered by the ligand, such as to cause exclusively cell cycle arrest or induce programmed cell death.

The study of ES has provided, as well, a few examples of how proteomics may deepen our understanding about the mechanisms regulating the response to different treatments. The disease expresses several deregulated autocrine loops mediating cell survival and proliferation that contribute to its pathogenesis. Insulin-like growth factor I receptor (IGF1R) and KIT are transmembrane receptors that mediate two of these loops [139, 162], and are therefore directly involved in the growth and survival properties of ES [163–165]. Their blockade is a promising therapeutic approach for this neoplasm. Martins et al. reported the in vitro impact of IGF1R/KIT pathway blockade on ES cell lines [166] and afterwards they extended their observations to the level of proteomic changes induced by this treatment, to find and validate new possible therapeutic targets. Two-dimensional PAGE analysis and MALDI-ToF studies of ES cell lines treated with ADW742 and/or Imatinib (specific IGF1R/KIT inhibitors) revealed a large panel of differentially expressed proteins, some of them related to stress-induced response. Among them, the changes in protein expression between cell lines sensitive and resistant to IGF1R/KIT inhibitors were particularly significant in the case of HSP90 [167].

Response to stress is a key mechanism conditioning drug sensitivity. Stress-protective HSP are often overexpressed in neoplastic tissues and cancer cell lines [168–170], and therefore HSP inhibition might become a new therapeutic strategy to inhibit multiple receptor pathways. The authors illustrated that inhibition of HSP90 with 17-AAG (a specific HSP90 inhibitor) and siRNA reduced ES cell line growth and survival, especially in cell lines that previously showed resistance to IGF1R/KIT pathway blockade. 17-AAG treatment induced HSP90 client protein degradation, including AKT, c-KIT or IGF1R, by inhibiting their physical interaction with HSP90. Animal models confirmed that HSP90 inhibition, alone or combined with IGF1R inhibition, significantly reduced tumor growth and expression of client proteins. The authors postulate, for the first time in ES, that in addition to the levels of expression and basal activation of IGF1R/KIT, the development level of the stress response mechanism is another important determinant of sensitivity to ADW/IMA in ES cell lines. Importantly, targeting HSP90 function might be of therapeutic value in ES, especially in cases of previous resistance to IGF1R/KIT pathway blockade.

In the same sense, another study has recently confirmed the susceptibility of targeting Heat Shock Proteins (HSP) as a potential anticancer therapy in ES and neuroblastoma (NB) [171]. In the study, to perform a comprehensive evaluation of the HSP response, the authors firstly identified the HSP expressed in ES and NB cell lines by a sensitive proteomic profiling. Cell lysates were analyzed by a combination of 1-D PAGE and automated nano high-performance-liquid-chromatography coupled with electrospray quadrupole time-of-flight (nano HPLC-ESI-Q-TOF). Then they studied the response to doxorubicin (an antibiotic used as an anticancer drug) mediated by HSP on the cell lines. As previously described, quercetin was shown to inhibit HSP at transcriptional level [172, 173]. The effect of quercetin caused a potent doxorubicin sensitization in NB and, to a lesser extent, in ES cells. In the experiments, quercetin exerted an intense pro-apoptotic effect and increased significantly the pro-apoptotic effect of doxorubicin. These results were mediated by HSP in all cases, and even to an extent in which, interestingly, quercetin sensitizing effect was higher in cells with higher HSP levels. The sensitization to doxorubicin found in NB and ES cell lines might be of potential clinical interest because maximal quercetin effect was observed at quercetin concentrations that could be reached in plasma following intravenous administration without serious side effects.

34.7 Applications: Molecular Diagnosis of Translocation

34.7.1 Techniques for Detecting Translocations

Quantitative RT-PCR is a common technique in our clinical setting, especially when we have frozen samples in stock. cDNA is used as template and primers exon sequences flank

the rupture points of translocations. Amplified products are resolved in an agarose gel. Optionally, DNA product in agarose gel may be transferred onto a nylon membrane and incubated with DNA complementary probes. Some authors suggest the use of quantitative RT-PCR for diagnosis [174].

Rupture points in translocations usually take place in certain introns. However, the site within the intron where the rupture takes place is very variable. As a result the fusion structure at genomic DNA level is less predictable than that at RNA level, where it has a more constant number of exons from each gene involved in the fusion. This is the reason why RNA is the material of choice for detecting translocations in sarcomas using RT-PCR. We therefore insist on the creation and maintenance of tumor banks, as frozen material is the best source of good quality RNA.

Other diagnostic methods include *conventional cytogenetics* and fluorescent *in situ* hybridization (FISH). Specific probes flanking rupture points in translocations *(fusion signal probes)* are marked with fluorescent molecules. At least two probes are necessary for detecting sequences, one for each gene involved. Each probe is marked with a different fluorochrome. We recently developed a FISH probe to detect EWS-FLI translocations which allow us to show that MSC-P does not show the chimeric rearrangement [10]. Other times, probes are designed for detecting any gene rearranging in the fusion *(split signal probe)*. The advantage of the FISH method is that it can yield trustful results even when the amount of available tissue is scarce or when there is only paraffin-embedded material left, and it can be used for tissue microarrays [175], or it can even be used in tumor tissue samples. The rub is that a fluorescent microscope is necessary, and this makes the FISH method a technique difficult to be integrated in a small pathology lab. The CISH technique, wherein immunofluorescence is substituted by a chromogen (similar to those employed in immunohistochemistry), is employed in diagnostic routine for detection of gene amplifications (e.g., HER2 in breast carcinoma) but at least with current technology has a poor use for detecting translocations [175]. In the future, this technique could be used for detecting translocations in sarcomas if it were suitably improved.

Very differently to what takes place with lymphomas, a few types of proteins can be detected with *immunohistochemistry*. The alveolar sarcoma in the soft tissues is a good example of it; it shows a t(X;17)(p11;q25) translocation and a TFE3-ASPL fusion. An effect derived from fusion is the TFE3 overexpression. This can be detected by over-the-counter monoclonal antibodies, and represents a practically specific finding which is shared by some kidney carcinomas in children [176]. Another example is seen in the desmoplastic tumor of small round cell tumor, wherein a fusion is detected; it includes the EWS amino-terminal end and WT1 carboxy-terminal. Immunohistochemistry can be accomplished by antibodies directed to WT1 amino domain and carboxy-terminal [177]. The fusion is detected thanks to the immunoreactivity of the latter and the absence of it within the first domain. Similarly, NPM-ALK fusion can be detected in 60 % of inflammatory myofibroblastic tumors; the overexpression of ALK1 carboxyl domain is detected thanks to a specific antibody [178], while in other similar morphological lesions (nodular fasciitis, fibromatosis) no immunoreactivity is found for ALK1. Last example is the atypical lipomatous tumor/well-differentiated liposarcoma (ALT-WDLPS) and dedifferentiated liposarcoma (DDLPS) which may be difficult to distinguish from benign adipose tumors and from poorly differentiated sarcomas, respectively. Genetically, they are characterized by amplification of *MDM2* and *CDK4* genes on chromosome 12q13-15. MDM2 and CDK4 immunostainings, which correlate with gene amplification, are helpful adjuncts to differentiate ALT-WDLPS from benign adipose tumors and to separate DDLPS from poorly differentiated sarcomas [179]. Although in practice it is hard to have specific antibodies for each epitope of interest, this system could be employed in some other translocations that are present in sarcomas.

34.7.2 Detection of Translocation in Clinical Material

Despite the fact that sometimes we have to rely on a small or morphologically distorted biopsy, a great advantage of molecular pathology techniques is the fact they provide material fixed in formaldehyde and embedded in paraffin [180]. RT-PCR can detect them in roughly 50 % of cases, depending on the author's experience. RNA is extracted with a longer proteolytic treatment than usual and employing primers that delimit a very short PCR product. For instance, the French Sarcoma Group [181] proved, through a study that includes the detection of SYT-SSX fusions, characteristic of the synovial sarcoma in 250 tumors fixed with several usual fixatives and embedded in paraffin, that the technique's sensitivity is over 95 % (as long as tissues are not fixed with Bouin) and specificity reaches 100 %. FISH output is, at least, similar to that of RT-PCR with regard to paraffin-embedded material [180].

As for cytologic material, not only extensions but also material obtained through fine needle aspiration cytology is a good source of high-quality RNA for cytogenetic and molecular studies [79, 80, 182]. Routinely, once the diagnosis is certain, we carry out an additional sample for molecular studies. RT-PCR and FISH are especially easy applicable techniques for cytological samples from mesenchymal tumor origin.

34.7.3 Should Molecular Techniques to Detect Translocations Always Be Carried Out?

It is obvious that anatomopathological diagnosis, in most sarcomas, is carried out with many difficulties when it is represented under its usual clinical-pathological context (age, localization, etc). To answer this question, we would like to make a distinction between essential and convenient indications. The following are essential ones:

- The appearance of an unusual morphological variant (e.g., a synovial sarcoma, poorly differentiated, which appears in the usual place and age for a 27-year-old male, close to knee joint; a tumor similar in morphology to an adamantinoma on the frontal tibia side, but having areas with round cells, may suggest the differential diagnosis with a ES).
- The appearance of a sarcoma with a usual morphological aspect, but at an unusual age. It is applicable to round cell or spindle-shaped sarcomas, having translocations that are characteristic in patients over 40 years (Fig. 34.5).
- The appearance of a sarcoma with a usual morphologic aspect, but in an anomalous localization (e.g., a cutaneous ES, vesical or renal; they may be mistaken for small cell/neuroendocrine carcinomas).
- Differentiation between a sarcoma and some other tumor which may simulate it, the latter not being a sarcoma. The most usual example in my experience is that regarding a fusocellular tumor in the costal ribs which suggests a differential diagnosis between synovial sarcoma in pleura and pleural mesothelioma or a malignant solitary fibrous tumor; or the differential diagnosis between a melanoma and a clear cell sarcoma of soft tissues.
- Detection of point mutations in genes is key for cellular signaling. The best example at present is detecting the presence and exonic localization of c-kit mutations for the differential diagnosis of GIST and diagnosis of their secondary resistances to imatinib/sunitinib.

When in previous situations it was *necessary* to resort to molecular techniques to be able to confirm a diagnosis, perhaps it may be convenient, from a dimension more bound to research, to carry out molecular assessments in as many cases as possible. This must be specially taken into account with regard to the design of clinical trials, wherein molecular data may become inclusion criteria for patients or in the case of tumor banks whose value is proportional to the quantity and quality of clinical and molecular data attached to each sample.

34.8 Minimal Residual Disease Detection

RT-PCR is extremely specific and sensitive; it permits the detection of very low levels of tumor cells, even if they are mixed with a high number of healthy cells, as in the case of bone marrow samples, or peripheral blood. Therefore, it is a robust method for carrying out a molecular staging, or monitoring the response to treatment. Determining the presence of cells with chimeric transcripts by RT-PCR has an unquestionable potential in clinical applications, as tumor staging is the variable having more prognostic value in sarcomas. Presumably some patients with localized disease may have an unfavorable prognosis due to a minimal metastatic disease presence, undetectable by conventional methods. There are, for instance, several groups who report that the detection

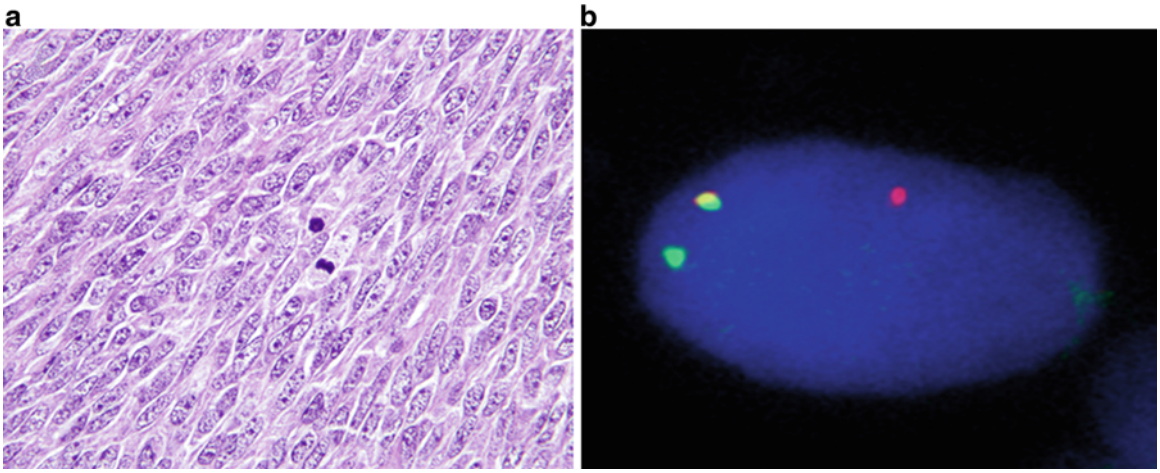

Fig. 34.5 Molecular pathology applied to diagnosis. This case corresponds to a 72 year-old woman with a solitary nodule in the lung, with a wide involvement of the pleura. Tumor morphology shows (**a**) a spindle cell malignant tumor; differential diagnosis in this location included a synovial sarcoma and a sarcomatoid mesothelioma. Demonstration of SYT rearrangement by FISH (**b**), characteristic of synovial sarcoma, seen as a splitting of one pair of green-red signals, was useful to confirm the diagnosis of synovial sarcoma.

of cells having EWS-FLI1 or EWS-ERG fusions in peripheral blood or bone marrow in patients with localized disease is associated to tumor progression or systemic relapses of Ewing tumor [79, 80, 183]. Similar results have been observed by detecting PAX3-FKHR fusions, which are characteristic of alveolar RMS [184]. However, there are still a large number of methodological and clinical questions to resolve in order to know what sort of prognostic and therapeutic implications entail the detection of any circulating disease through RT-PCR.

34.9 Translocations as Therapeutic Targets

From now on, determining the molecular mechanisms involved in the genesis of the different sarcomas may have very important consequences at the time of improving treatments for patients who suffer from these neoplasms. The point is that new drugs can be designed for acting specifically on some of these gene alterations. As we have expressed previously, some chimeric proteins have kinase tyrosine activity; some of them may respond to imatinib (Gleevec). For example, some clinical studies on the treatment of dermatofibrosarcoma protuberans with imatinib have been published and they show an excellent response rate [185]. Let us not forget this tumor overexpresses a tyrosine kinase activity, and imatinib shows an intense action against it [186]. Some other chimeric proteins will probably benefit from new drugs, as shown in Table 34.2. Lastly, in the case of chimeric proteins (mostly in sarcomas) as transcription factors, the RNA interference phenomenon has been put into practice experimentally on, for instance, some cellular lines in Ewing tumor with EWS-FLI1 fusion; a diminution in both, the transcription and translation of the fusion, as well as a marked modification of the tumorigenic capacity of tumor cells, both in cellular and animal models, was observed (Fig. 34.4) [124, 187]. Interestingly, some recent reports have shown some drugs with certain specificity towards EWS-FLI inducing tumor cell death [188]. These results are very stimulating as they open the door to new therapeutic possibilities, although it will not be easy to transfer this model to clinical trials. Besides, it is believed this experimental technique, together with opposite experiments, namely, studies on inducible expression of fusions [189] will be useful for the research of target genes in chimeric proteins; these genes, in turn, could become therapeutic targets.

Table 34.2 Gene fusions that trigger tyrosine kinase activity

Tumor	Protein	Imatinib treatable?
Dermatofibrosarcoma protuberans	COL1A1-PDGFB[a]	Yes
Infantile fibrosarcoma	ETV6-NTRK3	No
Inflammatory myofibroblastic tumor	TMP3/TMP4/ CLTC2-ALK	No

[a]Through PDGFR

34.10 Sarcoma Classification

34.10.1 Contribution of Translocations

(a) At present, we accept that both Ewing sarcoma and peripheral primitive neuroectodermal tumor of bone and soft tissues (pPNT) are the same entity, having a variable degree of neural differentiation, due fundamentally to the fact that they share an equal function (for instance, EWS-FLI1, to mention the most frequent one) [190].
(b) TLS-CHOP fusions are present both in round cell liposarcomas and myxoid liposarcoma; this confirms it is the same entity, something we suspected, as tumors having areas with both patterns had been previously reported.
(c) Most extraskeletal myxoid chondrosarcomas have EWS-CHN fusion, which is absent in bone myxoid chondrosarcomas. This fact, together with some clinical–pathological differences, suggests they are diverse entities.
(d) Some undifferentiated RMS, having a solid growing pattern, and liable to be diagnosed as embryonary, turn up in localizations and age groups typical for alveolar RMS. They also have PAX3-FKHR fusion, very typical of the latter, and represent the solid variant of alveolar RMS.
(e) DSRCT is not only peculiar for its clinical presentation in the form of peritoneal nodules in male adolescents, and for its divergent immunophenotype, but also for its characteristic gene fusion EWS-WT1, which was actually reported simultaneously to the tumor entity.

34.10.2 Genomics Contribution: Application of Multiple Expression Techniques

Even though genomic and proteomic mass analysis techniques may be employed for sifting mutations or detecting polymorphisms, the study of gene expression profiles is the most straightforward application in the field of gene expression. Although all cells have the same genes, only 5 % of them are expressed in a particular cell at a particular moment. Therefore, the study of gene expression through multiple expression techniques yields a privileged piece of information on the function and state of a healthy tumor cell. Whatever the technology employed in the multiple expression studies (DNA or oligonucleotides arrays), it is advisable to mention the result that has been obtained consists in the relative level of expression of a problem sample with regard to that of control. That is to say, it represents quantitative

changes in the gene of the problem sample between two different samples. These differences may reach several hundred-fold. The great amount of data obtained calls for the application of a bioinformatics technique in an attempt to group all studied problem samples with regard to their similarity in expression patterns. There are two systems of grouping, called supervised or non-supervised. In supervised grouping systems some previous knowledge of the analyzed objects is taken into account (e.g., anatomopathological diagnosis) for carrying out a comparison between two tumor groups differing in a specific characteristic (e.g., liposarcoma versus leiomyosarcoma, good response versus bad response). On the other hand, non-supervised analysis is carried out without paying attention to any previous knowledge in order to avoid any bias in the classification [191].

There are few studies employing this technology in sarcomas. Nielsen and col., for instance, employed various types of cDNA microarrays to analyze 46 samples from all types of sarcomas [60]. First carrying out a non-supervised study they found five large groups of genes that express coordinately. Three of these groups correspond to GIST, synovial sarcomas, and schwannomas, the fourth group represented leiomyosarcomas, and the fifth one represented a group of tumors that included all malignant fibrous histiocytomas, pleomorphic liposarcomas, and a second group of leiomyosarcomas. It is comforting, and not surprising, that a non-supervised analysis comprising tens of thousands of genes reproduced quite well the classification of sarcomas pathologists have been using for the last 100 years; nevertheless, this analysis represents certain refinement in the classification of sarcomas. As an example, malignant fibrous histiocytoma is not an entity itself; it represents a group of high-grade sarcomas including liposarcomas and pleomorphic leiomyosarcomas. Secondly, Nielsen et al. carried out a supervised analysis (that is to say having the diagnosis in mind) to see what genes make one type of tumor different from another. In this study, they saw some genes codifying proteins already known and employed for differential diagnosis in sarcomas through histochemistry (e.g., Kit for GIST, or S-100 for schwannomas), but also tens of genes with differential expression, unknown until now, that could be employed from now on in the differential diagnosis [60].

Some studies are rather focused on specific groups of tumors, as in the case of a study that supports the classification of clear cell sarcomas in soft tissues as a subtype of melanoma thanks to its expression profiles [192]. However, some other studies yield contradictory results, for instance, with regard to differentiation between synovial sarcoma and malignant peripheral nerve sheath tumor (malignant schwannoma). While a study by Nielsen and col., previously mentioned, sets them apart, an article appeared almost simultaneously showing them to be associated in the same group. A number of methodological aspects can be in the origin of this situation.

A new group of studies seems to be more useful and practical. For instance, a new study carried out by a British group [193] is capable of finding a few genes whose expression levels arrange, at the diagnostic instant, leiomyosarcoma patients into two groups, showing a clearly different probability of producing metastasis during the course of the disease. A study including 29 RMS (alveolar and embryonary), well characterized from the cytogenetic point of view, finds a group of genes that differentiate both subtypes, and, best of all, finds a new type of translocation when a patient showing no known translocations and included in the alveolar RMS group was re-studied [194]. A profound study on the genomic profile of extraskeletal myxoid chondrosarcomas points out this tumor has a high PPARG expression; there are specific inhibitors against it and it could become a therapeutic target [89]. A complete expression study was published on 181 sarcomas, with the help of cDNA arrays, wherein some important molecular targets are identified in some tumor subtypes [59]. The authors have made a public database available on the Internet (http://Watson.nhgri.gov/sarcoma).

Multiple expression techniques must be regarded as a potentially useful complement to the usual diagnostic techniques [195]. The aim of microarray technology is not based on classifying tumors that can be classified by simpler, more economical, more conventional methods, but to get, on a genomic level, markers yielding new information on a prognostic or therapeutic basis [196]. It does not seem probable, in the short or medium term, that conventional techniques will be substituted by new molecular pathology techniques.

Contradictions shown in the genomic studies, previously mentioned, reflect the limitations these techniques show at present. They are very expensive, available in few centers and reproducibility is affected by the type of *arrays* or the sampling carried out in the tumor samples. An interesting study published recently [197] makes us reflect on the effect sampling has on the reproducibility of microarray studies. It is worth noting that the pathologist's role is to portray sarcomas (and other types of tumors) as heterogeneous entities with regard to their morphology and molecular characteristics, and therefore it is crucial, for the quality of the experiment, to carefully select the tumor areas to be studied. On the other hand, it is worth bearing in mind that results of multiple expression studies are not the objective themselves, and must be validated by RT-PCR, or immunohistochemistry on tissue section.

Bearing that in mind, it is expected that high output techniques, both genomic and proteomic, which allow a massive study of human tumor samples, will have a profound impact on the classification of sarcomas, and they will provide new diagnostic and response markers over drugs. However, we must have in stock a series of easy-to-implement tools for the clinical sphere; that is to say, its information must be easily integrated with that generated by platforms already existing.

Current platforms, for instance, are not directly applicable to the daily diagnostic routine of a National Health System such as ours. The introduction of proteomics and genomics in the clinical field will probably be carried out in the short run through the design and validation of markers that may employ the existing technological platforms in this medium, such as immunochemistry, FISH or flow cytometry, and only in the medium run through the design and validation of new genomic and or proteomic tools. In other words, it is predictable, for instance, that most markers that are derived from studies of microarrays will be adapted through immunohistochemistry to the clinical-pathological context by the development of new antibodies that may be used in paraffin-embedded material. A good example of this is the finding and subsequent validation of two new markers that are very useful in the clinical management of GIST. This was thanks to genomics and immunohistochemistry studies carried out in large series of patients. These markers are DOG1 [198] and protein kinase C theta (PKC) [199]; they are not only markers, and specific to a greater extent, but also probable therapeutic targets.

34.10.3 Proteomic Profiling and Classification of Sarcomas

Proteomics is the large-scale study of proteins, particularly their expression levels, structures, and functions. It can be defined as the study of the proteome, the complete set of proteins produced by a species, using the technologies of large-scale protein separation and identification. The term proteomics was coined in 1994 by Marc Wilkins, who defined it as "…*the study of proteins, how they're modified, when and where they're expressed, how they're involved in metabolic pathways and how they interact with one another*…" [200]. In oncological research, proteomics is an emerging technology that can evaluate normal and abnormal protein expression in tissues. To date, tissue profiling has been successfully utilized to detect proteins specific to almost any type of cancer.

For instance, Suehara et al. performed a global protein expression study on soft-tissue sarcoma (STS) in order to develop novel diagnostic biomarkers and allow molecular classification [201]. Two-dimensional electrophoresis was used to generate the global protein expression profiles of 80 soft-tissue sarcoma samples with seven different histological backgrounds. They found that 67 protein spots distinguished the subtypes of soft-tissue sarcoma. Among them, the expression pattern of a reduced group of proteins could discriminate certain types of sarcomas into low-risk and high-risk groups, which differed significantly with respect to survival. These results open the road in proteomics to develop novel biomarkers for diagnosis and molecular classification of soft-tissue sarcomas. Identification of proteins associated with survival in specific cases of sarcomas will allow delineation of a high-risk group that may benefit from adjuvant therapy leading to likely clinical benefit.

In a similar approach, Holt et al. described tissue profiling by matrix-assisted laser desorption ionization mass spectrometry (MALDI MS) as a tool for orthopedic research [202]. The usefulness of proteomic over histopathological analyses to predict STS behavior is reported to be based in its ability to objectively predict tumor grade and behavior. They detected differentially expressed proteins in high-grade and low-grade STS.

Recently, a differential approach was used to highlight proteomic changes between human osteosarcoma cells and mature osteoblasts [203]. Changes in expression profiles for 17 proteins were ascertained in human mature osteoblasts compared to pre-osteoblasts (differentiation markers). Results also showed a relative over-expression of 8 proteins (proliferation and tumor indicators), as well as under-expression of proteins also found downregulated in pre-osteoblasts (specific markers of osteoblast differentiation). In particular, three markers reported in the article exhibited features potentially related to the osteosarcoma metastatic potential. These findings also confirmed the differences between cell lines and primary human cell cultures.

34.11 Mouse Models of Sarcoma

Roughly, mouse animal models of sarcomas can be divided into two: the xenograft models and genetically engineered mouse models (GEM). Xenograft models are developed by implantation of tissue of human (xenogeneic or xenograft model) or mice origin (syngeneic model) mainly into immunocompetent mice. These models have been used mainly to test the effects of new drugs [160, 204, 205]. Such is the case of the Pediatric Preclinical Testing Program supported by the National Cancer Institute (NCI), aimed to identify new drugs active against childhood cancers, which makes use of a panel of 61 childhood tumor xenografts [205]. Xenograft models have been used also to gain knowledge about the pathogenesis and histogenesis of ES and to generate a biobank of sarcoma samples [2]. However, despite of the great amount of information that these models provide, they have some limitations. For instance, normal architecture present in the patient tumor specimens is altered in xenografts and the genetic heterogeneity is diminished as a result of the selective pressure of cell culture or tissue explantation. Moreover, in these models is not possible to assess accurately the metastasis formation, which is a key issue in the survival of patients. Therefore, the data obtained by using these models should be taken into account carefully, especially when a drug is checked [206].

Development of GEM has allowed gaining insight into the origin cell of sarcomas (Table 34.3). Several strategies

Table 34.3 GEM of fusion genes of sarcomas[a]

Model	Fusion	Promoters	Expression place	Phenotype	Reference
– Conditional transgenic (Cre-loxP) – Deletion of p53	EWS-FLI1	Prx1 (Cre mouse)	Primitive mesenchymal tissues of the embryonic limb bud	Poorly differentiated sarcomas	Lin et al. [214]
Conditional knock-in (Cre-loxP)	SYT-SSX2	– Rosa26 (loxP mice) – Myf5 (Cre mouse) – Myf6 (Cre mouse) – PAX-7; PAX3 (Cre mouse)	Myoblast Myocyte, myofiber Progenitors cells	Sinovial Myopathy Lethality	Haldar et al. [57]
Conditional knock-in (Cre-loxP)	EWS-FLI1	Rosa26 (loxP mice) MX1-cre	Bone marrow Liver, spleen, and hematopoietic tissues	Myeloid/erythroid leukemia	Torchia et al. [207]
Invertor	EWS-ERG	EWS endogenous (loxP mice) Rag1 (Cre mouse)	Lymphocyte	Leukemia	Forster et al. [210]
Conditional knock-in (Cre-loxP)	PAX3-FKHR	Pax7 (Cre mouse)	Progenitor cells (satellite)	No tumor	Keller et al. [49]
– Conditional knock-in (Cre-loxP) – Knock-out Trp53 or Ink4/ARF	PAX3-FKHR	Myf6 (Cre mouse)	Myofiber	No tumor Rhabdomyosarcoma	Keller et al. [48]
Transgenic	FUS-CHOP	EF1-α	All tissues	Liposarcoma	Perez losada et al. [208, 282]

[a]Table obtained from Ordonez et al. [2]

have been used to develop genetic engineered models of tumors showing translocations as sarcomas and hematological malignancies. These models can be generated by injection of cDNA into fertilized oocytes (transgenic mouse) or through gene targeting in embryonic stem cells. The embryo lethality as a consequence of the expression of fusion genes is the main problem to overcome [57, 207].

Some transgenic mice have been engineered to induce the expression of fusion genes in a nonphysiological manner under the control of exogenous promoters or enhancer elements [206, 208]. In its simpler version transgenic mouse are developed by pronuclear injection of gene-fusion cDNA constructs under the control of exogenous both ubiquitous or tissue specific promoters.

Another big group of models expresses the fusion genes from their native promoters through knock-in technology. Some of them make use of specific recombinases as Cre allowing a spatiotemporal control of the chimeric gene expression. These models include the knock-in model, the conditional knock-in model, the translocator model, and the inverter model [209–212]. These models use homologous recombination in embryonic stem cells (ESC) to induce gene fusions and transfer them into the mouse germ line. The knock-in strategy approach of creating fusion genes by homologous recombination in ESC was initially tested in the development of hematological malignancies [209]. However, the knock-in model has two important limitations as the embryonic lethality usually conferred by the fusion genes and the difficulty of obtain cell-specific effects. These problems can be solved by generating conditional mouse models using site specific recombinases that allow a spatiotemporal control of the chimeric fusion gene. The P1 bacteriophage Cre-Lox system is the most widely use. The Cre-recombinase mediates the recombination between loxP sites, a pair of inverted repeat DNA elements. Depending on the orientation and location of loxP sites, recombination mediates by Cre induces deletion, inversion, or translocation of the sequence of interest. To generate a Cre-lox mice expressing the fusion gene is necessary to engineered two transgenic mouse lines, a cre mouse, and a loxP mouse. The cre mouse harbors the Cre-recombinase gene under the control of a tissue specific promoter. The loxP mouse can be engineered to harbor the chimeric fusion gene and a stop cassette upstream of the fusion place or gene flanking by loxP sites in the same orientation. After breeding the two mouse lines, expression of Cre in the Cre-lox mice induces the excision of the stop cassette and subsequently expression of the fusion gene.

34.11.1 Ewing Sarcoma

Until 2001 only a few studies with models of ES, mainly xenograft had been developed [213]. At present, there have been also reported several GEM models harboring ES gene fusions but they did not show the expected ES phenotype [207, 214].

Xenograft models of ES were developed in mice implanted with murine primary bone-derived cells and mesenchymal

progenitor cells expressing EWS-FLI1 to gain knowledge about the origin of ES [22, 215]. Several ES metastatic models were also developed by injecting ES tumor cells through the tail vein of immunocompetent mice. These models resemble human ES metastatic pattern, including skeletal and extraskeletal locations [187, 216]. Recently, a different strategy to induce metastasis formation was reported. Gonzalez et al. injected cells transduced with the EWS-FLI fusion types 1, 2, and 3 into the left cardiac ventricle of athymic mice. The aim of this approach was to overcome the limitation impose by the fact that lung metastasis formation after injection of cells via tail vein could not reflect necessarily metastatic activity as lungs bear the first capillary bed that cells face after tail vein injection [217]. This model is useful to test the effects of drugs and new systems in inhibiting the tumor growth.

At present, a GEM of ES has not been developed and even there was no report indicating any attempt to achieve that model until recently [207]. The embryo lethality as a result of the expression of the fusion genes characteristic for ES is probably the main explanation to the no existence of a transgenic model to date [207, 210]. *Torchia* et al. bypassed the embryo lethality induced by EWS-FLI1 and published the first GEM of EWS-FLI1 [207]. They generated a GEM of EWS-FLI1 by using a knock-in conditional approach, using a loxP-flanked (floxed) transcription stop (loxP-STOP-loxP). The cre mouse was engineered to produce a Cre-inducible recombinase under the promoter Mx1 after administration of α/β interferon (pIpC). However, EWS-FLI expression after Cre induction after a single administration of pIpC did not generate ES tumors but instead myeloid/erythroid leukemia and provoked the death of the animals about 15 days after administration. Moreover, a group of animals that were not pIpC administered developed a similar pathology as pIpC-treated mice indicating a basal expression of Cre and consequently of EWS-FLI1 [207]. More recently, a conditional transgenic GEM was created by inducing type-1 EWS-FLI1 expression in the primitive MSC of the embryonic limb buds, making use of specific recombinases (Cre-lox system), which allow for a spatial-temporal control of the chimeric gene. However, it did not induce tumor formation, but did elicit several limb defects. Animals developed poorly differentiated sarcomas (but not ES) only in the setting of p53 deletion [214].

A different strategy was used by the Professor Rabbitts´ group, who generated T-cell lymphomas by conditional expression in haematopoietic cells of the EWS-ERG, a characteristic ES fusion gene. This goal was achieved by making use of the inverter model, (a new version of *knock-in* strategy using loxP sites) in which the target gene is orientated in the reverse direction for transcription [210]. Recently, Torres et al. using a different approached named as, RNA-guided CRISPR-Cas9 system, generated de novo EWS-FLI translocations in vitro [218].

34.11.2 Osteosarcoma

Various syngeneic and xenogeneic models of osteosarcoma have been developed. A syngeneic orthotopic model of primary osteosarcoma and pulmonary metastases was developed by implantation of tumor pieces of mouse osteosarcoma into the tibia of nude mice. These tumor pieces derived from two mouse osteosarcoma cell lines (K7M2 and K12) which showed different aggressive behavior regarding the metastatic potential [219]. The histology of these tumors was very close to the human counterpart. Another xenogeneic model of primary osteosarcoma and pulmonary metastatic lesions resembling the human lessons was developed by orthotopic implantation of a rat osteosarcoma cell line name UMR 106 into the proximal tibia of athymic mice [220]. This model has been used to study the role of urokinase plasminogen activator system (uPA) and its receptor (uPAR) showing that downregulation of uPAR expression provokes reduction in tumor growth and metastases [220, 221]. Another metastatic murine model established by using LM8 murine osteosarcoma cells which metastasizes to lung after subcutaneous implantation, has been used recently to test the efficacy of new anti-osteosarcoma treatments as gemcitabine an interleukin-18 [222, 223]. Xenograft models of osteosarcoma by using human cell lines (U2OS, SaOS-2, HOS, KRIB, and 143b) have also been reported. U2OS model of primary and metastatic disease was developed by subcutaneous and intravascular injection of cells, respectively. In this study it was assessed the anti-angiogenic effect of transfecting the alkaline phosphatase gene [224]. However, at present it has not been reported a study of testing drugs using this model. Tail vein injection of SaOS-2 cells and derived cells such as SAOS-LM6, SAOS-LM7 in athymic mice has allowed establishing other metastatic model of human sarcoma. This model was used to study the effects of new anti-metastatic drugs such as adriamycin, interleukin 12, gemcitabine [225–227]. More recently an orthotopic murine model of primary and metastatic osteosarcoma has been induced by implanting the non-transformed SaOS-2 cell line into the tibia, probing be useful in testing the anti-tumor effects of pigment epithelium-derived factor (PEDF) [228–230]. Other models have been established by using derivatives of the human osteosarcoma cell line HOS, such as KRIB, MNNG/HOS, and 143B, created by using several transforming agents as v-Ki-Ras, N-methyl-N´-nitro-N-nitroguanidine, and Ki-Ras, respectively [231]. Orthotopic intratibial inoculation of KIRB cells induced primary and secondary lesions in lungs in 100 % of mice. As review by Dass et al. other models derived from the HOS cell line derivatives has been used to test the effects of new treatments [231]. A study published recently showed a different tumorigenicity potential of HOS, MNNG/HOS, and 143B cell lines after orthotopic intratibial administration in mice. HOS mice did not develop tumors

showing the lowest grade of tumorigenicity while 143B mice develop primary a metastatic lesions showing the higher grade. The use of the three cell lines was proposed as a model to study the osteosarcoma biology [232]. Nevertheless, these models have the great inconvenient that after transformation several signaling pathways are altered and therefore do not longer mimic the human disease.

34.11.3 Liposarcoma

Some xenografts models of liposarcoma have been developed to study the biology of tumor, the efficacy of new drugs and the histogenesis [38, 233]. Perez Losada et al. generated a transgenic GEM of liposarcoma by pronuclear injection into fertilized eggs of a cDNA construct including the human FUS-CHOP gene under the control of the elongation factor 1α promoter (EF-1α). Despite the use of a ubiquitous promoter, animals developed specifically liposarcomas and the phenotype of these tumors was very close to the human phenotype, mimicking the chromosomal translocation effects [208]. Moreover, induction of FUS-CHOP seemed not to be lethal for the mice as compare with other sarcoma fusion genes such as EWS-FLI1, EWS-ERG, SYT-SSX, Pax3-Fkhr [57, 207, 208, 210].

34.11.4 Synovial Sarcoma

Haldar and col. developed a model of synovial sarcoma by inducing the expression of SYT-SSX2 fusion gene in myoblast. When the expression of the chimeric gene occurred in other cells of skeletal muscle lineage animals not developed synovial sarcoma phenotype but myopathy or embryonic lethality. They used a conditional *knock-in* strategy in which two transgenic mouse lines (loxP mouse and Cre mouse) were generated. The loxP mouse was engineered to express SYT-SSX2 from the endogenous Rosa26 promoter on chromosome 6. Between the promoter and the SYT-SSX2 cDNA there was a transcriptional termination signal (Neo-PA) flanked by loxP sites. In absence of Cre, SYT-SSX2 is not transcribed but in the presence of Cre, Neo-PA is excised and the transcription starts. The Cre mouse was engineered to induce Cre in those myoblasts expressing Myf5. This is a myogenic regulatory factor playing a crucial role in the specification of skeletal muscle lineage and whose expression starts early in embryogenesis. They also investigated the effects of expression of SYT-SSX2 in other skeletal muscle cells, which were less or more undifferentiated than Myf5 expressing myoblasts. When the chimeric protein was induced in more undifferentiated cells such as myocytes and myofibers expressing the Myf6 myogenic regulatory factor, mice developed myopathy. When SYT-SSX2 was induced in less differentiated cells such as Progenitors expressing Pax3 or Pax7 mice suffer embryonic lethality [57]. All these findings indicate the relevance of correct selection of the target cell line in which the fusion gene should be expressed. Recently, the same investigators, using a tamoxifen-inducible CreER strategy, suggested a possible non-myoblast origin for synovial sarcoma as well [58].

34.11.5 Alveolar Rhabdomyosarcoma

A conditional knock-in strategy was used to generate an alveolar RMS model, by inducing the expression of PAX3-FKHR gene in muscle skeletal cells by using a Myf6-Cre mouse line [48]. However, the only expression of PAX3-FKHR did not produce an alveolar RMS phenotype and additional inactivation of the Ink4a/Arf and Trp53 pathways was necessary [48]. Interestingly, expression of PAX3-FKHR early in development in muscle satellite cells by using a Pax-7-Cre did not trigger RMS [49, 234].

On the other hand, another GEM of RMS has been published. PTC heterozygous knock-out mice develop spontaneous RMS in a model of basal cell carcinoma [235]. Other models of RMS were developed in *knock-out* mice of p16-INK4a (−/−) transgenic for the hepatocyte growth factor/scatter factor [236]. Double *knock-out* mice Trp53−/−; Fos−/− developed invasive RMS [237]. On the other hand, an HER-2/neu transgenic mouse coupled with p53 inactivation can induce RMS [238]. Tsumura et al. developed a pleiomorphic RMS mouse model by conditional activation of RAS and P53 loss [239].

34.12 Conclusions

Sarcoma research is expected to be extremely fruitful in the next years. Both US and European opinion leaders agree in that major needs for translational research in sarcomas include some of the following ones: (1) focus research on key areas of sarcoma biology, including, i.e., cell of origin, targets of chimeric proteins, secondary genetic alterations indicating possible new tumor suppressor genes; (2) new targeted therapies in sarcomas, using key signal transduction molecules or the translocations themselves; (3) development of sarcoma-specific animal models, allowing availability of good experimental models for target discovery; (4) availability of high-throughput technologies to screen cases at the genomic DNA, RNA, or protein levels; (5) development of sarcoma-specific sample repositories (biobanks) including frozen tumor samples, cells, and plasma from sarcoma patients; and (6) development of collaborative networks of sarcoma research, allowing for interchange of materials, researchers, and sarcoma centers.

Among all of them, we believe priority should be given to the development of large research networks that avoid current fragmentation in sarcoma research, allowing for a more efficient use of research funds, and also to the development of feasible animal models carrying the genetic background of human sarcomas, especially in the case of translocation-bearing sarcomas.

Acknowledgements The authors would like to thank the members of the Diagnostic Molecular Pathology and Molecular Pathology of Sarcoma Laboratory at CIC-Salamanca, and at Hospital Virgen del Rocío- IBiS, Sevilla, as well as pathologists and oncologists of the Grupo Español de Investigación de Sarcomas (GEIS) for their collaboration and commentaries. They would also like to acknowledge: AECC (Asociación Española contra el Cáncer); European Commission (NoE EuroBoNet); the European Project EuroSARC (FP7-HEALTH-2011-two-stage, Project ID 278742 EUROSARC); Ministry of Health of Spain-FEDER (PI081828, RD06/0020/0059 RD12/0036/0017, PT13/0010/0056, PI110018), Instituto de Salud Carlos III (Contrato postdoctoral Sara Borrell CD06/00001), Regional Government, Castilla y León, Asociación Española Contra el Cáncer, Fundación Ramón Areces, Fundación Marcelino Botín, and Fundación Solórzano for their financial support. JLO was sponsored by the CSIC and the European Social Fund (postdoctoral grant JAE DOC) and by the AECC.

Molecular Biology of Human Brain Tumors

35

Daniel Coluccia, Adrienne Weeks, Javier Fandino, Christian Schneider, Christian Smith, and James T. Rutka

35.1 Introduction

The Central Brain Tumor Registry of the USA estimates the annual incidence of primary brain and central nervous system (CNS) tumors at 7.3/100,000 for malignant and 13.3/100,000 for nonmalignant tumors [1]. A true comparison of incidence numbers across different time periods and countries is difficult given the inconsistency of data collection methods and the diversity in diagnostic criteria. Available diagnosis rates for malignant gliomas spanning the last three decades do not allow the determination of an increase or decline of age adapted incidence [2, 3], despite remarkable changes of environment and lifestyle in industrial nations.

The etiology of most brain tumors is largely unknown. In gliomas, familial clustering is found in about 5 % and in 1 % an autosomal dominant inheritance is assumed [4]. Besides family history, demographic risk factors listed are age and gender. Most brain tumors such as gliomas occur in older adults with a slight predominance in males [1]. However, this might be different depending on origin and location of the tumor. For example, brainstem gliomas, medulloblastomas or intracranial ependymomas are usually found in children and adolescents [1]. Even though children constitute only 7 % of all CNS tumors, these tumors comprise 25 % of all cancers in infants and are the most frequent solid tumor and the second most common neoplasm in their age group after leukemia [1, 5]. The only established environmental risk factor is exposure to elevated ionizing radiation [2, 3]. Other environmental carcinogens possibly related to increased brain tumor formation have been examined, such as n-nitroso compounds and polycyclic aromatic hydrocarbons, but no correlation was found [2, 3]. Nonionizing radiation such as cellular phones or smoking have also been extensively evaluated, but no reliable causal link has been established [2, 3]. Chronic viral infections, which are recognized as important risk factors for various cancers [6], are also implicated as triggering processes in brain tumors. Studies of persistent immunohistochemical detection of cytomegalovirus (CMV) in glioblastoma and the benefit of adding antiviral drugs to the standard treatment protocols are still premature, but importantly remain part of an ongoing debate into the etiology of some gliomas [7, 8].

The term brain tumor applies to cancers that arise in different parenchymal layers and tissues from various cellular origins within the central nervous system. The 2007 WHO classification identifies seven categories of brain tumors, depending on the presumed histogenetic origin: (1) neuroepithelial, (2) cranial and paraspinal nerves, (3) meningeal and mesenchymal, (4) lymphomas and hematopoietic neoplasms, (5) germ cell tumors, (6) sellar region, and (7) metastases [9].

In this chapter we will focus on neuroepithelial tumors derived from central neuroglia, which have an annual incidence of 6.6/100,000 and account for the most malignant forms of primary brain tumors [1]. We review the basic biology of human brain tumors with a special focus placed on the most common primary brain tumors in adults and children including the astrocytoma and medulloblastoma (Fig. 35.1). These and other human brain tumors will be discussed insofar as their relationships to the familial predisposition syndromes,

The management strategies of human brain tumors rely mostly on histopathological characteristics that are used to predict the clinical behavior and eventual patient prognosis of a diagnosed brain tumor. Features including degree of anaplasia, mitosis, infiltration, necrosis, and neovascularization define the corresponding tumor grade, which ranges from benign, WHO grade I, to the most malignant, WHO grade IV [9]. The advances in molecular diagnostics over the last 5 years however have led to rapid genetic profiling of many brain tumors, which allow us now to recognize remarkable differences in prognosis for tumors harboring similar histopathological patterns [10, 11]. Currently, the utilization of some molecular markers informs individualized treatment decisions for patients with the same histological tumor [10]. Future revisions of brain tumors classification systems need to implement molecular profiles in order to support the differential diagnosis and to be of value in predicting the efficacy of treatment options.

Despite concerted efforts in the field of neuro-oncology, brain tumors represent perhaps the most intimidating and difficult to treat type of cancer. Compared to other neoplasms, patient with malignant gliomas still face disproportionately high rates of morbidity and mortality [12] (Table 35.1). Fortunately, recent advances in molecular biology have

Table 35.1 Clinical characteristics of common primary brain tumors

Tumor	Preferential location	Age	Gender	Annual incidence	WHO grade	Present treatment strategy	Prognosis
Medulloblastoma [1, 424–427]	Cerebellar	Median: 8 y 93 % < 15 y	m: f ~ 1.6:1	0.6/100,000 (age 1–9)	Grade IV	– Maximal safe resection followed by C (<3 y) and RT (>3 y) – High-dose C and autologous stem cell transplantation with or without RT to be considered, especially for *high-risk* group – Re-resection at progression followed by C with or without RT	Pediatric: – *5-y survival* • 42 % (infants < 1 y) • 72 % (1–9 y, including *high-* and *average-risk* (*ar*)) – *10-y survival* for *ar* group: • 81 % Adults: – *5-y survival* • 67 % WNT group correlates with good prognosis (>90 % long-term survivals)
Intracranial ependymoma [1, 208, 428]	Infratentorial (60–70 %), supratentorial (30–40 %)	Median: 8 y	m: f ~ 1.1:1	0.3/100,000	Grade II (~50 %) Grade III (~50 %)	– Maximal safe resection followed by RT – C for Grade III, non-resectable tumors, low EOR and at progression – Re-resection at progression followed by RT with or without C	Pediatric: – *5-y survival* • 66–79 % – *10-y survival* • 55–68 %
Pilocytic astrocytoma [1, 247, 249, 429]	Cerebellar (in children > 50 %), optic pathway, hypothalamus	Median: 18 y 38 % < 15 y 75 % < 20 y	m: f ~ 1:1	0.9/100,000 (age 0–19)	Grade I (>90 %)	– Maximal safe resection – Post-OP: • Usually no additional therapy, depending on EOR • RT optional for non-resectable tumors and at progression • C optional for non-resectable tumors and at progression – Re-resection at progression	Pediatric: – *10-y survival* Cerebellar: 100 % Overall: 97 % Adults: – *5-y survival* Overall: 84 %
Diffuse low-grade glioma (DLGG) – Astrocytoma (A) – Oligodendroglioma – (OD) – Oligoastrocytoma (OA) [107, 430-432]	Frontal (50 %), temporal (25 %) Insular (10 %)	Median: 45 y	m: f ~ 1.3:1	1/100,000 – A 20–50 % – OD 35 % – OA 10–45 %	Grade II	– Maximal safe resection – Post-OP: • C to be considered, especially for OD, non-resectable DLGG, low EOR and at Progression • RT for non-resectable DLGG and at Progression – Re-resection at progression, followed by C and/or RT	*5-y survival* – >95 % After GTR – 78 % if Resection < 50 % *10-y survival* – 90 % After GTR – 54 % if resection < 50 % OD and LOH 1p/19q tend to correlate with better outcome

(continued)

Table 35.1 (continued)

Tumor	Preferential location	Age	Gender	Annual incidence	WHO grade	Present treatment strategy	Prognosis
High-grade/anaplastic (A) glioma – AA – AOD – AOA [121, 206, 433–435]	Parietal, frontal, temporal	Median: 43 y	m: f ~ 1.4:1	0.6/100,000	Grade III	– Maximal safe resection followed by RT or alkylating C (AA, AOD and AOA without LOH 1p/19q) – Maximum resection followed by C with or without RT (AOD and AOA with LOH 1p/19q) – Re-resection and C/RT at progression	*Median survival* – 4.6- 6.5 y (AOD, AOA) *5-y survival* ~50–65 % (AOD, AOA) ~15–50 % (AA) *10-y survival* ~20–45 % (AOD, AOA) ~15–30 % (AA) AOD, IDH1 mutations and LOH 1p/19q correlate with increased sensitivity to RT/C and better outcome
Glioblastoma [433, 436, 437]	Temporal, frontal, parietal	Median: 57 y	m: f ~ 1.7:1	5/100,000	Grade IV	– Maximal safe resection, followed by RT plus concurrent TMZ, followed by adjuvant TMZ (age < 65–70 years) – Maximal safe resection, followed by RT or TMZ with or without RT based on *MGMT* status (age > 65–70 years) – Re-resection and C/RT at progression to be considered	*Median survival* – 14.6 mt (overall) – 23.4 mt with methylated (met) *MGMT* promoter *5-y survival* – 9.8 % (overall) – 13.8 % with met *MGMT* *IDH1/2* mutations and met *MGMT* correlate with better outcome

y Year(s), *mt* months, *m* male, *f* female, *C* chemotherapy, *RT* radiotherapy, *EOR* extent of resection, *GTR* gross total resection

provided a wealth of new information that can now be applied to improving patient treatment strategies and outcome. Modern medicine is on the threshold of achieving many tangible gains in overall patient survival based on the progress that has been made in several areas of experimental neuro-oncology.

35.2 The Familial Central Nervous System Tumor Syndromes

Most CNS tumors occur in adults and arise spontaneously with no previous family history or genealogic pattern of inheritance. In some cases, especially in younger patients, they may present as a familial syndrome and transmitted most frequently in an autosomal dominant (AD) pattern of inheritance. Advances in the identification and characterization of gene mutations have permitted insight into the molecular basis of both familial and sporadic CNS tumors.

Many familial CNS cancer syndromes are associated with mutations in tumor suppressor genes, which mediate functions such as DNA repair and cell cycle arrest. Affected individuals typically inherit a germ-line mutation in one copy of the genetic locus and in the cases of non-AD mutations, are associated with somatic loss of the wild-type allele in order to promote the initiation of tumor growth. One important distinction of the familial syndromes is the predisposition of patients to develop multiple tumors in the CNS as observed in neurofibromatosis 1 (NF1), neurofibromatosis 2 (NF2), von Hippel–Lindau disease, tuberous sclerosis complex, Gorlin syndrome, Li–Fraumeni syndrome, Turcot syndrome, and Cowden syndrome.

35.2.1 Neurofibromatosis Type 1

NF1, also known as von Recklinghausen's disease, is one of the most common inherited monogenetic syndromes predisposing individuals to the formation of CNS tumors, with an incidence of 1 in 3500 individuals and an equal predominance in both genders [13] (Fig. 35.2). NF1 is AD, with marked pleiotropy and variability in clinical expression. Approximately 50 % of newly diagnosed patients have no previous family history, suggesting the occurrence of de novo mutations, with a bias for the paternal germ-line. The disease is caused by loss-of-function mutations of the *NF1* gene. The diagnosis of NF1 is made according to well defined clinical criteria (NIH criteria) [14], which are usually diagnostic by the age of 8 years [15]. Detecting mutations in the *NF1* gene is difficult and complex given the large size of the gene and the lack of established mutation hotspots. Protocols combining PCR and high-performance liquid chromatography to detect germ-line mutations have been developed and have reported the identification of more than 95 % of individuals fulfilling clinical NF1 criteria [16].

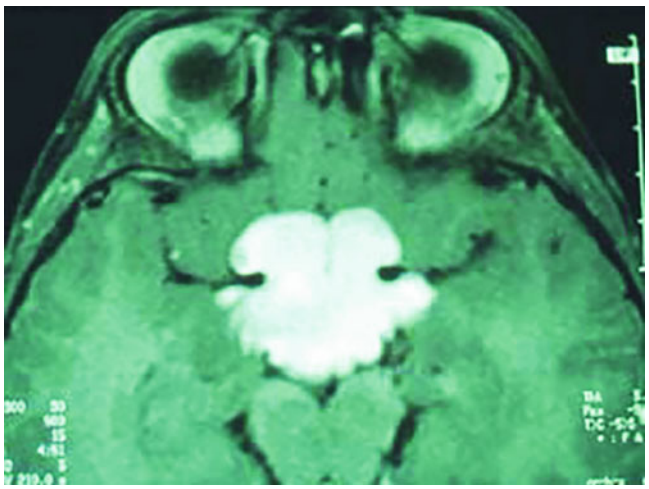

Fig. 35.2 T1-weighted and gadolinium-enhanced MRI sequence showing a Pilocytic Astrocytoma of the optic pathway in a patient with neurofibromatosis type 1.

The disease is characterized by the presence of multiple neurofibromas, pilocytic astrocytoma within the optic nerve pathways, malignant peripheral nerve sheath tumors (MPNST), and susceptibility to other astrocytomas. The optic pathway astrocytoma (OPA) represents the most common CNS tumor in NF1, affecting up to 20 % of all patients and usually arising in children under the age of six [17]. Remarkably, half of the individuals with OPA remain asymptomatic [17].

NF1 is inherited with high penetrance but the phenotypic expression is variable, suggesting a role for other disease-modifying genes and heterogeneous mutations of the *NF1* gene [18–20]. The timing of *NF1* gene inactivation or mutation is also assumed to interfere with disease manifestation [20]. The *NF1* gene is localized to chromosome 17q in 1987 and mapped to the 17q11.2 locus 3 years later [21–23]. The *NF1* gene encodes the protein Neurofibromin and spans at least 350 kilobases (kb) and includes over 60 exons. More than 1000 mutations resulting primarily in Neurofibromin truncations have been identified [24] and complete gene deletion is associated with a severe phenotype [25].

Neurofibromin functions as a tumor suppressor and is a cytoplasmic protein of that is highly expressed in neurons, Schwann cells, oligodendrocytes, astrocytes, leucocytes and the adrenal medulla, while its expression in other tissues is minimal [26]. Neurofibromin harbors a Guanosine Activating Protein (GAP)-related domain, conferring homology to other guanosine triphosphatase (GTP) activating proteins [27]. Ras is a GTP-binding oncoprotein, which promotes cell growth and differentiation. By accelerating the conversion of active GTP to its inactive, guanosine diphosphatase (GDP)-bound form, Neurofibromin acts as a negative regulator of Ras.

Defects in Neurofibromin are thought to increase cell growth and facilitate tumor formation due to loss of Ras regulation. In addition, Neurofibromin regulates other proteins including adenylate cyclase in astrocytes, and potentially plays a role in neural stem cell proliferation, survival, and astroglial differentiation [28, 29].

While most of the neoplasms encountered in NF1 patients are not considered malignant, adults with NF 1 have a 50–100-fold increased risk of high-grade glioma formation [30, 31] and a 20 % lifetime risk to develop a malignant peripheral nerve sheet tumor (MPNST) [32, 33] which are assumed to arise from preexisting neurofibromas [32]. To date, only two genetics alterations have been identified as progression pathways. Mutation in the *TP53* loci and genetic alterations in *INK4A* have been frequently identified in malignant but not benign forms of neurofibromas [30, 34].

Numerous animal models have been employed to explore the molecular basis of NF1 pathogenesis. NF1 heterozygous mice with selective inactivation of *NF1* in Schwann cells develop tumors with histologic and molecular features of human neurofibromas [35]. The generation of astrocyte-specific *NF1* knockout mouse yielded similar findings, with low-grade optic astrocytomas developing only when Neurofibromin expression was ablated in astrocytes of NF1 heterozygous mice [36].

Several therapeutic approaches based on blocking the dysfunctional neurofibromin pathway have been attempted in animal studies [37]. However, most clinical studies have not extended beyond Phase II trials [38]. The mTOR pathway is regarded as a key mediator of optic pathway glioma development. Currently, an ongoing Phase II study is investigating the growth inhibition of NF1 related low-grade gliomas using the mTOR-inhibitor everolimus [39].

35.2.2 Neurofibromatosis Type 2

NF2 is approximately tenfold less common than NF1 and has distinct phenotypic and genetic features. It is an autosomal dominant syndrome that occurs at an incidence of 1 in 25,000–40,000, with a penetrance close to 100 % by the age of 60 [40]. Half of the individuals inherit a germ-line mutation from a parent or acquire a de novo mutation at the stage of embryogenesis [41]. Bilateral vestibular schwannomas are pathognomonic of the disorder, which is also characterized by schwannomas of other nerves (cranial, spinal or peripheral) as well as intracranial and intraspinal meningioma and ependymomas. NF2 is characterized by a variable age at onset, with a majority of patients developing signs in the second to third decade of life, and thus, NF2 schwannomas and meningiomas occur at an earlier age compared to their sporadic counterparts [41]. NF2 is clinically diagnosed according to the 2005 Manchester criteria [42].

The *NF2* gene was mapped to chromosome 22 in 1987 and further localized on locus 22q12.2 [43]. The gene responsible for this disorder was cloned in 1993 by two groups by positional cloning and was notably also found to be mutated or deleted in the majority of sporadic meningiomas and schwannomas [44, 45]. The gene spans 17 exons distributed approximately over 110 kb, and it encodes for a protein of 595 amino acids called merlin (for moesin, ezrin, radixin-like) due to its homology to three proteins of the ezrin, radixin, moesin (ERM) family [45]. Merlin, alternatively named Schwannomin, is expressed in many normal human tissues, including the brain, and functions as a tumor suppressor [46]. Tumors resulting from dysfunction or loss of Merlin activity are mostly benign [47].

Several studies have shown that Merlin controls cell proliferation and cell motility by regulating cytoskeletal organization, but the pathways involved in its mediation of growth suppression are poorly understood [46, 48]. Merlin interacts with F-actin and negatively regulates cell motility through cytoskeletal reorganization. Moreover, it may act with CD44 (a hyaluronic acid receptor), β1 integrin (a transmembrane glycoprotein) and paxillin (a cytoskeletal adaptor protein) to regulate cell motility [48]. Merlin deficiency has also been linked to abnormal activation and overexpression of receptor tyrosine kinases such as EGFR family receptors [49].

A number of NF2 mouse models have been developed. Homozygous mutation of *NF2* results in embryonic lethality, indicating that its function is essential at early stages of mouse development [50]. Heterozygous *NF2* mutant mice develop many neoplasms but do not manifest the classical tumors linked to NF2. However, as observed in NF1 murine models, the model of conditioned Schwann cells for knockout mice show many similarities with NF2 patients [51].

Merlin dysfunction or loss affects various signaling pathways, therefore several therapeutic targets have been proposed. As schwannomas represent the most common symptomatic and limiting tumor in NF2 patients, clinical trials are primarily directed against schwannoma formation [52]. A recent Phase II study in NF2 patients with progressive vestibular schwannomas observed some decrease in tumor volume and improvement in hearing in response to the EGRF inhibitor Lapatinib [53].

35.2.3 von Hippel–Lindau Syndrome

von Hippel–Lindau (VHL) is a rare inherited disease with an AD pattern of transmission and was first described in the early 1900s by Eugen von Hippel and Arvid Lindau [54, 55]. It is characterized by the development of benign hamartomatous tumors in the CNS and adrenal glands including hemangioblastoma and retina angioma, pheochromocytoma, pancreatic neuroendocrine tumors and inner ear

tumors as well as malignant tumors of the kidney such as renal cell carcinoma [56]. Its incidence is estimated at 1 in 36,000–45,000 births per year [57, 58]. Up to 20 % of VHL patients are estimated to derive from de novo mutations [59]. The disease shows variable expressivity with almost 95 % penetrance at the age of 60 years [60]. A combination of characteristic clinical features, with or without a positive family history, permits the establishment of a clinical diagnosis. The most frequent lesion observed is hemangioblastoma, a mesenchymal solid and cystic tumor mainly localized in the brain (mostly located in the cerebellum), which occurs in 60 to 80 % of all VHL patients [61]. Depending on specific mutation in the gene locus, VHL is classified as type 1 or type 2, according to the absence or presence of a pheochromocytoma [56].

The gene responsible for this disease is the VHL tumor-suppressor gene, located on chromosome 3p25-26 [57]. Under normoxic conditions, the gene product targets hypoxia-inducible factors (HIF) for polyubiquitination and proteosomal degradation. Under hypoxic conditions, the accumulation of HIF will induce the transcription of hypoxia-regulated genes such as vascular endothelial growth factor (VEGF), platelet derived growth factor (PDGF) and transforming growth factor (TGF) -α. This explains the high vascularization of VHL-related tumors. Loss of the VHL gene can also result in aberrant expression of genes that control cell cycle progression and invasion [62, 63]. It has been shown in renal carcinoma cells that loss of the VHL gene results in the accumulation of hepatocyte growth factor (HGF), which interacts with the β-catenin pathway [64]. Loss of VHL protein activity has also been recently correlated to the activation of kinases required for Ras-induced cell transformation, thus representing a possible target for molecular)inhibition [65].

Hemangioblastoma is a mesenchymal-derived hamartomatous tumor and patients with VHL-syndrome are not typically linked with glioma manifestation. However, there is some evidence that VHL expression interferes also with neuroepithelial tumor formation via suppression of HIF-1α/VEGF, which is coupled with inhibition of glioma proliferation and invasion [66].

35.2.4 Tuberous Sclerosis Complex

Tuberous sclerosis complex (TSC) is a multisystem autosomal dominant disorder, affecting 1 in 6000–10,000 individuals [67]. It was first described by Bourneville in 1880 and is characterized by CNS tumors including cortical hamartomas named tubers, subcortical glioneuronal hamartomas, subependymal glial nodules, and subependymal giant cell astrocytomas. TSC patients often suffer from debilitating neurologic disorders, including epilepsy, mental retardation, and autism. Essentially, any organ system can be involved and common features of TSC include dermatologic manifestations such as cutaneous angiofibromas, subungual fibromas, cardiac rhabdomyomas, renal angiomyolipomas, intestinal and visceral cysts, and pulmonary lymphoangiomyomatosis,

The diagnostic criteria consists of a set of major and minor features which appear at distinct points in development, but most patients have manifestations of the disease before 10 years of age [68]. Neurologic disabilities seem to be intimately related to the presence of cortical tubers, which occur in approximately 70 % of patients [69].

The penetrance of the disease is high but the clinical manifestations are considerably variable [70]. There is a high rate of new mutations, accounting for up to 85 % of cases [71]. TSC results from the mutation of one of two genes, *TSC1* on chromosomes 9q34 and *TSC2* located on 16p13.3. Clinical and pathological features caused by mutations in these two genes are indistinguishable, but the prognosis seems to be more severe when the disease is associated with a *TSC2* mutation [72]. The *TSC1* gene encodes a transcript of 8.6 kb called Hamartin, containing 23 exons, whereas the *TSC2* gene encodes a transcript of 5.5 kb called Tuberin, containing 41 exons. Mutations in these genes can be identified in 60–80 % of TSC patients, with a wide spectrum of specific genetic alterations [73]. Hamartin and Tuberin function as a regulatory complex inhibiting the small GTPase RHEB and consequently limiting the activity of the mammalian target of rapamycin complex 1 (mTORC1), which is an intracellular regulator of cell growth and metabolism [74]. In a recent Phase I–II open-label study of patients receiving the mTOR-inhibitor everolimus, a clinically significant reduction in tumor volume of TSC related subependymal giant-cell astrocytoma was shown [75, 76].

35.2.5 Gorlin Syndrome

Gorlin syndrome is also known as nevoid basal cell carcinoma syndrome (NBCCS) or basal cell nevus syndrome (BCNS) and was first described by Goltz and Gorlin in the 1960s. It is a rare AD disorder occurring in 1 of 57,000 live births and characterized by basal cell-carcinoma, skeletal anomalies and a 2–5 % incidence of childhood medulloblastomas (mostly SHH medulloblastomas) [11, 77]. The penetrance is very high but the clinical expression is variable, with up to 30 % of patients presenting with de novo mutations [78]. The clinical criteria are based on the association of multiple basal cell carcinomas and odontogenic keratocysts [79]. Other manifestations include the presence of palm or sole pits, intracranial calcifications in particular along the falx and macrocephaly [77].

The disease results from a mutation of the human homologue of the *Drosophila melanogaster* gene *PTCH* located

on 9q22.3 [80]. It contains 23 exons and encodes for a transmembrane protein (Ptch), which is a receptor and negative regulator for the secreted Hedgehog family proteins such as Sonic Hedgehog (Shh).

35.2.6 Li–Fraumeni Syndrome and TP53 Germ-Line Mutations

Li–Fraumeni syndrome (LFS) is an AD disorder predisposing patients to an early onset of a wide spectrum of neoplasms. The syndrome was defined by Li and Fraumeni after they noticed a high incidence of cancer among family members of children with rhabdomyosarcoma [81]. Often described as a very rare syndrome with only several hundred identified individuals, its effective incidence is probably underestimated [82], in part also due to the existence of different classification schemes [83]. The most frequent tumors observed are breast cancer, sarcomas, osteosarcomas, brain tumors, acute leukemia and adrenocortical carcinomas.

The major genetic abnormality underlying this syndrome is a germ-line mutation of *TP53*, which has been identified in 70 % of LFS cases and in 22–44 % of families with the LF variant form [84]. Importantly, 50 % of the families with a *TP53* germ-line mutation meet the diagnostic criteria of LFS. In the remaining cases of LFS without *TP53* mutation, a germ-line mutation of the *hCHK2* gene involved in G2 checkpoint control has been identified [84]. *TP53* germ-line mutations occur most frequently in exons 5–8, with major hotspots on codons 245 and 248. In the 143 LFS families reported, the most frequently identified mutations are point mutations (85.3 % of cases). Interestingly, low grade and anaplastic astrocytomas of LFS patients harbor somatic *IDH1* mutations at much higher rates compared to sporadic gliomas [85].

35.2.7 Turcot Syndrome

Turcot syndrome is an AD disorder characterized by the occurrence of adenomatous colorectal polyps or colon carcinomas and malignant brain tumors, mainly anaplastic astrocytomas, as well as glioblastomas and medulloblastomas (95 %) [86]. Turcot described the first cases in 1959, where two siblings developed malignant CNS tumors and numerous adenomatous colorectal polyps [87].

There are two major subgroups of Turcot syndrome. The type 1 pattern is characterized by an association of glioblastomas and hereditary non-polyposis colorectal carcinomas (HNPCC). This subgroup results from a germ-line mutation in DNA mismatch repair genes such as *hPMS1* (ch 2q32), *hPMS2* (ch 7p22), *hMSH2* (ch 2p16), or *hMLH1* (ch 3p21) [86]. These deficiencies lead to DNA replication errors and microsatellite instability, which is rare in brain tumors in the absence of Turcot syndrome [88]. In this subgroup, the mean age for occurrence of glioblastoma is lower than in the general population (18 years old versus 40–70 years old). The type 2 subgroup is characterized by association of WNT subgroup medulloblastomas with familial adenomatous polyposis (FAP). These patients tend to have a germ-line mutation in the *adenomatous polyposis coli* (*APC*) gene that lies on chromosome 5q21 [86]. In the type 2 Turcot syndrome subgroup, the median age of occurrence of medulloblastoma is 15 years, compared to 7 years of age in the general population.

35.2.8 Cowden Syndrome and Lhermitte–Duclos Disease

Cowden syndrome (CS) is a rare AD condition associated with multiple benign hamartomatous lesions mostly involving the skin and mucosa, but various organ systems including the cerebellum may be affected [89]. CS predisposes patients to malignant tumors, especially of the breast, thyroid, intestine, and endometrium [89]. The penetrance of CS is high and approaches over 90 % by the age of 20 years [89]. The syndrome was first documented in 1963 by Lloyd and Dennis and named after the first patient [90]. In 1991, more than 70 years after its first description [91], it was recognized that dysplastic cerebellar gangliocytoma or Lhermitte–Duclos disease (LDD) is often a manifestation of CS [92]. The prevalence of CS is estimated at 1:200,000, but the frequency is likely underestimated given that many non-symptomatic mucocutaneous manifestations related to this disease are also common in the general population and thus may not lead to extensive diagnosis [89]. Approximately half of the CS cases are recorded as inherited and half occur spontaneously [93]. The most common germ-line mutation) involves the tumor suppressor gene *PTEN*, located at the chromosome 10q23.3 [94, 95]. Early clinical data including nearly 50 CS families suggest that 85 % of patients with CS harbor a *PTEN* mutation [96, 97] However this may not be universally adopted given that application of risk assessment criteria from the National Comprehensive Cancer Network (NCCN) results in many patients diagnosed as CS despite the absence of *PTEN* mutations [98]. Germ-line mutations downstream of PTEN signaling were found in the PI3K/AKT pathway in up to 10 % of CS patients lacking *PTEN* gene alterations [99]. Not all patients with LDD show clinical manifestation of CS [100] and dysfunction or inactivation of *PTEN* is found in 67–83 % of LDD lesions [100, 101]. Selective inactivation of *PTEN* in neural cells of mice results in impaired migration of granular cell precursors and formation of cerebellar tumors histopathologically resembling LDD [102, 103]. Inactivation of *PTEN* is linked with increased levels of PI3K/AKT, which promotes cell growth and proliferation [102, 103]. Activated AKT regulates various pathways involved in protein synthesis and

cell growth, including the mTOR pathway, suggesting that mTOR inhibitors may be effective in reversing cellular hypertrophy and tumor growth [101].

35.3 Cytogenetics and Molecular Genetics of Neuroepithelial Human Brain Tumors

35.3.1 Glioma (Astrocytoma and Oligodendroglioma)

Gliomas comprise tumors of astrocytic or oligodendrocytic histopathological appearance. Whether these tumors have the same origin of tumor-initiating cells from neural progenitors or arise from dedifferentiated astrodendrocytes/oligodendrocytes is a matter of ongoing debate [104, 105]. The WHO distinguishes between gliomas with more circumscribed growth (WHO Grade I) and gliomas with diffuse infiltration (WHO Grade II: low grade, WHO Grade III–IV: high grade) [9]. Diffuse low-grade gliomas are considered a precancerous disease, as over time they progress to anaplastic, malignant tumors in most instances [106].

Gliomas demonstrate the full spectrum of cytogenetic and molecular abnormalities: From numerical and structural chromosomal alterations, to gene amplifications and overexpression, deletions and small-scale mutations up to and including epigenetic deregulations.

35.3.2 Chromosomal Alterations

Chromosomal number alterations occur with increased frequencies in high grade and adult gliomas, and chromosomal losses are observed more frequently than gains [107]. One of most common numerical autosomal changes seen in high-grade astrocytomas includes gain of chromosome 7, and loss of chromosome 10 [107–109]. Gain of chromosome 7 is seen in up to 83 % of adult high-grade astrocytomas, whereas chromosome 10 is reported to be lost in up to 86 % [109, 110]. In some studies, a combined gain of chromosome 7 accompanied by loss of chromosome 10 ($7^{+}/10^{-}$) occurs in over 80 % of GBM samples [108, 111].

The occurrence of trisomy 7 and monosomy 10 together has often been correlated with short-term survival, although currently available data does not allow a distinct conclusion [112]. Gains of chromosome 7 are also among the most common autosomal changes in low-grade gliomas (LGG), seen in 57 % of cases [110] and loss of chromosome 10 may be correlated with shorter overall survival [113]. Chromosomal alterations commonly observed in secondary GBM include 19q loss (see Box 35.1) [114]. An additional numerical chromosomal abnormality is the presence of *double minute chromosomes*, seen in approximately 20 % of GBM specimens, which can further confer oncogene amplification and drug resistance [115].

Oligodendroglioma (OD) and oligoastrocytomas (OA) constitute a subtype of glioma for which the specific loss of

Box 35.1: Primary Versus Secondary GBM

According to current evidence, there are two different routes of glioblastoma tumorigenesis, both with different genetic alterations but ultimately undistinguishable histology [114]. GBM mostly occurs as a rapidly growing de novo tumor from a glial progenitor or dedifferentiated cell and affecting patients with a mean age around 60 years. This Primary GBM constitutes 90 % of the cases, where no evidence of a less malignant precursor lesion can be detected. Secondary GBMs (10 %) affect typically younger patients around a mean age of 45 years. These tumors progress from a preexisting diffuse low-grade or anaplastic astrocytoma, are more often located frontally, and the overall survival after diagnosis is significantly longer. Histologically, Secondary GBMs show less necrosis and frequent regions of oligodendroglioma-like appearance when compared to the Primary form. From a molecular basis, the Primary tumors often show loss of chromosome 10, *EGFR* amplification and *PTEN* mutation, whereas in Secondary GBM, *TP53* mutations, loss of chromosome 19q and *PDGFRA* alterations are more frequent. Classification of GBM origin has been significantly improved by the recent identification of mutations in the enzyme gene *IDH1/2* (isocitrate dehydrogenase, involved in the citric acid pathway), which are predominantly found in Secondary (80 %) but only rarely (<5 %) in Primary GBMs [132–134]. Consequently, *IDH1/2* mutations are now commonly accepted as molecular markers of Secondary GBM.

Over 90 % of secondary GBM diagnosed through *IDH1/2* mutations belong to the proneural subgroup, which indicates that this tumor subgroup is homogeneous compared to the primary form. *IDH1/2* mutations occur early during progression from low-grade to high-grade glioma given they are detected in over 80 % of grade II and III astrocytoma and oligodendroglial tumors [134, 141]. It is possible *IDH1/2* mutations precede 1p/19q loss in oligodendrogliomas and *TP53* mutation in low-grade astrocytomas [242]. Finally, there is evidence that primary and secondary GBMs derive from different glial progenitor cells. In support of this, CD133 positive cancer stem cells could only be cultured from Primary GBMs, whereas samples from secondary GBMs did not have CD133 positive stem cells within [243].

portions of 1p and 19q (loss of heterozygosity, LOH 1p/19q) is associated with important prognostic implications and is used as a marker to support the histological diagnosis of OD [116, 117]. Approximately 50–80 % of ODs have allelic loss of chromosomes 1p and 19q, whereas OA (mixed oligodendrogliomas, arrangement of cells presenting astrocytic or oligodendroglial differentiation) show this co-deletion 40 % of the time [118–120]. LOH 1p/19q is frequently observed in WHO grade II oligodendric tumors compared to those of grade III, though conflicting data exists in this regard [118–120]. Notably, oligodendric gliomas of the frontal lobe show higher incidence of 1p/19q co-deletion than those of non-frontal origin [119]. Low-grade OD (WHO II) treated by surgical resection and nitrosourea-based chemotherapy without radiotherapy show favorable long-term outcome (10-year overall survival rates over 90 %) irrespective of LOH 1p/19q status [121]. Anaplastic pure and mixed oligodendrogliomas (WHO III) identified with 1p/19q co-deletion are generally associated with marked higher overall survival and chemosensitivity in comparison to non-co-deleted WHO III oligodendrogliomas, where the addition of chemotherapy to radiotherapy did not prove beneficial over radiotherapy alone [120, 122].

35.3.3 Gene Amplification and Overexpression

Gene amplification has been described for several target genes in astrocytic tumors, and appears to be more common in high-grade lesions than low-grade astrocytomas [109, 123]. Genes continuously found to be amplified in high grade gliomas include *EGFR, MET, PDGFRA, MDM4, MDM2, CCND2, PIK3CA, MYC, CDK4,* and *CDK6* [124]. Amplification and overexpression of *EGFR* occurs frequently and predominantly in primary GBMs (60 % of the samples), but rarely in the secondary form [114, 125]. In up to 30 % of the cases this gene has undergone loss of exon 2–7, resulting in the production of a constitutively active, truncated EGFR receptor (EGFRvIII) [109, 126, 127]. At this time, Phase II and III vaccination trials using rindopepimut to stimulate immune response against the EGFRvIII peptide in GBM patients are ongoing [128, 129]

35.3.4 Gene Mutations and Deletions

Tumor suppressor gene silencing events in astrocytomas may be the result of gene deletions, mutations, or promoter methylation events. Primary GBMs are characterized by *CDKN2A* deletion (31-50 %), and *PTEN* mutation (32 %) [109, 130, 131]. While *CDKN2A* deletions occur in primary GBM, *TP53* mutations appear more common in secondary GBM [109, 114]. In the progression of low-grade tumors to secondary GBM, *TP53* mutations are the most common and early-detected genetic abnormality—seen in about 2/3 of precursor low-grade astrocytomas and secondary GBMs derived from them. *TP53* mutations occur in primary GBM but at a lower frequency (35 %) compared to secondary GBM [108, 109, 130]. Additionally, in secondary GBM, 60 % of the *TP53* mutations are clustered in two hot spot codons (amino acids 248 and 273), whereas in the primary form, *TP53* mutations appear more equally distributed within exon 5–8 [108].

Mutations in the gene encoding for NADPH-dependent isocitrate dehydrogenase (*IDH1*) were identified from a large-scale genomic sequencing analysis of astrocytoma [131]. Since the initial description, multiple studies have shown that *IDH1* mutations are common in low-grade diffuse astrocytomas, anaplastic astrocytomas and tumors of oligodendroglial origin [132–134]. Notably, there is evidence that *IDH1* mutations precede *TP53* mutations, suggesting an important role in tumor initiation [114]. A proportion of low-grade astrocytomas that lack *IDH1* mutations (e.g., pilocytic astrocytoma, and ependymoma) contain mutations of the related *IDH2* gene [134]. As *IDH1* mutations are very common in secondary (>80 %) but markedly rare in primary GBM (<5 %), a consensus is that *IDH1* mutation can serve as a molecular marker of secondary GBM, as this form is neither clinically nor histologically distinguishable from the primary form [114]. *IDH1* status is important to clinicians as patients with tumors harboring *IDH1* mutations have a survival benefit [135–139]. *IDH* mutations also seem to correlate with both *TP53* mutational status and 1p/19q deletions, both of which predict survival [137, 140, 141].

35.3.5 Epigenetic Alterations

In addition to aberrant changes in the genome, epigenetic alterations have emerged as important factors in gliomagenesis [142]. Potentially reversible and more amenable to treatment than numerical or structural changes in chromosomes, studies of epigenetic deregulations is a promising strategy in glioma therapy. GBM cells showing high activity level of the DNA repair enzyme *MGMT* (O^6-methylguanine-DNA methyltransferase) are more resistant to therapies including alkylating agent such as temozolomide (TMZ) [143]. About 40 % of GBM have a methylated *MGMT* promoter status resulting in epigenetic silencing of the *MGMT* gene and thus higher sensitivity to TMZ and distinctive longer survival with actual standard therapy [143, 144]. Hence, *MGMT* promoter methylation is a strong prognostic and predictive biomarker.

The increased awareness of the role of metabolic enzymes in astrocytoma pathogenesis has brought about a resurgence of interest in the Warburg Effect [145]. The Warburg effect first described in 1956 by biochemist Otto Warburg promotes the observation that tumors predominantly use a high rate of

aerobic glycolysis to meet metabolic demand [146]. Recently, isoforms of both pyruvate kinase (PK) M1/M2 and hexokinase (HK1/HK2) have shown differential expression in glioblastoma, in which PKM2 and HK2 predominate, promoting glycolysis [147, 148].

35.3.6 Pediatric Versus Adult Gliomas

The genetic changes that are found in pediatric astrocytomas are distinct from those in the adult variant of these tumors. No consistent karyotypic abnormalities have been identified in pediatric low-grade astrocytomas [149, 150]. Even in high-grade gliomas, the number of chromosomal aberrations is generally lower from their adult counterparts with up to 15 % lacking detectably number irregularities [107]. Relatively frequent compared to adult GBM, some pediatric GBMs have gain of chromosome 1q (up to 30 %) and loss of 16p (up to 24 %), while numerical aberrations of chromosome 7 and 10 are relatively rare (<30 %) [151, 152]. Cytogenetic changes recurrently observed in pediatric anaplastic astrocytomas and GBM include gains of 1q, 5q, and loss of 6q, 9q, 10q, 12q, 13q, and 22q [152, 153]. In contrast to adult tumors, amplification of the *EGFR* gene is not common in pediatric astrocytomas and *PDGF*-driven signaling is preferentially activated [151, 154]. Notably, this feature is also prevalent in secondary GBM [155]. Similarly, pediatric astrocytomas rarely exhibit loss or mutation of *PTEN*. Aberrant activation of the *BRAF* proto-oncogene (7q34) by copy number alteration or formation of an abnormal fusion protein is an important marker of pilocytic astrocytoma but not diffuse infiltrating pediatric astrocytomas (see Box 35.2) [156–158]. Aberrant BRAF activation leads to increased signaling through the MAP kinase/ERK pathways, which results in high levels of mTOR activation, and ultimately to increased cell growth [159, 160].

35.3.7 Core Signaling Pathways and GBM Subgroups

The understanding of the molecular basis of astrocytoma has benefited from large-scale genomic profiling approaches from networks such as The Cancer Genome Atlas (TCGA) and the International Cancer Genome Consortium (ICGC) [109, 130, 131, 161] GBM was the first cancer to be systematically analyzed by TCGA, highlighting the role of oncogenes such as *ERBB2* and *PDGFRA* and suppressor genes such as *NF1* and *TP53* as well as reinforcing core defects in three signaling pathways involved in the pathogenesis: (1) retinoblastoma (RB)-signaling (79 %), (2) p53 signaling (90 %), and (3) PIK(3)K/RAS signaling (88 %) (Fig. 35.3). Large-scale genomic consortia have allowed the stratification of astrocytomas based

Box 35.2: Pilocytic Astrocytoma

Pilocytic Astrocytoma (PA) is a non-infiltrative, slow growing, and often cystic tumor typically classified as WHO grade I. It is one of the most common CNS neoplasms in childhood accounting for ~20 % of all pediatric brain tumors [1]. Almost three-fourths of the patients are younger than 20 years [1]. Approximately half of PAs are located in the cerebellum, but they can occur throughout the neuraxis such as the optic pathway, hypothalamus, and spinal cord (mostly in pediatric patients) as well as in the cerebral hemispheres (mostly in young adults) [244]. Optic nerve PAs are often associated with NF1. Provided that the tumor is accessible and extensive surgical resection is performed, most patients show a favorable outcome with a 10-year survival rate of over 95 % [244–246]. Until recently, the genetic mechanisms underlying this disease were not extensively investigated. Early genomic analysis of tumor samples showed often balanced karyotypes, whereas whole chromosomal gains occurred in about 30 %, frequently affecting chromosomes 5 and 7 [247]. Activating alterations within the MAPK-signaling pathway are considered a hallmark aberration in the pathogenesis of PA, affecting 80–100 % of analyzed tumor samples [248, 249]. Consequently it is hypothesized that PA represents a single-pathway disease [249]. The most frequent genetic event leading to MAPK activation is *BRAF-KIAAI549 (B-K)* fusion, which produces a fusion protein that lacks the regulatory domain of BRAF [249, 250]. In addition, various MAPK pathway-activating fusions)typically involving BRAF are described [249]. The somatic mutation rate is very low (<0.1/Mb) and *BRAF, FGFR1, K/-NRAS, PIK3CA, CDKN2A,* and *NF1* are the main genes found to be mutated or rearranged [245, 249, 251]. Similar to other tumor types, the copy number changes and mutation rates positively correlate with patient age and potentially with an aggressive clinical course [245, 247, 249]. The distribution of oncogenic hits within the MAPK pathway may vary depending on tumor location: *NF1* mutations are more often detected in optic PA, while PAs in other locations are dominated by BRAF activation [248]. BRAF fusions are more common in cerebellar PAs and mutations are typically seen in supratentorial PAs [248]. In adult PAs, *BRAF* V600E mutations appear to be very infrequent compared to the pediatric counterpart [245]. As B-K fusions are particularly rare in diffuse astrocytomas (~2 %), the presence of this event can be considered an adjuvant diagnostic tool for PA [245].

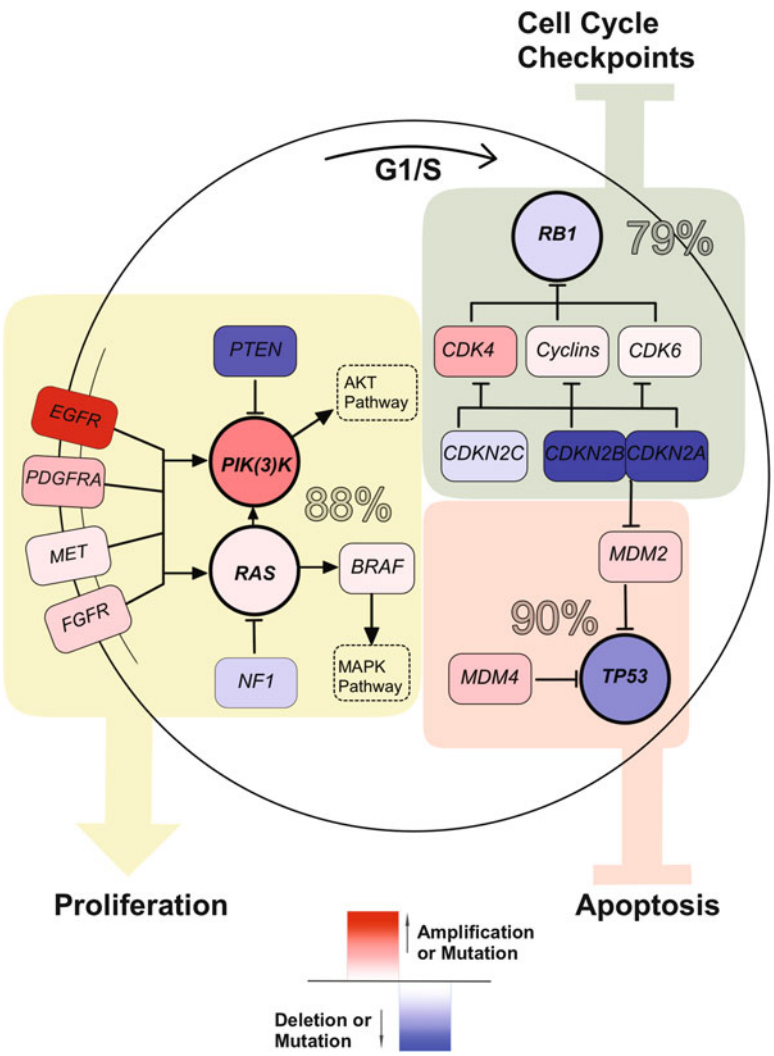

Fig. 35.3 Core defects in three signaling pathways involved in the pathogenesis of Glioblastoma. Overall alteration rate is summarized for the TP53 pathway (eluding apoptosis), PI(3)K/RAS pathway (increasing proliferation), and RB1 pathway (avoiding cell cycle checkpoints).

on genetic profiles giving valuable clinical information. The first subgrouping analysis on high-grade astrocytomas was reported by Philips et al. differentiating three distinct GBM clusters: proneural, proliferative, and mesenchymal, with the proneural subgroup predicting better survival [162]. A recent TCGA based study classified GBM into four molecular subgroups: classical, proneural, neural, and mesenchymal [155]. Genetic alterations in *EGFR*, *PDGFRA/IDH1* and *NF1* characterize the classical, proneural, and mesenchymal subgroups respectively [155]. Classical GBMs are further delineated by amplification of chromosome 7 paired with loss of chromosome 10, while often lacking *TP53* mutations [155]. No distinctive genetic alteration is known that distinguishes the Neural from the other subtypes [124]. It still has to be elucidated to what extent the subgroup defining molecular profile may affect clinical outcome and sensitivity to specific therapeutic agents. DNA methylation profiling of 272 TCGA glioblastomas revealed a subset of tumors with a hypermethylation phenotype that was assigned to the proneural subgroup, further correlated with *IDH1* mutations and in extended analysis also often found in low-grade gliomas [109, 163]. This glioma phenotype is an expression subtype and termed G-CIMP (CpG island methylator phenotype). G-CIMP positive gliomas affect younger patients, are probably more common in secondary GBM, and are associated with improved outcome [163]. In anaplastic oligodendroglioma the G-CIMP phenotype also consistently exhibit *IDH1*-mutations, *MGMT* promoter methylation, and LOH 1p/19q and is used as a predictor for better survival [164].

35.3.8 Medulloblastoma

Medulloblastomas are considered embryonal tumors arising from the dorsal brainstem or the cerebellum. Progenitor cells from the cochlear nucleus, dorsal brainstem, and neuron precursors from the external granular layer of the cerebellar germinal zone are the proposed cells of origin [165].

Medulloblastomas exhibit a high amount of heterogeneity at histomorphological and subcellular level resulting in variable clinical behavior. Histological subtypes comprise classical (70–80 %), nodular desmoplastic/extensive nodular (16 %) and large cell anaplastic (10 %), while all are classified as WHO Grade IV [9, 166]. Over the past few years novel molecular subclassifications have been established that put histopathologic differentiations into perspective.

35.3.9 Chromosomal Alterations

Almost all medulloblastoma samples show various numerical gains or losses of chromosomal regions. The most common specific cytogenetic abnormality seen in this tumor type is isochromosome 17q (iso17q), which occurs in about 50 % of medulloblastomas [167, 168]. The breakpoint is often in the proximal p-arm (17p11), producing a dicentromeric isochromosome. Loss of one arm of chromosome 17p (25–35 %) is often a consequence of isochromosome 17q formation, but may also occur in isolation [169, 170]. In certain cases, smaller deletions are seen, with the minimal deleted region occurring at 17p13.3 [171]. The frequent involvement of 17p in medulloblastoma has resulted in efforts to identify the targeted putative tumor suppressor gene (TSG). *REN(KCTD11)* maps to 17p13.2, and is a candidate TSG for medulloblastoma on chromosome 17p [172]. Aberrations of chromosomal regions have also been evaluated as prognostic markers, whereas iso17q and losses of 10q and 17p are correlated with a poor prognosis and loss of chromosome 6 (monosomy 6) with good outcome across all subgroups [173]. Loss of chromosome 9q, which contains the suppressor gene locus *PTCH 1*, promotes activation of Sonic Hedgehog (SHH) signaling pathway and is used as a co-determinant of the SHH molecular subgroup [11].

35.3.10 Gene Amplification and Overexpression

Gene amplifications are relatively infrequent in medulloblastoma (<10 %), and typically involve the *MYC* and *MYCN* proto-oncogenes [166]. Such amplifications have been observed in the context of double minute chromosomes [174]. Amplification and/or overexpression of *MYC*-family genes are regularly observed in the large cell anaplastic variant of medulloblastoma, and correlate with poor clinical outcome [175, 176]. In addition to gene amplifications, certain genes are aberrantly overexpressed in medulloblastoma such as *ERBB2* [177]. Increased ERBB2 and ERBB4 expression correlates with higher risk of metastasis and is associated with a poor prognosis [178–180].

35.3.11 Gene Mutations and Deletions

Various mutations of tumor suppressor genes important in developmental signaling pathways have been described in medulloblastoma. Mutations in *PTCH1, SMOH*, *Gli2*, and *SUFU* lead to loss of inhibitory factors and thus promote constitutive activation of SHH pathways [181–184]. Germ-line *APC* mutations as found in familial adenomatous polyposis (FAP) syndrome or Turcot syndrome predispose to medulloblastoma formation [86]. The APC-protein is encoded on chromosome 5 and is part of a protein complex inhibiting the WNT signaling pathway. Loss of APC function results in intranuclear accumulation of ß-catenin, which activates transcription factors and promotes the pathogenesis of medulloblastoma. Overall, mutations involving the WNT pathway occur in approximately 10 % of sporadic medulloblastoma cases, including activating mutations in the *CTNNB1* gene [185–188]. In addition, *TP53* mutations have been found in 10 % of medulloblastoma cases (16 % in WNT, 21 % in SHH, virtually absent in Group 3 and 4) and are considered a risk factor for poor outcome in the SHH subgroup [189].

35.3.12 Epigenetic Alterations

Epigenetic alterations such as modification of histone or DNA methylation status are important factors in medulloblastoma pathogenesis and mostly recorded in Group 3 and 4 medulloblastoma [190, 191]. Large-scale genomic analyses have identified *OTX2*, a developmentally regulated transcription factor important for early brain morphogenesis, as a frequently occurring focal genetic gain in medulloblastoma (21 %) [168, 192, 193]. Overexpression of *OTX2* results in impaired demethylation activity of histone modifying proteins. Consequently, levels of trimethylated histone H3 lysine 27 (H3K27me3) are increased which in turn leads to specific chromatin condensation [194]. Medulloblastoma patients with *OTX2* gene amplification (mostly restricted to subgroup 3 and 4) exhibited poorer survival and were more likely to have anaplastic tumors [193]. There is also epigenetic deregulation of DNA methylation as an underlying mechanism of medulloblastoma formation. Subgroup specific patterns of DNA methylation have already been proposed as a biomarker for improving survival prediction in non-WNT medulloblastoma [195, 196].

35.3.13 Subgroups

Advances in next generation DNA sequencing and ultrahigh-resolution genetic mapping over recent years have enabled

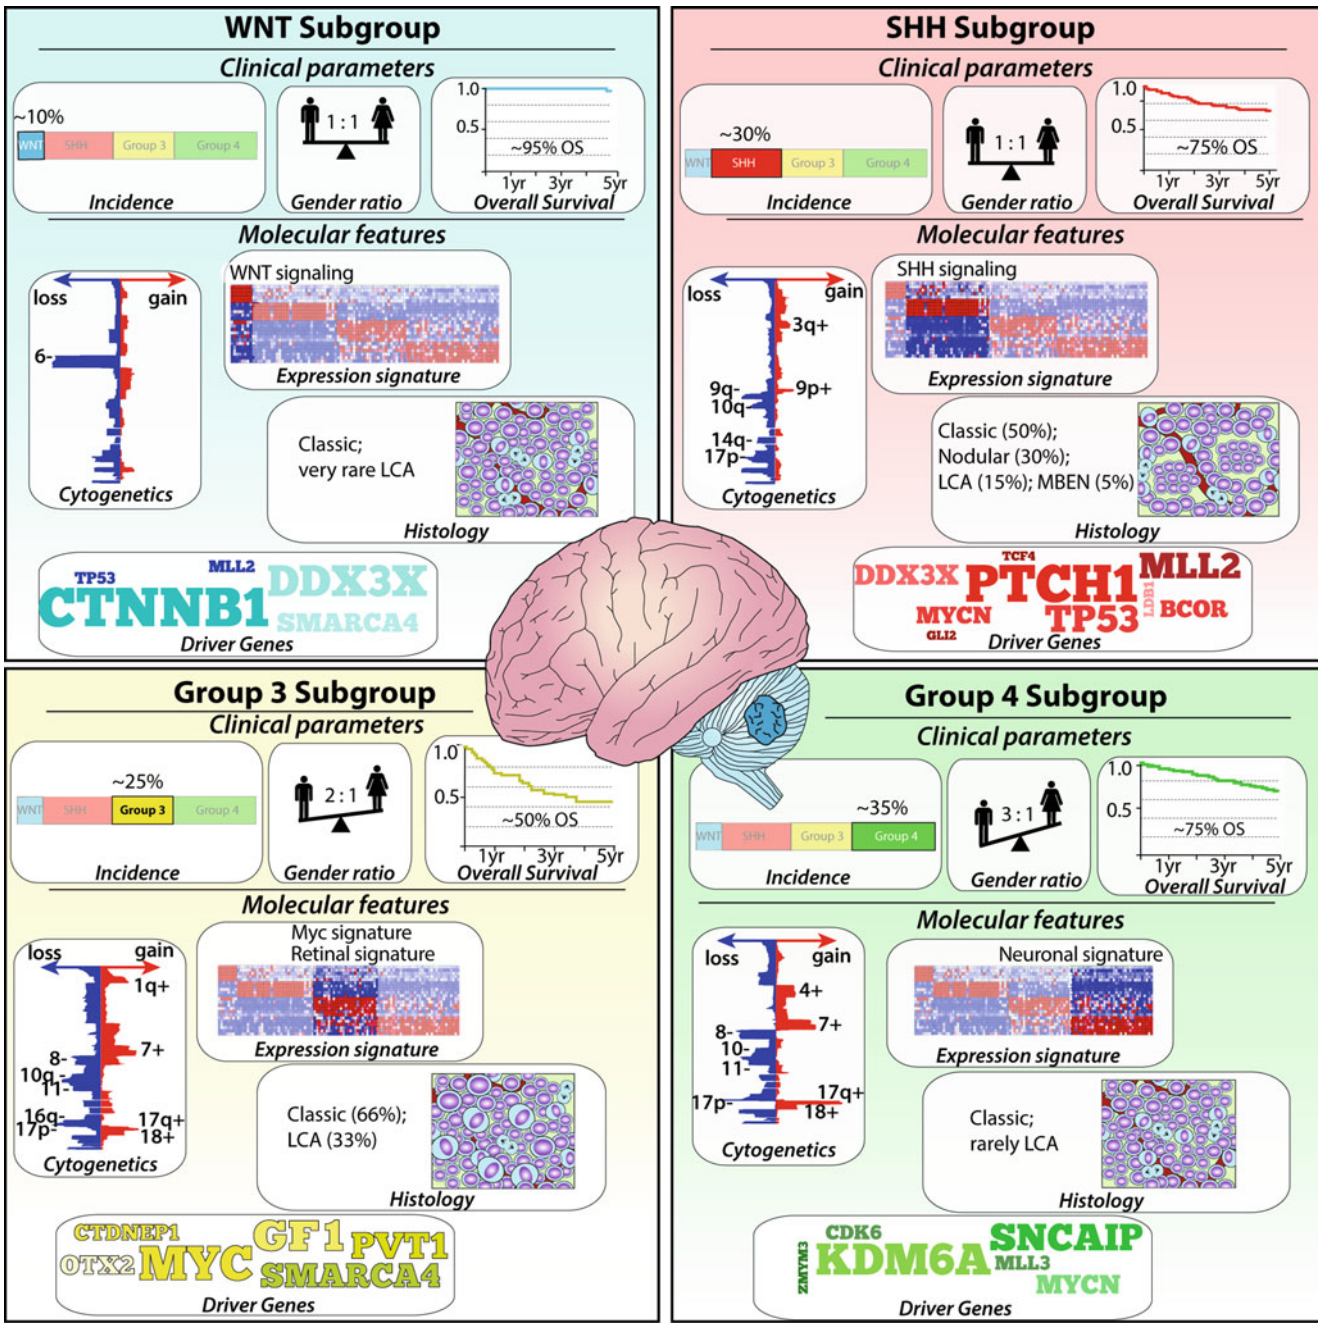

Fig. 35.4 Medulloblastoma Subgroups. Infographic illustrating the incidence, gender ratio, survival, histology, cytogenetic alterations, and common driver genes for each group. *LCA* large cell anaplastic, *MBEN* medulloblastoma with extensive nodularity.

remarkable insight into some of the underlying molecular interactions leading to the observed heterogeneity in clinical behavior. According to current consensus among investigators, four main subgroups can be distinguished: WNT, SHH, Group 3, and Group 4 [11, 197, 198] (Fig. 35.4). The WNT and the SHH group are marked by mutations in the WNT and SHH pathway, respectively. For Group 3 and 4, no single pathway alteration has been identified and the diagnosis relies primarily on transcriptional profile clusters. However, recent studies detected prevalent drivers in particular for Group 3 [199]. These molecular subgroups typically do not correlate with the histological phenotypes. The histopathological classic type occurs in all four medulloblastoma subgroups. The nodular desmoplastic or extensive nodular type falls within the SHH subtype, although it should be mentioned that the SHH subgroup is the only subgroup that may include all of the known major histological variants. Large cell anaplastic tumors are also found in all four subgroups but the majority will be classified to Group 3. The WNT subgroup has mostly classic histology and accounts for 10 % of

all medulloblastomas and has the best prognosis with >90 % long-term survivals. Alterations resulting in increased activity of the WNT pathway results from sporadic somatic mutations of *CTNNB1* encoding ß-catenin or less common in germ-line mutations of the *APC* gene as in Turcot or FAP syndrome. Monosomy 6 and *TP53* mutation are often found. The SHH subgroup (30 %) has a good to intermediate prognosis; almost half of the cases exhibit desmoplastic/nodular histology.

In sporadic SHH tumors, somatic mutation in *PTCH*, *SMO*, and *SUFU* leads to increased SHH activity. In addition, amplifications of *GLI1* and *GLI2* can trigger this pathway. Deletion of chromosome 9q, which includes the *PTCH* gene, is primarily limited to SHH tumors. Hereditary SHH medulloblastomas are found in Gorlin syndrome and are characterized by germ-line mutation of the tumor suppressor gene *PTCH1*. *MYCN* amplification and mutations at *TP53* are regularly observed. Recently, small molecules targeting smoothened (SMO), a positive regulator of the SHH pathway, showed rapid (although transient due to acquired drug resistance) regression of tumor volume in a subset of patients with SHH medulloblastoma [200, 201]. Group 3 medulloblastomas (25 %) primarily demonstrate classic histology but have a high incidence of large cell anaplastic types. They are almost never observed in adults and harbor the worst prognosis of all subtypes. Metastases are frequently found and coupled to poor prognosis. *MYC* and *OTX2* amplification are common features and some tumors show loss of both 5q and 10q and gain of chromosome 1q. Recently, somatic genomic rearrangements resulting in GFI1 and GFI1B activation have been found to occur in approximately one-third of Group 3 patients; thus enhancer hijacking is now considered a prominent mechanism driving Group 3 medulloblastoma [199]. Group 4 is the most common medulloblastoma subgroup (35 %), usually of classic histology and with an intermediate prognosis. Isochromosome 17q is the major cytogenic alteration observed (60–80 % of Group 4 samples). Amplification of *OTX2*, *CDK6*, and *MYCN* are also frequently associated with this subgroup, whereas structural variants associated with GFI1 and GFI1B activation are detected in 5–10 % [199].

Molecular classification will have a large impact on future treatment recommendations and strategies. Given the four subgroups show distinct clinical behavior that does not correlate with histological features, the use of histopathology alone is considered inadequate for the classification of medulloblastoma. It remains to be seen how the revealed diversity in molecular patterns and clinical outcome will influence the WHO Grade IV classification for medulloblastoma. The current treatment modality of surgery, radiation and chemotherapy is highly toxic to the developing brain. Complication and morbidity observed in patients with tumors subgrouped into good prognosis, such as the WNT subgroup, could correspond to a higher extent with iatrogenic interventions than with the natural course of disease. These patients may benefit from a reduction in radiation and chemotherapy, whereas patient with tumors subgrouped into more aggressive lesions may benefit from exhaustive therapeutic strategies.

35.3.14 Ependymoma

Ependymomas originate from the wall of the ventricular system with possible manifestations along the entire craniospinal axis of the CNS [202]. Radial glia cells are presumed to constitute the progenitor cells [203]. In children, over 90 % of ependymomas occur intracranially with 70 % arising in the posterior fossa, whereas in adults the spinal manifestation is more common [204–206]. Based on histopathological features, the WHO divides ependymomas in grade I–III and recognizes four histological types: subependymoma (grade I), myxopapillary (grade I, usually spinal), classic (grade II), and anaplastic (grade III) [9, 202]. However, as for most tumors, molecular characteristics will have to complement and specify future grading systems. Recent studies indicate that ependymomas from different compartments of the CNS display distinct genetic signatures, reflecting their unique origins, despite appearing histologically homogeneous [203, 207].

35.3.15 Chromosomal Alterations

Cytogenetic changes are seen in a significant proportion of ependymomas and are overall more common in adults [206, 208, 209]. About 30 % of sporadic ependymomas have monosomy 22, and deletions or translocations involving chromosome 22 are also observed [210]. The *NF2* gene is located on chromosome 22 (22q12), and NF2 patients are predisposed to develop spinal ependymomas in addition to other CNS tumors [211]. In fact, *NF2* mutations are almost exclusively found in spinal ependymomas [212], thus another tumor suppressor gene on chromosome 22 might be involved in cranial ependymomas [210, 213]. Gain of chromosome 1q is the most common genomic aberration in pediatric intracranial ependymomas, possibly associated with anaplastic histology [206, 214]. Besides numeric chromosomal alterations within the ependymoma genome, translocations are frequently reported to affect chromosomes 1, 11, and 22 [208]. The assumption that tumor location-specific genomic alterations exist in ependymoma has been encouraged by recent revelation of chromothripsis within chromosome 11q13.1 [215]. In more than two-thirds of supratentorial ependymoma samples, a fusion of the oncogene *RELA* to an uncharacterized gene involving 11q13.1 occurs, which is absent in posterior fossa tumors. The aberrant RELA-fusion proteins modulate activation of the transcription factor *NF-kB*. The largest molecular analysis of ependymoma to date, including 583 tissue samples, demonstrated that posterior

fossa ependymomas can be classified in to two subgroups, Group A and B, which differ in their genomics, transcriptomics, location and clinical outcome [209]. Group A ependymomas affect younger patients, are more laterally located and exhibit more frequent recurrence and metastasis with an overall poorer prognosis compared with Group B. The genome in Group A is more balanced, shows increased occurrence of chromosome 1q gains, whereas in Group B the genome is highly unstable with frequent segmental gains of chromosomes 9, 15, 18, as well as losses of chromosomes 6 and 22 [209].

35.3.16 Gene Amplification, Overexpression, Mutations, and Deletions

In ependymoma and especially in children, the overall genetic mutation rate appears to be lower than astrocytic tumors. Expression profiling by microarray analysis on pediatric ependymomas have identified a subset of genes abnormally expressed in this tumor, including increased expression of EGFR, WNT5A, TP53, and many cell cycle, cell adhesion, angiogenesis, and cell proliferation genes, with downregulated genes including *SCHIP-1* and *EB1* [213]. EGFR overexpression has been recorded as a prognostic marker in intracranial grade II ependymomas correlating with reduced progression free and overall survival [216, 217]. Amplification and rearrangement of the *c-erb B* gene has been identified, as well as rearrangements of the *MEN1* gene (11q13) [212, 218]. A large genomic analysis of ependymoma including tumors from 207 samples demonstrated focal amplification of genes involved in stem cell proliferation, pluripotency, and neuronal differentiation such as *THAP11, PSPH, EPHB2, KCNN1, RAB3A, PTPRN2, PCDH* cluster, and *NOTCH1* [207]. This same study identified focal deletions of known tumor suppressor genes (*PTEN, INK4A/ARF)* and novel genes such as *STAG1* and *TNRC6B* [207].

35.3.17 Epigenetic Alteration

Epigenetic modifiers involved in the formation of ependymomas have recently been identified. The methylation status of CpG islands occurs more frequently in posterior fossa Group A (PFA) tumors, leading to transcriptional silencing of the histone methyltransferase *Polycomb repressive complex 2 (PRC2),* which in turn results in repressive effect on expression of cell differentiation genes [219]. This epigenetic mechanism predicts for the more aggressive behavior of Group A tumors. Mice xenograft models implanted with human PFA showed a decreased tumor volume and longer survival after that PRC2 was reactivated through demethylation by administration of established epigenetic drugs that target either DNA or histone methylation [219].

35.4 Cell Cycle Dysregulation and Mitogenic Factors in Human Brain Tumors

The cell cycle can be conceptualized as a circle divided by a number of discrete phases during which nuclear content changes in preparation for cell division (Fig. 35.5). In healthy neural tissue, with advancing differentiation and age, most cells will become quiescent and do not express cell cycle genes due to the presence of cell-type specific repression mechanisms. In human brain tumors, the intrinsic machinery of the cell cycle is the target of mutations or functional derangements leading to release of repression mechanisms and rapid, uncontrolled proliferation—a hallmark of cancer.

35.4.1 General Mechanisms of Cell Cycle Dysregulation

Cyclins (A-E) are a group of proteins whose expression levels are differentially and tightly regulated during the cell cycle. When bound to their respective cyclin dependent kinases (CDKs), an activated complex promotes transcription of products required for a specific stage in the cell cycle [220]. The activity of the various CDKs are coupled to both binding of the cyclins and a series of phosphorylations and dephosphorylations on specific residues by cyclin-dependent kinase activating kinases (CAKs) and cyclin-dependent kinase inhibitors (CKIs) [221, 222].

One of the most important cell cycle pathways known to be perturbed in human brain tumors, especially astrocytomas, is the cyclin D-CDK4-RB-E2F pathway, (RB-pathway) (Fig. 35.5). Here, cyclin D forms an activated complex with CDK4 and/or 6. This active complex partially phosphorylates a previously hypophosphorylated retinoblastoma protein, RB [221, 222]. Partial phosphorylation of RB liberates E2F-DP such that it can act to upregulate target genes involved in the continued regulation of cell cycle, such as cyclin E [221, 222]. Thus, the phosphorylation of RB is a key regulatory step of the G_1–S checkpoint.

Whereas the cyclins and CDKs could be termed accelerators of the cell cycle, inhibitor of cyclin-dependent Kinase 4 (INK4) and Cip/Kip could be termed the brakes of the cell cycle. INK4 is a family of four proteins A-D, $p16^{INK4a}$, $p15^{INK4B}$, $p18^{INK4C}$, and $p19^{INK4D}$. INK4A is encoded from a gene on 9q21. Interestingly, this gene also encodes for a novel second protein, using an alternative reading frame in exon 1 and splicing it to the common exons 2 and 3. This protein is called ARF ($p14^{ARF}$), alternative reading frame, and is also involved in cycle arrest with p53.

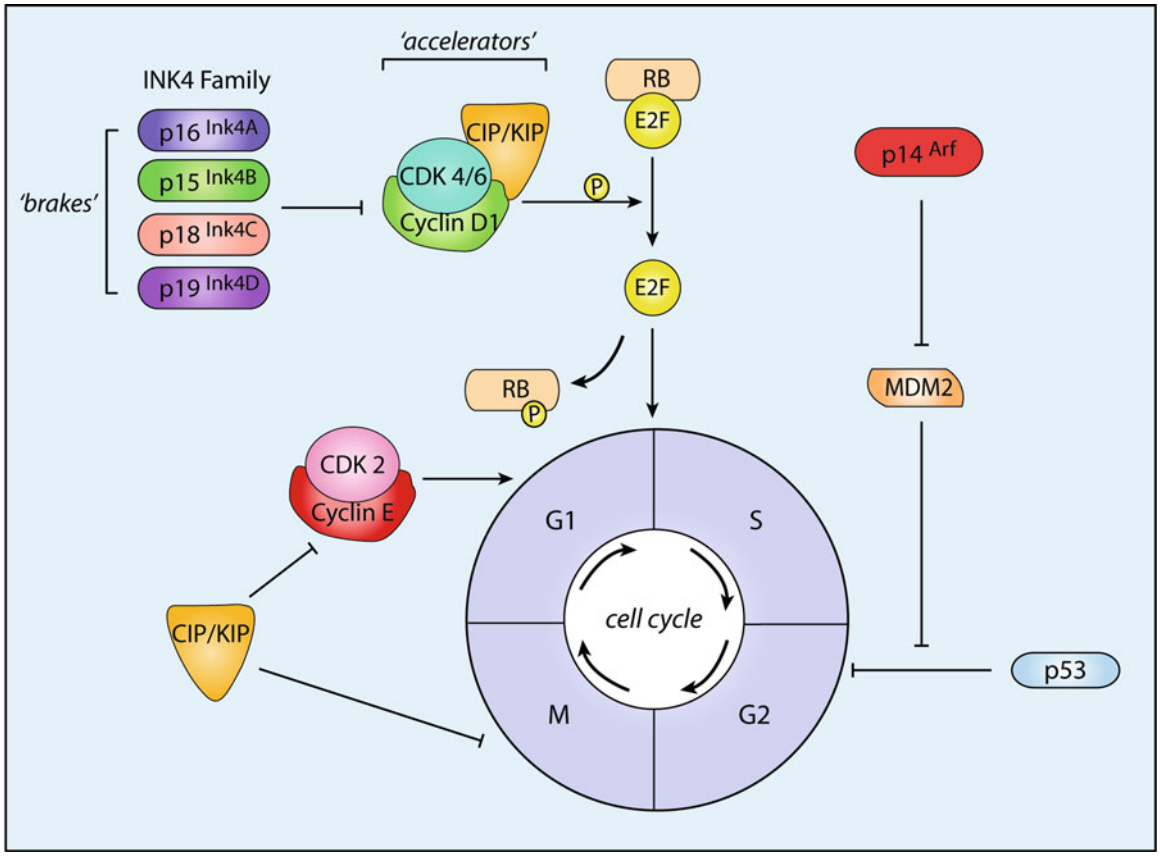

Fig. 35.5 Dysregulation in cell cycle pathways involved in the pathogenesis of astrocytomas.

The Cip/Kip family of CDK inhibitors ($p21^{CIP1}$, $p27^{Kip1}$, $p57^{Kip2}$) can bind and inhibit the G1/S cyclin-CDK complexes, and the mitotic cyclin B/A complexes. They can also act as both positive and negative regulators of the cell cycle. In early G1 phase Cip/Kip family members bind and aid in the formation of cyclin D/CDK4/6 complexes without inhibiting kinase activity and therefore contribute to the formation of hyperphosphorylated RB and cell cycle progression [223]. Once RB is partially phosphorylated and transcription of Cyclin E and Cdk 2 are upregulated, the Cip/Kip members then bind with higher affinity to Cyclin E/CDK 2 complexes and inhibit CDK 2 activity and halt cell cycle progression (Fig. 35.5).

35.4.2 The Importance of p53 and Cell Cycle Control

The *TP53* gene encodes the most well studied tumor suppressor, p53 and to date has been implicated to play a role in almost 50 % of human cancers, including human brain tumors [224]. Mutations in the *TP53* gene can lead to missense or loss of protein expression, whereas the missense mutation is associated with earlier cancer onset and more aggressive tumor profile [225, 226]. P53 has a multitude of stress-induced effects on cellular homeostasis by blocking cell cycle passage and promoting apoptosis. Several cell cycle proteins interact as negative or positive regulators with p53. One such mechanism of regulation of p53 is via the Murine Double Minute-2 protein (MDM2) (Fig. 35.4), which is able to repress p53 activity both at the transcriptional and protein levels [227–229]. MDM2 binds and conceals the p53 transactivating domain and blocks the basal transcriptional machinery for p53. In response to DNA damage both MDM2 and p53 are phosphorylated resulting in conformational changes that incapacitate binding [230, 231]. This allows p53 to be stabilized in the nucleus where it is able to upregulate genes involved in either cell cycle arrest or apoptosis. The ability of MDM2 to block the p53 pathway is reversed by ARF which binds to and sequesters MDM2 in the nucleolus away from p53, as also impairs MDM2's ubiquitin ligase activity [232–234]. This allows for stabilization of p53 levels and downstream activation of p21 and cell cycle arrest.

35.4.3 Mitogenic Signals That Impact on Brain Tumor Growth

The decision of the cell to divide is provided by both internal stimuli and external conditions. External conditions favorable

to cell division, growth, and survival are conveyed via cell membrane tyrosine kinase receptors that typically dimerize upon ligand binding, phosphorylate their cytoplasmic tails and activate downstream signaling molecules. One key growth activator is the small GTPase Ras. It activates multiple mitogenic pathways: RAF-MEF-MAPK, CDC42-RAC-Rho, and PI3K-PTEN-AKT [235]. These downstream signaling molecules subsequently activate cyclin/CDK complexes triggering growth, demonstrating these pathways are commonly targeted during tumor mutagenesis.

Epidermal growth factor receptor (EGFR), platelet derived growth factor receptor (PDGFR), fibroblast growth factor receptor (FGFR), C-Met, and C-kit are all tyrosine kinases implicated in the formation of astrocytomas and other neurological tumors.

35.4.4 Analysis of Cell Cycle and Mitogenic Pathway Disturbances in Brain Tumors: Low and High Grade Astrocytomas

Our understanding of the pathways involved in tumor initiation and progression has been enhanced through molecular genetic analyses of cell cycle and mitogenic stimulation pathways. Genetic alterations of *TP53* are present in low grade, anaplastic and GBMs, and the genetic aberrations are higher for the secondary GBM (up to 80 %) compared to the primary GBM (around 30 %) suggesting a role in astrocytoma initiation [114, 123].

Mutations in the RB pathway of *INK4A, CDK4*, *and RB* represent about 80 % of GBMs and only a small portion of low-grade astrocytomas [109] [236]. There are also differences between primary and secondary GBMs. Deletion of the *CDKN2A* locus leading to reduced CDK4 inhibition is found in over 50 % of primary and 20 % of secondary GBMs [114, 130, 131]. This locus encodes both *INK4A* and *ARF* and therefore disrupts both the p53 and RB pathways indirectly, perhaps contributing to the rapid rate of growth attributed to primary GBMs. Alterations of *RB* itself are found in up to 14 % of GBMs [130, 131]. *CDK4* amplification is present in 14 % of GBMs. Other mutations found to arise in GBMs have been identified in *CDK6*, *cyclin D*, and *cyclin E* [237, 238].

EGFR is amplified or altered in up to 57 % of glioblastomas, mainly detected in the primary and rarely in secondary GBM, which is why this alteration might not be involved early in tumor initiation [109, 239]. A mouse model expressing the mutated *EGFR* alone was insufficient to cause astrocytomas, but expressed in a background of *TP53* +/− or *Ink4A/ARF*−/− astrocytoma formation occurred rapidly [240]. This suggests that EGFR may be responsible for tumor progression but require additional mutations in other genes for tumor initiation.

PDGFRA is a surface tyrosine kinase receptor repeatedly found to be altered in both high and low-grade human astrocytomas [109, 241]. As a growth factor it interacts with the MAPK/RAS pathway, which is implicated in primary GBM formation, however the role of PDGFR in tumor initiation or progression has yet to be elucidated.

The tumor suppressor PTEN acts as a negative regulator of the PI3K-AKT growth control pathway. *PTEN* mutations may be found in 30 % of primary GBMs and up to 8 % of secondary GBMs [114], however these numbers are inconsistent among the different study groups to allow conclusive interpretation regarding order in succession of tumorigenesis.

35.5 Brain Tumor Migration and Invasion

Brain invasion by infiltrative tumor cells is one of the most sinister histopathological hallmarks of malignant brain tumors. Brain tumor invasion is a complex cellular phenomenon including permissive changes in the extracellular milieu and intracellular biomechanical systems. The spread of brain tumor cells within the cerebral tissue involves changes in cell/cell and cell/extracellular matrix (ECM) adhesion, enzyme degradation of the ECM by proteases, and cell motility into normal brain parenchyma [252, 253]. Specifically, cell migration requires a complex balance between extracellular cues and responsive intracellular signals that lead to dynamic regulation of the interactions between actin microfilaments, microtubules, intermediate filaments and associated adhesions [254, 255]. The driving force for cell movement is normally provided by dynamic reorganization of the actin cytoskeleton, which directs protrusions at the front of the cell and retraction at the rear [254, 255]. For a cell to move, it must establish polarity resulting in leading and trailing edges with directionalized forces. One of the first steps in cell migration is the formation of actin-rich structures called lamellipodia at the leading edge of the motile cell [256, 257]. Subsequent attachment of these protrusive structures to the substratum followed by tension across the cell, generated by myosin motor proteins, will lead to the contractile force ultimately required for cell body translocation [256, 257].

Ultimately, this interplay of contractile elements with adhesive matrix increases metabolic demand and triggers enzymes for enhanced glycolysis. As shown recently, GBM cells overexpress glucose-6-phosphatase (G6P) to overcome glycolytic inhibition [258]. By downregulating glucose-6-phosphatase in human derived GBM cells the migration and invasion rate was markedly reduced [258].

Migration along the tight extracellular space requires also considerable adaptation in volume and shape of glioma cells [253, 259], which is mediated by modulation of Cl^- and K^+

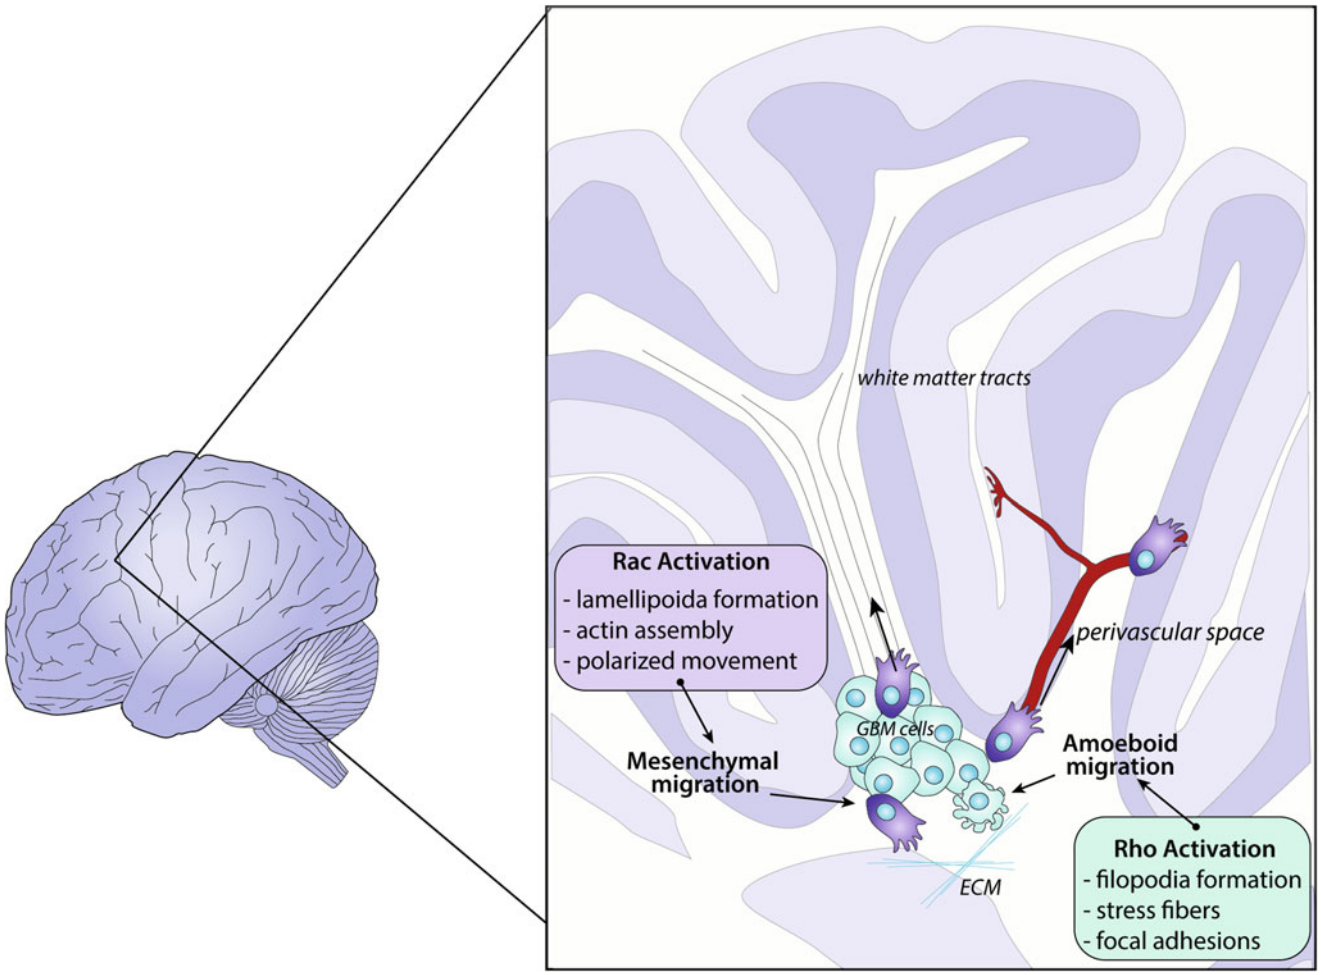

Fig. 35.6 Mechanisms involved in the migration and invasion of Glioblastoma (GBM) cells along the perivascular space and white matter tracts.

channels. The Na^+-K^+-Cl^- co-transporter (NKCC1) is highly expressed in glioma cells, which accumulates intracellular Cl^- leading to opening of Cl^-channels (ClC3) and resulting in volume shrinkage [260]. In recent studies, glioma migration and invasion could be decreased after inhibiting NKCC1 or ClC3 channels [261, 262].

In contrast to solid tumors of other organs, malignant glioma cells usually do not spread through an intravascular route but rather within the perivascular zone. Moreover, lymphatic channels do not exist in the brain. Despite their profound parenchymal invasiveness, metastasis outside the brain is negligible in primary malignant gliomas [263], which is likely due to the blood–brain barrier and an unsuitable environment for growth in other organ systems. The migration is mainly directed into two compartments: the perivascular space and the brain parenchyma, which then results in a spreading of glioma satellites at distant sites from the main tumor mass [253] (Fig. 35.6). The alignment towards existing structures such as white matter tracts, blood vessels and meninges resembles the movement observed in neural progenitor cells during tissue maturation [253].

There have been numerous reviews describing many of the extracellular factors relating to invading brain tumor cells such as the proteolytic degradation by various proteases (MMPs, cathepsins, serine proteases, urokinase plasminogen activator receptor), and ECM deposition and adhesion facilitated by matrix receptors [252, 264, 265]. The increased release of glutamate by glioma cells additionally acts as an autocrine and paracrine ligand supporting Ca^{2+} triggered cell migration and invasion [266]. Indeed, blocking intracellular glutamate uptake through sulfasalazine resulted in reduced tumor spreading in a rodent model [266]. There are also many well characterized genetic lesions in brain tumors which have been shown to affect astrocytoma progression [254, 267, 268], but the understanding of the intracellular and molecular mechanisms that mediate brain tumor invasion is still in its infancy. These molecular pathways include signaling regulated by (1) the non-receptor tyrosine kinases

focal adhesion kinase (FAK) and proline-rich tyrosine kinase 2 (Pyk2), (2) members of the Rho family of small GTPases, (RhoA and Rac1) including signaling by lysophosphatidic acid (LPA) and sphingosine-1-phosphate (S1P), and (3) the nuclear factor-kB (NF-kB) family of transcription factors.

The Rho family of small GTPases is essential in cellular migration pathways. RhoA activation mediates formation of stress fibers and focal adhesions in the trailing edge of the cells and leads to a rounded amoeboid form of movement, while Rac1 directs actin assembly in lamellipodia at the leading edge of migrating cells which results in cells moving in an elongated mesenchymal manner [269, 270]. Attempts to reduce cell motility by blocking migration pathways have to take into account that cells can switch between these different modes of migration. CDC42 is a well-studied member of the Rho family and, while not essential for cellular movement, aids in regulating filopodia formation and cellular polarity [271, 272]. Inhibition of Rac1 with siRNA leads to decreased lamellipodia formation and cellular movement [273, 274]. Using a dominant negative Rac1 inhibitor induced death on GBM cells but not normal astrocytes [275]. Additionally, it was shown that downstream inhibition of Rho-Kinase (downstream of RhoA activation) lead to increase motility through activation of Rac1 [276]. Therefore, it may be a balance between RhoA and Rac1 that regulates cellular migration and invasion in astrocytoma cells.

The greatest limitation of brain tumor invasion research to date has been the lack of a reliable and reproducible in vivo animal model of brain invasion. Current applications of existing animal models are currently not optimized or characterized for use in brain tumor invasion research. Induction of invasion in vivo, tracking infiltrative cells and quantitation of brain invasion are the most critical considerations of a live animal model of brain tumor invasion.

35.6 Brain Tumor Angiogenesis

Angiogenesis is defined as the formation of new blood vessels from the sprouting of previously existing vessels. In the fetal brain, angiogenesis begins during embryogenesis when soluble angiogenic factors are secreted to cause capillary sprouting from the extracerebral plexus and neovascularization. In contrast, the adult brain shows very little angiogenic activity due to expression of antiangiogenic factors.

Solid tumors beyond 2 mm in diameter require recruitment of blood vessels for continued growth [277]. In pathological states such as tumors, an angiogenic signaling switch occurs that results in a cascade of events including enzymatic degradation of basement membrane proteins, endothelial migration, endothelial proliferation, and tubular vessel formation. The most important mitogen orchestrating vascular neogenesis in brain tumors is vascular endothelial growth factor, VEGF.

35.6.1 Mechanisms of Angiogenesis in Human Astrocytomas

A distinguishing histopathological feature of astrocytoma is endothelial proliferation, which can be 40 times higher than in normal brain [278]. VEGF overexpression is central to the neovascularization observed in these high-grade lesions such as GBM [279–281]. Monoclonal antibodies directed against VEGF in GBM mice xenografts and withdrawal of VEGF from implanted GBM cell lines in mice resulted in vessel regression underscoring the importance of VEGF in these lesions [282, 283].

VEGF is a 34–45 kDa glycosylated homodimeric protein that acts as a specific mitogen and chemotactic factor for endothelial cells [284]. There are five other VEGF homologs, VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and placental growth factor (PGF) [285]. VEGF, itself, is composed of five splice variants, which have equivalent effects in regards to angiogenesis [286]. Expression of VEGF results in increased permeability of the microvasculature, endothelial production of proteases to break down basement membrane, endothelial survival, and endothelial proliferation [287].

The effects of VEGF are exerted via the tyrosine kinase receptors vascular endothelial growth factor receptor one and two, VEGFR1-2, and neuropilin-1 (Nrp-1). Binding of VEGF to VEGFR-2 promotes endothelial proliferation, whereas binding to VEFGR-1 regulates endothelial cells [288]. VEGF-2 is considered a core driver in complete activation of the angiogenic cascade and thus progression of neovascularization observed in high grade astrocytomas [280].

Central to the expression of VEGF is hypoxia. Increased transcription of VEGF mRNA in vitro can be efficiently induced by hypoxic conditions and upon restoration of oxygen levels, basal VEGF expression is returned [289]. Rapidly proliferating tumors, such as GBMs, quickly outstrip their blood supply creating a hypoxic and necrotic environment. Indeed, VEGF expression of cells at the rim of necrosis shows 50 times basal VEGF expression [290, 291]. This is mediated through hypoxia inducible factor, HIF-1 [292].

HIF-1 is a heterodimer consisting of an α and β subunit. Under normal physiological conditions the α subunit is ubiquitinated by the tumor suppressor von Hippel–Lindau, VHL [293]. As a result of hypoxia, HIF-1α interacts with the hypoxia-response element leading to the increased expression and upregulation of pro-angiogenesis genes, such as VEGF [292]. HIF-1 also cooperates in the stabilization of the VEGF protein and increasing VEGF secretion [294]. VEGF expression

can also be upregulated by fibroblast growth factor (FGF), PDGF, EGF, tumor necrosis factor α, (TNF-α), transforming growth factor β (TGF-β), and interleukins 1 and 6 [287].

Angiopoietins are a four-member family of secreted ligands that bind to the endothelial specific tyrosine kinase Tie-2. The two best understood angiopoietins are angiopoietin 1 (Ang-1), and angiopoietin 2 (Ang-2), which act antagonistically at the Tie-2 receptor. In the presence of VEGF, Ang-2 promotes vessel destabilization in preparation for neovascularization [295]. The combination of VEGF and Ang-2 is found at the hypoxic rim of GBMs [296], whereas Ang-1 stimulation of Tie-2 results in vessel stabilization and is found at the tumor periphery [287].

Bevacizumab, a human monoclonal antibody against VEGF-A, leads to a marked reduction in tumor size and prolongation of progression-free and overall survival in GBM patients in promising preclinical and clinical studies [297, 298]. Two highly awaited and large Phase III randomized trials have been conducted recently (RTOG-0825 and AVAGlio trial) [299, 300]; however neither study demonstrated any benefit in overall survival, albeit a slight increase in progression-free survival was observed.

35.7 Developmental Signaling Pathways and Human Brain Tumors

During normal neuroembryogenesis multiple signaling pathways are active to allow fast proliferation and increased migration of neural progenitor cells. The phase of differentiation and maturation requires a precisely adapted regulation of expression and silencing of the involved signaling networks. In the past decade, an increasing number of genes and pathways involved in this maturation process have been discovered and characterized. As advanced molecular analysis in human brain tumors recurrently revealed mutations and other alterations in these genes, it is assumed that such alterations are involved in the early phase of brain cancer initiation and eventually enable tumor cells to acquire proliferation and migration proprieties similarly found in primitive neural cells. Here we discuss three developmental signaling cascades with proven associations with formation of human brain tumors.

35.7.1 The Notch Signaling Pathway

The Notch signaling pathway mediates cell–cell signaling and is a key developmental pathway regulating cell decisions regarding cell survival, maintenance of stem cell self-renewal, proliferation, differentiation, and apoptosis [301–303]. The Notch protein forms a transmembrane receptor, whereas the extracellular region contains an epidermal growth factor-like ligand domain. When engaged with ligand from the *Jagged* or *Delta* families, the extracellular component gets cleaved by ADAM metalloproteases, which then leads to a second cleavage at the transmembrane region by a *γ-secretase*. This second proteolytic event releases the Notch intracellular domain which promotes transcription of Hes family genes, among others [301] (Fig. 35.7).

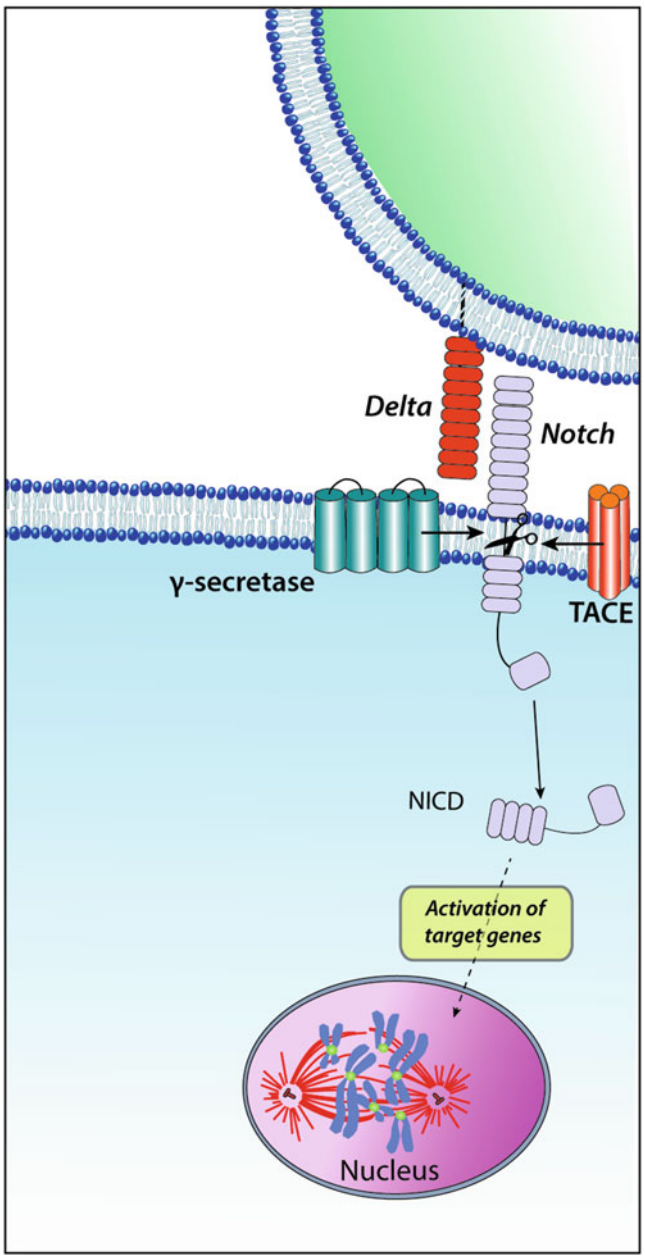

Fig. 35.7 Notch signaling pathway.

The functions of the Notch genes (Notch1-4) are time-dependent and cellular context-dependent, and thus, they may act as an oncogene or a tumor suppressor [304–306]. Activation of Notch signaling is known in various human neoplasms such as cervical carcinomas, T-cell leukemia, pancreatic

cancer, and mucoepidermoid carcinoma [307, 308]. In the nervous system, Notch regulates stem cells in developing and modeling the shape and cytoarchitecture of brain and spinal cord [309, 310]. Notch upregulation was observed in glioma cell lines and primary human glioblastomas resulting in stem cell maintenance and tumor proliferation [311, 312]. Specifically, the self-renewal of stem cell-like GBM cells is sustained in the perivascular stem cell niche by endothelial cells, which provide Notch ligands, promoting radioresistance [313, 314]. Notch inactivation by *γ-secretase* inhibitors (GSI) resulted in increased radiosensitivity through regulation of the PI3K/Akt pathway [314]. GSI induced suppression of Notch can also enhance the antitumoral effect of temozolomide (TMZ) [315]. From the four GBM subgroups, the proneural type particularly shows high Notch pathway activation and sensitivity to GSI in the mouse model [316].

Notch signaling deregulation also occurs in medulloblastomas, primarily within the SHH subgroup, where *Notch 2* amplification and overexpression correlated with tumor progression and poor prognosis [317–319]. Interestingly, inhibiting the Notch pathway in medulloblastoma cell lines using inhibitors of GSI could decrease the number of CD133+ cells and block in vivo engraftments [320]. The role of *Notch* in medulloblastoma genesis and how the Notch pathway interacts with the SHH pathway remains to be elucidated given that recent studies demonstrate that Notch signaling may not be crucial for SHH-driven medulloblastomas [321–323].

Several studies reported an upregulation of the Notch pathway in ependymomas, supporting its potential role in the pathogenesis of these tumors [203, 324, 325]. Taylor et al. identified genetically distinct ependymomas by patterns of gene expression that recapitulated those of radial glial cells in corresponding regions of the CNS [203]. Specifically, it was shown that supratentorial tumors expressed markedly elevated levels of Notch family members.

35.7.2 The Sonic Hedgehog Signaling Pathway

The SHH signaling pathway plays a primary role in morphogenic development of different organs during embryogenesis [326]. The secreted Sonic Hedgehog ligand, encoded on chromosome 7q36, binds and inactivates the transmembrane receptor Patched (PTCH), which results in releasing the inhibition of Smoothened (SMO) [304, 327]. SMO subsequently acts to activate transcription factors of the GLI family to express target genes, while SUFU (Suppressor of Fused) regulates Gli (Gli1–4) proteins to inhibit the SHH pathway [327, 328] A model of SHH signaling is shown in Fig. 35.8.

Dysregulation of the SHH pathway is implicated in cancers of different tissues, including the brain, lung, mammary gland, prostate, and skin [329]. In the nervous system, SHH is crucial for pattering the midline structures in brain and spinal cord as well as controlling of axonal spreading and stem cell proliferation [330]. Proper regulation of SHH is particularly critical for normal development of the cerebellum, explaining the frequent implication of this pathway in medulloblastomas when one or more genes of this pathway are dysregulated [331, 332]. Through analysis of gene expression in medulloblastomas, it has been shown that tumors with mutations in SHH pathway express high levels of Gli1, as well as N-myc and C-myc, cyclin D1 and D2 [333]. Interestingly, sporadic Gorlin's syndrome and medulloblastomas are often characterized by inactivation of *Ptch1* gene or activation of SMO [80, 184, 334]. *Bmi1*, a polycomb group gene, is involved in the clonal expansion of granule cell precursors, and its overexpression is linked to that of Ptch and is ultimately required for SHH driven tumorigenesis [331, 332]. A recent genome sequencing of SHH pathway medulloblastoma showed that the most frequently detected gene mutations were found in *PTCH1* (45%), *SMO* (14%), and *SUFU* (8%) [335]. Interestingly, while *PTCH1* mutations were found at roughly equal distribution in infants, children, and adults, *SMO* alterations were markedly more frequent in adults, and *SUFU* almost exclusively in infants under 3 years [335]. On the other hand, children older than 3 years exhibited strong *MYCN* and *GLI2* amplification together with *TP53* mutations (possibly in correlation with Li–Fraumeni syndrome), while all of these findings were rare in infants and adults [335].

SHH pathway is best studied for the pathogenesis of medulloblastoma, but there is increasing data revealing involvement in glioma incurrence. Amplification and overexpression of *Gli1* has been associated with some low- and high-grade astrocytomas [336, 337], and is assumed that the SHH pathway might have a stronger role in glioma initiation compared to other developmental pathways such as Notch or WNT [338]. Furthermore, it has been demonstrated that $CD133^+$ glioblastoma cancer stem cells (CSC) are promoted by endothelial cells through SHH pathways and inhibition of SHH by SMO knockdown in vitro and in vivo results in reduction of CSC phenotype-appearance [337]. High expression of SHH and Gli1 in glioma patient samples were correlated with both increasing WHO grade and worse prognosis [337].

Therapeutic approaches targeting the SHH pathway have mainly focused on SMO inhibition [335, 339]. Preclinical and clinical studies appeared initially promising with evidence of marked reduction in tumor growth; however, point mutations in *SMO* and *GLI2* amplifications eventually lead to drug inefficacy [340, 341]. Recent xenograft models revealed that SHH medulloblastomas with *PTCH1* mutations were responsive to SMO-inhibition, while tumors with *SUFU* or *MYNC* mutations, which are often found in infants, showed resistance [335]. The addition of PI3K inhibitors to SMO antagonist therapy may be a strategy to delay the development of resistance [340, 341].

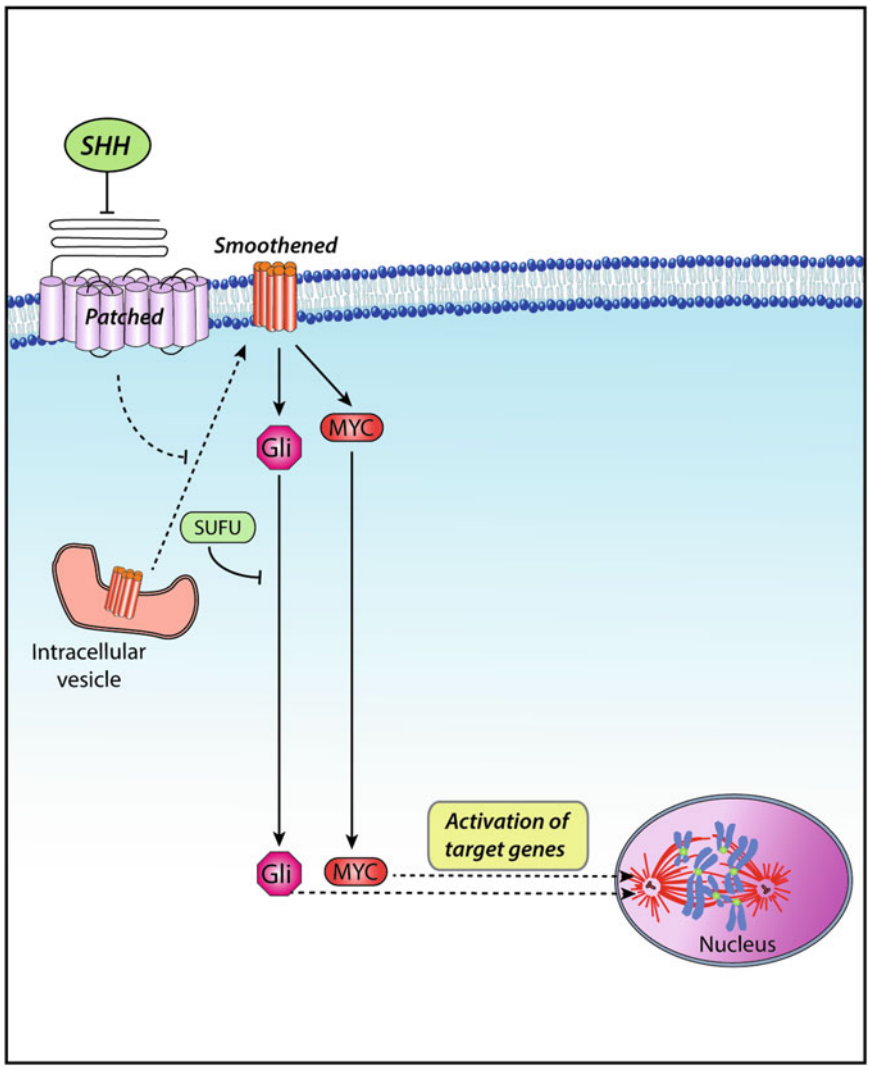

Fig. 35.8 Sonic Hedgehog (SHH) signaling pathway.

35.7.3 The Wingless Pathway

The Wingless (WNT) proteins form a family of secretory molecules that regulate cell–cell interactions during embryogenesis. To date, 19 *WNT* genes and more than 15 associated receptors have been identified in the human genome [304, 342]. WNT binds to the G-protein-coupled receptor Frizzled, which results in intracellular signaling carried out by the phosphoprotein Dishevelled (DSH) and leads to a release of inhibition of the transcription factor β-catenin [343]. With inactive WNT signaling, the cytoplasmic concentration of β-catenin is regulated and decreased by a destruction complex, which mainly is formed by Axin, APC, GCK-3, and CKI [344]. A current model of WNT signaling is shown in Fig. 35.9.

Through its interactions with other families of secreted growth factors, including EGFR, FGF, TGF-β, and the Hedgehog proteins, WNT signaling can regulate diverse processes including cell proliferation, migration, polarity and differentiation [345–347]. The canonical WNT pathway is also a critical regulator of stem cells properties, and its activation has been associated with various cancers [348].

Evidence for the involvement of the WNT signaling pathway in brain tumors has come from studies of Turcot's syndrome, characterized by the development of medulloblastomas and astrocytomas resulting from a germ-line mutation in the *APC* gene [188]. Since then it has been established that WNT signaling influences the proliferation and the renewal of neural stem cells and progenitors [347]. There is increasing evidence that aberrant activation of WNT signaling, resulting in accumulation or increased activity of β-catenin, will lead to the development of sporadic brain tumors, Notably, pediatric medulloblastomas harbor mutations of *β-catenin*, *APC*, and *Axin* [188, 329]. These point mutations are found in approximately 10–15 % of medulloblastomas but are mutually exclusive. For instance, 4 % of sporadic medulloblastomas harbor missense mutations in *APC*, and 1–5 % have *Axin1*

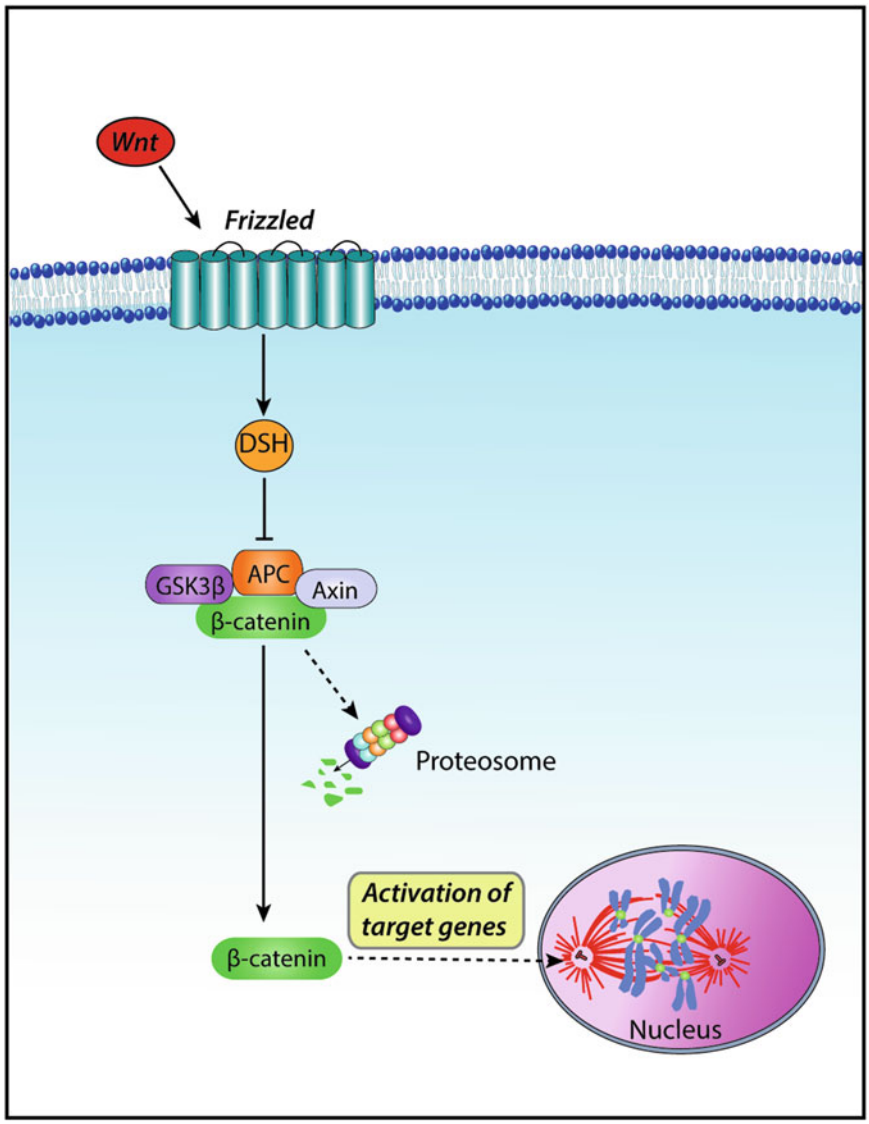

Fig. 35.9 Wingless/Int 1 (WNT) signaling pathway.

point mutations [186, 349]. Interestingly, there is evidence of cross-talk between the WNT and SHH signaling pathways as SUFU has been shown to regulate the activity of β-catenin [350]. *SUFU* mutations in medulloblastomas may lead to the activation of the two pathways: WNT and SHH [351]. The role of WNT signaling in brain tumor formation has primarily been studied in the context of medulloblastoma, but there is increasing evidence that WNT signaling may also modulate the early phase of tumorigenesis in some gliomas [346, 347, 352].

So far, agents targeted against the WNT pathway in medulloblastoma cells or tumors have only been explored in preclinical setting [353, 354]; however given that medulloblastoma patients harboring mutations involving WNT signaling show favorable outcome compared to other subgroups [198], WNT targeted strategies seem to be of lower priority.

35.8 Stem Cells in Brain Tumors

The cancer stem cell (CSC) hypothesis was initially derived from the concept of CSCs giving rise to the hematopoietic malignancies. Since then the CSC hypothesis attempts to explain the development of solid tumors, such as brain tumors. Furthermore, the CSC hypothesis provides important concepts for future brain tumor treatment. The failure or only short lived beneficial effect of chemotherapy drugs and radiotherapy in addition to rapid tumor recurrence for most malignant brain cancers lead to the assumption that actual therapies might not adequately target a subset of dormant or slow cycling cells with abilities of self-renewal and adaptation [105]. Brain tumor stem cells are hypothesized to reside within a nutritive perivascular niche [355] (Fig. 35.10).

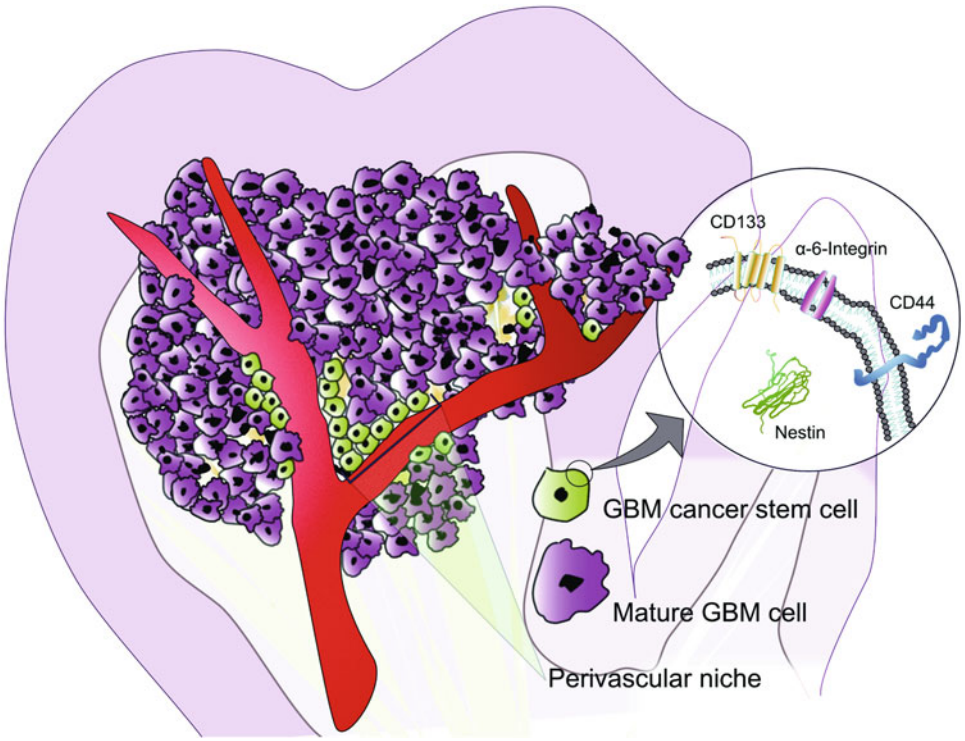

Fig. 35.10 Glioblastoma stem cells and perivascular niche. *GBM* glioblastoma multiforme.

As in normal tissue, tumors are organized in a cellular and functional hierarchy based on stem cells. Neural stem cells (NSC) are defined as cells that have the ability to perpetuate themselves through self-renewal (symmetric division) and to generate mature cells of a particular tissue through differentiation (asymmetric division) [356, 357]. These cells have been isolated from the embryonic brain of humans and persist in the adult in the subventricular zone of the frontal lateral ventricles and dentate gyrus of the hippocampus [105]. Different markers have been proposed to characterize the NSC population, but none have proven to be specific enough to ensure the identification of a pure population. The expression of Nestin is a widely used marker to delineate NSCs, as is the cell surface marker CD133. Additionally, some NSCs have characteristics of glial cells and will express on their surface SSEA-1, CD44, α-6 integrin, BLBP, GLAST, RC2, and GFAP markers [358–361].

Many genes that have been identified as regulators of neural stem cells properties are also known to be involved in brain tumorigenesis [361]. For instance, Bmi-1 is important for cell proliferation and maintenance, and PTEN acts as a tumor suppressor and important negative regulator of cellular proliferation [362, 363]. The Notch, Sonic Hedgehog, and Wingless pathways have also been implicated in regulating NSCs [348, 364–366]. Importantly, deregulation of these pathways is also strongly implicated in the initiation and progression of CNS cancers when they are deregulated.

To date, CSCs have been identified in many solid tumors, including breast carcinoma, CNS tumors including astrocytomas, ependymomas and medulloblastomas, skin malignancies, and colon cancer [203, 367–373].

Evidence supporting the CSC hypothesis in brain tumors, include finding that these cells have indefinite potential for self-renewal, proliferation, differentiation, and have clonogenic potential based on neurosphere assays. Several studies demonstrate a close link between developmental biology, stem cells and cancer cells. In vitro, CSCs have been shown to express molecular markers of neural precursors as Sox2, Bmi1, Musashi, Notch, Emx2, Pax6, and Jagged1 [374]. These findings suggest that CSCs may have been initially derived from normal stem cells. Several proteins have been proposed as markers of the CDC population in brain tumors including CD133, CD15, α-6 integrin, and ATP-Binding cassette transporters (ABCT) [371, 375–377]. However, other studies have shown that the negative populations of these markers can also give rise to tumors and therefore these markers may only enrich for CSC and not define CSC [378]. Importantly, it is not clear yet if cancer-initiating events occur in the NSC, progenitor cells, or terminally differentiated cells, which reacquire a de-differentiated state [379]. Recent studies have suggested the microenvironment is important in defining the CSC. In melanoma, for example, the complete obliteration of the immune response of the xenograft host lead to a larger fraction of the tumor population exhibiting CSC properties [380].

Using a high-throughput drug screen, Diamandis et al. demonstrated that the functional ground state of neural stem cells may not only be dependent on developmental signaling

Table 35.2 Pros and cons of common animal models of brain tumors

	Brain tumor in vivo model	Pros	Cons
	Orthotopic xenograft	Cell lines can be genetically manipulated prior to transplantation in order to explore specific genetic events Large numbers of animals can be generated in relatively short time and at low breading costs Relative consistent histology and chromosomal profile supports standardization	Brain tumor cell lines generally show genotypic deviation and homogeneity compared to the original patient tumor (applies less to biopsy xenografts, at the cost of longer engraftment time and more variable tumor histology) Mostly demonstrate an expansive growth with only limited infiltration into the perivascular space and occurrence of necrosis or microvascular alterations (better results with sphere cultures compared to monolayer cell lines) Inhibited immunological tumor-host response
	Chemically induced model	Immune competent animals can be used Tumors show relative high degree of invasive growth	Genotype and phenotype of the tumor is not reproducible Histologically present more like gliosarcomas or "glioma-like tumors"
	Genetically engineered mouse model (GEMM)	Tumors arise de novo and in situ within immune competent animals Induction of defined genetic alterations allow to study the role of oncogenes and tumor suppressors in tumorigenesis Intact immune system and distinct molecular characterization of induced brain tumors improves validation of drug testing	Time point of tumor initiation cannot be controlled Biological differences of murine and human malignancies Complex and expensive breading

Transplantable, chemically induced, and genetically engineered mouse models (GEMM)

pathways such as Notch, SHH, and WNT, but also on pathways relating to neural transmission [381].

Although the cancer stem cell hypothesis remains somewhat controversial it offers a unique prospective to examine and understand brain tumor biology. The properties required for a population of cells to become tumorigenic requires a dynamic interplay between genetic aberrations, tumor hierarchy, and microenvironment.

35.9 Animal Models of Brain Tumors

The ideal animal model of a human brain tumor recapitulates the molecular, genetic, histopathologic, and clinical features that are found in the human tumor. While none of the current animal models can fully achieve these requirements, these models are critically important as they can be used to investigate tumor biology, screen novel molecular targets and pave the way towards preclinical trials. In the past 10 years, great progress has been made in establishing several relevant and reproducible animal models of human brain tumors that are based on the molecular genetic alterations that characterize the human tumors. Here we describe transplantable, chemically induced, and genetically engineered models [242] (Table 35.2).

35.9.1 Transplantable Allograft and Xenograft Models

Classic modeling involves transplantation of cultured rodent (allograft) or human (xenograft) cell lines under the skin (subcutaneous) or in the brain (orthotropic) of immunodeficient/immunonaive rodents [382, 383]. These rodent models are highly reproducible in terms of tumor formation, growth, and survival pattern. The cell lines can be genetically manipulated prior to transplantation in order to explore specific genetic events. However, these tumors may not faithfully recapitulate the original tumor histology, and pathobiology [384]. Established brain tumor cell lines generally show genotypic deviation and homogeneity compared to the original patient tumor [385]. One strategy to overcome this is the use of orthotopic serial passaging of primary human brain tumors in mice, as these xenografts often retain the original tumor phenotype. A common drawback of tumor transplants

is that they mostly demonstrate an expansive growth with only limited infiltration into the perivascular space of the brain and rare occurrence of necrosis or microvascular alterations [242]. The advancement in cell selection and preparation of growth media now allows for cultivating cancer stem-like cells which grow as spheres [242, 368]. These sphere cultures closely retain the genetic profile of the patient tumor and are highly tumorigenic, invasive, and angiogeneic [242, 386]. However, *EGFR* amplification is rather rare in neurosphere cultures and some cell populations lose glial and gain mesenchymal features in a process known as mesenchymal drift [387]. The retention of the initial chromosomal profile and tissue architecture of the tumor can be improved when biopsy tissue is directly cultivated as multicellular organotypic spheroids and implanted into immunodeficient rodents [388]. Biopsy xenograft models usually maintain their heterogeneity and show invasiveness, necrotic areas and frequently display *EGFR* amplification [242]. However given that the tumor histology differs between animals and initial engraftment may take up to 1 year, experimental planning becomes problematic [242].

35.9.2 Induction of Brain Tumors via Embryonic Mutagenesis

The second classical method of modeling is inducing tumor formation in the developing brain of embryonic rodents with early exposure to mutagenic alkylating agents (chemically induced model) [389, 390]. These tumors, mostly established in rats (e.g., 9L, C6), show some degree of invasion and necrosis, but histologically present more like gliosarcomas or glioma-like tumors [242]. An advantage over transplanted tumors is that immunocompetent animals can be used, which mimics the situation normally found in humans. However, when cell lines from chemically induced tumors are used as an allograft transplant, immunogenic tumor rejection may still occur and interfere with the interpretation of the effect of experimental antitumoral agents. An essential disadvantage of chemically induced tumors in embryonic animals is that the genotype and phenotype of the tumor is not reproducible, given the inciting genetic event is unknown and reveals little about the molecular etiology of brain tumors in humans.

35.9.3 Genetically Engineered Mouse Models (GEMM)

GEMMs are created by germ-line modifications or somatic cell gene transfer techniques. An advantage over xenografts is that the tumors arise de novo and in situ within immune competent animals. GEMMs have allowed further insight into the molecular events behind tumor initiation and maintenance, although mouse tumors that phenotypically resemble human tumors still behave differently with respect to their genetics and therapeutic response [391].

The generation of transgenic mice involves inserting a DNA construct (usually an oncogene) downstream of a promoter into a fertilized oocyte, which is then implanted into the mouse [392, 393]. All cells of the resulting transgenic offspring homogenously contain the new genetic material. Conditional expression can be conferred using tissue/developmental stage specific promoters, drug response elements such as tetracycline or doxycycline, or recombination techniques (*Cre/lox*) [394, 395]. Strategies employing conditional expression allow the study of genes that would otherwise result in embryonic lethality, and confer tissue and stage specificity.

Knock-out mice or loss-of-function models traditionally involve using homologous recombination to substitute a mutated gene with a selection marker (i.e., antibiotic resistant gene) for a wild type gene. The cells of interest are then selected for and placed into embryonic stem cells, which are then transferred to mouse embryos and generate chimeric mice, which can be mated to generate a homozygous mouse with the inactivated gene [393, 396]. These mice as well as transgenic mice can be mated for a combination of genetic modifications.

Somatic cell transfer techniques allow the infection of only a population of cells in an effort to more closely model the spontaneous genetic events responsible for the majority of brain tumors. These techniques employ the use of viral vectors for the delivery of genetic information. One strategy takes advantage of the Moloney Murine Leukemia Virus (MMLV) and its wild-type helper virus to deliver genes to dividing cells [397]. A second more specific system uses the replication incompetent avian leukosis virus (ALV) to only deliver genes to cells engineered to express the viral receptor tv-a [398, 399]. The ability to study secondary mutations in these systems is related to infection efficiency, as well, the inclusion of large genes in the vectors decreases viral efficiency. However, multiple viral constructs can be coinfected to study multiple genetic hits.

35.9.4 Models of Astrocytoma

Alterations within the three core signaling pathways (p53, RB, RTK/RAS) as characterized by the TCGA are often used to induce astrocytoma formation in GEM models [391]. Transgenic mice with constitutively active H-RAS driven by a GFAP promoter (astrocyte specific) develop Grade II–IV astrocytomas in a dose dependent manner [400]. High H-RAS expressors develop tumors characteristic of GBM and moderate expressors develop low-grade or anaplastic astrocytomas [393, 400].

Mice with tumors characteristic of GBMs can be created by breeding mice with *TP53* deletions with mice with *Nf1*

(the mouse form of the human NF1) deletions [401]. Nf1, as in humans, is a RAS-GAP protein that downregulates RAS activation, therefore, its loss would result in RAS activation.

Transgenic mice with v-src expression driven by a GFAP promoter develop low grade or anaplastic astrocytomas 14.4 % of the time [393, 402]. The src receptor interacts with the EGFR and PDGFR signaling pathways.

Anaplastic astrocytomas were modeled in mice engineered to express the SV40 T-antigen late in development. SV40 inactivates RB and RB family member p107 and p103. These mice develop anaplastic astrocytomas within 10 months in almost 100 % of cases [393, 403]. Interestingly, mutating RB alone does not result in astrocytomas suggesting redundancy between RB family members.

Using the RCAS/tv-a retroviral somatic cell transfer technique to over express K-RAS and AKT in nestin positive CNS progenitor cells results in the formation of tumors characteristic of GBM [404]. Neither K-RAS nor AKT overexpression alone formed tumors. AKT over expression may be analogous to PTEN deletions in human GBM as the inhibitory effects of PTEN are immediately upstream of AKT activation [393]. Marumoto et al. transduced a small number of GFAP$^+$cells heterozygous for *TP53* with lentivirus harboring activated oncogenes H-RAS and AKT in the cortex, subventricular zone and hippocampus of mice [405]. Tumors that recapitulated human GBM arose only from transduced cells in the subventricular zone or hippocampus [405].

Deletions and alterations in tumor suppressor or oncogenes can be combined in order to generate mouse models of GBM subgroups. For example, knocking down p53 and activating RAS signaling resulted in tumors harboring a molecular profile resembling the mesenchymal GBM subtype [104]. Furthermore, the first orthotopic xenograft model of anaplastic oligodendroglioma with mutations in *IDH1* and tumor suppressor genes *FUB1* and *CIC* (both involved in MYC expression and RTK signaling repression) has been reported recently [406].

35.9.5 Models of Oligodendroastrocytoma

Overactive PDGFR has been implicated in the pathogenesis of human oligodendroastrocytoma tumors and as such murine models of this tumor have focused on this abnormality. Holland et al. used the RCAS retroviral system to express oncogenic PDGFB in either nestin or GFAP expressing cells [407]. The nestin group acquired mainly low grade oligodendroastrocytomas approximately 60 % of the time, whereas the GFAP group developed mixed oligoastrocytomas or oligodendroastrocytomas 40 % of the time [407]. When the oncogenic PDGFB mice were crossed with mice lacking the INK4A/ARF gene, the proportion of anaplastic tumors increased the latency to tumor formation [407]. Recently, oligodendroglioma cells from fresh human tissue samples with co-deletion of chromosomes 1p and 19q have been successfully cultivated as permanent cell lines (BT054 and BT088). BT088 was shown to engraft in the brain of immunocompromised mice, and demonstrated extensive infiltration and histology resembling anaplastic oligodendroglioma [408].

35.9.6 Models of Medulloblastoma

Mice heterozygous for mouse *PTCH* deletion develop tumors similar to human medulloblastoma at a rate of 15 % by 10 months [409]. This incidence can be increased to 98 % by 12 weeks if the *PTCH* +/- mice are combined with *p53* null mice [409]. Using the RCAS retroviral and inducing Sonic Hedgehog mis-expression in the cerebellum of fetal or newborn mice resulted in medulloblastoma formation at high rates [410, 411]. The co-overexpression of C-MYC in these mice enhanced the effect [393]. In murine transgenic models, the overexpression of MYC in concert with loss of *TP53* resulted in medulloblastomas that expressed markers typical of Group 3 medulloblastoma [412]. Interestingly, while trying to create astrocytoma models in GFAP expressing cells of mice by deletion of both *TP53* and *RB*, tumors phenotypically similar to medulloblastoma developed in the cerebellum [413]. The WNT subgroup could be recapitulated in mice with activating mutations in the WNT pathway effect protein CTNNB1 [414]. These WNT pathway tumors in the mouse model revealed that this subgroup of medulloblastoma arise from regions in the dorsal brainstem as opposed to other genetically distinct medulloblastoma subgroups such as SHH which arise from the cerebellar hemispheres [414].

35.9.7 Models of Ependymoma

For a long time, preclinical models of ependymoma were lacking [415]. Johnson et al. introduced the first mouse model in 2010 using genetic engineering techniques [207]. After transducing the oncogene *EPHB2* in neural stem cells that were *INK4A/ARF−/−* the mice developed tumors that were histologically indistinguishable from human ependymomas at a rate of 50 %. Advances in optimum medium preparation have permitted ependymoma cell culture derived directly from primary patient material and to create orthotopic xenograft mice models for posterior fossa ependymoma [416]. Recently, an ependymoma stem cell line (*DKFZ-EP1NS*) derived from a patient with metastasizing supratentorial anaplastic ependymoma has been cultivated as

neurospheres and used to establish the first orthotopic animal model for supratentorial ependymoma harboring homozygous deletion for *CDKN2A* [417].

35.10 Conclusion

Continued pursuits in understanding the molecular and genetic events in brain tumor initiation, maintenance and progression will lead to improved therapies in the future. It will one day be possible to analyze the molecular biology of a particular patient's brain tumor and tailor individual therapies based on these findings. The goal of improving patient outcomes in this devastating disease will only be accomplished through the continued application of the latest technologies to the field.

Cancer Drug Discovery and Anticancer Drug Development

36

James Turkson

36.1 Introduction

Studies of the molecular basis of carcinogenesis have led to the realization that cancer is fundamentally a disease of multiple genetic aberrations. The multiple genetic changes in cancer are predominantly the result of accumulating mutations that have occurred in the genome over time, which in turn lead to gene products with upregulated, repressed, or loss of functions, as well as aberrant signal transduction pathways and dysregulated cellular functions. Bulk of evidence demonstrate that dysregulated signal transduction pathways promote malignant transformation and support the formation, maintenance, and progression of cancers. Numerous investigative studies that cover this area and the compelling observations supporting the genetic basis of cancer, as well as the details of the identified molecular alterations that present themselves in cancer fall outside the scope of this chapter. It is noteworthy to mention that the reality that cancer has underlying multiple fundamental changes at the molecular level ushered in a new era in cancer drug discovery that comprises of the development of a new family of anticancer drugs different from the conventional cytotoxic, chemotherapeutic drugs. This new generation of anticancer drugs is based on the new paradigm known as molecular-targeted therapy, largely reflecting the concept of targeting only the specific key molecular abnormalities or dysregulated molecular entities that exist in cancer cells and that drive tumor progression. The concept of targeted therapeutics is therefore referring to the selective interference with or the thwarting of the functions of the critical, cancer-relevant biological molecules in cancer cells and thereby exerting specific biochemical effects mainly in the cancer cells, and producing a desirable biological outcome. It is also important to note that the altered critical biological molecules may have normal physiological functions in the unaltered state, but by being aberrant or dysfunctional, those functions contribute to promoting the development and the progression of the cancer phenotype. Molecular-targeting has now become the new drug discovery paradigm that drives the development of novel anticancer therapeutic modalities and influences how anticancer drug discovery is approached today.

The multiple genetic changes that are evident in the many human cancers have given rise to several gene products that are aberrant in activity or are defective in function. The underlying general hypothesis is that the abnormal functioning of these molecular entities together lead to the development, maintenance, and the progression of the cancer phenotype. In general, there is substantial and compelling evidence to support this hypothesis, and in a large number of cases, the evidence is strong to demonstrate the all-important requirement for the abnormal molecular entities in the pathological events that drive the cancer. Thus, the premise for the new drug discovery paradigm of molecular-targeting is that those cancer-critical abnormal biological events or molecular entities represent potentially viable therapeutic points or targets for developing effective and safe anticancer therapeutic agents. For this new concept, a large emphasis is placed on the knowledge of those crucial cancer-relevant biological events or molecular entities that are associated with the cancer cells or tissues, their role in the cancer phenotype and how the absence of their functions modulates the cancer phenotype. Without going into much detail here, it is worth mentioning that the genetic alterations that are evident in cancer can be generally classified into two main types: (1) the gain-of-function mutations, and (2) the loss-of-function mutations. Gain-of-function mutations are random mutations that occur in the genes that promote growth and survival and that result in the aberrant activation of the gene products. This type of mutations frequently leads to the dysregulation of critical physiological processes, including cell cycle and cell growth, cell survival, and angiogenesis, or promote events

that lead to cancer cell migration, invasion, and metastases. Loss-of- function mutations are typically evident in genes whose products function as tumor suppressors, cell cycle inhibitors, or inhibitors of apoptosis. Thus, the loss of the functions for the gene products eliminates the negative regulation and the restrictions on cell growth and survival, or leads to a loss of differentiation. Overall, therefore the evidence indicates the multiple genetic aberrations and the consequent alterations in gene products that are evident in cancer culminate in abnormal biochemical and biological processes, which together contributes to promoting the malignant transformation, tumor formation, and tumor progression. Given these underlying abnormal molecular events in cancer, the focus of molecular-targeted therapy in drug discovery is to design novel agents that directly target those altered molecular entities so as to modulate their abnormal activities and/or rectify their functions, thereby restore the physiological harmony and alter the cancer phenotype.

Given the molecular aberrations in cancer and the propensity of the altered biological processes to promote cancer formation and progression, it is reasonable to conceptualize that cancer is a disease emerging as a result of cell growth and cell survival surpassing cellular differentiation and cell death. Thus, the ultimate goal in the application of molecular-targeted anticancer therapy is to successfully alter the disequilibrium between these opposing processes and to shift the dynamics away from cell growth and survival in favor of cell differentiation and cell death. This will in turn promote the preferential loss of cancer cells that make up the tumor tissue. To accomplish this, the ideal molecular-targeted anticancer agent must be capable of selectively repressing the abnormal molecular events that support cancer cell growth, viability, and survival, while inducing processes that promote cancer cell terminal differentiation or cell death. Furthermore, the ideal anticancer agent will not affect normal cells or their functions so as not to induce toxicity in the patient, although to accomplish this may be idealistic. Certain toxicities have been observed for molecular-targeted therapeutics in patients, which are in part due to the normal functions of the biological targets and the degree to which the inhibition in normal cells affect their functions. However, it needs to be mentioned that many of the currently available anticancer drugs belonging to the category of chemotherapy are purely cytotoxic agents and non-selective, and they mainly promote cell death in the rapidly proliferating tumor and normal cells. It is expected that molecular-targeted therapeutic approach will not have the same level of toxicity that is associated with chemotherapy as these drugs are designed to selectively and preferentially target cancer, but not normal cells, thereby reducing the extent of toxicity in the patient. Other challenges associated with molecular-targeted therapy is the extent to which targeting of a single entity alone might be sufficient to alter the tumor phenotype. Thus, the clinical outcome of the few molecular-targeted anticancer agents has not lived up to expectations. This may be explained in part by the well-structured architecture of intracellular signaling pathways comprised of an array of proteins and other macromolecular structures that are uniquely arranged to promote signal cross-talk and provide redundancies. Thus, the less than a complete appreciation of the targets' functional relationship with other molecular entities that exist in the network of molecular and biochemical processes poses a challenge. In light of this, it is becoming increasingly clear that the targeting of a single biological molecule or pathway might be insufficient and that multiple molecular-targeted therapeutics might be needed to eliminate the cancer cells. In presenting a discussion on the development of new anticancer drugs that target specific cancer-relevant pathways under the new molecular-targeting paradigm, the discovery and the development of cytotoxic chemotherapeutic agents will not be discussed [1–6].

36.2 Molecular Targeting: A Modern Day Concept to Anticancer Drug Discovery and Development

Non-specificity of effects and severe toxicity to diverse organ systems and tissues in patients are some of the limitations of conventional chemotherapy. These problems further compound the already difficult health condition of the patient and frequently lead to patient non-compliance or the unwillingness to proceed with the chemotherapy. In contrast to conventional chemotherapeutic agents, which exert effects via acting on multiple processes that affect highly proliferating cells of both normal and tumor tissues, and which also lack specific tumor-selective targets of action, the molecular-targeted anticancer drug design and therapeutic strategies represent a shift in paradigm by focusing on specific cancer-relevant molecular targets. The concept of molecular-targeting includes a focus on the identification and the targeting of specific altered molecular entities of relevance to cancer. The molecular abnormalities may be specific biological processes or molecular entities whose functions are critical to the underlying events for initiating and developing the tumor and for tumor maintenance. Those causal events become the target areas for candidate molecular-targeted therapeutic agents.

Although the ideal candidate drug will have a well-defined target and mechanism(s) of action, the discovery and development process for new candidate drugs does not always begin with the knowledge of the target. The present-day drug discovery and development process is rather a lengthy one with a high failure rate. For the drug discovery process, with its objective to identify a molecule that is selectively active and potent against the cancer phenotype and that exerts lim-

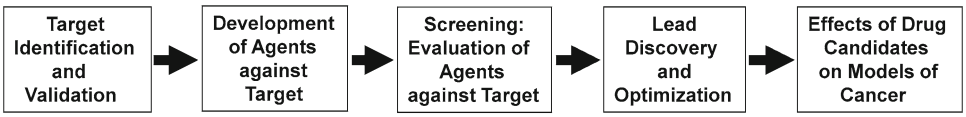

Fig. 36.1 Schematic representation of target-based drug discovery and development process. Drug discovery process typically begins with the identification and the validation of the target in vitro and in vivo studies. The next stages involve the choosing of the agents, compound libraries, or assessment of the approaches for obtaining agents to be screened. Also involved at these stages are the assays and their development, the choice of which must be based on the target, and the evaluation of agents against the target, lead discovery and optimization, with medicinal chemistry, and ultimately the evaluation of candidate drugs against suitable in vivo models of the type of cancer.

ited undue toxicity to normal cells, and which produces clinical benefits with minimal toxicity in the patients, there is no set rule or way to reach this goal, as long as it is accomplished. There is no more higher emphasis on the manner in which to begin the drug discovery and development process than there is on accomplishing the goal of delivering an effective and safe drug, although a particular strategy might offer certain advantages and may be preferable to an organization based on logistical and technical issues. Aside of these, two main models may be used to describe the present-day drug discovery and development process. With model one, as illustrated in Fig. 36.1, an agent may be identified and designed against a known target, which through rigorous experiments has been validated and established to have a critical role in carcinogenesis and tumor formation. Ultimately, the modulation of the target by the identified agent is expected to inhibit growth of cancers in an experimental setting. This model is described as the forward, target-based, hypothesis-led approach to drug discovery. With model two, the alternative, reverse approach may be taken that initially focuses primarily on finding drug candidates that have the ability to alter specific biological events relevant to the cancer phenotype without knowledge of the potential target(s) or the molecular mechanisms of action of the drug candidates. The antitumor properties of the candidate agents will then be pursued at a later stage in studies that focus on the identification of the target(s), validation of target(s) in regard to the cancer phenotype, and the determination of the molecular mechanism(s) of action of the candidate drugs in the context of the biological response of the cancer cells and the effect of the candidate drugs on the target. Both of these models have been utilized with positive results. Each approach has its advantages and disadvantages, which together with other factors will influence the decision of an organization in how the drug discovery process is initiated and carried out. Although the two models are different in the order and sequence of pursuing the objective of identifying new anticancer drugs, in both cases the target and the target identity remain important parameters and the need to ultimately solidify the validity of a candidate agent as an anticancer drug remains. Drugs that are discovered and developed based on these approaches, called molecular-targeted drugs, are aimed at suppressing dysregulated biological molecules with functions that are critical to the cancer. We will start by discussing the target-based model and the important concepts, such as cancer drug target, and their significance [1, 2].

36.3 Target-Based Drug Discovery and Development Approach

Molecular-targeted drugs are designed with the aim of modulating the cancer phenotype by interacting with and altering the properties of specific biological molecules. Those biological molecules are altered in such ways that make them crucial for the initiation of cancer, and for the survival of the cancer cells and are therefore important for maintaining the cancer phenotype. The target of any molecular-targeted drug may be cell surface entities (extracellular domains of receptors, membrane phospholipids, integrins, and adhesion molecules), membrane-anchored proteins (receptors), or intracellular, cytoplasmic entities (intracellular domains of receptors, enzymes and signaling proteins, RNA, microRNA, and DNA). They are typically dysregulated in some fashion in tumor cells, compared to normal tissue and are expected to be specifically modulated by the novel anticancer agent. Therefore the forward, target-based approach to drug discovery builds on the premise that the biological molecules that make up the target(s) have potential roles in terms of their aberrant functions and thereby contribute to the development and the progression of the cancer phenotype. However, it needs to be stressed that what constitutes an important target for consideration for a drug development project is a crucial question that should not be taken lightly. In that context, it needs to be stressed that the mere association of a biological molecule or event with malignant transformation and tumorigenesis does not constitute sufficient evidence for target status nor does it necessarily make the biological molecule a good target. Although a biological molecule or event may have an association with the disease phenotype, one ought to be open-minded, but critical going into the drug discovery project, especially at the initial phase of the discovery process and recognize the need for a thorough examination of the target-worthiness of the biological entity prior to making any commitment to pursue the biological entity. In that regard, there are key issues that need to be considered

following the initial observations of an association of a biological entity with the disease phenotype, but prior to deciding to focus on the biological entity as a target in terms of designing, adopting, and applying a strategy for evaluating and identifying compounds that modulate the biological entity. We will now look at these important issues and discuss their significance within the context of the forward, target-based approach to drug discovery [7–9].

36.3.1 Target Identification, Selection, and Validation, and Criteria to Establish Validity

36.3.1.1 Target Identification and Selection

Any type of disease condition will likely be associated with several abnormal molecular entities and pathological events. For discovering and developing molecular-targeted therapeutics against a disease condition, it will be important to determine which of those altered molecular entities and biological events are essential to the disease onset and to the underlying pathological mechanism(s) that initiate, support, and maintain the disease condition, and also promote its progression. The knowledge of this information is crucial for determining the suitability of the biological entity as a target and for defining the significance of the target to the disease. Target identification thus represents the key first step in the target-based discovery approach. A cancer drug target represents a biological entity with molecular and biochemical functions that are critical to the key biological processes underlying the existence of cancer. The altered biological entity may be a genetic material, a gene or gene product, or a molecular or biological mechanism present within cancer. The identity or the knowledge of the critical target also provides a basis for defining some aspects of the biological and molecular underpinnings of the disease. A defined target may be distinctive to the particular cancer type, representing part of the properties that define the cancer phenotype, as well as distinguish the cancer from other cancer types or subtypes, or the cancer cells from their normal counterparts from which the tumorigenesis events may have originated. It provides a means of characterization of the cancer in terms of differences in specific molecular and biological properties that are the foundation of the disease and for which the target is critically important. Identifying and defining a target is also an important step toward setting priorities regarding the specific aspects of the target that need to be focused on that might be relevant to function. Selecting the target influences the decision on what approach to take in order to maximize the potential to achieve the highest level of selectivity and specificity of effects for the candidate drug. The knowledge of the target is also useful for making predictions about the potential to regulate specific tumor types with minimal toxicity to the patient. It could be said that a defined target for a tumor type provides the platform for predicting the potential clinical outcome when the new drug is used in a patient against the target, which is aberrantly regulated in some fashion, although it needs to be stressed that this prediction is no guarantee of the clinical success of the candidate drug. Other important considerations in determining target identity that impacts significance are the cellular location and the expression profile of the target, molecular status in normal versus tumor cells, the functional status in relation to the tumor phenotype, as well as other physical/biochemical and biological properties of the target.

The functional status of the candidate target should be considered relative to the mechanism of carcinogenesis and the development of the cancer phenotype. The important questions to address here are what role the target has and in what manner, as well as how important the target's role is to the disease phenotype. Determining the answers to these key questions provides the framework for making the critical decision on whether to focus on the target for drug discovery purposes. These questions are addressed experimentally to ensure that the selected candidate target sufficiently meets certain minimum conditions or set guidelines. Information from those studies becomes the basis for making critical decisions on moving forward. Other important issues include druggability and how well drugs can be designed and developed against the target, as well as the tractability of the target or the difficulty of inhibiting the target. It is proposed that of the genes in the human genome, only a small percentage is druggable and is associated with diseases. This is even more important when the disease phenotype is linked to several similar targets, and the question becomes which one of these possible targets should be pursue in the discovery program. It is worth stating that what constitutes a good target may be regarded as an ongoing debate and this debate and the evaluation of the target should continue throughout the drug discovery process to ensure suitability. In that regard, what is now emerging is a sense of value that the potential target presents and this influences the "go-no-go" decision. Moreover, emphasis is placed on target value for the sake of patentability and intellectual property matters, which are important considerations from financial standpoint, given how much of resources would need to be invested and how much efforts would be allocated for pursuing the target in the discovery program, and the overall cost associated. It is a common practice for one target to be pursued by many organizations, particularly if it is highly relevant to the cancer type and its druggability is high. Overall, the concept of target is generally accepted as one of the most critical factors to consider in the anticancer drug discovery process [10–14].

36.3.1.2 Target Validation

The concept of target represents one of the most important issues in anticancer drug discovery. Granted the multiple genetic alterations, which are associated with the cancer type, lead to a myriad of functional aberrations in the gene products with altered biological outcome, it is reasonable to expect many factors to become associated with any particular cancer phenotype. While such associations are significant and may suggest some level of importance for the altered entities in relation to the carcinogenesis and the tumor formation processes, rigorous investigative studies are required before any major conclusions can be made regarding target validity. The point needs to be made that an observation that a biological molecule is altered in some fashion in cancer cells, while suggesting an association with the cancer phenotype, should not necessarily be taken as an indication the altered entity is essential for the events that led to the cancer phenotype or that it is important within the underlying mechanisms leading to carcinogenesis, tumor formation, and tumor progression. Ideally, to be considered as potential targets, altered proteins, or biological molecules and their functions should have critical roles in the underlying events leading to the cancer formation. Adopting this viewpoint is to safeguard against selecting and focusing on spurious biological entities that may not be essential to the basis of the disease phenotype, but may be readily available for targeting for reasons other than a requirement for the cancer formation. This brings us to the issue of the cause and effect. This is an important consideration, which indicates the need to establish the causal relationship between the altered molecular entity (and its function), as a potential target, and the biological or pathological events underlying the cancer phenotype. It will be ideal to envision that the altered molecular entity will have a causal role in the induction of the cancer phenotype in order to represent a validated and credible target for drug discovery and development.

Although the validation of a putative target may be viewed as a complex and long process, when successfully done, it authenticates the drug discovery process and has the potential to improve the chances of success in terms of the clinical outcome in patients for the drug candidate that emerges from targeting the altered biological entity. The question of what makes a good target for anticancer drug design and development may not be answered in one study. The attempt to address this question may take the form of a number of observations made from a series of studies throughout the drug discovery and development process. The significance of these studies is primarily in terms of establishing the nature of the relationship between the candidate target and the disease. The type of relationship will have a strong influence on the potential response of the drug candidate in the treatment of the disease based on the effect of the drug on the target. Thus, a high importance should be placed on defining the importance of the altered biological entity, as a target, in relation to the cancer. In that regard, there ought to be a set of criteria with minimum requirements that need to be fulfilled by the putative target in regard to its consideration as the target of choice for the cancer phenotype, and to the justification to develop agents that modulate its activity or function. The validation does not only make certain that the target is critical to the cancer type in terms of the viability and the survival of the cancer cells, but also serves to minimize the chances of toxicity by ensuring that the potential drug candidate would exert specific effect preferentially on tumor cells without indiscriminate effect on normal cells. Overall, target validation is an important consideration in the drug discovery process, and establishing the causal role for a target in the disease phenotype is a good beginning of a potentially viable anticancer drug discovery process. However, target validation should be perceived as an ongoing process pursued at all stages of the drug discovery and development process. By its very nature, the validation therefore represents a complex process that will require diverse experimental approaches and important decision-making steps in order to accomplish and establish a tractable and viable drug target [10, 14].

36.3.1.3 Criteria for Validating a Target

An important issue in considering a candidate target for drug discovery is whether an entity hypothetically associated with a disease necessarily represents an appropriate point for new drug intervention. It is vital to establish the credibility of the hypothetical target as it relates to its activity in the context of the disease and the target's mechanism(s) of action, and to establish a cause and effect relationship between the disease and the candidate target. There are no standard processes for validating and establishing the credibility of a target, and different organizations may consider different approaches for accomplishing this goal. Notwithstanding, the main goal is to present a clear definition of the position of the target in relation to the disease phenotype and the molecular and biological events leading to cancer. Achieving this goal will require using various experimental models of the disease and diverse approaches. It should be pointed out that disease-relevant systems that are available for experimental use outside of humans may not be accurately reflective, but nonetheless serve the purpose at this stage of the discovery process. While the establishment and the use of appropriate disease models for target validation present some challenges, the lack thereof for evaluating a potential target for credibility will only compromise the pharmacological usefulness of the emerging drug candidate. Given the objective, which is to verify the credibility of the potential target in relation to its role in the cancer phenotype, one could propose some minimum conditions and lay out a set of criteria that need to be

fulfilled by a molecular entity that is being considered or evaluated as a potential target for cancer drug discovery:

1. There should be evidence in cell culture and whole animal models that changes in the function of the candidate target alone is sufficient to alter the relevant disease phenotype. Here, studies need to establish that the elevation of the expression or function of the putative target alone, in the case where it is stimulatory, is sufficient to induce the cancer phenotype. Where the function of the putative target is suppressive, there should be evidence that its overexpression alone is sufficient to abrogate the malignant phenotype. Such studies when appropriately conducted will provide information to build confidence in the target and to establish the causal relationship between the putative target and the cancer type.
2. Definitive proof from studies in disease-relevant models of cell culture, and whole animals, and in clinical models that modulating the function of the molecular entity as a target alters the disease phenotype. Complementary to the studies conducted in response to the requirements in the criterion (1) above, it is important to employ the appropriate disease models, both in vitro and in vivo, to investigate the underlying critical role of the potential target in the incidence and the progression of the cancer phenotype. Granted that the putative target has a critical role in the disease, the modulation of the candidate target will be expected to result in a corresponding change in the cancer phenotype that is consistent with the purported role of the target in the disease.
3. Finally, the molecular mechanism(s) of oncogenesis must be clearly outlined and defined in accordance with the assertion that a potential biological entity as target has a critical role in the development of the cancer type. One needs to ascertain how the function of the biological molecule is essential to the events that ultimately lead to the cancer phenotype. This will ensure that targeting this biological entity modulates some critical underlying mechanism(s) that support(s) the maintenance of the tumor.

These target-focused requirements are important considerations in determining the validity of a target for developing novel anticancer drugs for therapeutic purposes. The ultimate test of the validity of the target in relation to the cancer type is the clinical outcome in the appropriate cancer patients who are given the drug. An example is seen in the good clinical activity of Bevacizumab, the humanized anti-VEGF monoclonal antibody as standalone or used in drug combination. Various genetic, molecular, biological, and pharmacological approaches are frequently used to evaluate and validate a putative target and its relevance to cancer. While the experimental approaches to evaluate the potential for a molecular entity or biological event to make a good target may vary from one organization to the next, the basic premise remains the same and that is to establish the credibility of the putative target for the disease phenotype. The emphasis is on ensuring that a particular biological entity has all the necessary properties and fulfills the criteria for its consideration as a valid drug target. It suffices to mention that even when a target is validated, its credibility as a good target continues to be evaluated at every stage throughout the drug discovery process and finally at the level of clinical response when the drug is administered to patients [8, 10, 11, 14–18].

36.3.2 Lead Identification and Optimization, and the Development of a New Drug

The successful identification and validation of a target pave the way for the next step in the discovery process, which could be classified as designing and identifying leads that target the biological entity or entities and modulate their function (Fig. 36.1). This is an important phase in the discovery and development process and thus carrying out the studies in this phase may take several months to complete. Also, many small-molecule drug discovery approaches do not result in clinical candidates in a large because of the lack of a good lead [19, 20], thus securing a suitable lead for the drug discovery and development process is critical for the success of the program. There are no specific set of guidelines regarding how this phase may proceed. However, further studies defining and expanding on the understanding of the molecular and biochemical bases for the induction of the target could be incorporated into this phase so as to facilitate identifying specific key aspects of the target's properties that may be amenable to exploitation for the design of lead molecules as modulators and potential anticancer agents. To some extent, studies here will also serve as proof-of-concept testing in order to establish the validity and viability of the strategy for generating suitable lead compounds. These studies may also test the therapeutic potential of the candidate drug in modulating the target(s) and the function of the target(s). The work at this stage includes the development of assays, both in vitro and in vivo, the screening of compounds, which may be on a high throughput screening (HTS) platform to identify leads, and a medicinal chemistry component with lead optimization steps, and subsequent further evaluation of derivatives or analogs. Where appropriate, these steps may be interspersed with the evaluation of activity, with the expectation of progress in terms of enhancement and improvement over previous generations of agents.

It should be noted that there are variations in the sequence of the conduct of these studies. The use of the lead compounds in studies to further provide proof-of-concept could also be conducted, and different types of assays can be

performed simultaneously to evaluate multiple targets. Because each of the steps involved in the evaluation in this phase of the discovery and development process is crucial and will impact the final outcome, there are key considerations. These include the assay development and factors driving the assays and the screening strategy, such as specificity to the target, robustness, and the reproducibility of results, with minimum inherent errors or tendency for false positives, high sensitivity, and the cost-effectiveness. It is also important to establish criteria for the consideration of compounds for the initial screening and for the next stage of the evaluation following the first screening. The availability of set criteria allows to define and select suitable agents with optimum characteristics that lend themselves to the drug discovery process [21].

36.3.3 Specific Strategies to Identify and Develop Novel Anticancer Drugs

We will now examine some specific models of anticancer drug targets and the strategies taken to develop agents that modulate the functions of these targets. The discovery, identification, and validation of a molecular entity as a critical cause for the development, maintenance, and progression of cancer, and as a target are all important initial steps in the development of a new drug. Those initial investigations and evaluations together represent the rationale for initiating a discovery process with the focus on the target, and serve as the proof-of-concept in the support of the development of new anticancer agents that are directed at that target. Many of the critical biological entities that are altered in cancer and are considered as targets are signal transduction mediators or signaling intermediates, although there is also focus on nucleic acids as targets for developing anticancer therapeutics. Frequent genetic aberrations, including activating-mutations that lead to hyperactive behavior of the target proteins, suppressive mutations that result in repressed or lost functions, gene silencing by methylation that causes loss of functions, and abnormal post-translational modification patterns that create altered functions of proteins altogether serve as the driving force for the altered cellular phenotype and tumorigenesis. The abnormal functional properties of those altered biological molecules contribute to the dysregulation of the cell growth and survival processes, and induce angiogenesis, migration, invasion and metastasis, and the repression of host immune surveillance.

Several strategies have been taken for developing effective agents against validated cancer targets or tumor processes. The objective is to develop a product that selectively modulates the cancer target in question and alters its function in the context of the tumor processes promoted by the target, and thereby eliminate the support of the target for the tumor maintenance and progression. The drug candidate should be able to affect the target and its function and undermine the survival of the tumor cells without exerting undue effects on unrelated biological entities and their functions or on normal cells. Given these requirements, limitations, and expectations, let us look at specific examples of novel molecular-targeted therapeutics that target specific signaling pathways, or modulate biological processes or macromolecular structures. This is a brief discussion on the subject matter and readers are encouraged to consult the cited papers for more detailed information.

36.3.4 Modulation of Signal Transduction Pathways

In the past few decades, there has been an increased interest in exploring signal transduction pathways for novel targets for anticancer drug discovery due to their importance in regulating diverse tumor processes. This is based on the compelling evidence demonstrating multiple aberrations in signal transduction networks in many human cancers. Numerous research studies provide evidence that the abnormalities in signal transduction serve to provide the necessary foundation for the biological events that drive tumorigenesis, maintain the tumors, and induce tumor progression. Multiple mutational events are detected in ligands, receptors, and signaling intermediates, which result in their aberrant functions. These events consequently lead to and support uncontrolled cell growth and survival, and promote angiogenesis and other events that lead to tumor metastasis, and additionally compromise host immune competence. In the end, the aberrant signaling pathways become a necessary requirement for tumor cell survival, and for the maintenance and the progression of the tumors. The implication is that targeting any of those corrupted molecular entities in the signal transduction pathways or the dysregulated signaling intermediates will undermine the support for the tumor cells, and thereby induce tumor cell death, and eradicate tumors. While details of the signal transduction pathways and their importance to cancer are discussed elsewhere in this volume, herein is outlined specific examples of the molecular-targeted therapeutic approaches that are based on signal transduction pathways [22–24].

36.3.4.1 Inhibitors of Receptor and Non-receptor Tyrosine Kinases

Aberrations occur very frequently in receptor and non-receptor tyrosine kinases (TKs) and are associated with human cancers. Thus, the receptor tyrosine kinases (RTKs) represent a group of biological molecules that are most widely explored as targets for anticancer drug discovery. The rational for targeting the growth factor RTKs and the

non-receptor TK pathways is based on a strong evidence of frequent activating gene mutations and/or over-expressions in these proteins, which are common in many human tumors. Fundamentally, growth factor receptor-mediated signaling, including the Human Epidermal growth factor Receptor (HER or ErbB) family, c-Met/hepatocyte growth factor receptor (HGFR), insulin-like growth factor receptor (IGFR), vascular endothelial growth factor receptor (VEGFR), platelet-derived growth factor receptor (PDGFR), and fibroblasts growth factor receptor (FGFR), and the receptors for cytokines, such as IL-6 and other polypeptide ligands are all important in cell growth and proliferation, survival, development, inflammation and immune responses, and other cellular and physiological processes. As a result, studies have shown that the aberrations in the receptors or their ligands lead to uncontrolled growth and survival of tumor cells, the induction of tumor angiogenesis, and the promotion of tumor metastasis. In particular, the molecular-targeting and the inhibition of the members of the EGFR family is presently one of the most explored approaches in anticancer drug design, and inhibitors of the HER family as anticancer therapeutic agents are currently in various stages of development or in clinical application. Among the strategies, antibody and protein-based modalities that block the extracellular surface of the receptor were some of the first to be considered in the development of targeted therapeutics for human tumors. In addition, small-molecule inhibitors (SMI) of the EGFR TK have been explored. Both the antibody-based and SMI approaches against growth factor receptors have resulted in viable therapeutic agents that are in the clinic or candidates that have the potential to become agents for the treatment of many solid tumors. Monoclonal antibody (Mab) therapies are presently approved for the treatment of human breast and lung cancers, diseases in which the ErbB family of receptors, including ErbB2 (HER2/neu) are validated to be essential. Small-molecule EGFR TK inhibitors include Gefitinib and Erlotinib, which compete at the adenosine triphosphate (ATP) binding site of the catalytic domain of the receptor kinase and block the EGFR signaling and are a consideration for the treatment of non-small cell lung cancer, pancreatic cancer, ovarian, and head and neck cancers. Another small-molecule inhibitor in clinical application is Imatinib (Glevec), which targets the TK activity of the breakpoint cluster region (BCR)-Abelson (ABL) fusion protein that results from the chromosomal abnormality, Philadelphia chromosome and causes the chronic myelogenous leukemia (CML). Other kinases of interest in the novel drug discovery and development include Src (a tyrosine kinase), the protein serine-threonine kinase, Aurora kinase, and cyclin-dependent kinases, as well as other non-receptor protein and lipid kinases. Consideration is also now being given to agents that inhibit multiple targets, as is the case with Sorafenib, that inhibits PDGFR family, Flt-3, Kit, RET family, VEGFR2, VEGFR3, and Raf protein kinase family, Dasatinib that inhibits Abl, Fyn, Src, Lck TKs, Sunitinib, that inhibits Flt-3, Kit, VEGFR2, and PDGF TKs, and Lapatinib, which inhibits EGFR and ErbB2 TKs [25–56].

36.3.4.2 Inhibitors of Protein:Protein Interactions

In the past, protein-protein interactions have posed a significant challenge to researchers for developing effective disrupting agents as therapeutics. These interactions were considered intractable in a large part due to the large surface areas presented by the proteins at the interface and hence, the difficulty of achieving sufficient interference using small-molecules. The focus on disrupting protein-protein interactions as drug discovery approaches has now emerged and there are several efforts in this arena from both the pharmaceutical industry and academia. Approaches to evaluate and target protein-protein interactions for drug discovery purposes range from traditional medicinal chemistry to non-traditional strategies. The strong rationale for targeting protein:protein interactions is the incidence in many human tumors of aberrations that occur in the proteins that are engaged in protein:protein interactions and how the altered functions of these proteins promote tumor processes. Details about signal transduction involving proteins that engage in protein-protein interactions, their importance to normal physiological processes and their involvement in the molecular events that contribute to malignant transformation and tumor progression are discussed in detail elsewhere in this volume and will not be presented here. Among the targets being pursued for drug discovery are the interaction of the tumor suppressor, p53 and its natural antagonist, MDM2 or the human congener, HDM2, the Bcl-2 or Bcl-xL/BH3, the XIAP/Caspase (and XIAP/Smac), the Myc/Max, and the Stat3:Stat3 dimerization, all of which are critical mechanisms that regulate cell growth and survival and are important for tumor-associated processes. Diverse approaches that are under consideration for modulating interactions involving these proteins include peptides and peptidomimetics that mimic the displayed recognition surface, and non-peptide analogs, natural products, oligonucleotide-based approaches, terphenyl, and other alpha-helix mimetics, chalcones, piperidines, piperazines, fused indoles, isoindolinones, spiro-oxindoles, cis-imidazolines (nutlins), quinolinol, and benzodiazepines [17, 57–77].

36.3.4.3 Protein:DNA-Binding Complex Inhibitors

Another approach to designing antitumor agents focuses on modulating protein:DNA complexes and disrupting their functions in tumor cells. Topoisomerase inhibitors, such as anthracyclines, and camptothecin and analogs (irinotecan and topotecan) mediate their antitumor cell effects by this mechanism. Here, the complex between the protein

(example Topoisomerase enzymes) and DNA becomes the target for the binding by the drug, thereby stabilizing an otherwise cleavable complex and leading to DNA lesions and apoptosis. Inhibitors of protein:DNA complexes, such as Topoisomerase I and II inhibitors are currently in clinical use or are being considered for clinical use in a variety of human cancers, including ovarian and lung cancers [78–83].

36.3.4.4 Modulation of Protein Synthesis

The inhibition of protein expression at the translation level is one of the ways for modulating aberrant proteins and that can be exploited for the design and development of novel therapeutic agents against cancer. Recent reports have shown the therapeutic potential of the molecular modulation of the complex formation of the set of initiation factors (eIFs), factors required to dissociate the 40S and 60S ribosomal subunits, and to recruit the mRNA and the initiator tRNA to the 40S subunit, and to promote the joining of the 60S subunit for elongation to begin. In that regard, studies were recently reported that showed that the inhibition of the association between eIF4A and eIF4G (eIF4A:eIF4G complex) and the promotion of the formation of a stable ternary complex between eIF4A and eIF4B by a natural product, or the disruption of eIF4E:eIF4G complex by a small-molecule, identified through a high throughput screening, which ultimately modulated the translation and the expression of oncogene proteins. The antitumor cell effects of the modulation of those molecular events in multiple cancer cell lines are a positive sign of the potential to explore this approach in drug discovery and development. More recent approaches are also focusing on the deregulation of microRNA and the application of siRNA or antisense oligonucleotides to target the protein expression at the level of translation. For microRNAs, these short non-coding RNA molecules control the gene expression of their respective target mRNAs and in doing so control different physiological and developmental processes. The deregulation of microRNA expression and function is frequently observed in many human cancers, with studies showing that the aberrant expression and function of certain microRNAs modulates tumor cell proliferation, survival, angiogenesis and metastasis, which makes them suitable targets for the development of therapeutic approaches [84–94].

36.3.5 Reverse Approach to Drug Discovery: Beginning with Modulating a Biological Response and a Cancer Phenotype

In contrast to the forward, target-based approach, the reverse approach to drug discovery and development process is initiated by focusing on the identification of agents that modulate general biological or biochemical processes that contribute to malignant transformation without the initial consideration to what constitutes the drug target. With this strategy, the knowledge of the potential targets that are critical for malignant transformation and tumor progression or the molecular mechanisms underlying the cancer phenotype is not essential at the initial stage of the drug discovery process. Instead, the emphasis may be on the modulation of a specific response that is consistent with antitumor cell effects of the candidate agent. Such readouts may be in terms of biological responses, biochemical activity or may be within the context of the changes in molecular property, but in none of these cases is the knowledge of the potential target that is being modulated by the candidate drug necessarily required. Thus, rather than focusing on the target at the beginning phase of the discovery process, the reverse approach will identify an active candidate agent based on the potential to produce a defined desirable and tumor-specific biological or molecular response. The emphasis on the biological response as a readout is based on the principle that a desirable change in the biology of cancer cells or in the cancer phenotype, which is consistent with the ultimate goal of any anticancer therapeutic modality, is the result of modulation of specific biochemical events or molecular entities in the cancer cells. Thus, by focusing the initial screening on biological response or the modulation of the cancer phenotype as readouts to identify a potential drug candidate, the reverse approach serves to assess the antitumor cell activity of the agent at the very early stage. This approach provides an indication of the potential for the candidate agent to induce antitumor cell effects prior to acquiring any knowledge of the mechanism(s) of action and/or what the target(s) might be. Illustrated in Fig. 36.2 is a model of the reverse approach showing an initial screening of compound libraries or natural products using biological response as readout. A variety of assays have been employed for evalu-

Fig. 36.2 Flow chart of the reverse (non-target-based) approach to anticancer drug discovery. The approach is initiated with the screening of compounds or libraries using assays that may be cell-based to identify active compounds that induce a well-defined biological response or a response within a molecular context. Subsequent steps include structure-activity relationship studies and medicinal chemistry efforts for the identification of lead compounds. The next stages involve the evaluation of the activity of select compounds in biological assays, and the identification, characterization, and validation of target(s) relative to the candidate compounds and the disease model, and ultimately the identification of drug candidates.

ating compounds in this approach. In most cases, the measurable response is biology-based, which examines a change in phenotype, such as tumor cell growth inhibition or induction of apoptosis, or evaluating and selecting active agents that inhibit angiogenesis, migration and invasion, or tumor growth. Additional biological responses that have been considered or used are autophagy (the dynamic process of subcellular degradation) and tumor metastasis. In the case of a non-biological response, this will involve the induction of changes within specific molecular mediators, which may be critical for tumor processes, malignant transformation, and tumor progression. Such biochemical or molecular analyses include gene or protein array technology for screening to identify active agents that modulate cancer-relevant molecular entities prior to any knowledge of the potential target for the agent. The completion of the human genome project provides a suitable platform for evaluation and to identify genes of relevance to human cancers.

Overall, the objective at the initial screening stage is simply to identify agents that modulate specific tumor processes, or produce biological or molecular responses relevant to malignant transformation and tumorigenesis. While the focus at the initial stage of the drug discovery process is shifted away from determining what the target entities or pathways are for the active agents, it is presumed that those agents that modulate tumor cell phenotype do so by interacting with specific molecular entities or pathways that have functions crucial to the cancer phenotype. Targets may include cancer-specific cell surface entities, extracellular domains of receptors or other membrane-bound molecules, intracellular entities, or a combination of these targets. In accordance with the objectives of this approach and therefore by the nature of the initial assay design, the candidate compound(s) may interact with one or multiple entities or pathways, thereby modulating multiple aspects of cellular functions and producing the measurable biological response. Thus the measured biological response can be presumed to be due to some combination of the molecular modulations that are induced by the candidate drug of the specific biological entities or pathways important to the cancer cell and essential for maintaining the cancer phenotype. The overall response of the drug will be expected to be influenced by the level of expression, as well as the functional importance of each of those molecular entities, which are modulated by the candidate agent and that contribute the measured biological response [2, 95–102].

From the initial screening stage, compounds that are identified as possessing bioactivity and are selected will progress through the drug discovery process to the next stage, which is to characterize the compound in more detail in terms of activity, potency, and selectivity, determination of the identity of the target, and then target validation, and also to perform studies of the interaction of the drug candidate with the putative target. Also important at this stage are studies of the structure-activity relationships that are directed at establishing a correlation between the activity of the compound and the chemical moieties, thereby identifying the chemical functionalities that confer activity, and medicinal chemistry and lead optimization processes to further enhance the activity and the potency of the candidate agent and to derive more suitable drug candidates. Optimized drug candidates will ultimately be evaluated for in vivo pharmacological properties and antitumor efficacy in tumor models.

36.4 Summary

Until recently, the potential targets for drug discovery has been limited to a select few molecular entities that evidence has established have a critical role in cancer, including the Ras small G protein. New biological entities emerged as potential new targets following the increased understanding of the molecular basis of cancer. Those entities that were confirmed to be highly critical in malignant transformation and tumor progression became the focused areas for targeting in the drug discovery arena. Moreover, the completion of the human genome project has further opened the way for identifying novel cancer-relevant genes and gene products and hence, increased the potential to identify new targets. It is expected that substantial information will be derived from the analyses of the human genome that will be useful in many areas, including identifying important cancer-related genes and gene products, and this possibility has generated a strong excitement from both academic institutions and the pharmaceutical industry. Such information would facilitate the identification of novel tractable and druggable targets and help drive the discovery and development of more effective and safe drugs for a variety of human diseases, including cancer. We are already seeing an upsurge of information from the genomics and proteomics analyses. The large volume of information demands substantial and suitable evaluation procedures and diverse analytical tools in order to make insightful deductions and meaningful decisions on what constitute druggable and tractable targets, thereby promote the development of novel effective anticancer drugs. Moving forward therefore in the era of genomics, proteomics, and other omics approaches, it is expected that appropriate data mining and chemical genetic approach will continue to expand and improve the drug discovery and development process. The expectation is also that as advancement in technology occurs, this will enhance the ability to design and generate more effective tools and approaches for identifying good candidate lead anticancer agents and drive the drug discovery and development process. New analytical tools also enhance the drug discovery process in many ways, including the identification of new targets, and in assay

development and screening, and lead identification and optimization. For example, the availability of molecular modeling and the in silico virtual screening strategies in combination with structural biology have all enriched the modern-day drug discovery and development process in more ways than it ever was in the past. There is therefore increased chance to find new drugs that are focused on cancer that will be more effective and safe, and which will provide a much need relief to the many cancer patients who receive them [21, 97, 98].

Biological Principles and Clinical Application of EGFR Inhibitors in Cancer

37

Zhuo (Georgia) Chen, Suresh Ramalingam, and Dong M. Shin

37.1 Introduction

Epidermal growth factor receptor (EGFR), an important oncogenic protein, has attracted intensive research efforts for over 40 years. In the 1960s, epidermal growth factor (EGF) was discovered by Stanley Cohen as a factor from submaxillary glands that induced precocious eyelid opening in newborn mice [1]. EGF was purified in the year 1962 and identified in 1975 as a mitogenic polypeptide and an initiator of cellular response to epithelium proliferation and growth through its cell surface receptor [2, 3]. Like other growth factors, the binding of EGF to its specific receptor EGFR triggers a series of signal transductions and is essential in cellular regulation for normal physiological activities. In the 1980s, EGFR was purified as a transmembrane protein from A431 epidermoid carcinoma cells [4]. The cDNA of EGFR was then isolated and the coding sequence of this protein was determined [5, 6].

The oncogenic function of EGFR was first suggested by Downward et al. [7], who described a close similarity between EGFR and the avian erythroblastosis virus (AEV) v-*erbB* transforming protein [7, 8]. In fact, EGFR overexpression has been documented extensively in a wide variety of malignant tumors, supporting its oncogenic function and making it an appropriate molecular target for cancer treatment. The importance of EGFR is underscored by the publication of over 10,000 papers since its discovery that described EGFR signal transduction pathways and interaction partners [9]. These studies have resulted in the development of EGFR inhibitors, which have shown clinic efficacy in the treatment of several solid tumor types.

This chapter first summarizes the structure, biological function, and signal transduction pathways of EGFR and then provides an overview of EGFR inhibitors, their preclinical studies, and clinical applications in cancer treatment. Recent advances in understanding cancer cell response to EGFR inhibitors by using biomarkers are discussed at the end of the chapter.

37.2 Biological Characteristics of EGFR

37.2.1 EGFR Gene Structure and Localization

EGFR is encoded by a gene located on chromosome 7p12 [10]. Wild-type EGFR contains 1186-amino acids translated from a 5.8 kb mRNA, which was first identified in A431 cells [5, 11–13]. Studies of A431 cells illustrated that human EGFR has a striking homology to v-erbB, particularly in the amino acid residues beginning at the junction of the cytoplasmic and transmembrane domains to the carboxy-terminus of EGFR. Ninety-five percent of the residues in this region, which includes an ATP-binding domain, are conserved, indicating the functional significance of this portion of the receptor. The amplification and variation of EGFR encoding sequences were also found to result from chromosomal translocation (M4) involving chromosome 7 [5, 11, 14]. Currently, there are over 600 publications reporting *EGFR* gene structures in the National Center for Biotechnology Information database.

37.2.2 EGFR Protein Structure and Function

The mature EGFR is a 170 kDa single polypeptide belonging to the erbB family [6, 15, 16]. Four receptor proteins have been identified as members of the erbB family. They are EGFR or erbB1, Her2/neu or erbB2, erbB3, and erbB4 [15, 17, 18]. EGFR consists of several featured domains, including an extracellular domain (residue 1–621), a hydrophobic

(**a**) Schematic representation of EGFR sequence. *L and CR*, ligand-binding and cysteine-rich domains, *TM* transmembrane domain, *TK* tyrosine kinase domain, *CT* carboxyl-terminal domain. (**b**) Tyrosine-phosphorylation sites of EGFR and the bound signaling protein mediators.

transmembrane domain (residue 622–644) and a cytoplasmic domain (residue 645–1186) (Fig. 37.1a). The extracellular domain of EGFR is responsible for binding EGF and other EGFR-specific ligands with high affinity. Structurally, this domain of the receptor contains 10–11 N-linked oligosaccharide chains which are required for translocation of EGFR to the cell surface [19, 20], and 10 % comprises half-cystine residues. The ligand-binding domain lies between the two half-cysteine-rich clusters.

The cytoplasmic domain of the receptor is characterized by a highly conserved tyrosine kinase (TK) domain. This region contains an ATP-binding pocket which is essential for the intrinsic TK activity of EGFR. The substrates of TK are several tyrosine residues next to the ATP-binding region or outside the ATP-binding pocket near the C-terminus of the receptor. Autophosphorylation of tyrosine residues induces conformational change of the protein, creating a docking structure for EGFR interaction with its downstream signaling mediators. In addition, seven serine and threonine residues bordering the TK domain are substrates for phosphorylation by non-receptor kinases, such as protein kinase C. Phosphoserine and phosphothreonine are also required for protein-protein interactions and have been inferred to be important for the receptor downregulation processes.

37.2.3 EGFR Ligands and Its Activation

EGFR activation is triggered by binding of its specific ligand. Since the discovery of EGF, several other ligands containing EGF-like domains have been identified as specific EGFR binding partners [9, 21, 22], including transforming factor α (TGF-α), amphiregulin, epiregulin, and β-cellulin. The soluble ectodomain of EGFR binds ligand, and this formation of a ligand-receptor complex on the cell surface induces the dimerization of EGFR [23, 24]. A 2:2 complex is formed in which the affinity of EGF or TGF-α to EGFR is 100–500 nM [25–27].

In the absence of ligand binding, EGFR exists on the cell surface as either monomer or dimer. However, ligand-induced dimerization is required for activation of the intrinsic TK activity [28–30]. Studies of the kinetics of stimulated and unstimulated EGFR have shown that ligand binding doubles the V_{max} parameter and decreases the K_m parameter for ATP by tenfold [31]. Binging to ligand increases the proportion of dimerized EGFR and reorientates the kinase domains in a way that increases the affinity for ATP binding due to conformational change, thus enhancing the enzymatic activity.

EGFR is autophosphorylated on several C-terminal tyrosines, including Tyr 992, Tyr 1045, Tyr 1068, Tyr 1086, Tyr 1148, and Tyr 1173 (Fig. 37.1b). The role of this autophosphorylation is to create a specific docking structure and facilitate the formation of protein complexes with EGFR downstream signal transduction partners. The formation of these protein complexes requires specific ternary configurations depending on autophosphorylation at specific tyrosine sites, leading to phosphorylation-dependent activation of major intracellular signaling pathways.

37.3 Biological Function and Related Signal Transduction Pathways of EGFR

Depending on the functional diversity of the proteins that EGFR complexes with, or is phosphorylated by, stimulation by EGFR ligands results in simultaneous activation of

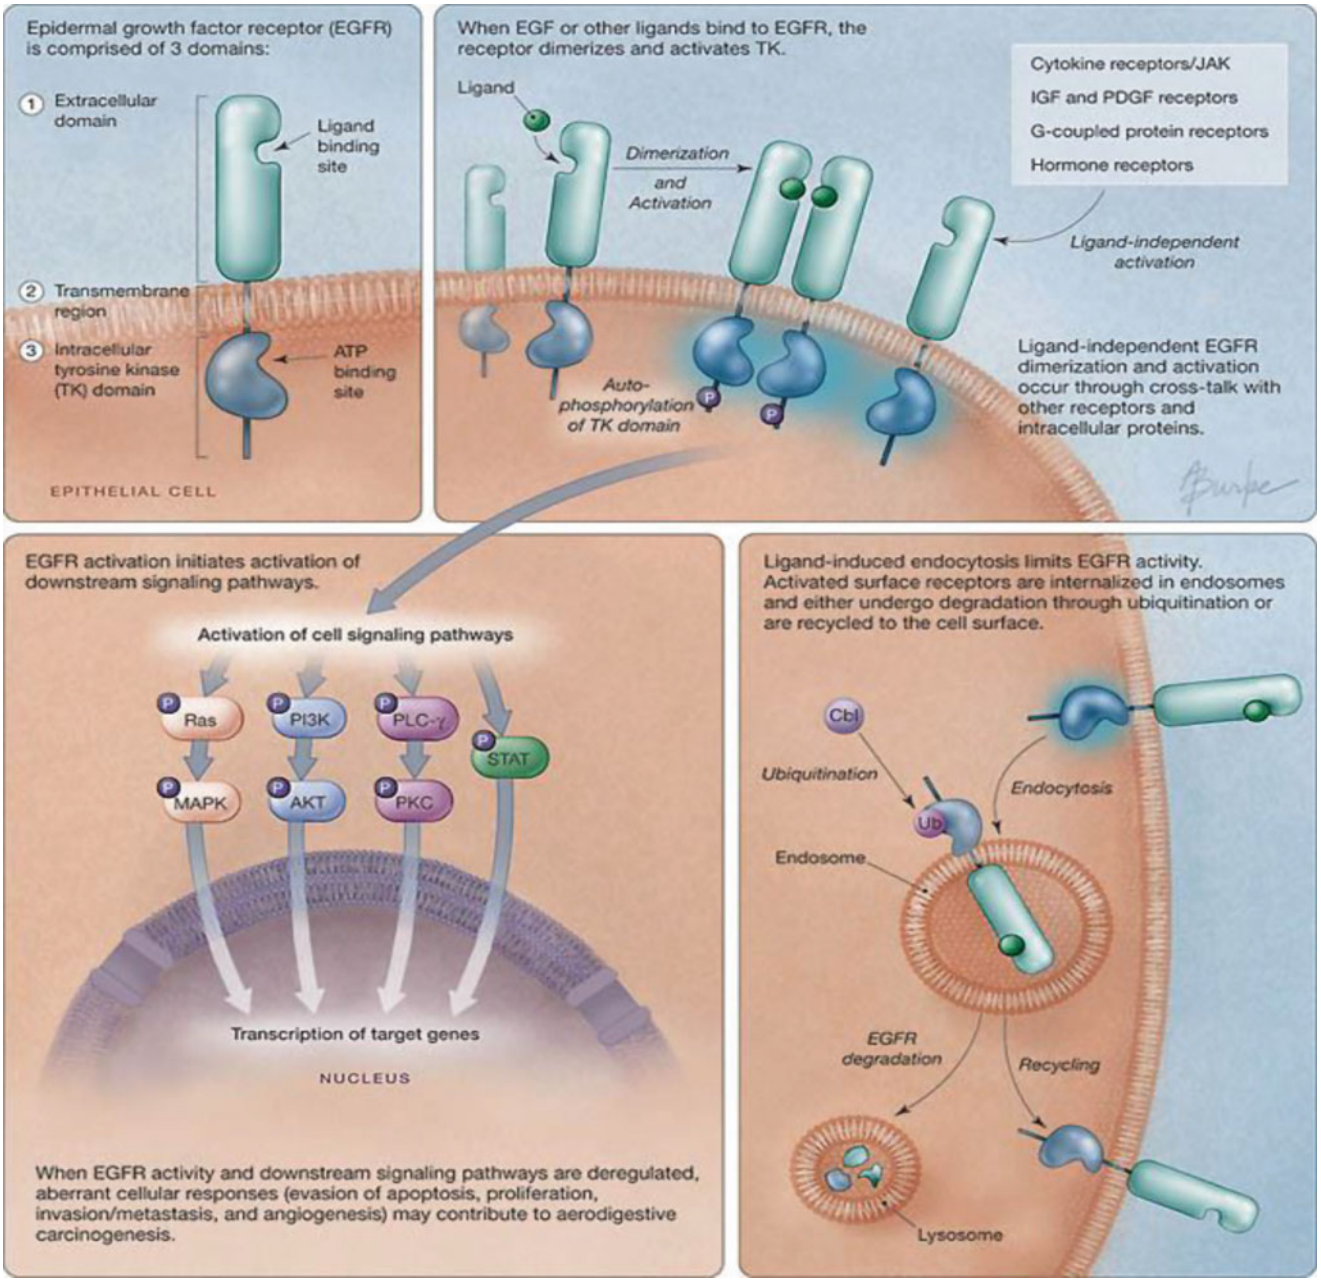

Fig. 37.2 Epidermal growth factor receptor activation, processing, and signaling. *ATP* adenosine triphosphate, *Cbl* a ubiquitin E3 ligase, *IGF* insulin-like growth factor, *JAK* Janus kinase, *MAPK* mitogen-activated protein kinase, *P* phosphate, *PDGF* platelet-derived growth factor, *PI3K* phosphatidylinositol-3-kinase, *PKC* protein kinase C, *PLC* phospholipase C, *STAT* signal transducers and activators of transcription, *TK* tyrosine kinase, *Ub* ubiquitin (adapted from Karamouzis, M. V. et al. JAMA 2007;298:70–82).

multiple signal transduction pathways (Fig. 37.2). Thus, activation of EGFR induces many biological activities, including evasion of apoptosis, promotion of cell growth, and cell migration. At the same time, ligand binding induces a rapid internalization of the receptors and enclaves them in endosome [32–34]. The internalized EGFR either undergoes degradation by locating to lysosomes or is recycled back to the cell membrane.

37.3.1 Ras/Mitogen-Activated Protein Kinase (MAPK) Pathway

RAS/MAPK is one of the major signaling pathways activated by EGFR. The formation of a protein complex between EGFR and Grb2 initiates signal transduction through the RAS/MAPK pathway. Grb can associate with EGFR either directly at Tyr 1068 and 1086 sites, or indirectly by binding

to EGFR-associated Shc, which recognizes phosphorylated EGFR at Tyr1148 and 1173 [35, 36]. It can constitutively bind to Ras exchange factor Sos, resulting in the exchange of Ras-bound GDP for GTP and thus Ras activation. The activated Ras then activates the serine/threonine kinase Raf-1 [37, 38]. Activated Raf-1, through MEK, contributes to the phosphorylation, activation, and nuclear translocation of ERK1/2 (MAPK). ERK1/2 is responsible for phosphorylation of several nuclear transcription factors, such as c-fos and C/EBPs, which regulate cell proliferation and cell cycle progression [39, 40]. Activated MAPK also provides a negative feedback loop for this pathway by promoting dissociation of the Grb2/Sos complex and a reduction in the strength of signal transduction.

37.3.2 Phosphoinositide-3-Kinase (PI3K)/AKT Pathway

PI3K is a major regulatory protein that is involved in a variety of cellular activities, including cell proliferation, survival, adhesion, and migration [41–43]. Among its three classes, only Class Ia is activated by a tyrosine kinase receptor. One of the PI3K subunits, p85, can directly interact with Grb1/2 through its SH2 domain when Grb1/2 associates with EGFR at Tyr 1068 and Tyr 1086 [44]. Although the major binding partner of p85 is not EGFR, but ErbB3 [45, 46], activation of PI3K is found in response to the EGFR ligand through EGFR/ErbB3 heterodimers. Activated PI3K-Ia produces phosphatidylinositol-3,4,5-trisphosphate (PIP_3). One of the well-known targets of this second messenger is the ser/thr kinase AKT [47]. Phosphorylated AKT can prevent apoptosis through targeted inhibition of Bad, a pro-apoptotic member of the Bcl-2 family and caspase 9, an enzyme involved in the Fas-mediated death pathway [48, 49]. PI3K/AKT also regulates the mammalian target of rapamycin (mTOR), which is responsible for the activation of translational machinery [50] and regulation of angiogenesis [51].

37.3.3 Phospholipase C-γ (PLCγ) and Protein Kinase C (PKC) Pathways

EGFR signaling also affects cellular phospholipid metabolism. In addition to PI3K, it is found that PLCγ is regulated by EGF stimulation [52]. PLCγ binds directly to EGFR at Tyr 992 and 1173 and can be phosphorylated by EGFR at Tyr 771 and Tyr 174 [53]. The activated PLCγ catalyzes the hydrolysis of PtdIns [4, 5]-P_2 to yield the important secondary messengers 1, 2-diacylglycerol (DAG) and inositol 1,3,5-triphosphate (IP_3). IP_3 mediates calcium release and at the same time affects the Ca^{2+}-dependent enzyme PKC, which uses DAG as its cofactor. Thus, through PLCγ, EGFR can activate the Ca^{2+}-dependent PKC pathway, which plays important roles in cell differentiation, proliferation, migration, and invasion [54, 55].

37.3.4 Janus Kinases (JAKs) and Signal Transducers and Activators of Transcription (STATs) Pathways

STATs are identified as signal transducers upon activation by cytokine receptors [56, 57]. There are at least seven STAT genes that have been identified in mammals, including STAT-1 to STAT-4, STAT-5a, STAT-5b, and STAT6. Homo- and heterodimerization of STAT proteins allows them to translocate into the nucleus and work as transcription factors for activation of gene expression in response to cell growth and proliferation. STATs, particularly STAT-1, STAT-3, and STAT-5, have been implicated in EGFR signaling. However, their mode of activation is significantly different from that by cytokine receptor. First, the EGFR ligand-stimulated phosphorylation of STATs does not require cytokine receptor JAK kinases. Second, STATs do not bind to the C-terminal phosphotyrosines of EGFR; instead they are constitutively associated with EGFR [58, 59]. Activation of STAT transcription activity strictly depends on EGFR tyrosine kinase activity [60, 61]. Moreover, Src kinase may play a role in EGF-dependent STAT activation [59, 62].

37.3.5 Src Pathway

Src and its family members have been extensively reported to support EGFR activity [63–65]. Overexpression of Src proteins strongly enhances EGF-mediated proliferation and transformation of fibroblasts and epithelial cells [66, 67]. Src does not bind to the major autophosphorylation site of EGFR, but phosphorylates EGFR in its kinase domain at Tyr891 and 920 sites [68]. These two phosphotyrosines bind the SH2 domain of Src and may provide a docking site for the p85 subunit of PI3K. In addition, two other Src-dependent phosphorylation sites were identified at Tyr 845 and Tyr 1101 in the EGFR cytoplasmic domains [69]. Phosphorylated Tyr 1101 facilitates Src binding to EGFR, while phosphorylation of Tyr 845 is required for Src mediated STAT5b binding [62]. It is possible that Src serves as a signal transducer downstream of EGFR or a contributor to EGFR activation.

37.3.6 Transactivation of EGFR

In addition to ligand binding, EGFR can be functionally activated through cross-talk with other cell surface receptors. G-protein-coupled receptors [70, 71], such as prostaglandin

E2 receptors and gastrin-releasing peptide receptor, platelet-derived growth factor receptor [72], insulin-like growth factor receptor [73], and some hormone receptors [74] also transactivate EGFR-mediated signal transduction pathways.

37.4 Oncogenic Activities and Expression of EGFR in Human Cancer Cell Lines and Tissues

37.4.1 In Vitro and In Vivo Studies of EGFR

The oncogenic activity of EGFR is evident from its ability to transform normal cells and promote cell proliferation. EGFR, by itself, is insufficient to cause transformation, but the addition of EGF, TGF-α, or other EGFR-specific ligands, or the existence of activation mutations is necessary for manifestation of the transformation phenotype [8, 75–77]. In addition to cell line studies, the use of transgenic animals has allowed the study of whether overexpression of EGFR or its ligands is indeed causative for hyperproliferation or tumor formation. Using TGF-α as an example, transgenic mice that overexpressed TGF-α driven by a keratin promoter show hypertrophy and hyperkeratosis accompanied by alopecia or stunted hair growth [78, 79]. TGF-α transgene expression is also linked to the appearance of papillomas following irritation or wounding. Targeted expression of TGF-α in the mammary gland results in hyperplasia, cystic expansion, and papillary adenoma following multiple pregnancies and lactation [80]. Therefore, overexpression of TGF-α is responsible for hyperproliferative responses but does not generally lead to tumors in rodents, suggesting that the TGF-α/EGFR signaling pathway provides the initial step in multistage carcinogenesis. Neoplastic transformation requires the overexpression or mutation of other proteins in the target tissues, such as c-Myc oncoprotein. This notion is supported by studies using mice with double transgenes of TGF-α and c-Myc that show development of mammary tumors [81].

Constitutively activated EGFR with no requirement for ligand binding can result from mutations that are found in many tumor tissues. A well-known example of a naturally occurring EGFR deletion mutant is EGFRvIII (Δ2-7) [82, 83], although other classes of EGFR ectodomain mutations EGFRvI and vII have also been discovered [84]. The EGFRvIII mutant has been detected in 40–50 % of grade VI glioblastomas [85], in up to 70 % of medulloblastomas and a small proportion of breast, ovarian, prostate, lung, and head and neck carcinomas [86–90]. Due to the deletion of exons 2–7, EGFRvIII lacks most of the extracellular domain, thus cannot be activated by ligand. Instead, it is constitutively activated and not internalized, resulting in constitutive long-term signaling which supports cell proliferation. A similar situation is observed in breast cancer, in which the Her2/neu or erbB2 oncogene was identified [91]. Her2/neu has a truncated extracellular domain and a point mutation in the transmembrane region, which activates the protein by inducing its dimerization in the absence of ligand. This receptor is a major oncogene and is overexpressed in 20–25 % of breast cancer tissues and associated with shortened survival [92].

Other activating mutations of EGFR are commonly found in lung cancers, and also observed in esophageal and head and neck cancers [93–96]. A deletion in exon 19 and nucleotide substitution in exon 21, such as L858R and L861Q, are the most common EGFR mutations in lung cancer cells. These genotypes have been identified as EGFR-TK inhibitor (TKI)-sensitizing mutations, because tumor cells harboring these mutations showed greater sensitivity to an EGFR-TKI (gefitinib) than those maintaining the wild-type gene [97, 98]. The mutations were suggested to stabilize the binding of EGFR with ATP or its competitive inhibitors. These mutations also induce anti-apoptotic pathways mediated by STAT-3 and AKT, strengthening the oncogenic activity of EGFR. However, a recent study using samples from the NCIC CTG trial showed that the presence of an EGFR mutation may increase responsiveness to EGFR-TKI, but is not indicative of a survival benefit [99].

37.4.2 EGFR Expression in Solid Malignancies

Since EGFR activation results in cell proliferation, inhibition of apoptosis, and the formation of neo-vasculature, several studies have evaluated the impact of EGFR activation on the clinical outcomes of patients with various solid malignancies. These include evaluation of ligand expression/concentrations, receptor expression, and activation of downstream signals such as MAP kinase.

EGF is a potent mitogen in the gastrointestinal tract and has been shown to increase proliferation in glandular cells in the colon [100]. TGF-α, another EGFR ligand, is also a growth factor in colonic epithelial cells [101]. Varying levels of receptor overexpression have been noted in colon cancer. Although overexpression of the receptor is noted in tumor tissues of approximately two-thirds of patients with colon cancer, the impact on prognosis is less certain [102–104]. EGFR expression may increase the propensity to develop hepatic metastasis [105]. EGFR is also frequently over expressed in aerodigestive malignancies. In patients with non-small cell lung carcinoma (NSCLC), EGFR overexpression is noted in approximately 40–80 % of the tumors [106–109]. In some studies, a higher level of EGFR expression has been linked to more advanced stages of disease at the time of diagnosis, and also to a poor prognosis [110–112]. More recently, aberrant activation of the EGFR pathway has been

shown to result from mutations in the tyrosine kinase binding domain of EGFR [93]. Such mutations are noted in approximately 10–15 % of Caucasian patients. EGFR mutations are noted more frequently in women, patients with adenocarcinoma histology, those who have never smoked and in patients of Asian ethnicity [94]. High copy numbers of the EGFR gene also appear to have an impact on prognosis and may also predict heightened sensitivity to treatment with EGFR inhibitors [113, 114]. However, there does not appear to be a clear correlation between protein expression, gene copy number, or mutational status in NSCLC.

EGFR overexpression is also noted in a vast majority of tumor specimens from patients with head and neck carcinoma [115–117]. A higher level of EGFR expression in the tumor tissue relative to surrounding normal tissues has been noted by several investigators [118]. In many of these reports, EGFR overexpression was associated with an inferior clinical outcome and higher rate of disease recurrence following definitive local therapy. Aberrant activation of EGFR has also been noted in other solid malignancies such as breast, ovarian, pancreatic, and prostate cancers [102].

Based on reports of aberrant activation of EGFR in a variety of epithelial cancers, several agents that inhibit EGFR pathway activation have been tested in preclinical and clinical studies. Overexpression of the receptor in the tumor tissue relative to surrounding normal tissue provides the opportunity for cancer-selective therapy. Overexpression of EGFR and its ligands and the expression of constitutively active EGFR mutants support diverse cellular biological activities utilized by cancer cells to progress, including cell cycle progression, cell growth, differentiation, angiogenesis, invasion, and metastasis [9, 119, 120]. Elucidating the effects of EGFR on these biological activities has been greatly accelerated by the development of EGFR inhibitors in recent years.

37.5 Development of EGFR Inhibitors

The crucial roles that EGFR plays in tumor progression make this receptor an ideal target for the development of anti-cancer therapeutics [121–127]. There are several potential approaches to blocking EGFR signaling pathways. The receptor can be inhibited through its extracellular domain by antibodies and at the TK domain by small molecules [128]. In addition, antisense DNA/RNA, siRNA, or ribozymes can also be used to reduce expression of the receptor [129–131]. Table 37.1 summarizes EGFR-targeting agents that are currently being developed or are used in the clinic.

Many synthetic and semi-synthetic compounds have been identified as EGFR-selective TK inhibitors [128, 132–134], such as gefitinib (ZD1839, Iressa) [135, 136], CI-1033 [137–139], and erlotinib (OSI-774, Tarceva) [140]. These compounds are orally bioavailable and work as competitive inhibitors in the ATP-binding domain of EGFR. Both in vitro and in vivo preclinical studies show that they have various effects on tumor cells expressing EGFR. EGFR-TKIs inhibit cell growth of several human tumor cell lines by blocking phosphorylation of EGFR, ERK, and AKT, which may result from G1 arrest of the cell cycle by reduction of cyclin D1 [141] and upregulation of cyclin-dependent kinase inhibitors p21 and $p27^{kip1}$ [142, 143]. These inhibitors also downregulate the secreted growth factors TGF-α, basic fibroblast growth factor (bFGF), and vascular endothelial growth factor (VEGF), which are important autocrine/paracrine factors stimulating both tumor cell growth and angiogenesis [144, 145]. Thus, it is no surprise that EGFR-TKIs can provide significant growth inhibition of human tumor xenografts in animal models [144, 146–148]. Particularly, they markedly enhance the efficacy of cytotoxic agents including cisplatin, paclitaxel, and other platinums in the treatment of human tumor xenografts in nude mice [149–151]. Furthermore, EGFR-TKIs show synergistic inhibitory effects when they are combined with other targeted agents [152, 153]. For example, studies from our group and the others illustrate that the combination of EGFR-TKIs with cyclooxygenase-2 inhibitors (COX-2Is) either additively or synergistically reduces the growth rate of several types of cancer cells [154–157]. In addition, EGFR-TKIs have been combined with inhibitors of IGF-1R [158–160], mTOR [161, 162], and VEGF/VEGF-Receptor [144, 163–165], and antisense oligonucleotides against Bcl-2 [166] and MDM2 [167]. Simultaneously blocking the expression and/or activity of both EGFR and these proteins results in effective induction of cell cycle regression and apoptosis in vitro and in vivo.

Table 37.1 EGFR inhibitors in clinical use

Agent	Disease	Indication (FDA approved)
Gefitinib	Non-small cell lung cancer	Treatment of advanced NSCLC following prior chemotherapy
Erlotinib	Non-small cell lung cancer Pancreatic cancer	For advanced stage NSCLC, following 1 or 2 prior chemotherapy regimens In combination with gemcitabine for previously untreated advanced stage pancreatic cancer
Lapatinib	Breast cancer	In combination with capecitabine for HER2-positive breast cancer
Cetuximab	Colorectal cancer Head and neck cancer	For advanced stage colorectal cancer, in combination with irinotecan or as monotherapy (EGFR-positive tumors) In combination with radiation or as monotherapy
Panitumumab	Colorectal cancer	Monotherapy following failure of prior chemotherapy for advanced stage colorectal cancer (EGFR-positive tumors)

Monoclonal antibodies (mAbs) directed against the extracellular domain of EGFR are another class of therapeutic agents that has been well-studied in recent years. Among the available anti-EGFR mAbs, the one currently used in the clinic is the chimeric human:murine mAb cetuximab (IMC-225, Erbitux) [168]. This antibody binds to EGFR with high affinity (K_d = 0.39 nM), thereby competing with EGFR ligand binding and preventing ligand-induced EGFR activation [169–172]. In addition, cetuximab and other anti-EGFR antibodies can induce EGFR dimerization, resulting in receptor internalization and downregulation [173, 174]. Cetuximab also induces G1 arrest because of elevated levels of $p27^{kip1}$ [175], followed by apoptosis [176]. Blockade of EGFR by cetuximab decreases tumor cell production of angiogenic factors, such as bFGF, VEGF, and interleukin-8 [177, 178], leading to a significant reduction in microvessel density and enhancement of apoptotic endothelial cells in human xenograft tumors. Cetuximab and similar anti-EGFR mAbs also inhibit the expression and activity of several matrix metalloproteinases (MMPs). The antibody-mediated reduction of MMPs results in inhibition of tumor cell invasion in vitro and metastasis in vivo [178–180]. Similar to EGFR-TKIs, cetuximab markedly augments the antitumor effects of chemotherapeutic agents such as cisplatin and doxorubicin in human xenograft tumor models [181, 182]. However, the functions of EGFR-TKIs and anti-EGFR mAbs are not completely overlapping. Anti-EGFR antibodies, but not EGFR-TKIs, have the ability to induce receptor internalization, an important mechanism for attenuating receptor signaling. Accordingly, the combination of an EGFR-TKI with cetuximab demonstrated a synergistic inhibitory effect on tumor cell growth in an in vitro study [183].

Recently, high-throughput screening approaches and rational drug design have been used to develop new EGFR inhibitors. These methods allow the identification of novel EGFR inhibitors that can be further modified chemically to target a tumor population that is resistant to current EGFR-targeting agents [184]. Structure-based rational drug design utilizes nucleic acid-directed gene silencing molecules including antisense oligodeoxynucleotides, RNA interference, and ribozymes to prevent EGFR translation from its mRNA [185]. Although these approaches are still in the early phase of development, they have great potential to enhance our ability to block EGFR and its related signaling pathways in a clinically applicable manner.

37.6 Clinical Application of EGFR Inhibitors

37.6.1 Non-small Cell Lung Cancer

EGFR inhibitors are now in routine clinical use for the treatment of advanced stage NSCLC. Gefitinib was the first drug among this class of agents to demonstrate anti-cancer activity in NSCLC. Two doses of gefitinib (250 and 500 mg/day) were compared to each other in patients with advanced stage NSCLC following progression with standard therapy [186, 187]. The objective response rate was 10–19 % and an additional 30–40 % of the patients experienced disease stabilization. Improvements in quality of life and lung cancer symptom scores were also noted in many patients. No difference in efficacy was noted between the two doses, though the lower dose was associated with a more favorable tolerability profile. This led to the approval of gefitinib for the treatment of advanced NSCLC by the Food and Drug Administration (FDA). However, a subsequent phase III study that compared gefitinib with placebo failed to demonstrate a survival advantage when gefitinib was used in second or third line treatment settings for advanced NSCLC [188]. Despite a response rate of 9 %, and modest disease stabilization rate, the lack of improvement in progression-free survival and overall survival with gefitinib effectively halted the use of this agent for the treatment of advanced stage NSCLC. However, there were selected sub-groups of patients, including never-smokers and those of Asian ethnicity, who did experience superior survival with gefitinib over placebo. This is suggestive of a role for this agent in clinically-selected or molecularly-selected subsets of patients with NSCLC.

Erlotinib, another EGFR-TKI, is also FDA approved for the treatment of advanced NSCLC. Following the demonstration of its anti-cancer activity in a phase II study [189], erlotinib was compared with placebo in a randomized phase III study (2:1 randomization) for advanced NSCLC patients. Those who progressed following one or two prior chemotherapy regimens were eligible for the study [190]. The median survival was superior with erlotinib (6.7 months vs. 4.7 months). The response rate was 9 %, and 35 % of patients experienced disease stabilization with erlotinib. Improvements were also noted in time to symptomatic deterioration for patients treated with erlotinib. The main side effects were skin rash (75 %) and diarrhea (54 %). The data from this study led to the approval of erlotinib for use as either second line or third line therapy of advanced stage NSCLC.

Cetuximab, a monoclonal antibody against EGFR also has efficacy as monotherapy, although the activity appears to be relatively modest. In a phase II study for patients with previously treated advanced NSCLC, cetuximab therapy demonstrated a response rate of 5 % and disease stabilization rate of 30 % [191]. The incidence of skin rash was more frequent, but diarrhea was uncommon with the antibody.

Following the demonstration of efficacy of EGFR inhibitors as monotherapies, randomized clinical trials have been conducted to study them in combination with chemotherapy. This approach was supported by preclinical data that demonstrated supra-additive effects when an EGFR inhibitor was co-administered with chemotherapeutic agents in NSCLC cell lines. However, there was no improvement in overall survival and progression-free survival for the combination of

an EGFR-TKI and standard platinum-based chemotherapy over that with chemotherapy alone in patients with advanced stage NSCLC [192, 193]. Although the reasons behind the conflicting pre-clinical and clinical findings are not entirely clear, further development of combination regimens with EGFR-TKIs and chemotherapy has been discontinued.

On the contrary, the monoclonal antibody cetuximab was associated with promising response rates and survival duration when combined with chemotherapy in phase II studies for patients with advanced stage NSCLC [194–196]. This prompted phase III studies of chemotherapy with or without cetuximab in patients with chemotherapy-naïve advanced stage NSCLC. The results have been conflicting, with one study that combined cetuximab with chemotherapy (carboplatin and a taxane) showing no improvement in progression-free survival over chemotherapy alone, whereas another study demonstrated improved survival in patients with EGFR-expressing tumors who were treated with cetuximab in combination with chemotherapy (cisplatin and vinorelbine) (Press release, Imclone Pharmaceuticals, Inc., September 2007). The detailed results of this trial are yet to be reported. Of note, the positive study with cetuximab was unique in selecting patients for therapy based on EGFR expression status.

The clinical development of panitumumab, a fully human monoclonal antibody against EGFR, was discontinued based on data from a randomized phase II study (carboplatin and paclitaxel administered with or without panitumumab) [197]. There was no improvement in any of the efficacy parameters evaluated in the study with the addition of panitumumab to chemotherapy. Presently, the reasons behind the differential interaction of EGFR-TKIs and monoclonal antibodies with chemotherapy are unclear. It is conceivable that antibody-mediated cellular cytotoxicity (ADCC) might play a role. Furthermore, it can be hypothesized that the non-target effects of EGFR-TKIs may be responsible for their unfavorable interaction with chemotherapy.

EGFR inhibitors are now being evaluated for the treatment of earlier stages of NSCLC. This includes combination approaches with external beam radiation for locally advanced, surgically unresectable NSCLC and in the adjuvant therapy setting for patients with surgically-resected early stage NSCLC. Appropriate patient selection, using molecular and clinical factors is a key focus of ongoing research efforts.

37.6.2 Head and Neck Cancer

Several studies have documented the efficacy of EGFR inhibitors for the treatment of head and neck cancer. Both gefitinib and erlotinib have demonstrated single agent activity in this setting. Administration of gefitinib to patients with advanced head and neck cancer following progression with one prior chemotherapy regimen was associated with a response rate of 11 % and an overall disease control rate of 53 % [198]. In a small subset of patients who underwent sequential tumor biopsies, no consistent correlation was noted between response to therapy and changes in various biomarkers. Erlotinib was also associated with objective tumor responses in patients with advanced head and neck cancer [199]. Some recent studies have evaluated the combination of gefitinib or erlotinib with chemotherapeutic agents. A phase I/II study of erlotinib with cisplatin found response and disease stabilization rates of 21 and 49 %, respectively, in previously untreated patients with advanced head and neck cancer [200]. In another study that evaluated the combination of erlotinib, cisplatin, and docetaxel, a high response rate of 67 % was noted [201].

The monoclonal antibody cetuximab has received FDA approval for the treatment of patients with locally advanced head and neck cancer, either as a single agent in patients with advanced platinum-refractory disease, or in combination with radiation for localized disease. Since EGFR activation is a survival pathway for irradiated cells [202], the combination of radiotherapy with an EGFR inhibitor was evaluated in a randomized phase III study in patients with locoregional head and neck cancer [203]. Concurrent administration of external beam radiation with cetuximab resulted in near doubling of the median survival over that with radiation alone. The median duration of local control was 24 months with cetuximab and radiation compared to 15 months with radiotherapy alone. Notably, there was no increase in radiation-related toxicities with the addition of cetuximab, with the exception of skin rash. These results led to the evaluation of cetuximab in combination with radiation in the treatment of other solid malignancies.

When given to patients with advanced head and neck cancers as monotherapy following failure with prior platinum-based therapy, cetuximab was associated with a response rate of 13 % and a disease stabilization rate of 46 % [204]. Cetuximab has also been shown to overcome resistance to platinum-based chemotherapy. The administration of cetuximab in combination with cisplatin to patients who failed prior platinum-based therapy resulted in a response rate of 10 % and disease control rate of 53 % [205]. The favorable tolerability profile and anti-cancer activity associated with the combination of cetuximab and platinum-based chemotherapy was further substantiated by a phase II study by Herbst et al. [206]. These findings were confirmed by a phase III study, which demonstrated a superior response rate with cetuximab and cisplatin when compared with cisplatin alone (26 % vs. 10 %) and a non-significant trend towards improved progression-free survival with the combination (4.2 months vs. 2.7 months) [207]. Another phase III trial conducted recently confirmed the utility of cetuximab in first line therapy of head and neck cancers. The median survival associated with cetuximab in combination with platinum-

5-fluorouracil was superior to that of chemotherapy alone in patients with recurrent or metastatic squamous cell carcinoma of the head and neck (10.1 months vs. 7.4 months) [208]. EGFR inhibitors are now being evaluated in combination with other targeted agents and also in earlier stages of head and neck cancer as adjuvant or neo-adjuvant therapy.

37.6.3 Colorectal Cancer

Cetuximab is efficacious in the treatment of advanced colorectal cancer, both as a monotherapy and in combination with chemotherapy. In a large phase II study ($n=346$ patients), cetuximab was administered as a monotherapy to patients who had progressed with standard chemotherapeutic regimens [209]. Expression of EGFR in the tumor (immunohistochemistry positive) was mandated as an entry criterion. The response rate (12 %) and median overall survival (6.6 months) were suggestive of single agent activity for cetuximab in this setting. Subsequently, a phase III study compared cetuximab with best supportive care in patients with EGFR-expressing colorectal cancer, following progression with standard chemotherapy [210]. The response rate was 8 % with cetuximab and there was a significant improvement in progression-free survival and overall survival. Patients treated with cetuximab reported less deterioration in global health status at 8 weeks and 16 weeks of therapy, compared to that with supportive care alone.

Cetuximab has also undergone extensive evaluation in combination with chemotherapy for the treatment of advanced colorectal cancer. In a study for irinotecan-refractory colorectal cancer, patients were randomized to treatment with cetuximab alone or in combination with irinotecan [211]. The combination was associated with a higher response rate than that with monotherapy (23 % vs. 11 %). The median time to progression (4.1 months vs. 1.5 months) and overall survival (8.6 months vs. 6.9 months) were also superior for the combination. Interestingly, anti-cancer activity was also noted when irinotecan was added to cetuximab after progression with monotherapy. This was consistent with preclinical studies that demonstrated reversal of resistance to irinotecan by the addition of cetuximab [212]. This notion was further substantiated by a non-randomized study ($n=1123$ patients) that treated irinotecan-refractory, EGFR-expressing colorectal cancer patients with the combination of cetuximab and irinotecan [213]. The median progression-free survival rate of 34 % at 24 weeks met the primary endpoint of the study.

Recent studies have focused on the evaluation of cetuximab in patients who had not received any prior chemotherapy for advanced colorectal cancer. A large phase III study randomized EGFR-expressing advanced colorectal cancer patients to treatment with 5-fluorouracil, leucovorin, and irinotecan (FOLFIRI) with or without cetuximab [214]. The addition of cetuximab to chemotherapy resulted in a superior response rate (47 % vs. 39 %) and a modest improvement in median progression-free survival (8.9 months vs. 8 months). Cetuximab also improved the efficacy of oxaliplatin-based chemotherapy regimens. In a randomized phase II study, the addition of cetuximab to 5-fluorouracil, leucovorin, and oxaliplatin (FOLFOX) resulted in a higher response rate than with FOLFOX alone (46 % vs. 37 %) [215]. These studies suggest a role for cetuximab in combination with chemotherapy as front-line therapy for advanced colorectal cancer. Cetuximab also appears to enhance the efficacy of other molecularly-targeted agents. Bevacizumab, a monoclonal antibody against the vascular endothelial growth factor, is commonly used in combination with standard chemotherapy for advanced colorectal cancer. In a randomized phase II study, the combination of cetuximab and bevacizumab resulted in a response rate of 23 % in patients with irinotecan-refractory colorectal cancer [216]. Thus, in addition to its routine use in patient care, cetuximab is being extensively studied in various settings for the treatment of colorectal cancer.

Panitumumab has also demonstrated anti-cancer activity in advanced colorectal cancer. A phase III study randomized patients with EGFR-positive, chemotherapy-refractory colorectal cancer to panitumumab monotherapy or supportive care [217]. The response rate with panitumumab was 10 %. There was a modest improvement in median progression-free survival for patients treated with panitumumab. This led to the FDA approval of panitumumab for advanced colorectal cancer in the setting of progressive disease following standard chemotherapy. This agent is now being evaluated in combination with chemotherapy.

In contrast to the single agent activity in colorectal cancer noted with EGFR monoclonal antibodies, the small molecule inhibitors appear less active as monotherapies. In a phase II study of erlotinib for advanced colorectal cancer, no objective responses were noted although some patients experienced disease stabilization [218]. Consequently, gefitinib and erlotinib are now being studied in combination with standard chemotherapy regimens. A phase II study of gefitinib in combination with 5-fluorouracil, leucovorin, and oxaliplatin in patients with previously treated colorectal cancer demonstrated a response rate of approximately 30 %. Similarly, the combination of erlotinib with oxaliplatin and capecitabine has been demonstrated to be safe and efficacious in the treatment of advanced colorectal cancer [219]. Randomized studies are currently underway to confirm the promising results from phase II studies with these agents.

37.6.4 Pancreatic Cancer

Erlotinib has recently been approved by the FDA for the treatment of pancreatic cancer in combination with gemcitabine. Its efficacy was established in a phase III study that randomized patients with advanced pancreatic cancer to treatment

with gemcitabine alone or in combination with erlotinib [220]. There was a statistically significant improvement in median overall survival in patients treated with the combination (6.2 months vs. 5.9 months). There was no difference in response rate between the two treatment arms. While the clinical significance of the magnitude of additional benefit with erlotinib has been called into question, this is the first randomized study to establish improved survival for any combination regimen in patients with pancreatic cancer. Cetuximab, which demonstrated promising activity in combination with gemcitabine in a phase II study, did not improve overall survival in a confirmatory phase III study [221]. The median survival duration was 6 and 6.5 months, respectively, for gemcitabine and the combination of cetuximab with gemcitabine.

37.6.5 Breast Cancer

Lapatinib is a novel dual kinase inhibitor that targets both EGFR (HER1) and HER2. It has recently been shown to be an active drug for the treatment of metastatic breast cancer. Initial phase II studies with lapatinib demonstrated a response rate of approximately 20 % in HER2/*neu*-positive breast cancer patients following progression with trastuzumab-based therapy [222]. Subsequently, a phase III study was conducted for patients with HER2/*neu*-positive breast cancer with randomization to capecitabine alone or in combination with lapatinib. The study was restricted to patients who had progressed following prior therapy with trastuzumab-based regimens. Median time to progression, the primary endpoint, was superior for patients treated with the combination (8.4 months vs. 4.4 months), without a significant increase in serious toxic events. Lapatinib is now being studied in combination with hormonal therapy and in earlier stages of breast cancer.

37.7 Predictive Biomarkers for Patient Selection

As EGFR inhibitors are tested and used for the treatment of a variety of solid organ malignancies, it is clear that their clinical benefit is confined to a sub-group of patients. Methods to identify this sub-group have led to the evaluation of several clinical and molecular biomarkers as part of clinical trials (Table 37.2).

Table 37.2 Molecular predictive markers under evaluation for EGFR inhibitors

Marker	Agent	Disease	Comment
EGFR protein expression	Erlotinib Gefitinib Cetuximab Panitumumab	NSCLC Colorectal cancer	EGFR positivity linked with favorable outcome
EGFR gene copy number	Erlotinib Gefitinib Cetuximab	NSCLC Colorectal cancer	Higher gene copy number linked with favorable outcome
EGFR gene mutation	Erlotinib Gefitinib	NSCLC	Exon 19 and 21 mutations associated with high response rate
EGFR polymorphisms	Erlotinib Gefitinib Cetuximab	NSCLC Colorectal cancer	Gene polymorphisms may account for differential sensitivity
MALDI-TOF proteomics analysis	Erlotinib Gefitinib	NSCLC	Ability to identify patients with a favorable outcome

37.7.1 Clinical Predictive Markers

Initial studies conducted in patients with NSCLC identified certain patient sub-groups that had a higher likelihood of achieving objective responses. These included women, patients with adenocarcinoma histology, those of Asian ethnicity and patients who were life-long never-smokers. Although the reason behind this was initially unknown, the higher prevalence of EGFR mutations in these subsets of patients might account for the greater efficacy of EGFR inhibitors. The preliminary results of a recent phase II study in chemotherapy-naïve patients with advanced NSCLC demonstrated the feasibility of patient selection based on clinical factors [223]. The eligibility criteria for the study were female sex, former or never-smoking status, and adenocarcinoma histology. The median progression-free survival was 5.6 months and the median overall survival was greater than 23 months.

Skin rash has been correlated with improved outcome for patients treated with EGFR inhibitors in a variety of malignancies [189, 224, 225]. In metastatic colorectal cancer, patients who develop a skin rash upon treatment with cetuximab have a better survival outcome than those without a rash. Even among patients with a rash, the severity of the rash has been correlated with efficacy: the more severe the rash, the better the outcome [189]. The reasons behind the correlation between development of skin rash and survival are not clear. It has been postulated that the skin rash is a surrogate marker of the degree of EGFR inhibition in the tumor. Some have hypothesized that skin rash indicates the extent of immune response, which might also contribute to antitumor efficacy. Intra-patient dose escalation of the EGFR inhibitor until the development of skin toxicity is now being tested in prospective studies.

37.7.2 Molecular Predictive Markers

37.7.2.1 EGFR Protein Expression

Several studies have evaluated the correlation between EGFR expression in the tumor tissue and treatment outcome. In colorectal cancer, initial studies were conducted only in patients with EGFR-expressing tumors. Subsequent studies

have demonstrated efficacy of cetuximab even in patients with EGFR-negative tumors [226]. Similarly in NSCLC, some of the initial studies were conducted only in patients with EGFR-expressing tumors [189, 191]. However, subsequent studies have enrolled patients regardless of EGFR status, based on the lack of clear correlation between EGFR expression and response. In the BR 21 study that led to the approval of erlotinib for NSCLC, a retrospective analysis was conducted to evaluate the correlation between outcome and EGFR expression status. Tumor tissues were available for immunohistochemistry (IHC) analysis from approximately one-third of the participating patients. The survival benefit with erlotinib was seen in IHC-positive patients, whereas for IHC-negative patients there was no advantage over placebo [190]. The variation in results across studies could be due in part to the technical difficulties associated with the assessment of protein expression by IHC in a consistent manner. The low sensitivity associated with IHC, inter-observer variability in scoring, and the variation in EGFR expression both within the same tumor and between metastatic sites [227] are all potential challenges in the use of EGFR protein expression by IHC for patient selection.

37.7.2.2 EGFR Gene Copy Number

The number of EGFR gene copies has been linked with treatment outcomes with EGFR inhibitors [113, 228]. Amplification of the EGFR gene is noted in approximately 10–15 % of patients with NSCLC [114]. There does not appear to be a clear correlation between EGFR gene amplification and protein expression. In a predictive algorithm developed by Hirsch et al, higher numbers of gene copies, assessed by fluorescent in situ hybridization (FISH), was associated with improved outcome for patients treated with gefitinib or erlotinib for advanced NSCLC. FISH positivity was defined as the presence of >4 copies of the EGFR gene in at least 40 % of the tumor cells studied. Based on this definition, the investigators were able to identify patients who were more likely to experience improved survival. In a retrospective analysis conducted on tumor specimens from patients who participated in the ISEL study, the hazard ratio for survival with gefitinib for EGFR FISH-positive patients was 0.61, compared with 1.16 for patients with low copy numbers. A similar observation has been noted in a retrospective analysis of the BR 21 study [99]. Based on this finding, prospective studies are now underway to evaluate the predictive potential of EGFR gene copy number for treatment with EGFR inhibitors in NSCLC. However, planned subset analyses of two recently reported studies in NSCLC have yielded conflicting results. In the randomized phase III INTEREST study, gefitinib was compared with docetaxel as second or third line therapy. The study met its primary endpoint of non-inferiority for gefitinib in this unselected patient population. However, a pre-planned subset analysis in EGFR FISH-positive patients failed to demonstrate superiority for gefitinib over docetaxel [229]. Similarly, another randomized study (INVITE) that compared gefitinib to vinorelbine in elderly NSCLC patients demonstrated a lack of improved outcome for FISH-positive patients with EGFR inhibitor therapy [230]. Therefore, until results from ongoing prospective studies are available, testing for gene amplification cannot be recommended for routine clinical practice.

37.7.2.3 EGFR Mutations

The presence of specific mutations in the tyrosine-binding kinase domain of EGFR is associated with a higher likelihood of response to treatment with EGFR-TKIs. Either in-frame deletions with the removal of 4 amino acids in exon 19, or point mutations that caused the substitution of an amino acid in exon 21 of the EGFR gene were noted in tumors of NSCLC patients who had robust responses to EGFR-TKIs [93]. These mutations are not present in other tumor types besides NSCLC. These EGFR mutations do not confer constitutive activity, but result in heightened responsiveness to receptor activation. The prevalence of EGFR mutations in Caucasian patients is approximately 10–15 %, whereas a higher proportion of patients with Asian ethnicity harbor them [94]. Other patient subsets that have a higher prevalence of EGFR mutations are those of female gender, never-smoking status, and adenocarcinoma histology. Elevated levels of EGFR mutations might account for the higher response rates noted in these patient subsets. Contrary to this hypothesis, a retrospective analysis of the BR 21 study failed to demonstrate a survival advantage for erlotinib over placebo in patients with EGFR mutations [99]. This study was limited by the small number of patients whose tumor tissues were available for analysis. Recently, the results from prospective studies have suggested very high response rates and prolonged times to progression with EGFR-TKIs in patients with EGFR mutations. In a study by the Spanish Lung Cancer Group, 38 patients with EGFR mutations were given erlotinib monotherapy [231]. The response rate was 82 % and the median progression-free survival was >12 months. Of interest was the observation that the response rate was higher in patients with the exon 19 mutation than the exon 21 mutation. This is suggestive of differential biological effects of the two mutations. This observation has been confirmed further by other studies conducted in patients with EGFR mutations [232, 233].

Although TKIs are active in patients with EGFR mutations, the role of monoclonal antibodies against EGFR are unclear in this setting. In preclinical studies, the TKIs are more potent against mutant EGFR-bearing NSCLC cell lines compared with the monoclonal antibodies [234]. Furthermore, the question remains as to whether EGFR mutations have a prognostic or predictive effect in patients with NSCLC. An analysis of tumor tissues from patients who participated in a phase III study that compared chemotherapy with or without erlotinib noted better outcomes with chemotherapy alone even in patients with EGFR-mutated

tumors [235]. Therefore, the utility of EGFR mutations in patient selection for treatment with EGFR-TKIs remains a subject of ongoing investigation.

Recently, a secondary mutation in the EGFR, located in exon 20, has been reported. This mutation confers structural changes in the tyrosine kinase binding domain and results in resistance to therapy with EGFR-TKIs [236]. It is commonly found in the tumors of patients with an exon 19 or 21 mutation, following treatment with an EGFR-TKI. Agents specific for tumors with a secondary EGFR mutation are now under clinical evaluation. Alternative mechanisms of resistance to EGFR inhibition such as activation of the C-MET pathway have also been described in NSCLC [237].

37.7.2.4 Serum Proteomics

Mass spectroscopic analysis of serum samples has recently been demonstrated to enable the identification of patients who are likely to derive a survival benefit from treatment with EGFR-TKIs [238]. First, a predictive algorithm based on matrix-assisted laser desorption ionization (MALDI) mass spectrometry (MS) was developed based on sera from 130 patients treated with EGFR-TKIs. Eight specific protein peaks were noted to differentiate patients with a good outcome with EGFR-TKI therapy from those with a poor outcome. Subsequently, the algorithm was tested in a cohort of patients treated with EGFR-TKIs. The median survival was 307 days in patients with a good profile compared to only 107 days in those with a poor profile (hazard ration 0.41). The serum samples were analyzed in two independent laboratories and were found to have a concordance rate of 97 %. The predictive algorithm appears to be specific for EGFR-TKIs, since the outcomes in patients treated with chemotherapy were not different between those with a good vs. poor profile. The predictive potential of serum proteomics analysis to select patients for treatment with EGFR-TKIs is now being tested in prospective clinical trials. If proven useful, this could be an inexpensive, non-invasive tool to select the most appropriate patients for therapy with EGFR inhibitors.

37.8 Conclusions

Targeting the EGFR pathway is now a proven strategy for the treatment of a variety of solid organ malignancies. The development of this class of agents illustrates the complex and methodical process that is necessary for target identification, validation, and clinical evaluation for successful drug discovery efforts. Although these agents do have non-target effects that contribute to adverse events, they have a high degree of selectivity for cancer cells. There are still a number of unanswered questions regarding EGFR inhibitors. It is unclear why the tyrosine kinase inhibitors are effective in certain tumor types in which the monoclonal antibodies are less active, and vice versa. The association between skin rash and efficacy has yet to be understood clearly. Furthermore, optimal patient selection methods continue to be evaluated, and will hopefully result in the use of these agents in a truly targeted setting. Nonetheless, the incorporation of EGFR inhibitors into clinical practice has resulted in meaningful improvements in symptoms and survival for cancer patients.

The current crop of clinical trials will address the role of EGFR inhibitors in the treatment of earlier stages of cancer. EGFR inhibitors may also be useful in the chemoprevention setting in patients with high-risk pre-neoplastic conditions. The combination of EGFR inhibitors with other molecularly-targeted agents is a promising strategy that will be tested in the near future in clinical trials. The administration of anti-angiogenic agents in combination with EGFR inhibitors is already in advanced phase clinical trials in colorectal and non-small cell lung cancer. Such novel strategies will undoubtedly contribute to improved outcomes for patients with cancer.

Targeting Oncoproteins for Molecular Cancer Therapy

38

Joshua E. Allen and Wafik S. El-Deiry

38.1 Turning Chemical Warfare into Cancer Therapy

Cancer and efforts to treat cancer are described in Ancient Egyptian documents dating back to 1600B.C. The first successful cancer treatments were arsenic-based therapies for leukemias, with the first reported application to cancer in the nineteenth century [1]. However, nitrogen mustards are often accredited as the first modern chemotherapy. Originally intended as a chemical warfare agent in World War I, nitrogen mustard was stockpiled by several countries. During World War II, Axis bombers sunk a ship containing large quantities of nitrogen mustard and killed numerous Allied sailors. Autopsies revealed that most of the victims' white blood cells were depleted, suggesting that the nitrogen mustard destroyed these cells or inhibited cell division of these cells. This observation birthed the hypothesis that nitrogen mustards might prevent the rapid division of cancer cells, one of the few properties of cancer understood at that time. Today, the hallmarks of cancer as recently redefined by Hanahan and Weinberg [2] include several complex and connected cellular properties that allow for this phenotype: resistance to cell death, sustained angiogenesis, limitless ability to replicate, self-sufficiency in growth factor signaling, unresponsiveness to anti-growth factor signaling, genomic instability and mutation, deregulating cellular energetics, evading immune-mediated destruction, oncogenic inflammation, and invasiveness and metastasis [3]. The identification and understanding of these hallmarks is a direct result of our molecular understanding of cancer that has surfaced relatively recently. Each of these hallmarks is determined by a host of molecules which together represent distinct therapeutic opportunities to target molecules that give rise to these defining properties of cancer (Fig. 38.1).

The National Cancer Act of 1971, signed by President Richard Nixon, declared "…*war on cancer*…" and announced full Congressional and presidential support to eradicate the disease. As a result of increased funding and technological advancements, our understanding of cancer biology on the genetic and molecular level has exploded. Today, cancer phenotypes are associated with genetic and molecular culprits along with complex networks of various regulatory mechanisms that together cause and sustain cancer. Superficially, the genes capable of inducing carcinogenesis are divided into two categories. The first is a tumor suppressor, which is a gene that if inactivated, restricts cell division. Genes that confer pro-survival changes if activated are oncogenes. Intuitively, tumor suppressors such as p53 are commonly inactivated in cancer while oncogenes such as myc are activated and/or overexpressed. These carcinogenic changes manifest themselves by a number of avenues including overexpression, mutations, deletions, loss or gain of alleles, epigenetic modifications that alter genomic structure, alternative splicing, interference with the translation and transcription of the gene, chaperone-mediated protein folding, protein degradation processes, and posttranslational modifications that modulate localization, protein-protein interactions, and/or activity of the protein. Whether some of these changes occur simultaneously, sequentially, or otherwise is highly context-dependent and debated. Furthermore, the functional consequences of these alterations have a wide range of effects through crosstalk in cell signaling pathways. In the background of cancer-associated genomic instability, these wide-spread alterations and the functional redundancy of various genes provide a breeding ground for therapeutic resistance and make targeting cancer cells at the molecular level a challenging feat.

Radiation, surgical resection, and chemotherapy still comprise the vast majority of first-line cancer therapy today. While chemotherapy has yielded enormous patient benefit it is often accompanied by side effects that limit dose and therefore efficacy. Traditional chemotherapy is based on the notion that cancer cells divide more rapidly than normal cells and consequently will be differentially affected by an inhibitor of cell division. However, many types of normal cells need to divide for normal function. Our increased understanding of cancer has yielded numerous molecular targets for cancer therapy that may be less necessary for normal cell function and therefore may be less toxic. For instance, most normal cells divide a finite number of times, which is called the Hayflick limit. When cells divide, the ends of their chromosomes termed telomeres shorten as result of the DNA replication process, a phenomenon called the end replication problem. Upon reaching a critical telomere length, cells stop dividing and enter a dormant state referred to as cellular senescence. Cancer cells must evade senescence as they need to propagate indefinitely. Cancer cells escape this phenomenon by activating telomerase, an endogenous enzyme capable of elongating telomeres. As this oncogenic process is essential to cancer cells but not essential to most types of normal cells, telomerase is an attractive target for cancer therapy. Several types of inhibitors targeting various aspects of the telomerase molecular machinery and function are being investigated as a novel cancer therapy. There have been and continue to be efforts to discover therapies that alter the function of cancer-specific targets such as this. The rise of targeted therapies over the past two decades is a result of the rich marriage of our modern tools to understand cancer and our ancient desire to cure it. This chapter details the discovery, translation, development, and exemplified therapeutic concepts of several novel cancer therapies that specifically target oncoproteins and have molded how we discover and develop novel therapies today (Fig. 38.2).

38.2 Small Molecules with Big Consequences

A narrow library of atomic arrangements make up the relatively small number of molecular building blocks of cellular life such as nucleic acids that comprise DNA and RNA as

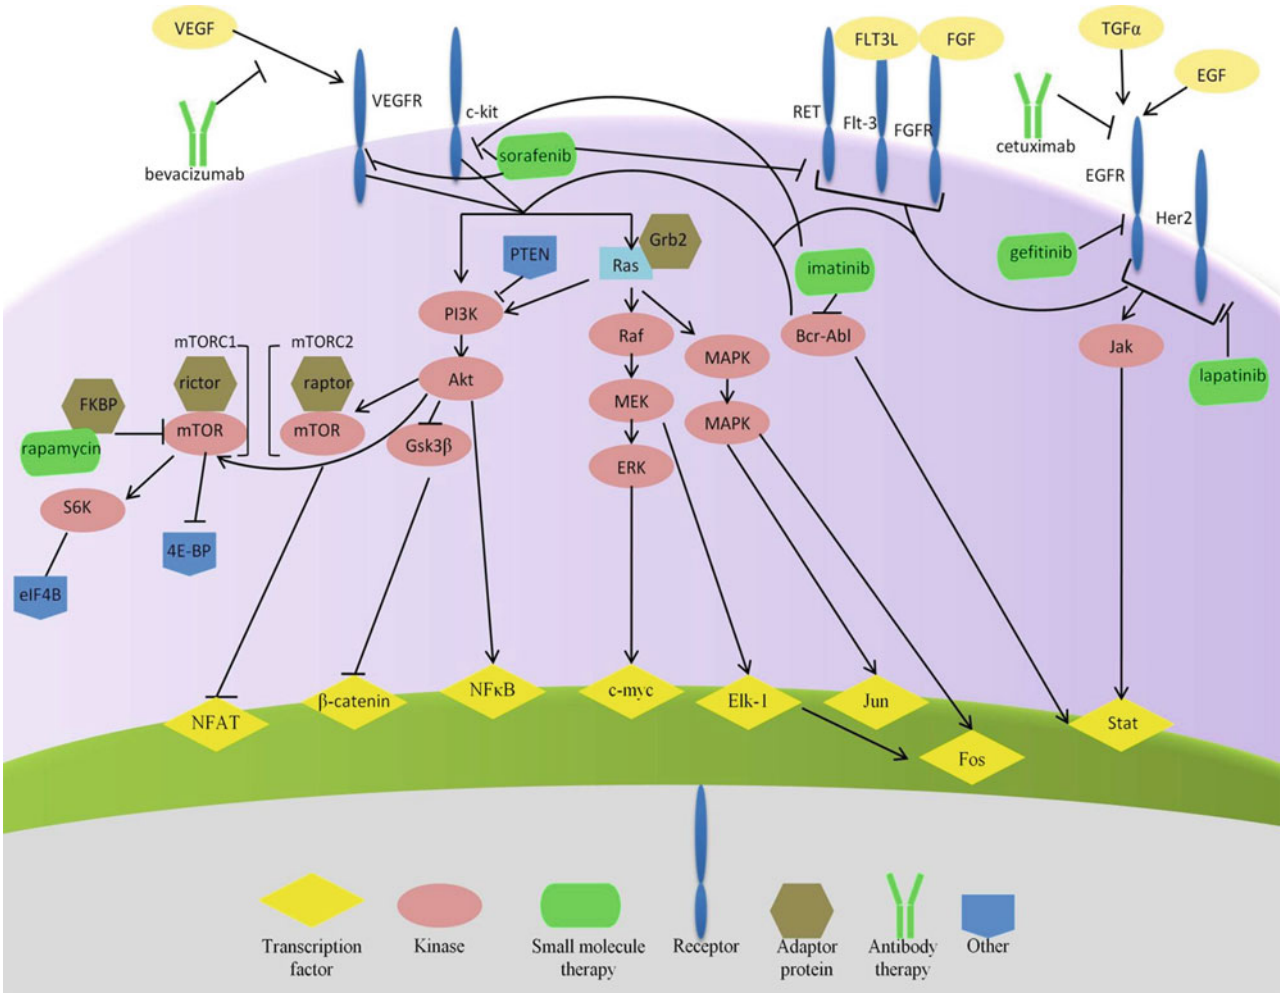

Fig. 38.2 Outline of exemplary molecular therapies targeting oncoproteins and their representative signaling networks.

well as amino acids that the end product, proteins, are made of. These building blocks are themselves synthesized from other molecules during cellular uptake and metabolism. Life has evolved to find chemical means for cells to convert small molecules to other molecules that are more useful for them. In a sense, we attempt to do the same for cancer therapy through medicinal chemistry to make more effective therapies from lead compounds. Small molecules offer a vast range of activity: sucrose sweetens foods and beverages, sodium pentothal is lethal, and amoxicillin can cure many bacterial infections. Our expanding knowledge in chemistry enables us to modify small molecules in nature or our synthetic libraries and create new molecules with altered functions, just as a cell does. Our understanding and ability to produce biological molecules on a therapeutic scale has been a relatively recent endeavor, therefore chemotherapies are almost entirely composed of small molecules. The availability, diversity, synthetic amenability, cost, and size of synthetic and natural compounds make small molecules an irreplaceable source of therapies.

38.2.1 A Rational Success Story: Imatinib

Chronic myelogenous leukemia (CML) is a cancer that causes increased amounts of white blood cells and is almost always associated with a specific translocation of chromosomes 9 and 22. The resulting shorter chromosome 22 is known as the Philadelphia chromosome, a tribute to the city housing the researchers who identified this in 1960s. The Philadelphia chromosome encodes a fusion of the two genes that results in the production Bcr-Abl. Abl is a tyrosine kinase that becomes constitutively active in the gene fusion product. This unregulated kinase activity causes oncogenic cell signaling shown to be sufficient to induce leukemia in mice. As a poster-child for translating modern cancer knowledge to clinical benefit, imatinib has significantly improved CML patient response rates. The FDA approved imatinib in 2001 for the treatment of CML as the first cancer therapy to target an intracellular molecule. Imatinib is a direct result of medicinal chemistry performed on a molecule identified as a protein kinase C (PKC) inhibitor [4]. Chemical modification

of the PKC inhibitor altered the specificity of the molecule and rendered the derivative a potent inhibitor of v-abl [5], c-kit, and platelet-derived growth factor receptor (PDGFR) [6]. All of these proteins are receptor tyrosine kinases (RTKs) that bind extracellular factors and transduce the signal by phosphorylating specific protein substrates. The observation that imatinib inhibits Abl and BCR-Abl led to preclinical development and ultimately clinical trials of imatinib as a cancer therapy for CML. The concept of taking the currently available knowledge of a particular target and identifying a way to alter its function for therapeutic benefit is known as rational drug design.

Structural biology has played a key role in understanding how molecules look, how they move, how they interact with other molecules, and how all of these things change in different environments. Computational molecular docking in concert with an X-ray crystallographic structure of the catalytic domain of Abl bound to imatinib revealed that imatinib binds to the ATP-binding site of Abl preferentially when the protein is in the inactive form (Fig. 38.3) [7, 8]. The crystal structure also showed that a chemical group added to increase solubility also forms hydrogens bonds with two residues of Abl. The insight gained from such structures provides an understanding of how and where a drug binds, what types of interactions are formed, and what role each residue or functional group plays. Due to the relatively facile excision and crystallization of the catalytic domains of many kinases, several atomic structures of these proteins are freely available in the Protein Data Bank (PDB). This provides fertile ground for numerous applications of computational chemistry to foster drug discovery and development. In addition to structural biology, medicinal chemistry also provides insight into the function of particular atoms of a molecule while searching for a more therapeutically potent derivative. The drug development process typically begins by identification of lead molecules using various screening techniques that search for a desired effect. Validation of these leads and optimization by medicinal chemistry ensues to identify the most promising compound to continue to develop. The process of lead optimization and elucidative structural biology intrinsically discerns the role of particular parts of drug and target molecules in the activity of the drug, giving rise to structure–activity relationships (SARs).

All of the kinases in the human genome, called the kinome, share a high degree of sequence and structural homology. This means that identifying inhibitors that are specific for a given kinase is challenging and often kinase inhibitors have multiple targets. Imatinib is no exception, as it inhibits autophosphorylation of c-KIT, platelet-derived growth factor (PDGF), and ARG [9] kinases in addition to BCR-ABL. c-KIT is a receptor tyrosine kinase that is almost ubiquitously mutated in gastrointestinal tumors (GISTs) during the transformation of interstitial cells of Cajal located in the gastrointestinal tract. This mutation typically occurs in exon 11 of the c-Kit gene, which results in constitutive autophosphorylation of the protein that continually activates downstream pro-survival signaling that is oncogenic. The observation that imatinib inhibits c-KIT lead to preclinical development and clinical trials with the treatment of GISTs. Seven years after its approval for treatment of advanced CML, the FDA approved imatinib for treatment of GISTs following surgical removal of the tumor.

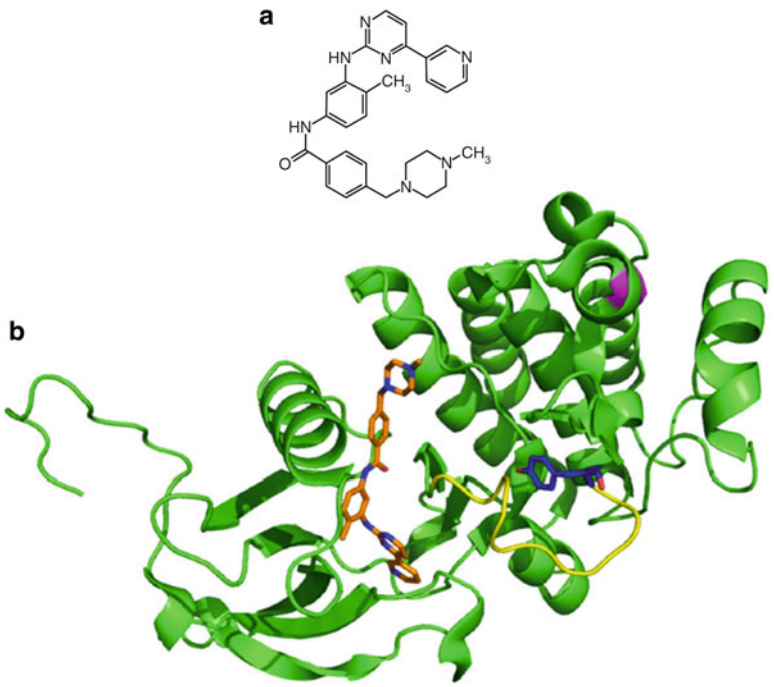

Fig. 38.3 Crystal structure of imatinib bound to Abl kinase. The Abl kinase (*green*) is represented as a secondary structure cartoon with its activation loop highlighted in *yellow*. The confirmation is in an inactive kinase state. PBD accession 1IEP.

This extension of clinical applications demonstrates a few key concepts in cancer therapy. Firstly, exclusive specificity of a cancer drug for a molecular target is a virtue rooted in our movement toward targeted therapy. We know that without specificity, effects on normal cells can yield side effects that are deleterious. However the distinction should be made that while cancer therapies should target cancer-specific properties, this does not have to be accomplished by targeting a single molecule. It is conceivable that evolving therapeutic resistance is easier against a single target rather than an array of molecules. Furthermore, different types of tumors seem to rely on alterations in multiple genes and so multiple targets may allow for broader spectrum and more potent antitumor activity. The clinical extension of imatinib to GISTs also underscores the importance of identifying and understanding the molecular targets of therapies and how they fit with our molecular understanding of cancer. The application of a therapy used in distantly related clinical settings is a concept that continues today. Such applications are often a direct result of rational drug design and typically have an expedited timeline for starting clinical trials as they have already been tested in humans. The time and cost associated with development of cancer therapies is astounding, taking an average of over 14 years and $2 billion to reach FDA approval of a cancer drug with a success rate of just over 7 % [10]. Clearly, reducing the time spent in early phase trials profiling safety of the drug would reduce cost and expedite evaluation and patient benefit.

Therapeutic resistance is frequent in cancer. Cancer is defined by its uncontrollable cellular division and therefore is a disease of evolution governed by natural selection. While our cells copy our genome during cell division with amazing fidelity, the molecular machinery that performs this task is not completely error free. This endogenous source of mutations, environmental mutagens such as UV radiation or tobacco, and the genomic instability associated with cancer provide a sufficient source of heritable variability. Cancer treatments serve as a selective force for the cancer cells. Imagine yourself looking at population of millions of CML cells circulating in the blood that have the oncogenic Bcr-Abl fusion gene. Now introduce imatinib into the blood stream, which inhibits Bcr-Abl, and watch as the CML cells begin to die due to their dependency on the function of this oncogenic protein. If any single cell out of these millions of CML cells evolved into cancer by a process not involving BCR-ABL or can continue to divide using other oncogenic alterations, the cell will survive and continue to divide. The entire offspring of such cells will not rely on BCR-ABL to propagate and thus the patient will now not respond to therapies that target BCR-ABL. The enhanced sources of genetic variability and the solitary goal to divide more rapidly give rise to heterogeneity of tumors. This heterogeneity has significant implications as to how cancer is diagnosed and managed.

There are several ways that cancer cells get around therapeutic road blocks in intracellular signaling to keep propagating. In the case of imatinib, mechanisms of resistance include increasing the amount of Bcr-Abl to saturate the drug, mutating Bcr-Abl to still be constitutively active in the presence of imatinib, bypassing BCr-Abl and activating its downstream targets to achieve the same end goal, or simply getting rid of the drug altogether. Following the first route, cell culture and patient data revealed that overexpression of Bcr-Abl by gene duplication occurred in refractory patients and that this was sufficient for imatinib resistance [11–14]. Additionally, several patients were found to have mutations in the BCR-ABL that allowed for sustained signaling in the presence of imatinib. Due to the availability of the drug-bound crystal structure of the Abl catalytic domain, the effects of these point mutations were rationalized at the molecular level. Another intriguing avenue of drug resistance is getting rid of drugs by upregulating molecular efflux pumps localized at the cell membrane. The most characterized member of this family of proteins that induce multidrug resistance is p-glycoprotein (PgP), exhibiting broad substrate specificity to include several chemotherapies such as vinblastine, doxorubicin, and paclitaxel. Upregulation of PgP was also found in imatinib-resistant clones and in advanced CML patients. Pharmacological inhibition of multidrug resistance proteins is being explored in clinical trials in combination with chemotherapy with mixed success [15–19]. Strategies to circumvent imatinib resistance in the clinic include increasing the dose, changing to other investigational therapies, and administering alternative Bcr-Abl inhibitors such as nilotinib and dasatinib. Nilotinib and particularly dasatinib also target Sarc-family kinase (Src) and have significantly improved patient outcome after imatinib failure [20–29]. Treating patients that are resistant to first-line therapies is a challenge in clinical oncology and is a major barrier in getting an investigational drug approved as these are often tested in these refractory patients.

Ten years after the discovery of imatinib, it was approved in the US, Japan, and Europe as the first-line therapy for CML. The story of imatinib is a testament to our modern molecular understanding of cancer. Computational biologists, chemists, cell biologists, translational oncology researchers, and clinical oncologists from various countries around the world collaborated to discover and translate this therapy. Such interdisciplinary integration is a recipe for success in modern drug discovery and development and is a theme found throughout molecular targeted cancer therapy and beyond.

38.2.2 Gefitinib

Growth factor signaling is intimately involved in tumorigenesis and propagation and is involved in two of the hallmarks of cancer. Growth factor signaling typically involves the binding of an extracellular factor by a transmembrane receptor on the cell surface, which triggers intracellular signaling events. These events such as substrate phosphorylation ultimately allow for cellular proliferation through various mechanisms such as turning on transcription factors that activate genes necessary for cell cycle progression. One group of receptors that mediate several of such signals is the epidermal growth factor receptor (EGFR) family and as a consequence, this family is commonly altered by mutations and/or overexpression in a wide range of solid tumors. These receptors form homo- or hetero-oligomers upon binding various ligands to trigger a range of intracellular signaling events via Ras/Raf/MAPK, PI3K/Akt, STAT, or Src kinase pathways. EGFR is one member of this family that homodimerizes upon binding and induces proliferation through ERK, PI3K/Akt, Ras, and STAT signaling pathways. Due to the frequency of their alteration in a variety of cancers and its plethora of potent downstream oncogenic targets, the EGFR family members have successfully targeted by a number of therapeutic approaches over the past two decades.

Gefitinib is an orally active EGFR inhibitor identified by Astra Zeneca and first reported in 1996. A quinazoline derivative was found to be an ATP-competitive inhibitor and highly specific to EGFR over its related family members. Cell-based events in accordance with the inhibition of EGFR activation were observed such as autophosphorylation, upregulation of the CDK inhibitor $p27^{Kip1}$, and transcriptional inhibition of the transcription factor c-Fos [30, 31]. Preclinical studies found that gefitinib had cooperative to synergistic combinations with several chemotherapies in EGFR-overexpressing cancer cell lines [32]. Interestingly, another group reported similar effects with gefitinib-chemotherapy combinations but in cancer cell lines with low EGFR expression [33]. Oral and intravenous administration of gefitinib in rats and dogs found the bioavailability of the drug to be ~50 % and that the drug was well distributed throughout the body [34]. Pharmacokinetic (PK) studies indicated that oral administration of gefitinib at 100–700 mg/day was well tolerated, had a terminal half-life between 1 and 2 days, and reached serum concentrations that inhibited 90 % of EGFR activity in vitro [35–39]. The first phase I trial of gefitinib was a dose escalation study in patients with various solid tumors that reported objective partial responses in NSCLC patients at oral doses ranging 300–700 mg per day on a 14 days-on, 14 days-off schedule [40]. The observed dose range with antitumor activity was below the dose-limiting toxicity (DLT) reported and was corroborated with another phase I trial [41]. These clinical trials used high-performance liquid chromatography (HPLC) with mass spectrometry (MS) to monitor serum concentrations of gefitinib [42].

HPLC along with complementary molecular identification techniques are often employed in clinical trials involving small molecules. HPLC allows for the separation and quantification of molecules based on their absorbance and interactions with a solid matrix. Molecular properties such as size and charge along with instrument and solvent parameters determine how the molecule interacts with this matrix. These interactions determine how long the molecule takes to migrate through the matrix column. HPLC conditions are optimized to allow for quantitative identification of a given molecule based on this empirically determined elution time, called retention time. The calculated serum concentrations can then be used to determine a plethora of pharmacokinetic parameters. These parameters are particularly important in guiding dosing schedules of new therapies and rationalizing patient responses. This technique is often coupled with mass spectrometry to allow for further verification that the molecule identified at a particular retention time is indeed the target molecule. Mass spectrometry is an electromagnetic separation method that distinguishes molecules based on their size to charge ratio of ionized forms of the molecule, which are generated by molecular collisions. Together, these ionized fragments yield a unique fingerprint for each molecule. Coupling HPLC and mass spectrometry has been instrumental in increasing the accuracy and reliability of pharmacokinetic data and identifying metabolites of drugs. Direct and indirect modifications of drugs often occur once delivered due to the staggeringly diverse mixture of molecules presence in the blood, digestive system, etc. As for gefitinib, HPLC-MS identified desmethyl-gefitinib as a metabolite of gefitinib that is inactive in vitro and in vivo [43]. Identification of metabolites is important for understanding and monitoring the various molecular species responsible for therapeutic activity as well as guiding chemical optimization.

Phase II trials with gefitinib again yielded some patient benefit in NSCLC along with low toxicity [44, 45]. With data available from phase III clinical trials, the FDA granted accelerated approval for gefitinib as a third-line therapy in NSCLC in 2003. This type of approval is granted based on promising clinical evidence of efficacy when there is no current therapy for a particular clinical setting. However, this approval is temporary and full approval is contingent on a more complete clinical data set. In the few years following accelerated approval of gefitinib, several studies found responses in the overall population of NSCLC patients [44–46]. However, a small subset of responders was identified amongst these trials with the following characteristics: female, Asian, never-smokers, adenocarcinoma, and mutant EGFR [46–48]. Several other studies confirmed efficacy of

gefitinib in NSCLC patients with EGFR mutations [49–52] though no benefit was found in NSCLC patients with EGFR gene amplification [53]. A breakthrough study published in 2004 found that the majority of gefitinib responders had EGFR deletions or point mutations clustered at the ATP-binding site of EGFR, which results in a ten-fold increase in sensitivity to gefitinib [54]. Others studies corroborated these EGFR alterations in gefitinib-responsive patients [55, 56]. These genetic alterations were structurally modeled and rationalized using the crystal structure of the human EGFR kinase domain bound to gefitinib (Fig. 38.4) [57]. These response-determining mutations occur at the active site of the kinase domain in structural regions that are responsible for autoregulation of kinase activity. Further studies found that these particular mutations in EGFR stabilize the active form of the kinase and shift its affinity from ATP toward gefitinib [58].

One study mandated by the accelerated FDA approval of gefitinib and another phase II clinical trial found no benefit with gefitinib in NSCLC refractory to first-line or second-line therapies. This led the FDA to restrict its usage to patients who have previously benefited or are currently benefiting from gefitinib in 2005. Subsequent clinical trials have supported gefitinib following chemotherapy resistance [59, 60]. Together, the clinical trials comparing gefitinib and chemotherapy are confusing as they conclude significant to no benefit of gefitinib over chemotherapy. These conflicting results have been ascribed to fundamental differences in the therapeutic mechanisms of chemotherapy and targeted therapy, differences in patient populations, and biomarker selection and technique accuracy [61]. Recent studies have supported gefitinib as a first-line therapy due to demonstrated superiority over standard of care therapy in mutant EGFR NSCLC patients [62–64]. This data is anticipated to extend the restricted use label of gefitinib to its use as a first-line therapy in NSCLC patients with mutant EGFR. The use of targeted therapy based on molecular determinants surfaces later in the chapter and is increasingly integrated into FDA approval stipulations as personalized medicine emerges in practice.

38.2.3 Two Birds with One Stone: lapatinib

As discussed elsewhere, the EGFR family is overexpressed in numerous cancers. One particular EGFR member, Her2, does not bind ligands but can form heterodimers with other ligand-bound family members to transduce oncogenic signaling through the Ras/Raf/MAPK cascade. By 2001, several recent EGFR family-targeted molecular therapies had demonstrated significant clinical efficacy in cancer including the EGFR-targeted therapies gefitinib, erlotinib, and cetuximab along with anti-Her2 monoclonal antibody herceptin. Her2 and EGFR are well-established therapeutic cancer targets based on these clinical successes, the prevalence of EGFR family alternations in cancer, and the highly homologous and druggable ATP-binding site shared by EGFR family members. A collaboration of private companies including GlaxoSmithKline launched a large synthetic effort to simultaneously target these two proteins [65–67]. Published results of these efforts detail the synthesis, specificity, and biological activity of several quinazoline or pyridopyrimidine compounds. One initial compound, GW2974, produced tumor stasis given orally at a dose of 30 mg/kg in squamous cell head and neck carcinoma and breast cancer xenografts. A later report found yet another compound, GW572016, to be a potent, reversible inhibitor of EGFR and Her2 even in the presence of excess EGF [68].

The full length 185 kDa Her2 protein can be proteolytically cleaved to shed its extracellular domain and give rise to its truncated form, $p95^{Her2}$. $p95^{Her2}$ is constitutively active which causes autophosphorylation, has a high oncogenic transformation ability, and correlates with lymph-node positive metastasis and poor therapeutic response [69–76]. $p95^{Her2}$ was found to be insensitive to trastuzumab, preferentially dimerize with ErbB3, and be regulated by the ErbB3 ligand heregulin [77]. Lapatinib blocked baseline autophosphorylation and downstream signaling events induced by

$p95^{Her2}$. Her2 was found to contribute to androgen receptor transcriptional activity [78, 79]. Accordingly, lapatinib cooperated with the small molecule estrogen receptor-agonist tamoxifen to reduce estragon receptor-dependent transcriptional activity and inhibit the growth of a tamoxifen-resistant xenograft [80]. Lapatinib-resistance clones were generated by chronic exposure of cancer cell lines and were enriched in androgen receptor signaling events, suggesting the importance of this signaling in lapatinib response [81]. Combining lapatinib with anti-Her2 antibodies such as trastuzumab enhanced downregulation of the anti-apoptotic protein survivin and apoptosis in Her2-overexpressing breast cancer cells [82, 83] and trastuzumab-resistant cells [84]. These preclinical observations served as the basis for combining lapatinib with hormone therapy and trastuzumab.

Phase I studies in healthy volunteers found orally administered lapatinib to reach peak serum concentrations at 3 h and achieve steady state concentrations after 1 week [85]. High fat content of the patient significantly increased bioavailability of the drug, highlighting yet another clinical variable impacting therapeutic response [86–88]. EGFR-overexpressing and Her2-overexpressing metastatic carcinoma patients receiving lapatinib showed significant clinical responses and tolerated oral daily doses up to 1600 mg [89]. Lapatinib was also safe and effective as a first-line monotherapy in Her2-amplified advanced or metastatic breast cancer [90]. The agent has shown preliminary efficacy in head and neck squamous cell carcinoma [91, 92], but not in NSCLC [93] or prostate cancer [94].

Lapatinib has been combined with a variety of chemotherapies, hormone agonists, and trastuzumab. Addition of lapatinib to the FOLFOX4 or FOLFIRI chemotherapy regimen was safe [95, 96] and is now being explored for efficacy. Based on the clinically active combination of trastuzumab with capecitabine, studies with this combination were conducted on Her2-overexpressing advanced or metastatic breast cancer patients [97, 98]. The study found that the time to progression doubled when lapatinib was added to capecitabine without significant additional toxicity. Efficacy within these $Her2^+$ patients was not limited to a subgroup [99], but a separate study found lapatinib to be effective in $Her2^+$ but not $EGFR^+/Her2^-$ inflammatory breast cancer patients [100]. This suggests that Her2 inhibition is a key mediator of antitumor efficacy in this malignancy. However, a higher lapatinib was recently found in preclinical models to have EGFR-independent and Her2-independent effects on death receptor upregulation that enhances efficacy when combined with TRAIL and TRAIL-receptor antibodies that bind to these receptors [101]. This rationalizes the clinical exploration of higher doses of lapatinib to gain increased efficacy via off-target mechanisms.

In 2007, the FDA approved trastuzumab and chemotherapy-resistant, for the treatment of $EGFR^+$ advanced or metastatic breast cancer. An increase in progression-free survival (PFS) from 3 to 8.4 months was observed with the addition of lapatinib to letrozole in estrogen receptor (ER)-positive metastatic breast cancer relative to letrozole monotherapy [102]. Based on this data, the FDA extended the indication for lapatinib to its use with letrozole in $Her2^+ER^+$ metastatic breast cancer in 2010. Addition of lapatinib to tri-weekly paclitaxel as a first-line therapy yielded a significant increase in time to progression of metastatic breast cancer patients that was restricted to the $Her2^+$ patients [103]. A recent study has also demonstrated the safety and potential efficacy of combination with weekly paclitaxel [104]. In agreement with lapatinib and trastuzumab combinatorial preclinical data, PFS was significantly prolonged in trastuzumab-resistant $Her2^+$ metastatic breast cancer with the combination of trastuzumab and lapatinib [105]. Lapatinib demonstrates the power of multitargeted therapies over single-targeted therapies such as trastuzumab and continues to be explored with various therapeutic combinations as a breast cancer therapy.

38.2.4 Rapamycin: From the Ground Up

The PI3K/Akt/mTOR pathway is a complex signaling network that controls cell survival, death, and division in response to a variety of stimuli such as hypoxia and growth factor deprivation. The elucidation of this pathway started in 1975, when rapamycin was first isolated as an antifungal agent from bacteria in a soil sample from the Polynesian island of Rapa Nui, where the compound got its name [106, 107]. Follow up studies in rats found that rapamycin was a potent immunosuppressant [108] but the molecule lost attention in the scientific literature. Over a decade later, a high-profile immunosuppressant macrolide, FK506, was found to inhibit the proliferation of activated T-cells [109]. The same investigators that reported this observation also noticed structural homology between FK506 and rapamycin, which prompted a comparison study of their effects. Interestingly, rapamycin and FK506 antagonized the biological effects of each other. Experiments with radiolabelled FK506 found that rapamycin could directly compete with FK506 in cells for its undescribed binding target [110], which turned out to be FK506 binding protein (FKBP) [111–114]. However, the two molecules had different effects on signaling events involved in T-cell activation such as the transcriptional activity of NFAT or induced IL-2 transcription [115]. The structure of FKBP alone was determined by NMR [116] and in complex with FK506 by X-ray crystallography [117] which together revealed a rather unique drug binding site and revealed a strong conformational shift in FK506 and to a lesser extent in FKBP. Rapamycin was later found to bind to the same site but did not demonstrate a significant conformational shift itself (Fig. 38.5) [118].

Genetic studies in yeast found two homologous genes to be determinants of rapamycin-toxicity and as such were

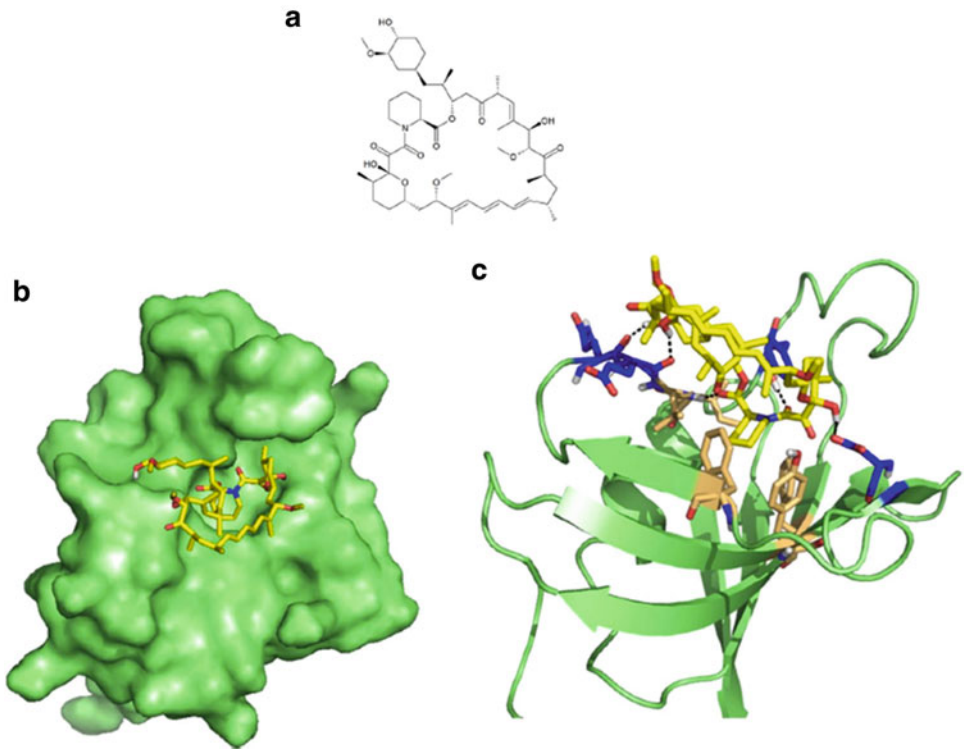

Fig. 38.5 Rapamycin and its association with FKBP. (**a**) Molecular structure of rapamycin. (**b**) Surface representation of rapamycin (*yellow*) bound to FKBP (*green*) at a hydrophobic pocket. (**c**) Key interacting residues of FKBP involved in hydrophobic interactions (*beige*) and hydrogen bonds (*blue*) indicated with *black dashed lines*. PBD accession 1FKB.

called targets of rapamycin (TOR1 and TOR2) [119]. Soon after, several reports identified a mammalian homologue of the proteins present in complex with FKBP that was dependent on the presence of rapamycin [120–122]. Furthermore, this mammalian target of rapamycin (mTOR) was required for the G1-arrest induced by rapamycin, which had been widely reported [110, 115, 123–126]. Rapamycin inhibits the function of the Akt-substrate mTOR [127–129], a serine/threonine kinase that phosphorylates $p70^{S6K}$, which mediates growth factor signaling in response to cytokines such as interleukin-2 [125, 130–132]. mTOR was also found to impact EIF4E, a protein that inhibits translation by binding to the 5′ end of mRNA [133–136]. In the absence of rapamycin, mTOR can associated with adaptor proteins rictor or raptor to form mTORC1 or mTORC2, respectively. These complexes have different substrate specificity and cause distinct downstream signaling events.

In 1999, the FDA approved rapamycin as an immunosuppressant to prevent graft rejection in combination with cyclosporine A and steroids. However, the properties of rapamycin extend beyond this applicaiton. Phenotypic evaluation of growth inhibition in a particularly rapamycin-sensitive fungus, *Candida albican*, found nucleotide degradation and inhibition of synthesis as a primary mechanism of action in 1979 [137]. Nucleotide synthesis is a target of several clinically effective chemotherapies such as methotrexate and fluorouracil. This observation caught the eye of the National Cancer Institute (NCI). NCI experiments and an independent report found rapamycin to have antitumor activity comparable to that of cyclophosphamide and 5-FU in several solid malignancies and leukemia [138]. Other studies supported anticancer activity of rapamycin B-cell lymphoma [139], small cell lung cancer (SCLC) [140], rhabdomyosarcoma [141], melanoma [142], and pancreatic cancer [143]. Rapamycin was also found to inhibit angiogenesis under hypoxia [144] by causing transcriptional inhibition of VEGF [145], a process detailed later in the discussion of bevacizumab. Furthermore, rapamycin sensitized promyelocytic leukemia [141] and ovarian cancer [146] cell lines to cisplatin-induced apoptosis and inhibited transformation by PI3K or AKT. However, the clinical trial data generated in early phase trials of rapamycin as an immunosuppressant uncovered a poor pharmacokinetic profile [147, 148]. To overcome this problem, a large array of rapamycin analogues were created that are collectively called rapalogues.

Temsirolimus (CCI-779) is one of the first rapalogues and is a water soluble, chemically stable derivative of rapamycin (also called sirolimus) developed by Wyeth Pharmaceuticals. Preclinical studies found temsirolimus to have PTEN-dependent antitumor activity in a number of cancers [149–155] and like rapamycin, bound FK506bp and inhibited phosphorylation of S6K and 4EBP-1 [156, 157]. Phase I evaluation of temsirolimus found reversible mucositis or skin-related toxicity, no immunosuppressive functions, and that the major metabolite of temsirolimus was rapamycin [158]. Another study reported a linear correlation of time to progression and $p70^{S6K}$ kinase activity as measured in peripheral blood mononuclear cells, thus providing a pharmacody-

namic marker [159]. Temsirolimus had similar toxicities and response rates at a dose of 25, 75, and 250 mg in renal cell carcinoma. A multicenter phase III study in renal cell carcinoma (RCC) demonstrated extended overall survival (OS) and PFS in patients relative to interferon A but found no support for the combination of these therapies [160]. In parallel with the publication of this study, temsirolimus became the first FDA-approved cancer therapy to explicitly target mTOR and joined sorafenib and sunitinib for the treatment of advanced RCC. A comparison of temsirolimus with other approved therapies for CML as chosen by the investigator found superiority of temsirolimus in terms of improving PFS and OS [161]. Combinations with anti-angiogenic therapies such as sorafenib, sunitinib, and bevacizumab have yielded additional toxicity and largely no benefit [162–164]. Temsirolimus anticancer activity is also being clinically explored in breast cancer [165], gynecological malignancies [166], multiple myeloma [167], glioma [168–170], small cell lung cancer [171], and neuroendocrine carcinomas.

Everolimus and ridaforolimus are two other rapalogues that are being investigated in clinical trials. Unlike temsirolimus, everolimus retains the immunosuppressive properties of rapamycin and was approved in 2010 for organ rejection prophylaxis. Clinical trials found oral everolimus to be safe at an oral dose of 10 mg/kg [172–175]. A phase III study in metastatic (RCC) patients who had failed sorafenib, sunitinib, or the combination demonstrated an increased PFS with everolimus [176]. This resulted in FDA-approval of everolimus in 2009 for this indication. Based on promising early clinical data, this agent further received accelerated approval in 2010 for subependymal giant-cell astrocytoma patients with tuberous sclerosis who are not eligible for surgery [177]. Everolimus has promising preliminary efficacy in Hodgkin's lymphoma [178], metastatic gastric cancer [179], refractory NSCLC in combination with docetaxel [180] or gefitinib, and in breast cancer as a monotherapy [181] or in combination with letrozole [182, 183] or trastuzumab [184]. Interestingly, a phase II study with everolimus in refractory CLL reported partial responses along with an unexpected increase in the absolute lymphocytic count [185]. This has important implications for therapeutic sensitization as these cancer cells are likely to be more sensitive intravenous therapies when in circulation rather than in situ, however there is no clinical data to support this. Everolimus along with best supportive care was recently found to double PFS in patients with pancreatic neuroendocrine tumors [186, 187]. Ridaforolimus is in earlier clinical development but has demonstrated some partial responses and acceptable toxicity profiles in as a monotherapy [188–190] and in combination with capecitabine [191] and paclitaxel [192] in solid and hematological malignancies.

These three rapalogues work by virtually the same mechanism of action and have been developed separately by pharmaceutical companies. As the development of these rapalogues has happened in a relatively short time span, one is left wondering if these therapies have the same clinical efficacy. This is a difficulty inherent in the drug development process as clinical trial design dictates combinations with approved therapies. Combined with conflicting private interests, discerning the efficacy and unique roles of competing therapies with a similar mechanism of action is challenging. A recent phase II study in advanced pancreatic cancer attempted to compare temsirolimus and everolimus but toxicity and lack of objective response in any treatment group confounded this comparison [193]. Nevertheless, the discovery and development of rapamycin and rapalogues has extended the life of numerous cancer patients across several malignancies, prevent transplanted rejections, and elucidated a critical cell signaling pathway. At a conceptual level, the rapamycin story highlights the ability of existing therapies to be applied to other medicinal situations, the insight that can be gleaned from mechanistic studies of pharmaceuticals, and the power of medicinal chemistry.

38.2.5 Sorafenib

Raf is a serine/threonine kinase that is the apical member of the MAPK signaling cascade, which mediates a variety of cellular processes such as cell death, proliferation, and differentiation in response to extracellular stimuli. Aberrant Raf is observed in about 30 % of human cancers and correlates with the progression of prostate cancer to androgen insensitivity [194]. This increased signaling can result from alterations in upstream members such as Ras or in one of the three isoforms of Raf1 (A-Raf, B-Raf, and C-Raf). The V600E mutation in B-Raf is seen commonly in melanoma and NSCLC [195]. C-Raf overexpression has been noted in hepatocellular carcinoma [196] and validated in preclinical models as a potent drug target for ovarian cancer [197]. Earlier reports found direct evidence for Raf in determining tumorigenicity and sensitivity to radiation that posed Raf as a drug target [198, 199]. Bayer Pharmaceutical and Onyx Pharmaceutical jointly performed a high-throughput screen for Raf1 inhibitors. The screen found 3-thienyl as a lead compound with a Raf1 IC_{50} of 17 μM and that adding a methyl group at a particular position results in a tenfold decrease in IC_{50}. A follow-up screen with a library of analogues yielded 3-amino-isoxazole with an IC_{50} of 1.2 μM [200]. Substitution of the phenyl group of this compound for a 4-pyridyl moiety lowered the Raf1 IC_{50} to 230 nM as well as increased aqueous solubility. This compound was found to be orally active, inhibit signaling downstream of Ras through MEK and ERK, and inhibit cancer cell growth in vitro and in xenografts [201]. Based on SARs found throughout this process, further chemical modifications were explored and ultimately yielded sorafenib with a Raf1 IC_{50} of 6 nM (Fig. 38.6) [202].

Sorafenib reduces MAPK signaling by inhibiting numerous oncogenic kinases: wild-type and V600E B-Raf, the

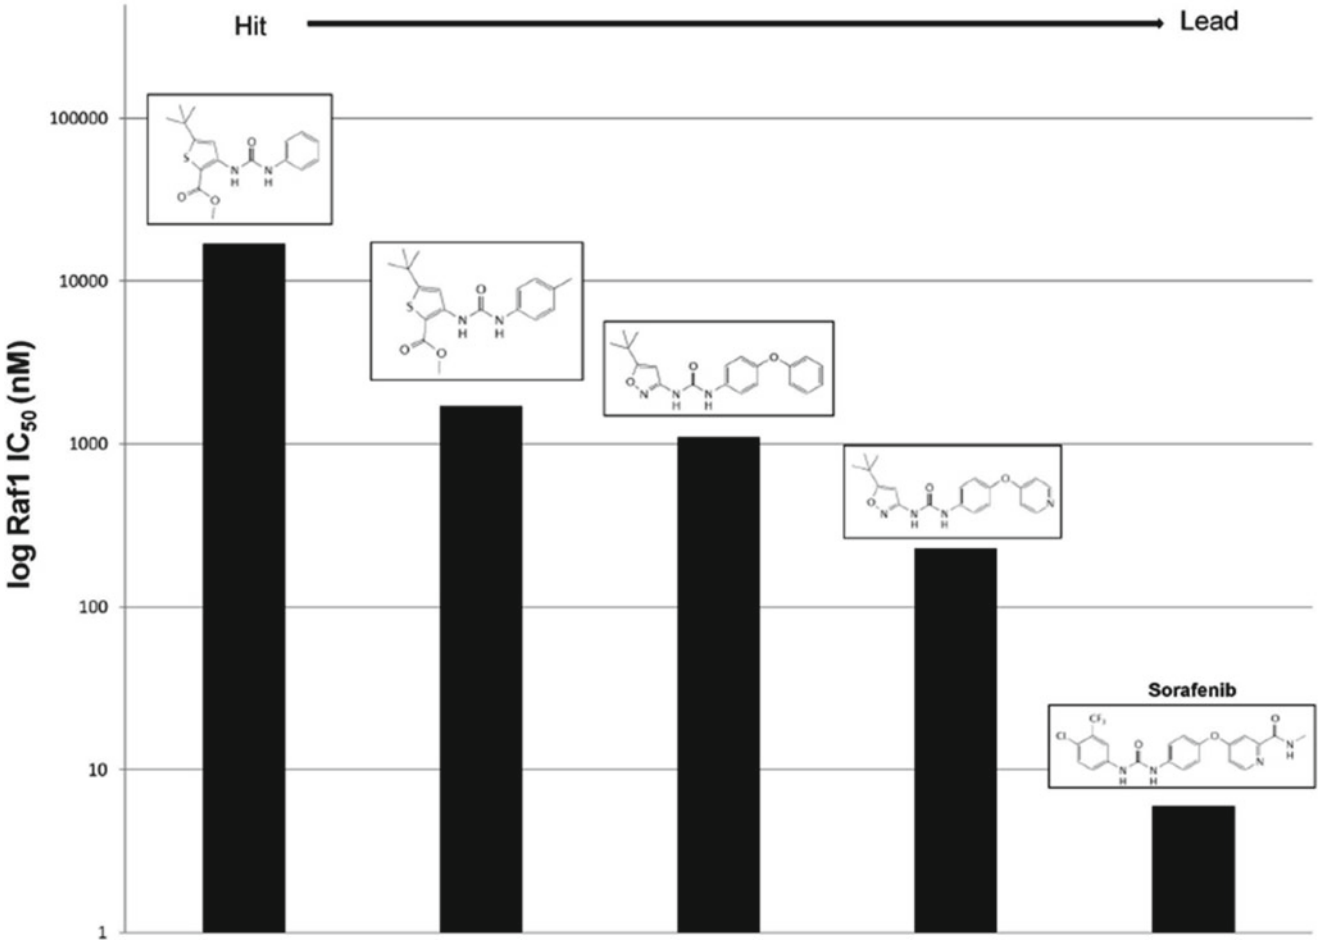

Fig. 38.6 Structure–activity relationships of Raf1 inhibitors explored during hit to lead development of sorafenib.

angiogenic VEGFR family, platelet-derived growth factor receptor-β (PDGFRβ), fibroblast growth factor receptor 1 (FGFR1), the neurotrophin receptor RET, and the cytokine receptors c-Kit and Flt-3 [203, 204]. The growth of several xenografts were inhibited by sorafenib though in a few cases, no change in MAPK signaling was detected but was rationalized by its anti-angiogenic effects of VEGFR inhibition [203]. Crystal structures of wild-type and V600E B-Raf in complex with sorafenib revealed key interactions with residues conserved in c-Raf [205]. The pyridyl ring occupies the ATP-binding pocket while the trifluoromethyl phenyl ring occupies a proximal hydrophobic pocket. Interestingly, the nitrogen of the pyridyl group forms a hydrogen bond with B-Raf and rationalizes the potent increase in activity following substitution of the pyridyl group for the phenyl group. The urea group bridging the rings was found to form a hydrogen bond network with protein, explaining its conservation throughout the analogue search and development. In this case, the structural data rationalized the previously found SARs. However, structural data can conversely be used to guide the exploration of analogue and can also potentiate in silico screen that computationally models the binding of a virtual library of ligands to protein structure. It should be noted that crystal structures do not provide a complete platform for computing binding affinities. While the biophysical details of ligand binding are beyond the scope of this chapter, the affinity of two molecules is determined by the change in enthalpy and entropy. As crystal structures represent a single average molecular conformation across the crystal lattice, they do not reflect the motions of the molecule. Therefore crystal structures cannot provide direct entropic information themselves and by extension do not fully represent binding affinity.

Since sorafenib inhibits a multitude of kinases, preclinical and early clinical trials explored a variety of malignancies. Several phase I trials found dose-dependent responses with an optimal oral dose of 400 mg [206–208] and addition of sorafenib to a variety of standard of care chemotherapy regimens did not increase toxicity profiles [209–214]. Renal cell carcinoma (RCC) is particularly resistant to the majority of chemotherapies and until 1997 was treated with interferon that causes significant toxicities and limited responses. Due to the poor clinical outcomes with standard of care therapies, preclinical efficacy of sorafenib, and an encouraging phase I

result in a metastatic RCC patient, phase II studies were enriched with RCC patients. This study found a strong response in RCC patients [215, 216] and led to a large-scale phase III study that reported a doubled PFS and ~40 % increase in OS [216, 217]. These results gained sorafenib FDA-approval at the end of 2005 for RCC. A subset analysis of this phase III trial found similar clinical benefits regardless of previous cytokine therapy [218] and a follow-up >1 year from treatment initiation found sustained efficacy and a well-tolerated toxicity profile [219]. Liver transplant has traditionally been the only treatment option available for hepatocellular carcinoma. However, many patients become ineligible while waiting for the transplant as a result of disease progression. Human xenografts of liver cancer cell lines showed partial tumor regression from sorafenib and inhibition of ERK and EIF4 [220]. A phase II trial found moderate efficacy and that time to progression correlated with phospho-ERK levels [221]. A multicenter phase III trial demonstrated an unprecedented increased OS in HCC and solicited the FDA to extend the indication of sorafenib to unresectable HCC [222].

Due to the multitargeted nature of sorafenib, it is being explored as a monotherapy and in combination with chemotherapies in a variety of malignancies, though biomarkers are difficult to find. A recent trial in metastatic melanoma found no correlation between clinical responses and BRAF V600E mutation status, cyclin D1, or the proliferation marker Ki-67 [223]. Early evidence was promising with sorafenib, carboplatin, and paclitaxel in melanoma [224] but a recent phase III study in advanced melanoma failed to demonstrate any benefit as second-line therapy [225]. A phase III trial in advanced HCC doubled PFS and OS with sorafenib plus doxorubicin compared to doxorubicin alone [226]. Other promising efficacy of sorafenib has been seen as a neoadjuvant in advanced RCC [227], as a monotherapy [228] or with erlotinib [229] or gefitinib [230] in NSCLC, metastatic RCC with gemcitabine and capectibaine [231]. Sorafenib has had limited to no clinical efficacy in malignant mesothelioma [232], prostate cancer [233, 234], uterine cancer [235, 236], sarcomas [237], advanced and metastatic squamous cell carcinoma [238], with paclitaxel and carboplatin in NSCLC [239, 240], or as a neoadjuvant in advanced ovarian cancer [241], sunitinib-refractory metastatic RCC [242].

38.2.6 Vemurafenib

Melanoma is particularly dependent on signaling through the c-Kit/NRAS/BRAF/MEK/ERK signaling axis. This solicits the clinical application of imatinib to melanoma as it inhibits c-Kit among other targets. However, targeting c-kit has been clinically limited in melanoma as several patients have gene amplification or have oncogenic alterations downstream in this signaling axis. Targeting BRAF in melanoma was explored during the clinical development of sorafenib but ultimately proved ineffective as a monoagent and did not improve OS in combination with carboplatin and paclitaxel in a phase III placebo-controlled trial [225]. Several reasons have been proposed for this failure such as unsaturated MAPK inhibition at the MTD of sorafenib [243] and furthermore, the ability sorafenib to target BRAF in vivo has been challenged [244].

The V600E activating mutation in BRAF is commonly observed in melanoma and results in resistance to therapies targeting upstream molecules. Using structural biology, vemurafenib was developed as a selective inhibitor of $BRAF^{V600E}$ [245, 246], though other targets have been uncovered such as CRAF, ACK1, SRMS, and MAP4K5 [247]. Phase I studies with Vemurafenib reported objective responses [248] that were corroborated in phase II studies and found pERK to be a valid correlative response marker [249]. A large phase III study in therapy-naïve patients ineligible for resection was recently reported an increased PFS and OS relative to dacarbazine [250]. In 2011, the FDA approved vemurafenib for the treatment of unresectable or metastatic melanoma with BRAFV600E.

While verumafenib is clearly a clinical oncology success, patients with wild-type BRAF still need better treatment options, biomarkers are needed to preemptively identify unresponsive patients with melanoma harboring $BRAF^{V600E}$, and many patients relapse despite the improvements in OS [251]. Verumafenib-resistant melanoma cells appear to upregulate PDGFR, NRAS, or MAPK signaling in vitro and in tumors [252, 253]. Preclinical evidence suggests that targeting MEK, PI3K, and mTORC in vemurafenib-refractory patients may be an effective combinatorial strategy [254]. Other preclinical reports have suggested the combination of vemurafenib with metformin [255], immunotherapy [256], or a monoclonal antibody targeting chondroitin sulfate proteoglycan 4 [257].

38.3 Antibodies

While evolution has allowed cells to use small molecules to remain viable, it has allowed organisms to protect themselves from disease through the immune system. Antibodies are large proteins used by the immune system to recognize, respond to, and remember foreign biological material. Antibodies contain a region that is highly specific for a protein target associated with the biological material known as the hypervariable region (Fv), which allows for a high degree of diversity and specificity. The constant region (Fc) of the antibody consists of a particular immunoglobulin that determines the class of antibody and ultimately the type of immune response mounted. Several factors including the

complexity of these large proteins have curtailed our ability to synthesize these highly specific binding molecules. However in 1975, medicine was forever changed by discovery the ability to harness cells to make antibodies [258]. This process consists of immunizing a mouse with the desired antigen, fusing splenic cells from the immunized mice with mouse myeloma cells using Sendai virus, selecting and growing desired clones. This capability has revolutionized modern medicine and biomedical research by offering an unparalleled ability to recognize any given protein with unparalleled specificity. Oncogene pathways mediated by soluble or cell-surface proteins naturally lend themselves as cancer therapeutic targets within the reach of antibodies.

38.3.1 Rituximab

CD20 is a B-cell-specific cell surface protein and as such, is expressed in B-cell cancers such as Non-Hodgkin's lymphoma (NHL). While the function of CD20 remains unclear, it is known that the protein is not secreted or cleaved from the cell surface [259] nor is it internalized following antibody binding [260]. An early study found that administration of murine anti-CD20 in malignant B-cell lymphomas produced a 90 % reduction of circulating malignant cells within four hours in humans [261]. Variable regions of the murine antibody were cloned in to an expression vector to allow for an antibody with human constant regions and would later gain the name rituximab [262]. Rituximab demonstrated a binding affinity for CD20 of 5 nM and resulted in a near complete depletion of peripheral blood cells and a 40–70 % depletion of B-cells in lymph nodes that began recovery around 2 weeks after administration. How does sticking an antibody to a surface molecule that does not have an obvious functional importance potently inhibit cancer? The currently understood answer is that rituximab induces three modes of cell death mediated by immune and cancer cells (Fig. 38.7). Unlike its murine counterpart, this hybridized antibody bound C1Q in vitro and furthermore induced cell lysis in the presence of serum as a source of complement. C1Q is part of a large protein complex that is found in serum and binds IgG or IgM to trigger a series of intra-complex cleavage events that ultimately form a transmembrane complex, called the membrane attack complex, to induce osmotic lysis of the antigen-expressing cell. This process is known as compliment-dependent cytotoxicity (CDC). CDC appears to be a key aspect of the antitumor activity of rituximab as rituximab-resistant patient samples were associated with CD59, which negatively regulates this process [263, 264]. Restoration of compliment has been shown to reverse resistance in small-scale patient studies [265, 266] though this has been challenged in preclinical models [267, 268] and follicular NHL [269].

In addition to CDC, effector cells such as macrophages and natural killer cells (NK) express a family of activating and inhibitory receptors called FcγR that bind the constant region (Fc) of IgG. A study in mice showed that blocking these various receptors mediated anti-CD20 mAb-induced B-cell depletion and was isotype-specific [270]. FcγR bound to IgG present on the surface of a cell can result in phagocytosis by

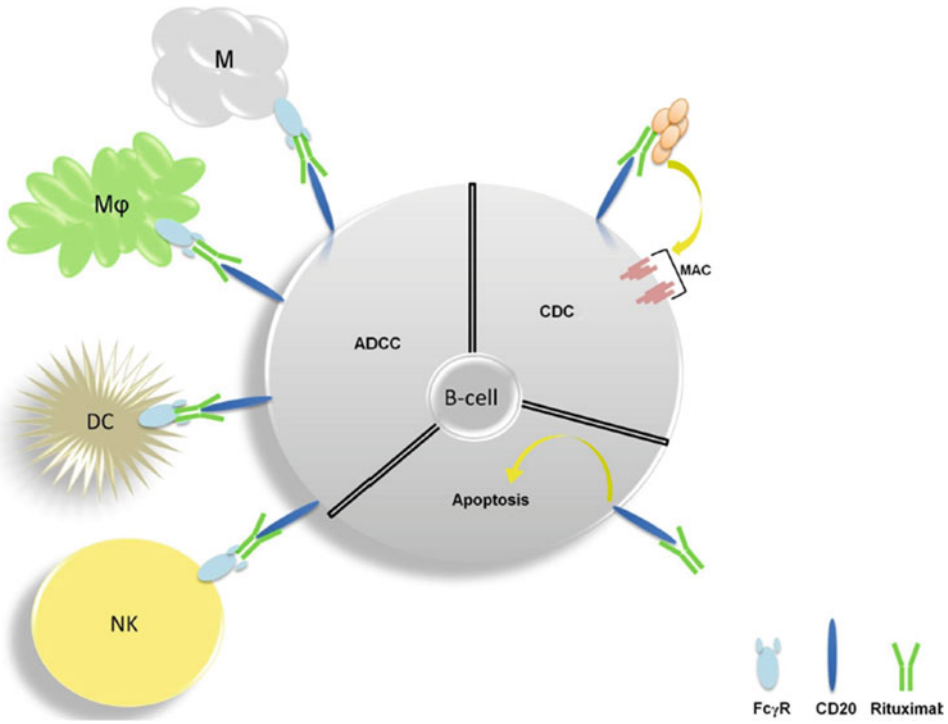

Fig. 38.7 Antitumor mechanisms of rituximab. Antibody-dependent cytotoxicity (ADCC) is mediated by natural killer cells (NK), dendritic cells (DC), macrophages (Mφ), and mast cells (M). Complement-dependent cytoxicity (CDC) involves a series conformational changes and cleavage events upon binding IgM or IgG that ultimately leads to the formation of the membrane attack (MAC) which induces osmotic lysis. Induction of apoptosis directly by CD20 also occurs but is less clear in mechanism.

effector cells but these events are determined by the affinity and balance of activating and inhibitory FcγR molecules [271–273]. Accordingly, a follicular NHL study found significantly higher rituximab responses in patients that harbor the FcγR 158V allotype compared to the 158F allotype, which has a relatively weaker affinity for IgG1 [274]. *Ex vivo* studies demonstrated that rituximab causes NK-mediated cell lysis [275–277] in a dose-dependent manner that was determined by the FcγR allotype [275]. There is also evidence that CD20 has direct effects. Early studies found that antibodies against CD20 significantly mediated RNA synthesis and cell cycle progression [278–280]. More recent evidence has found that cross-linking CD20 with antibodies in some, but not all, B-cell lines causes caspase-mediated, Bcl-2-independent apoptosis, and effects the tyrosine kinases Src, Jnk, and p38 [281–284]. The contribution of these different mechanisms appears to be highly context dependent and is likely to be a dynamic process varying between patients or even within a single patient.

Early clinical data found rituximab to have an average half-life of 18.5 days [285] and similar efficacy and favorable toxicity in relapsed NHL patients relative to CHOP chemotherapy (cyclophosphamide, doxorubicin, vincristine and prednisone) [285–289]. A small-scale study of rituximab found antitumor activity concentrated in the follicular subtype of NHL, though the population size prevented any significant conclusion [290]. Other studies corroborated the significant monotherapy efficacy of rituximab in follicular lymphoma [291, 292]. Adding rituximab to chemotherapy yielded an additive benefit and did not augment the toxicity of standard chemotherapy for NHL [293, 294]. Furthermore, polymerase chain reaction (PCR) of NHL patients with follicular histology treated with this combination showed a depletion of the chromosome 14 and 18 translocation often associated with follicular NHL [295, 296]. Another study found the disappearance of this translocation a year after a 4-week course of rituximab [292]. This translocation induces a sustained transcriptional upregulation of Bcl-2, a protein that prevents mitochondria-mediated apoptosis carried out by many tumor suppressors and inhibited by oncogenes. In 1996, rituximab became the first antibody approved by the FDA as a cancer therapy and was indicated for relapsed or refractory low-grade or follicular, $CD20^+$, B-cell NHL. Three phase III studies (E4494, GELA, and MiNT) that were highly enriched in therapy-naïve, large diffuse cell NHL patients found a significant increase in OS at a 2 year follow-up with the addition of rituximab to CHOP or other anthracycline-based chemotherapies. Analysis of biopsies from E4494 patients found p21 expression as a rituximab-specific, independent predictor of clinical outcome [297].

NHL patients who previously received at least a single 4-week course of rituximab therapy had equivalent efficacy and toxicity after an additional course with a median internal of 14.5 months [298]. The combination of rituximab and interferon yielded no significant additional benefit in the short term in follicular NHL [299]. Today, rituximab is also approved as a first-line therapy for low-grade or follicular cell $CD20^+$ NHL with CHOP and large diffuse B-cell $CD20^+$ NHL with CVP (cyclophosphamide, vincristine, and prednisone). Initial studies of rituximab were conducted with intravenous administration for a 4-week cycle. However, exploration of alternative dosing schedules has provided efficacy in small lymphocytic lymphoma [300] (SLL) and chronic lymphocytic leukemia (CLL) patients [300, 301].

The addition of rituximab to fludarabine and cyclophosphamide in CLL was found to be safe [302–307] and result in unprecedented clinical responses in CLL patients [305]. A phase III study found that this combination increased the amount of patients without disease progression (65 to 45 %) and overall survival (87 to 83 %) [308], resulting in the extension of its indication to this malignancy in 2010. Shortly after, it was also approved as a maintenance therapy following a response with chemotherapy and rituximab in $CD20^+$ NHL based on phase III evidence of prolonged PFS with 1 weekly dose [309]. Rituximab and the proteasome inhibitor bortezomib have been shown to synergistically induce apoptosis in preclinical cancer models [310, 311] and a phase II supported the combination but noted significant neurological toxicity [312]. Also targeting CD20, the monoclonal antibody ocrelizumab was approved in 2009 for CLL refractory to fludarabine and the anti-CD52 antibody alemtuzumab. Other anti-CD20 antibodies are in clinical development for lymphoma including ocrelizumab, veltuzumab, AME-133V, PRO131921, GA101. As seen with rapamycin, the ongoing elucidation of the mechanism of action of rituximab has strongly augmented our biological understanding within and beyond cancer.

38.3.2 Outcompeting Growth Factors with Cetuximab

A number of recent cancer therapies target the EGFR and its family members by inhibiting the intracellular tyrosine kinase domain. An alternative approach is to inhibit EGFR signaling by blocking the extracellular binding of the growth factor through use of antibodies. Cetuximab was FDA-approved for the first-line treatment of metastatic colorectal cancer in combination with irinotecan in 2004, making it the first monoclonal antibody approved by the FDA for this type of cancer. The discovery of cetuximab started with the observation that antibodies secreted from mouse hybridoma cells that target EGF receptors were able to block EGF-induced signaling events and proliferation [313]. A follow up study found that these antibodies potently inhibited the growth of human cancer cells in a murine xenograft [314]. Further studies of a particularly potent antibody against EGFR, mab

225, found that it competes directly with EGF-binding [315], is internalized after two hours in cells [316], blocks EGFR autophosphorylation, induces G1 cell cycle arrest by $p27^{KIP1}$ induction [317–319], induces caspase-8-mediated apoptosis [320], and preferentially accumulate in EGFR-expressing tumors [321]. The latter was found using a radiolabeled form of the antibody that was subsequently used for the first clinical trial of mab 225. This trial found mab 225 to be safe in squamous cell lung carcinoma patients and profiled the overall and liver drug uptake, serum clearance, and whole-body clearance as monitored radiographically [322]. Noninvasive molecular imaging of drugs and therapeutic targets remains an active area of research and informs on the distribution, concentration, and kinetics of therapies, their targets, and/or therapeutic response markers in their clinical setting.

As with rituximab, mab 225 was engineered into a chimeric human/mouse antibody. This process retains residues in the binding region (F_v) of the antibody from the mouse and replaces other residues not specific for the antigen (F_c) with related human residues. This substitution in the F_c region reduces side effects resulting from immune responses to foreign, e.g. mouse, immunoglobulins. The mab 225 chimeric antibody, called cetuximab and marketed as Erbitux, was used for further studies and clinical trials. An early phase II trial with cetuximab in combination with irinotecan, a topoisomerase I inhibitor, demonstrated objective responses in EGFR-expressing solid cancers that had become resistant to first-line therapy consisting of leucovorin, 5-fluorouracil (5-FU), and irinotecan [323]. Combining cetuximab with this treatment regimen also proved effective in a first-line therapy setting [324–326] and moderate efficacy as a monotherapy [327–330]. Safety and efficacy was reported with cetuximab in FOLFOX6 [331, 332] and FOLFOX4 [333–335] treatment regimens which consist of leucovorin, 5-FU, and oxaliplatin. A phase III trial also found cetuximab to be effective as a monotherapy and in combination with irinotecan in irinotecan-refractory, $EGFR^+$ colorectal cancer patients [329]. Based on the rational design and specificity of cetuximab, most of these clinical trials exclusively included patients that had EGFR-expressing tumors as determined by immunohistochemical assays. Interestingly, the intensity of EGFR express did not correlate to cetuximab clinical response and another trial has shown responses in $EGFR^-$ colorectal cancer patients [336]. This unexpected finding underscores the complex nature of therapeutic responses in the clinic and the principle that while rational design has well-evidenced benefits, it only allows for hypotheses that ultimately must be tested.

However, the notion that certain patients will respond better than other patients based on certain characteristics is gaining importance in clinical trial design and interpretation. As required by the drug development process, testing therapies in large-scale clinical trials results in considerable patient diversity. Imagine a clinical trial is conducted to examine the efficacy of a new cancer therapy in 1000 patients where 500 patients receive FOLFOX4 and 500 patients receive FOLFOX4 plus the new therapy. The results show no benefit by clinical response or overall survival. However, let us say that ten patients within this group showed a clinical response and improved overall survival due to a unique genetic characteristic. These patients comprise 2 % of the investigational therapy population and therefore will not impact response parameters with any level of statistical significance. Redesigning the clinical trial to include patients that harbor this response-determining characteristic may now show a strong therapeutic benefit otherwise concluded as ineffective. The obvious challenge in patient stratification in clinical trial design is determining what characteristic(s) confer therapeutic response. Clinical trials are sometimes analyzed retrospectively to find such biomarkers. Some of biomarkers have even been added as stipulations for FDA-approved cancer therapies, cetuximab being no exception.

Two years after FDA approval in 2004, a study found that among downstream targets of EGFR signaling, particular KRAS mutations were significantly associated with lack of response to cetuximab [337]. Other cetuximab trials also found KRAS to be a strong predictor of cetuximab response [330, 338, 339], which led ImClone, the company marketing cetuximab, to petition the FDA to add WT KRAS as a requisite for cetuximab treatment [340]. In 2009, the FDA updated the indications and usage label of cetuximab in colorectal cancer to include that cetuximab is not recommended for patients harboring KRAS mutations in codon 12 or 13.

38.3.3 Bevacizumab

Cell division is an active energy-dependent process and therefore cancer cells must gain alterations that provide more energy to allow for proliferation. While several mechanisms of harvesting intracellular energy are available, cellular respiration is a mainstay that relies primarily on oxygen. The oxygen source for cells is the blood stream and perhaps it is unsurprising that generation of new blood vessels to supply additional oxygen is seen in tumors. A number of pathways and proteins mediate this process of generating new blood vessels in for tumors, particularly the vascular endothelial growth factor (VEGF) family. VEGF is transcriptionally upregulated in a variety of solid tumors particularly in hypoxic regions due to stabilization of the transcription factor HIF1α that is stabilized under hypoxia. VEGF has four family members, VEGF-A being the prototypical member and itself has four isoforms as a result of alternative splicing which determines its localization and binding properties. Soluble VEGF can bind to VEGF receptors (VEGFR1, VEGF-R2) and its coreceptors (NRP-1,NRP-2) that are

expressed on the surface of endothelial cells. Secretion of VEGF ultimately causes the formation of new blood vessels by endothelial cell recruitment and proliferation. Due to the involvement of VEGF in several disease and disorders such as cancer and macular degeneration, antibodies designed to bind VEGF and thereby prevent cognate receptor binding were generated and first described in 1992 [341]. A follow up study found that one of these mouse monoclonal antibodies, A4.6.1, had potent antitumor activity in vivo but not in vitro [342]. Interestingly, xenografts of human cancer cells in mice found that introducing soluble VEGF receptors that bind both human and mouse VEGF was superior to a receptor binding only the human or mouse VEGF [343, 344]. Together, these findings indicate that both the tumor and other cells in the tumor microenvironment induce participate in generating a new vasculature system through VEGF. Over the last decade, the tumor microenvironment has increasingly garnered attention as a dynamic and strong influence on aspects of tumor biology including therapeutic response, growth rates, and metastasis through a variety of mechanisms.

Due to the potent antitumor activity of the A4.6.1 antibody, a humanized form of the antibody was generated using site-directed mutagenesis of the variable region of a human antibody to that of the murine A4.6.1 while maintaining a similar binding affinity for VEGF [345]. This humanized version of A4.6.1, known as bevacizumab, is specific for all isoforms of VEGF-A and its cleaved products that result from extracellular proteins such as matrix metalloprotease-9 (MMP9) present in the tumor microenvironment. A crystal structure of the antigen-specific fragment of bevacizumab bound to VEGF identified a critical residue for binding and specificity (Fig. 38.8) [346]. Bevacizumab was evaluated for safety in cynomolgus monkeys due to the complete conservation of VEGF isoforms between humans and monkeys [347]. After several weeks of administration at doses up to 50 mg/kg, adverse effects on ocular, ovarian, and uterine angiogenesis-dependent processes were evident but were dose-dependent and reversible. A phase I clinical trial found no additional toxicity associated with adding bevacizumab to various chemotherapies and a terminal half-life of 2–3 weeks [348, 349]. The following year, several phase II trials were conducted in a variety of solid tumors [350–354]. Particularly encouraging results were found in RCC as a first-line-therapy and metastatic colorectal cancer in combination with standard chemotherapy. A phase III trial in metastatic colorectal cancer with bevacizumab plus standard chemotherapy increased overall survival, progression-free survival, and objective response rate [355].

The addition of bevacizumab to a paclitaxel-carboplatin treatment regimen increased median survival and PFS but also increased treatment-related deaths, including pulmonary hemorrhage [356]. Based on the significant improvement in OS, bevacizumab in combination with carboplatin and paclitaxel was approved for first-line therapy in unresectable, locally advanced, recurrent, or metastatic NSCLC. Bevacizumab has now been approved for Her2-negative breast cancer, metastatic RCC, NSCLC, glioblastoma, and metastatic colorectal cancer. However, bevacizumab seems continually surrounded by controversy from a variety of perspectives including clinical, economic, and ethical issues. A highly debated meta-analysis of 15 clinical trials with bevacizumab found a significant increase in venous thrombosis [357–361]. A separate analysis also

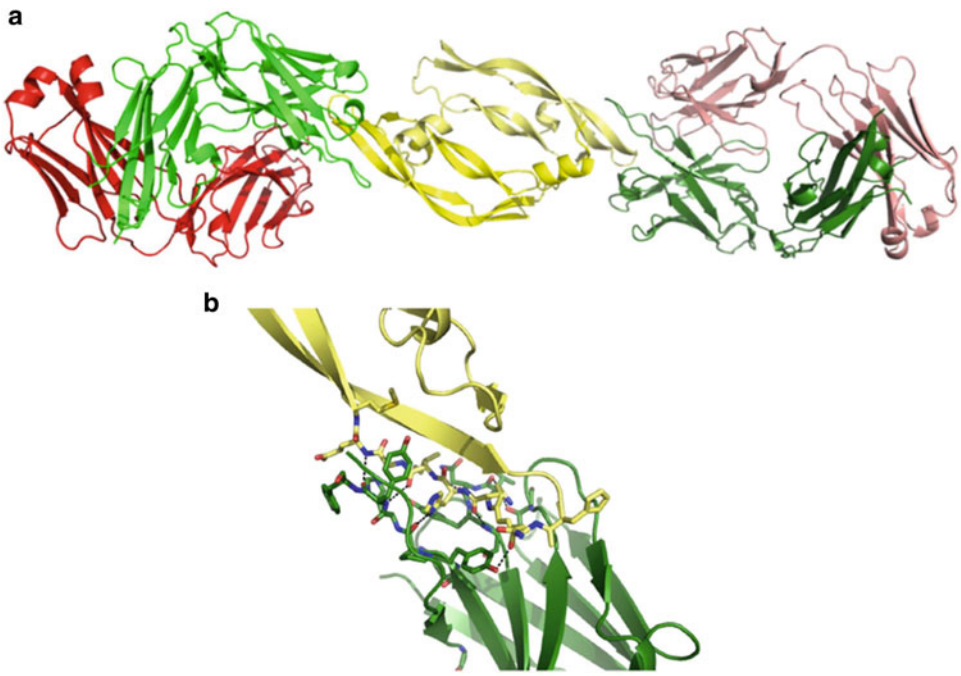

Fig. 38.8 Binding interface of bevacizumab Fab and VEGF. (**a**) Symmetric assembly of VEGF dimmers and Fab fragments of bevacizumab. There are two monomers of VEGF in the center (*light* and *dark yellow*) along with four flanking monomers of bevacizumab. (**b**) Binding interfaces of bevacizumab (*light yellow*) and VEGF (*green*) with interacting residues displayed and hydrogen bonds represented as *dashed lines*. PDB accession 1BJ1.

found an increased risk of high-grade bleeding [362]. At the end of 2010, the FDA decided to revoke its approval for bevacizumab in metastatic breast cancer based on the results of three large clinical trials (E2100 [363], AVADO, and RIBBON1). These trials found that while PFS was prolonged, this magnitude was variable among trials and life-threatening adverse events were increased without any change in OS. On the same day, the European Medicines Association decided to maintain its approval in metastatic breast cancer but only in combination with paclitaxel based on the same clinical trials.

Bevacizumab was granted accelerated approval in metastatic breast cancer based on promising data indicating prolonged PFS but was never shown to increase OS. Traditionally, OS has been the key parameter used to decide whether or not a new therapy receives FDA approval. This brings up difficult questions. Will the therapy provide a net benefit to the patient? How do you quantify this? These answers will be unique for every patient as each has a unique situation that determines how benefit is defined. Obviously, most patients want to live longer but quality of life is also a consideration, which raises yet another patient-specific question: what is quality of life? Clinically, fewer adverse events and prolonged PFS and OS are quantifiable parameters that may act as a partial surrogate definition but this consideration is more complex. For bevacizumab, even this incomplete surrogate definition is unclear as both adverse events and prolonged PFS have been reported in multiple large-scale clinical trials and the magnitudes of these are highly variable among these trials. These discrepancies and lack of improvement in OS have led to a range of decisions from removal to full approval by medical agencies across the globe. The U.K. National Institute of Health and Clinical Excellence (NICE) denied the approval of bevacizumab for metastatic breast cancer, citing no evidence in improvement of survival or quality of life.

One less obvious consideration of a therapy like bevacizumab is the possibility of its use as a neoadjuvant, i.e. shrinking tumors to a size where resection is then possibility. This type of consideration is difficult to evaluate in early clinical trials typically compare an investigational therapy to other therapies in patients where such data would be excluded. Proper examination of this nuance and its effect on OS is warranted in this case. In summary, bevacizumab significantly extends PFS to varying degrees in several solid cancers, may shrink tumors to allow for resection, does not increase OS, and significantly increases adverse events. Cost is the elephant in the room. The cost of bevacizumab treatment varies by country, about $90,000 per year in United States [364]. In addition to rejecting bevacizumab for metastatic breast cancer, NICE has also denied its approval in metastatic colorectal cancer and RCC. Cost was clearly an issue in renal cell cancer, as the benefits of bevacizumab with interferon was similar to sunitinib, a multi-kinase inhibitor already approved for RCC and available at a much lower cost. The various agencies that make the approval decisions on these therapies explain their decisions on the grounds of clinical parameters but patient and social burdens of treatment cost is clearly an underlying influence. Off-label explorations, more clinical trials, and altered clinical trial design are likely to yield more information on the utility of bevacizumab. Nevertheless, this controversial therapy highlights difficult questions lurking in the background of the clinical management of cancer: How do we determine quality of life? Should we consider costs in approval decision? What price is too high for a given therapeutic benefit? How do you weigh concomitant risks and benefits?

38.3.4 Ipilimumab

The immune surveillance of cancer is an endogenous mechanism of tumor suppression that is lost during cancer progression. Inactivating the RAG-2 gene, which is intimately involved in recombination events required for the activation and specificity of immune responses, renders mice more susceptible to carcinogenesis [365]. T-cells are part of the adaptive immune system that modulates the immune response to antigen threat. The immune escape of cancer may occur by multiple mechanisms such as altering proteins involved in antigen presentation or enriching for regulatory T-cells that secrete immune-inhibitory cytokines such as IL-10 [366]. Regulatory T-cells have other mechanisms of immune suppression such as elevated expression of cytotoxic T-lymphocyte-associated antigen 4 (CTLA4) [367]. CTLA4 is an inducible cell surface receptor that binds CD80 and CD86, which are expressed on the surface of antigen-presenting cells and function in concert to activate naive T-cells through CD28. CD28 is a costimulatory receptor expressed on naïve T-cells that cooperatively acts with CD4 as part of the major histocompatibility complex to activate T-cells in response to antigen. Thus, CTLA4 plays a key function in regulatory T-cells by inhibiting T-cell activation as an inhibitory receptor for ligands that are essential for T-cell activation. Accordingly, blocking CTLA4 with antibodies in mice reduces T-cell response and increased tolerability to immunogenic tumors [368].

Ipilimumab is a fully human antibody developed by Medarex Inc. that targets CTLA4. Cynomolgus monkey studies found that ipilimumab induces a humoral response without autoimmunity [369]. Early human studies with ipilimumab in melanoma and ovarian cancer reported tumor necrosis and lymphocyte infiltration in ipilimumab-responsive tumors, though several patients experienced grade III/IV adverse events and some developed T-cell reactivity to normal melanocytes [370, 371]. Autoimmunity was noted in other clinical studies with ipilimumab but was found to correlative with

response [372]. Enterocolitis was the most frequent adverse event, suggesting that CTLA-4 plays a critical role in protection from immune-mediated enterocolitis [373]. Similar efficacy and toxicity events were seen in metastatic RCC [374]. The investigation of single-nucleotide polymorphisms (SNPs) in the CTLA4 gene amongst ipilimumab-treated melanoma patients revealed a response-associated and nonresponse-associated haplotype comprised of seven single-nucleotides in the CTLA4 gene.

A phase II study of ipilimumab in previously treated melanoma reported that 30 % of patients were alive at 2 years in the highest dose cohort of 10 mg/kg [375]. Another phase II study in melanoma evaluated the safety and efficacy of ipilimumab at 3 mg/kg in combination with dacarbazine, noting a preliminary increase in objective response rate with the combination. The pivotal phase III study compared ipilimumab, the gp100 peptide vaccine, and the combination [376]. The overall survival as 10.1 months in the combination cohort, 10.0 months in the ipilimumab alone cohort, and 6.4 months in the gp100 alone cohort. This study corroborated survival adverse event observations noted in previous trials and was revered as the first trial to ever show survival benefit in metastatic melanoma. Another phase III study measured the efficacy of adding ipilimumab (10 mg/kg) to dacarbazine as a first-in-line therapy [377]. Adding ipilimumab to dacarbazine increased the overall survival from 36 to 47 %, though adverse events were increased by the combination.

Based on these phase III trials, the FDA recently approved ipilimumab for the treatment of unresectable or metastatic melanoma at 3 mg/kg every 3 weeks for four doses. Ipilimumab is a first-in-class cancer therapy that reactivates the adaptive immune system to restore antitumor immunity and provides unprecedented patient benefit in melanoma. The clinical efficacy and toxicity of ipilimumab highlights the potential benefits and dangers of immunotherapy as it clinically emerge as a valid new modality of cancer treatment. Despite frequent and severe adverse events associated with ipilimumab, it has been approved based on its unparalleled efficacy in a clinical situation that desperately needed better treatment options. Future trials with ipilimumab are exploring other malignancies and the combination of ipilimumab with other approved agents including chemotherapy and the recently approved vemurafenib.

38.3.5 Lexatumumab

Cell death is a very tightly controlled process that may be initiated by various inputs inside and outside of the cell. TNF-related apoptosis-inducing ligand (TRAIL) is an endogenous mammalian protein utilized by the immune system in the immune surveillance of cancer to potently induce apoptosis in cancer cells while exerting little toxicity to normal cells [378]. TRAIL binds four transmembrane receptors in humans at similar affinities that results in a homotrimeric receptor–ligand complex [379]. These receptors include two pro-apoptotic death receptors, DR4 and DR5, and two decoy receptors, DcR1 and DcR2. The ratio of decoy receptors to death receptors along with mediators of downstream signaling events are thought to determine TRAIL sensitivity and be utilized by normal cells to afford protection from TRAIL-mediated apoptosis. The two decoy receptors compete for TRAIL binding with the death receptors at similar binding affinities.

TRAIL-induced trimerization of the death receptors colocalizes their intracellular death domains, which recruit Fas-associated death domain (FADD) and procaspase-8, forming death inducing signaling complex (DISC). At the DISC, procaspase-8 is activated by autocatalytic cleavage to form caspase-8 which can cleave effector caspase-3, caspase-6, and caspase-7 to induce apoptosis by the extrinsic death pathway. Alternatively, caspase-8 can initiate the intrinsic death pathway by cleaving Bid to tBid, which primarily interacts with Bax and Bak at the mitochondrial membrane. This interaction induces oligomerization of Bax and Bak to promote cytochrome c release. In the cytosol, cytochrome c binds to apoptotic peptidase activating factor 1 (Apaf-1) and caspase-9 to form the apoptosome, which initiates the caspase cascade. While TRAIL directly targets death receptors that generally play a tumor suppressor role, several oncoproteins mediate this process and serve as potent resistance mechanisms. One of the most striking examples is Mcl-1, an anti-apoptotic member of the Bcl-2 family that interacts with pro-apoptotic family members such as Bax to inhibit mitochondrial-mediated apoptosis. Notably, this resistance mechanism can be overcome by combining TRAIL with sorafenib [380].

The ability of TRAIL to selectively induce apoptosis in tumors cell has led to the clinical trials with recombinant TRAIL. However, TRAIL has a short serum half-life and cytotoxic resistance can result from elevated decoy receptor expression. As a result, TRAIL-agonist antibodies targeting either of two pro-apoptotic death receptors were created and are currently in clinical trials [381]. Lexatumumab is one of the most developed DR5 agonist antibodies. A phase I study with lexatumumab in previously treated advanced solid tumors reported a MTD of 10 mg/kg when given once every 21 days, a second-phase serum half-life of ~16 days, and stable disease in approximately a third of the treated patients [382]. Another phase I study found lexatumumab to be safe at 10 mg/kg once every 14 days [383].

Several preclinical studies have suggested the use of lexatumumab in combination with other therapies to increase efficacy such as radiation [384], paclitaxel [385], bortezomib [386–388], HDAC inhibitors [389], doxorubicin [390], and cisplatin [391]. Phase Ib studies evaluated lexatumumab in

combination with gemcitabine, pemetrexed, doxorubicin, or FOLFIRI [392]. Severe adverse events potentially attributable to lexatumumab included anemia, fatigue, and dehydration. Tumor regression was noted in patient cohorts receiving the combination of lexatumumab and doxorubicin or FOLFIRI. Numerous other DR5-agonst antibodies including TRA-8, LBY135, Apomab, and Conatumumab and the DR4-agonist mapatumumab are also currently in clinical trials.

38.3.6 Custom Cures

We still have not won the war on cancer. However, we have greatly expanded our understanding and gained some highly effective therapies in the course of battle. Cancer was once understood as a simple clonal expansion of a cell that gained a growth advantage by a stepwise loss or gain of function of a few critical genes. This previously linear pathway of carcinogenesis is now a multinodal, interconnected network of events and we have begun to appreciate the immense heterogeneity of tumors and the dynamic parameters that govern their biology and therapeutic response. So how much has all of this research investment helped cancer patients? Clearly some types of cancer have benefited from new targeted agents such as NHL and breast cancer. Chemotherapy, radiation, and surgery remain the cornerstones of treatment regimens in many malignancies and none of these were developed with a molecular understanding of their mechanism of action. Serendipity has played a key role in the discovery of many cancer therapies still used today. Nevertheless, it has been our hypotheses and observations built upon our prior knowledge base that has guided the application of these serendipitous discoveries. The discovery of nitrogen mustards was certainly not found in a quest to cure cancer but it was applied to cancer by a hypothesis generated from the current understanding of cancer. It is the application of our knowledge to what is right under our nose that can yield new solutions, quite literally in the case of rapamycin. The more we understand how cancer works, the better we understand what we are looking for and how we can use the tools we already have.

Oncogenes, tumor suppressors, epigenetics, immunology, the tumor microenvironment, and several other factors play critical roles in tumor biology. Considering this multifactorial and complex nature of cancer and the level of effort put forth throughout history to cure it, it is likely that there will be no magic bullet that cures cancer. The future of cancer therapy lies in continued drug discovery, explorations of multimodal and combinatorial therapy, improved agent targeting, and personalized medicine. Combinations of existing therapies can yield antagonistic to synergistic responses in the clinic but is often difficult to interpret due to the heterogeneity of patient responses. Interpretation of inter-patient and intra-patient responses will also play a critical role in the future of cancer therapy and could benefit from the use of biomarkers and molecular imaging. It is important that we understand why a therapy fails in a certain situation so that successful situations can be clearly identified, future failures may be avoided, and other successful treatment options can be discovered.

Therapeutic Agents That Inhibit Angiogenesis

39

Francesco Torino, Roberta Sarmiento, Raffaelle Longo, and Giampietro Gasparini

39.1 Introduction

Angiogenesis is a complex multistep process leading to the formation of new blood vessels from the existing vascular network, tightly regulated by pro-angiogenic and antiangiogenic growth factors. Several potential pathways for tumor-induced angiogenesis have been proposed: (1) secretion by tumor cells of endothelial growth factors which may stimulate tyrosine kinase activities in endothelial cells (ECs), being vascular endothelial growth factor (VEGF) the most specific and potent pro-angiogenic agent; (2) downregulation of naturally occurring inhibitors of angiogenesis; (3) circulating CD34-positive EC precursors may contribute to vasculogenesis, by presently unknown mechanisms mainly involving genetic regulations.

Targeting the molecular pathways involved in tumor progression by biologically designed treatments is a new therapeutic paradigm aimed to reach cancer growth control. Inhibition of angiogenesis presents certain advantages on conventional therapies, such as the direct accessibility from the circulation, the potential low rate of drug resistance and the favorable toxicologic profile.

A recently proposed classification of antiangiogenic agents is based on their mechanisms of action, and include three categories: (1) direct antiangiogenic drugs acting by targeting the endothelial cells and their functions involved in angiogenesis (proliferation, migration, formation of new vessels); (2) indirect antiangiogenic drugs that inhibit the production of angiogenic factors by tumor and microenvironment cells, and/or interfere with extracellular processes; (3) mixed antiangiogenic drugs that may be able to interfere with both endothelial and tumor cells [1].

A functional classification, based on the potential targets for inhibition of angiogenesis, includes drugs that are directed towards activated endothelial cells, pericytes, hypoxia pathways, and nitric oxide [2].

- Endogenous antiangiogenic agents such as angiostatin, endostatin, caplostatin, and thrombospondin-1 (TSP-1) selectively block the proliferation and migration of intratumoral vascular endothelium and induce prolonged tumor dormancy in several experimental models [2]. In 2005, rh-endostatin was approved in China for the treatment of advanced non-small-cell lung cancer (NSCLC) based on the positive results of the phase III trial by Sun et al. [3]. Moreover, the recent identification and characterization of the endothelial progenitor cell (EPC) and its capability to migrate from bone marrow into circulation and then into other tissues where it stimulates angiogenesis may also open new selective anti-EPC therapeutic strategies [4–6].
- Pericytes are mural cells differentiated from pools of c-kit+sca-1+VEGFR-1+ perivascular progenitor cells mobilized from bone marrow in response to the platelet derived growth factor (PDGF)-BB. When PDGF is overexpressed, tumor microvasculature is covered by a high number of mural cells and tumor growth is accelerated. Drugs targeting PDGFR-β inhibit the recruitment of pericytes, induce dilation of tumor vessels and stimulate endothelial cells to enter apoptosis. The combined block of both VEGFR and PDGFR-β by multitarget tyrosine kinase inhibitors, such as sunitinib, increases the antiangiogenic effect, even in late stage solid tumors [7–10].
- Among angiogenesis promoting molecules identified and purified up to now, VEGF is a key regulator of angiogenesis, overexpressed in the majority of human tumor types. The most advanced in the clinic, among the anti-VEGF inhibitors, are the humanized monoclonal antibody bevacizumab and a number of VEGFRs selective tyrosine kinase inhibitors (Table 39.1). Additional compounds targeting VEGF in clinical development include a VEGF trap and antibodies against VEGFR-2,

Table 39.1 Angiogenesis inhibitors approved for clinical use

Date approved	Drug	Place	Disease
May 2003	Bortezomib	USA (FDA)	Multiple myeloma
December 2003	Thalidomide	Australia	Multiple myeloma
February 2004	Bevacizumab[a]	USA (FDA)	Colorectal cancer
November 2004	Erlotinib	USA (FDA)	Lung cancer
December 2004	Bevacizumab[a]	Switzerland	Colorectal cancer
December 2004	Macugen[a]	USA (FDA)	Macular degeneration
January 2005	Bevacizumab[a]	EMEA	Colorectal cancer
September 2005	Endostatin[a]	China	Lung cancer
December 2005	Sorafenib[a]	USA (FDA)	Kidney cancer
December 2005	Revlimid	USA (FDA)	Myelodysplastic syndrome
January 2006	Sunitinib[a]	USA (FDA)	Gastric (GIST), kidney cancer
June 2006	Lucentis	USA (FDA)	Macular degeneration
October 2006	Bevacizumab[a]	USA (FDA)	Lung cancer

[a]"Pure" antiangiogenic agents

VEGFR-1. Interestingly, anti-VEGF agents not only arrest proliferation and migration of endothelial cells, but also induce regression of existing vessels by inducing apoptosis and by suppressing the mobilization of EPCs from bone marrow [11–13].

- Oxygen limitation is central in regulating angiogenesis, glucose metabolism, survival, and tumor growth [2]. A major key factor is the hypoxia-inducible factor (HIF) which is required transcriptional factor in nutrient stress signaling. HIF is a pleiotropic factor that controls the expression of VEGF-A and angiopoietin-2 [14]. In the nucleus, HIF links the hypoxia-response-elements that control oxygen tension via oxidizing enzymes and hydroxylases. Moreover, HIF also transcriptionally regulates the expression of MET promoter that is a key regulator of invasive growth by driving cell motility and metastasis [2].

Nitric oxide (NO) is a multifunctional gaseous molecule and a highly reactive free radical that regulates several vascular functions, being capable to mediate VEGF and angiopoietin-1-induced angiogenesis in vivo [15]. Inhibition of NO signaling is another potential antiangiogenic therapeutic strategy. A number of compounds interfere with NO production, such as cavtratin, a caveolin-1 derived peptide, L-NNa, and NO-donating nonsteroidal anti-inflammatory drugs (NSAIDs) [16–18].

More than 50 antiangiogenic agents with different mechanisms of action have been discovered up to now. They include tyrosine kinase inhibitors (TKIs), monoclonal antibodies, small molecule inhibitors and transcription inhibitors. Recently, nanobodies have been introduced into the antiangiogenic armamentarium.

39.2 Anti-VEGF Targeted Therapies

39.2.1 Bevacizumab

Bevacizumab is a humanized monoclonal antibody against VEGF. In February 2004, bevacizumab received the Food and Drug Authorization (FDA) approval for first-line therapy of colorectal cancer (CRC) in combination with an IFL-based (irinotecan, fluorouracil and leucovorin) regimen. In CRC, a randomized multicenter study evaluating the clinical benefits of bevacizumab combined with a bolus IFL in front-line treatment of CRC showed an advantage in median duration of overall survival, median duration of progression-free survival (PFS), response rate (RR) and median duration of response [19]. The most significant clinical toxicities reported in bevacizumab-treated patients were thrombosis, hypertension, proteinuria, and bleeding. In addition, gastrointestinal perforation (1.5 %) as well as an increase in diarrhea, leukopenia, and hypertension was also described. Results from the Three Regimens of Eloxatin Evaluation (TREE)-2 trial study in patients with metastatic CRC showed that the addition of bevacizumab to an oxaliplatin/fluorouracil regimen in first-line therapy improves RR and time to progression (TTP) with acceptable tolerability, and no unexpected toxicity [20]. Several other trials studying the clinical benefits of bevacizumab combined with different anti-EGFR agents, such as erlotinib, panitumumab, or cetuximab are ongoing.

The clinical utility of bevacizumab in metastatic RCC was investigated in a randomized phase II trial in which 116 patients with metastatic clear-cell RCC refractory to immunotherapy were randomized to receive placebo, low-dose (3 mg/kg) bevacizumab, or high-dose (10 mg/kg) bevacizumab given intravenously every 2 weeks. Patients treated with bevacizumab experienced a significant prolongation of TTP compared with the placebo group [21]. There were four partial responses (10 % ORR), all in the high-dose bevacizumab arm. There were no life threatening toxicities or deaths attributable to bevacizumab. Common toxicity included hypertension and proteinuria, more commonly seen in the high-dose bevacizumab arm. All side effects were reversible with cessation of therapy. Grade 1 or 2 hemoptysis was observed in two patients receiving bevacizumab and two patients receiving placebo. No thromboembolic events were reported in any arm.

In a double-blind phase II trial comparing bevacizumab plus erlotinib versus bevacizumab plus placebo, data showed that the combination was safe and well tolerated, although adding erlotinib did not improve efficacy [22]. However, PFS of 8.5 months observed in patients treated with bevacizumab [23] appears to be more favorable than what is reported with the use of IFN-α, suggesting a potential clinical benefit of bevacizumab in RCC. Given the promising activity of bevacizumab, several clinical trials investigating

the clinical advantages of bevacizumab with IFN-α2b therapy (CALGB 90206; $n=600$) (Rini = 72) or in addition to erlotinib plus imatinib are currently in progress [24].

The addiction of bevacizumab to carboplatin/paclitaxel regimen caused a higher RR (31.5 % in the high-dose arm versus 18.8 %) and longer median TTP (7.4 months in the high-dose arm versus 4.2 months) than chemotherapy alone in NSCLC patients [25]. Bevacizumab was generally well tolerated. However, severe haemoptysis episodes among patients with squamous cell histology and central tumor mass were observed. Another study evaluated the clinical benefits of bevacizumab with the carboplatin/paclitaxel regimen as first-line therapy in 842 patients with NSCLC. This US cooperative group phase III trial (E4599) reported a higher RR, longer PFS and increased survival in the bevacizumab/chemotherapy arm compared with the chemotherapy-alone arm [26]. In a trial combining bevacizumab with erlotinib in patients with recurrent NSCLC, preliminary data showed a promising antitumor activity, with partial response achieved in 20 % of patients and stable disease in 65 % [27]. The most common adverse events reported ranged from mild-to-moderate and included rash, diarrhea and proteinuria. Bevacizumab in combination with erlotinib is still under investigation in recurrent or refractory NSCLC [28].

A phase II study assessed the combination of bevacizumab plus gemcitabine in 52 patients with stage IV pancreatic cancer [29]. The objective RR was 21 %, the median PFS 5.4 months and the 6-month OS of 77 %. Adverse events included hypertension, thrombosis, and bleeding episodes. The promising efficacy prompted two ongoing trials: the European phase III trial (BO17706) and the US Cooperative Group phase III trial (CALGB 80303), investigating both the therapeutic benefits of bevacizumab when added to gemcitabine alone or with erlotinib.

Zhu et al. reported encouraging results from a phase II study investigating the therapeutic benefits of bevacizumab combined with a gemcitabine and oxaliplatin regimen in patients with advanced hepatocellular carcinoma [30]. Data suggested that this combination was generally well tolerated, with the most common grade 3–4 adverse events being fatigue, transient elevation of transaminases, nausea/vomiting and hypertension. Although no patients achieved a complete response, the overall response rate was 20 % and the rate of PFS at 6 months 48 %.

In a phase III metastatic breast cancer (mBC) trial, the addition of bevacizumab to capecitabine in a cohort of taxane-refractory and-anthracycline-refractory patients failed to show an improvement in PFS and OS [31]. The addition of bevacizumab to a carboplatin/albumin-bound form of paclitaxel and trastuzumab regimen showed promising antitumor activity among patients with HER2-positive mBC [32]. Of nine evaluable patients, eight achieved a major clinical response. The clinical activity of bevacizumab alone or in combination is being examined in ovarian cancer, recurrent cervical cancer, hormone-refractory prostate cancer, refractory or relapsed AML and malignant melanoma, as well as head and neck cancer. Bevacizumab is also being evaluated as adjuvant treatment of CRC in combination with different regimens including FOLFOX4, FOLFOX6, or XELOX (capecitabine/oxaliplatin) in the National Surgical Adjuvant Breast and Bowel Project (NSABP) C08 trial, the AVANT (AVastin adjuvANT) trial, and the Intergroup Rectal Adjuvant trial [33].

39.2.2 HuMV833

HuMV833 is a humanized monoclonal antibody that recognizes VEGF121 and VEGF165 isoforms. Results from a phase I trial showed that HuMV833 was safe and well tolerated in patients with solid tumors [34]. Infusions were well tolerated without any grade 3 or 4 toxicities. The most common adverse events included fatigue/asthenia, nausea, vomiting, gastrointestinal symptoms, and rash. Recently, phase II/III clinical trials of HuMV833 have begun in Europe.

39.2.3 VEGF-Trap

VEGF-Trap is a novel, high-affinity molecule to VEGF molecule, generated as a fusion molecule of the VEGF receptor extracellular domain and the Fc portion of immunoglobulin G1. Data from phase I studies showed the clinical feasibility of these agents, which are currently being investigated in phase II/III trials [35, 36]. In particular, VEGF-Trap R1R2 is a derivative of the soluble form of VEGFR-1, which irreversibly binds to VEGF. This VEGF blocker is a chimeric fusion molecule composed of the second immunoglobulin domain of VEGFR-1 and combined with the third immunoglobulin domain of VEGFR-2 [37]. VEGF-Trap R1R2 was engineered to minimize interactions with the extracellular matrix, maintaining its potent affinity for VEGFR-2. Preclinical studies showed tumor growth inhibition in various models [38, 39]. In a phase I study, VEGF-Trap administered to patients with solid tumors did not induce antibody response with evidence of biological activity [40]. At present, a phase I clinical is investigating the side effects of VEGF-Trap R1R2 in patients with relapsed or refractory advanced solid tumors or non-Hodgkin's lymphoma.

39.3 Anti-VEGF Receptors Targeted Therapies

39.3.1 IMC-1C11

Among VEGF family receptor, the VEGFR 2/kinase-insert-domain-containing receptor (KDR) appear to be significantly upregulated during tumorigenesis. IMC-1C11, a chimeric

monoclonal anti-KDR antibody, blocks the binding of the ligand to the receptor and subsequently inhibits downstream events such as VEGFR and MAPK activation, inhibiting VEGFR-induced endothelial cell proliferation [41]. This agent is presently being examined in a phase I trial in patients with liver metastases from CRC carcinoma. IMC-1C11 appears to be safe and well tolerated, although 7 out of 14 patients experienced detectable levels of antibodies against IMC-1C11 [42]. A fully human anti-VEGFR-2 has been produced as a second-generation agent to be less immunogenic for chronic administration as monotherapy or in combination with chemotherapy or radiotherapy [43].

39.3.2 Sunitinib Malate

Sunitinib is an oral inhibitor of VEGFR-1, VEGFR-2, stem-cell factor receptor (c-KIT), PDGFRα, PDGFRβ, and fetal liver tyrosine kinase receptor 3 (FLT3) [44–46]. A phase I study investigating the biological activity of sunitinib in patients with AML showed that the phosphorylation of FLT-3 was inhibited in 50 % of patients with wild-type FLT-3 and in 100 % of patients with mutated FLT-3. The majority of gastrointestinal stromal tumors (GISTs) harbor mutations in the receptor tyrosine kinase KIT or PDGFR-A and are responsive to imatinib. Unfortunately, tumors develop resistance due to amino acid mutations in the kinase domain of the targeted receptor, thus preventing or weakening the interaction with the inhibitor. In vitro studies have demonstrated that sunitinib potently inhibited various imatinib-resistant KIT variants [47, 48]. In phase I studies sunitinib showed a manageable toxicity and the most common side effects reported were fatigue, hypertension, sore mouth, skin, gastrointestinal and hematological toxicity [49, 50]. Among side effects, an increased incidence of hypothyroidism was reported, related to a reduced drug-induced vascularity of thyroid gland [51]. Sunitinib demonstrated activity in patients affected by NSCLC, neuroendocrine and other tumor types, although most data are available for patients affected by GIST and RCC [52, 53].

The therapeutic advantages of sunitinib were examined as second-line therapy in patients with RCC. RCC is one of the most resistant tumor types, and, cytokines were the only moderately active agents. Two phase II clinical trials evaluated the activity of sunitinib (50 mg daily administered for 4 weeks followed by 2 weeks off) in patients with RCC after failure of previous immunotherapy [54, 55]. In the first study of Motzer et al. ($n=63$) 40 % of partial responses were reported and TTP was 8.7 months. In addition, 27 % of patients demonstrated stable disease lasting more than 3 months. The most common reported adverse event was fatigue (grade 3 in 11 % of patients). Therapeutic activity was confirmed by a further open-label study single-arm clinical trial as second-line treatment of mRCC that had progressed despite previous cytokine therapy. A partial response was observed in 36 of 106 patients (34 %) and the median progression-free survival was 8.3 months. Recently, Motzer et al. compared IFN-α to sunitinib as first line therapy in metastatic RCC in a phase III randomized clinical trial. Sutininib showed a statistically significant higher response rate (31 versus 6 %) and PFS (11 versus 5 months) as compared to IFN-α (HR 0.42; $p<0.001$) [9].

This agent was also investigated in a phase III trial in 312 patients affected by GISTs who progressive after imatinib therapy. The trial was unblinded because a planned interim analysis showed significant better outcome in the sunitinib arm [56]. Median time to tumor progression was significantly longer in the sunitinib group compared to placebo (27.3 versus 6.4 weeks, respectively; HR: 0.33; $p<0.0001$). The confirmed objective response rate was 7 % in the sunitinib group versus 0 % in the placebo group ($p=0.006$). The survival benefit could be underestimated as a result of the cross-over of patients receiving placebo.

Clinical activity of sunitinib is being investigated in NSCLC and preliminary data have shown that stable disease and partial response have been achieved [52]. Adverse events were generally mild-to-moderate and included fatigue, diarrhea and nausea. On the basis of these clinical results, in January 2006, sunitinib was approved by FDA for the treatment of advanced RCC refractory to cytokine therapy and for imatinib-resistant or imatinib-intolerant GIST.

39.3.3 Sorafenib

Sorafenib is an oral inhibitor targeting multiple kinases including VEGFR-2, VEGFR-3, PDGFR, FLT-3, c-KIT, c-Raf1, and B-Raf [57]. In a phase I study sorafenib showed activity in various tumor types and a manageable toxicity profile, both in monotherapy and in association with chemotherapy [58, 59]. Dose limiting toxicity was associated with diarrhea, fatigue, hypertension, skin rash, and hematological toxicity. The dose of 400 mg twice daily was recommended for phase II evaluation, showing interesting antitumoral activity in patients with various types of solid tumors, especially renal cell carcinoma (RCC) [60–63]. Data from a large phase II randomized discontinuation trial of sorafenib in patients with mRCC demonstrated significant disease-stabilizing activity in the arm receiving the active drug compared with placebo group. During the run-in period, 73 out of 202 patients had tumor shrinkage of >25 % and median overall PFS was 29 weeks for the overall population [64]. The most common drug-related adverse effects included rash, hand–foot syndrome, and fatigue. Grade 3/4 drug-related events occurred in 47 % of patients, with the most common being hypertension (24 %), hand–foot syndrome

(13 %), and fatigue (5 %) No patient died from sorafenib-induced toxicity. A subsequent phase III study including 769 patients with advanced or metastatic cytokine-refractory RCC, demonstrated antitumoral activity of sorafenib in this population and significant clinical benefit [65]. Median PFS was indeed 24 weeks in the sorafenib arm versus 12 weeks in the placebo group (HR = 0.44; $p < 0.00001$). Common side effects were diarrhea (33 %), rash (34 %), hand–foot skin reactions (27 %), fatigue (26 %), and hypertension (11 %). Updated results recently reported demonstrated a survival advantages as compared to placebo (median OS of 19.3 versus 15.9 months, respectively. HR = 0.77; $p = 0.015$) [66]. Based of these results sorafenib was approved by FDA for the treatment of advanced or metastatic RCC refractory to cytokine therapy. Feasibility of combination therapy with Interferon-α (IFNα) is under evaluation in phase II trials, as well as direct comparison between these two agents in patients with RCC [67–69]. Additional investigations are underway to better define role of sorafenib in combination with other targeted agents or cytokines in RCC and as adjuvant therapy following a nephrectomy. Ongoing phase III studies are evaluating the activity of sorafenib for treatment of HCC, melanoma, and NSCLC.

39.3.4 PTK-787/ZK-222584

Vatalanib (PTK787/ZK 222584) is a small molecule orally active TKI of all known VEGFRs, PDGFR tyrosine kinases and the c-kit protein tyrosine kinase. In phase I studies the most common side effects reported were fatigue, hypertension, nausea, vomiting, dizziness, and transaminases elevation [70–72]. Dose identified for further examination was 1250 mg daily. In phase II studies vatalanib showed clinical activity in several solid tumors [73–75]. Phase III trials did not show conclusive results in patients affected by mCRC. In fact CONFIRM-1 study, including 1168 patients with mCRC, demonstrated no beneficial effect of adding vatalanib (1250 mg once a day) to chemotherapy (FOLFOX-4) in first line treatment [76]. Adverse events attributable to PTK/ZK were generally reversible and similar to other antiangiogenic agents. In the phase III placebo-controlled CONFIRM-2 study, enrolling 855 patients with mCRC, adding valatinib to the same chemotherapy regimen (FOLFOX-4) in second line of treatment, demonstrated a longer PFS versus chemotherapy alone (5.5 months versus 4.1 months; HR: 0.83; $p = 0.026$). Response rate was similar in the two arms (18.5 % in the PTK/ZK arm versus 17.5 % in the placebo arm) and survival advantage was not reported (OS was 12.1 months in the PTK/ZK arm and 11.8 months in the placebo arm. HR: 0.94; $p = 0.511$) [77]. Recently, a meta-analysis of these two studies was performed, based on the preliminary results from CONFIRM trials that showed a greater clinical benefit and improvement of PFS in patients with high LDH levels. This analysis confirm that the effect of vatalanib in improvement of PFS is strong in high LDH population (HR 0.65, $p < 0.001$), as compared to overall population (HR 0.85, $p = 0.005$) [78].

A report of preliminary results from a phase II clinical trial investigating the therapeutic benefits of PTK-787/ZK-222584 as a single second-line agent for NSCLC showed that disease control was achieved in 58 % of patients [75]. Other clinical trials investigating PTK-787/ZK-222584 in metastatic neuroendocrine tumors and imatinib mesylate-resistant metastatic GIST are currently ongoing [74, 79].

Our group designed a dose finding phase I study with PTK787/ZK in combination with chemotherapy and trastuzumab, involving patients affected by HER-2/*neu* positive mBC who progressed after trastuzumab and anthracycline-based and/or taxane-based chemotherapy for metastatic disease. The schedule of study treatment includes vinorelbine (day 1-8-15, q 28 days, dose ranging from 25 to 30 mg/mq), weekly trastuzumab and daily PTK787/ZK (dose ranging from 500 to 1250 mg). Four dose levels are planned: the primary objective of the present study is to determine the maximum tolerated dose (MTD) and the pharmacokinetics interactions of PTK787/ZK with the cytotoxic agents. The secondary objective of the study is to evaluate the tolerability and the optimal schedule of the schedule.

39.3.5 AMG-706

AMG 706 is an oral small molecule multi-kinase inhibitor with both antiangiogenic and direct antitumor activity that selectively targets VEGF, PDGF, and Kit receptors [80]. It has demonstrated antiangiogenic and antitumor activity. Data from a phase I study presented at the 2005 American Society of Clinical Oncology (ASCO) meeting showed that AMG-706 in patients with advanced solid tumors was safe at doses up to 125 mg/day [81, 82]. Preliminary data were promising, as they indicated vascular changes and stable disease in the majority of patients. Most frequently reported adverse events were hypertension, fatigue, diarrhea, headache, and nausea. AMG-706 is currently undergoing several phase I/II clinical trials alone or in combination with chemotherapy in CRC, GIST, NSCLC and thyroid cancer. Among these studies, a phase I clinical trial evaluating the safety and clinical activity of AMG-706 in thyroid cancer showed that this agent was well tolerated and objective response was achieved in 43 % of patients [83]. AMG-706 is also being investigated in combination with panitumumab, an anti-epidermal growth factor receptor (EGFR) monoclonal antibody, in NSCLC, and preliminary data revealed that this regimen was safe and exhibited clinical activity [84].

39.3.6 ZD-6474 (Zactima, Vandetanib)

ZD6474 is a dual-kinase inhibitor that inhibits VEGFR-2, but also has moderate anti-EGFR activity and RET receptor. In phase I evaluation, ZD6474 was well tolerated at daily dose of 100–300 mg/day and adverse events commonly reported were diarrhea, rash, fatigue and asymptomatic QT-prolongation [85]. Preclinical studies have yielded data consistent with a potent inhibition of the VEGF signaling pathway, suggesting potential use in a broad range of tumors including colon, lung, prostate, breast, and ovarian cancers [86]. However, most clinical data in phase II studies are available in NSCLC. Adding of ZD6474 to carboplatin/paclitaxel in first line chemotherapy is safe and did not significantly increase treatment toxicity. In a phase II randomized study performed by Heymach et al., patients with locally advanced or metastatic NSCLC after failure of first line platinum-based chemotherapy were randomized to receive docetaxel plus ZD6474, either at dose of 100 mg 300 mg, or docetaxel alone. Median PFS was higher in patients receiving the combined therapy (19 versus 17 versus 12 weeks, respectively) [87]. Recently, a double-blind phase II randomized trial compared ZD6474 300 mg with gefitinib 250 mg in 168 advanced previously treated NSCLC patients, with the option of crossover at the time of progression. Preliminary data showed a response rate of 8 % in the ZD6474 arm and 1 % in the gefitinib arm and a statistically significant longer PFS with ZD6474 was reported (11.9 versus 8.1 weeks, respectively; $p=0.011$) [88]. These positive results were not confirmed in BC: in 44 patients refractory to anthracycline/taxane, ZD6474 either at dose of 100 mg or 300 mg did not show clinical activity [89]. ZD6474 displayed also promising evidence of activity in patients with hereditary medullary thyroid carcinoma; in a phase II trial in 15 evaluable patients, three had partial response and ten stable disease [90].

39.3.7 Axitinib (AG-013736)

Axitinib is an oral multitargeted TKI with inhibitory effects against VEGFR-2, VEGFR-3, and PDGFR-β, evaluated in a phase I clinical study among patients with advanced solid tumors, AG-013736 demonstrated clinical activity in RCC, adenoid cystic cancer and NSCLC [91]. Dose-limiting toxicities included hypertension, hemoptysis, and stomatitis [92], manageable with appropriate medication or dose reduction. A phase I study identified maximum tolerated dose of 5 mg twice daily. Rini and colleagues evaluated axitinib in a phase II trial in 52 patients with advanced RCC refractory to one prior cytokine-based therapy. Partial response was reported in 24 patients (46 %) and stable disease in a further 40 %. Median TTP has not been reached after 12- to 18-month follow-up in all patients. Most common serious adverse events (grade 3–4) were diarrhea (8 %), hypertension (15 %), and fatigue (8 %) [93]. Axitinib has been also evaluated in 32 patients with advanced thyroid cancer, refractory to or not suitable candidates for Iodine therapy. Although response assessments are still ongoing, partial response was achieved in three patients [94].

39.3.8 Other Multitargeted TKIs in Clinical Development

GW-786034 is another oral TKI with activity against VEGFR that has demonstrated antitumor and antiangiogenic activity in vitro and in vivo [95]. It is currently undergoing phase II clinical trials on refractory multiple myeloma, soft tissue sarcoma, ovarian cancer, and RCC.

CP-547,632 has shown antitumor and antiangiogenic activity against VEGFR-2 in several preclinical models [96]. This agent is currently in a phase II clinical trial for recurrent or persistent small-volume ovarian cancer.

The agent AEE-788 is a dual family EGFR/ErbB2 and VEGFR TKI [97], showing interesting antitumor activity in various models [98, 99]. In phase I studies AEE788 was generally well tolerated and most of the adverse events were generally mild or moderate diarrhea, asthenia, anorexia, rash, nausea, and vomiting [100–102]. Dose-limiting toxicities were observed at the 500–550 mg dose levels. Enrollment in clinical trials is ongoing.

XL647 is an orally bioavailable small molecule with inhibitory effect on EGFR, HER-2, VEGFR2/KDR and EphB4. In a phase I study XL647 showed a satisfactory toxicity profile. The maximum tolerated dose was established in 4.68 mg/kg orally administered for 5 consecutive days every 2 weeks [103].

CEP-7055 is a novel orally active inhibitor of all three VEGFR kinases with broad preclinical antitumor and antiangiogenic activity [104], now entering a phase I clinical study.

39.3.9 RPI-4610

RPI-4610 belongs to a new class of drug termed chemically stabilized ribozymes, synthesized to target and cleave a specific mRNA sequence. RPI-4610, administered intravenously, targets the VEGFR-1 mRNA [105]. A phase I clinical study in patients with refractory solid tumors showed grade 1/2 infusion reactions as the most common toxicities [106]. A phase II clinical trial is currently investigating the effectiveness of RPI-4610 in patients with metastatic RCC.

39.4 Targeted Therapies Interfering with Metalloproteinases

The involvement of proteolytic activity of metalloproteinases (MMPs) in angiogenesis is well established. The extracellular matrix (ECM) surrounding endothelial cells must be broken down to allow cell migration and proliferation. MMPs belong to a family of proteolytic enzymes that degrade ECM components and contribute through this mechanism to the angiogenic process. Aberrant MMP expression contributes to the invasive growth and spread of a variety of solid malignancies [11, 107, 108]. It has been suggested that the control of MMPs activity through inhibitors has been considered a potential target for anticancer therapy, but clinical trials yielded disappointing results. Incyclinide, an oral MMP inhibitor (MMPI), showed biological activity in AIDS-related Kaposi's sarcoma [109]. The most common adverse events were photosensitivity and rash. BMS-275291, a broad spectrum MMPI, failed to achieve partial or complete tumor responses in patients with advanced or metastatic cancer [110]. The most frequently reported adverse events were joint toxicity, rash, fatigue, headache and nausea. In a recent study evaluating two different doses, this agent demonstrated limited clinical activity in hormone-refractory prostate cancer with bone metastases [111]. Other MMPIs, such as BAY-129566 or BB-2516, have failed to show therapeutic activity in human malignancies despite preclinical antimetastatic and antiangiogenic activity. The reasons for the disappointing results observed with MMPIs in cancer therapy remain unclear. The negative results of MMPIs reported in several studies have definitely raised serious concerns about the opportunity to continue the evaluation of MMPIs as a therapeutic anticancer strategy.

39.5 Targeted Therapies Directly Interfering with Endothelial Cells

Thrombospondin-1 (TSP-1) is a naturally occurring inhibitor of angiogenesis that limits vessel density in normal tissues and curtails tumor growth. ABT-510, a promising new agent, is a TSP-1 analogue. A phase I study in patients with advanced solid malignancies showed a favorable toxicity profile, with the most common toxicities observed being injection-site reactions and fatigue. Stability of disease was observed in a significant number of patients, warranting further clinical trials [112]. A phase II trial testing the clinical benefits of ABT-510 in head and neck cancer is currently underway. An additional avenue being explored is integrin protein, which plays an essential role in cell–cell and cell–matrix adhesion. Integrins are cell surface adhesion molecules coupling the extracellular environment to the cytoskeleton, as well as receptors for transmitting signals important for cell migration, invasion, proliferation and survival. Deregulation of adhesion can lead to pathological processes, including tumor metastasis, either by disrupting the normal anchorage, thereby altering cell movement and regulatory signaling, or by promoting inappropriate adhesion. One member of the integrin family, αvβ3-integrin is overexpressed in tumor cells Supporting evidence for the integrin involvement in tumor angiogenesis was recently reported by Nikolopoulos and colleagues who demonstrated that the subunit of integrin promotes endothelial migration and invasion [113]. Therefore, agents targeting integrins are currently being evaluated as potential therapeutic options to treat tumors. Such agents include abegrin, a monoclonal antibody, and cilengitide (EMD-121974), a cyclic peptide. Both interfere with the αvβ3-integrin and are under investigation in phase I/II studies.

Another antiangiogenic drug tested in human malignancies is thalidomide, although its exact mechanism of action is still unclear. Thalidomide was once notorious for producing severe deformities in the arms and legs of newborn babies whose mothers were given the drug during pregnancy. Off the market for decades, it has recently emerged as a somewhat effective treatment for several cancers. Thalidomide and its immunomodulatory analogues are being investigated in several phase II/III trials for treating various tumors including multiple myeloma, RCC, prostate cancer, and hepatocellular cancer [114]. Finally, endostatin, an endogenous angiogenesis inhibitor, represents an additional target for cancer therapy [115]. Clinical trials evaluating the safety of r-hu endostatin in patients with advanced solid tumors showed that this agent has a good safety profile, but modest antitumor activity [116], with positive results only in NSCLC.

39.6 New Strategies for Antiangiogenic Therapy Combinations

39.6.1 Broad-Spectrum Targeting

Recently Folkman proposed the paradigm to block tumor growth indefinitely by the use of a broad-spectrum single multitarget agent capable simultaneously to interfere with several angiogenesis pathways or, alternatively, by combinations of different highly selective drugs. Two examples of the first strategy are the multitarget tyrosine kinase inhibitors sunitinib and sorafenib.

Examples of the second strategy include the combinations of bevacizumab and anti-EGFR agents taking into account that angiogenesis is linked to other tumor molecular pathways. Preclinical studies demonstrated that interactions between EGFR and VEGF signaling pathways sustained tumor growth and progression. They exert effects

both directly and indirectly on tumor cells, and combining drugs targeting both the targets confer additional clinical benefit. EGFR has been detected in the endothelial cells of tumor vasculature preclinically [117]. Co-expression of EGFR and TGFα has been correlated with increased vascularity in invasive BC [118]. VEGF is also downregulated by EGFR inhibition [119, 120] and a recent study suggests that blockade of VEGF may also inhibit the EGFR autocrine signaling [121].

A number of preclinical studies investigating the antitumor activity of combined anti-EGFR and anti-VEGF agents suggest promising activity [122–126].

Furthermore, VEGF blockade is critical in preventing resistance to EGFR inhibition. The use of agents such as erlotinib and bevacizumab targeting different signaling pathways and affecting different cell types (tumor cell and endothelial cell) may abide by different rules than standard cytotoxic chemotherapy because of the significant cross talk between the pathways in numerous cell types. These encouraging data have led to the initiation of a number of clinical studies evaluating the combination of erlotinib with bevacizumab in a number of tumor types, including phase II trials in RCC [127] and mBC [128] and a phase I study in patients with HNSCC [129].

Herbst et al. [130] evaluated the combination of bevacizumab and erlotinib in 40 patients (34 patients at phase II dose) with previously treated NSCLC. Eight patients (20.0 %) had partial response and 26 (65.0 %) had stable disease as their best response. The median OS for the 34 patients treated at phase II dose was 12.6 months, with a PFS of 6.2 months. The most common adverse events were mild to moderate rash, diarrhea and proteinuria.

In another multicenter phase II trial, 63 patients with metastatic RCC were treated with bevacizumab 10 mg/kg intravenously every 2 weeks and erlotinib 150 mg orally daily. Fifteen (25 %) of 59 assessable patients had objective response and an additional 36 patients (61 %) had stable disease after 8 weeks of treatment. The median and 1-year PFS was 11 months and 43 % respectively. After a median follow-up of 15 months, median OS has not been reached: survival at 18 months was 60 %. Treatment was generally well-tolerated: only two patients discontinued treatment because of toxicity (skin rash); grade 1/2 skin rash and diarrhea were the most frequent treatment-related toxicities [131].

Encouraging results have been reported with the combination of two different monoclonal antibodies with or without chemotherapy. The BOND II Trial evaluated the combination of cetuximab/bevacizumab +/– irinotecan in mCRC patients after irinotecan failure. Preliminary data showed a better efficacy in the experimental arm in terms of response rate (37 % versus 20 %) and median TTP (7.9 months versus 5.6 months) [132].

Based on preclinical results showing co-upregulation of VEGF and HER-2/neu in breast cancer, a recent phase I/II trial explored the combination of trastuzumab and bevacizumab in relapsed mBC HER-2 positive [133].

39.6.2 Metronomic Chemotherapy

Another therapeutic strategy is based on the use of antiangiogenic schedules of cytotoxic agents (i.e., metronomic chemotherapy) aimed to block endothelial cells proliferation. The most studied cytotoxic agent is oral cyclophosphamide, which is more active combined with selective antiangiogenic agents such as the TSP-1 peptide ABT-510, thalidomide and celecoxib, or anti-VEGF agents [134].

A recent phase II study in pediatric cancer patients with recurrent or progressive poor prognosis tumors for which no curative therapy remained, Kieran et al. [135] tested the continuous administration of oral thalidomide, celecoxib with alternating etoposide and cyclophosphamide. Such a therapy was well-tolerated and 40 % of patients had clinical benefit with 25 % of all cases continuing to be progression-free for more than 123 weeks. Elevated circulatory levels of TSP-1 correlated with prolonged response.

39.6.3 Bidirectional Block of Angiogenic Balance

At a certain time the angiogenic activity of a tumor is the result of the net balance between pro- and contra-angiogenic molecules. It is reasonable to hypothesize that the concurrent use of an anti-pro-angiogenic molecule (i.e., anti-VEGF) and a naturally occurring angiogenesis inhibitor (i.e., endostatin) should be more effective than the use of each single class of agents alone. Such a strategy is now feasible in the clinic due to the approval in China of therapy for NSCLC with rh-endostatin, a tumor type for which also bevacizumab is active and approved [3].

39.6.4 Nanobodies

A new attractive category of targeted agents is that of nanobodies, consisting of the smallest functional fragment of a single-chain antibody, with interesting pharmacodynamic and pharmacokinetic characteristics such as: high stability, alternative routes of administration (intranasal, pulmonary, oral, transdermal, etc.), high tissue penetration (properties more similar to small molecules) and high affinity/potency, to the target, and low inherent toxicity. In addition, nanobodies are easier to of manufacture in bacteria and yeasts, have low

immunogenicity and a wider range of epitopes including cavities. The BIV nanobody (Ablynx) has shown a high affinity against ~100 targets, one of them being VEGF-A; it has been demonstrated his activity as a potent antagonist in vitro against ~20 targets. In vivo his efficacy has been shown in over ten animal models [136]. Preclinical development is ongoing at the moment and phase I/II clinical trials are planned to be started in 2007.

39.7 Conclusions

From 2004 antiangiogenic agents improved the antitumor therapeutic armamentarium. Up to now four inhibitors of angiogenesis has been approved by FDA. Bevacizumab significantly improved clinical outcome of patients with advanced CRC, NSCLC, and BC as compared with standard chemotherapy. Two multitargeted TKI compounds, namely sunitinib and sorafenib, changed the natural history of advanced RCC, a tumor type characterized by its poor responsiveness to cytotoxic and immunomodulatory agents.

Taking into account that tumor angiogenesis is a multistep process very complex, novel strategies based on the use of broad-spectrum antiangiogenic compounds, schedules of multitargeted agents (i.e., anti-VEGF + anti-EGFR or antimTOR) as well as the development of new highly active and selective drugs (i.e., nanobodies) are expected to further ameliorate the efficacy of antiangiogenic therapy in future years.

With the promising results obtained in patients with advanced, metastatic disease it is likely to be reproduced and enhanced in the adjuvant setting. Because the angiogenic switch is an early event in tumor growth, the capability to develop orally active and safe angiogenic inhibitors may open the opportunity to develop novel strategies of chemoprevention for high-risk subjects.

Small Molecule Inhibitors

40

Xin Chen and Jian Jin

40.1 Introduction

Before the biomedical community had had any understanding of the molecular mechanisms that drive tumorigenesis, the discovery of cancer chemotherapy exclusively focused on the development of novel cytotoxic compounds targeting DNA processing and cell division including DNA alkylating and cross-linking agents, antimetabolites, topoisomerase inhibitors, and anti-tubulin agents [1]. Although these drugs can be very efficacious in killing tumor cells, serious side effects accompanied due to the lack of selectivity for tumor cells versus normal cells. The side effects, such as bone marrow suppression and gastrointestinal, cardiac, hepatic, and renal toxicities, significantly limit their use. In addition, drug resistance was frequently observed after initial stabilization or regression of the disease [2].

Starting from 1980s, the biomedical research community has begun to identify key molecular changes responsible for malignant transformation and understand the etiology of cancer at the molecular level [3]. For example, numerous cancer-causing oncogenes and tumor-suppressor genes that normally hold cancer in check have been discovered. Oncogenes are frequently activated by inherited or spontaneous gain-of-function mutations or fusions with other genes. They can be aberrantly expressed due to amplification, increased promoter activity or protein stabilization, thus have integral roles in the genesis of human tumors. The inherited or spontaneous loss of function of tumor-suppressor genes resulting from inactivating mutations or epigenetic events (for example, promoter hypermethylations) has also been implicated in tumorigenesis. As a result, the focus of anticancer drug discovery and development shifted from nonspecific chemotherapeutics to rationally designed drugs that target cancer-specific pathways or proteins that are unique to or upregulated in cancer cells. Such agents are typically less toxic than conventional cytotoxic anticancer drugs because they would spare normal cells and thereby offer improved safety benefits over standard chemotherapeutics and provide a higher therapeutic index.

Much of the pioneering work in the targeted anticancer drug discovery field has been carried out via targeting signaling pathways. Cells use a wide variety of intracellular and intercellular mechanisms to signal for processes, including growth, apoptosis, and intracellular protein degradation. Molecular and genetic approaches have uncovered the entirely new signaling networks that regulate cellular activities such as proliferation and survival. Many of these networks are found to be radically altered in cancer cells. Therefore, inhibition of these altered pathways via signal transduction inhibitors or secondary messenger inhibitors can lead to anticancer effect.

Research in the protein kinase area has led to 33 FDA-approved kinase inhibitor drugs for the treatment of various cancers to date [4]. Additionally, more than 100 kinase inhibitors are presently in various phases of clinical development for treating cancers [5]. In this chapter, rather than covering every FDA-approved kinase drug and every drug candidate in clinical development, we describe discovery stories of a number of representative kinase inhibitor drugs as examples to illustrate the tremendous success in this area. In addition to these kinase drug discovery stories, we describe the discovery of inhibitors of other proteins or protein families as targeted cancer therapeutics including inhibitors of poly(ADP-Ribose) polymerases (PARPs), DNA methyltransferases (DNMTs), histone deacetylases (HDACs), and heat shock protein 90 (HSP90).

40.2 Small Molecule Inhibitors as Targeted Cancer Therapeutics

40.2.1 Kinase Inhibitors

Kinases, also known as phosphotransferases, are a class of enzymes that transfer a phosphate group from high energy donor molecules, such as adenosine triphosphate (ATP), to specific substrates. The largest group of kinases is protein kinases, which constitute one of the largest protein families in the human genome, accounting for about 1.7 % of the human genome-encoded proteins [6]. Protein kinases modulate the signaling systems necessary for cell division, growth, survival, and migration. As many as 120 kinases, out of more than 500 kinases encoded in human genome, have been found to be present in various cancers [7]. Small molecule inhibitors that block the actions of protein kinases and the associated signaling pathways can thus have significant impact on the proliferation, differentiation, apoptosis, and migration of cancer cells.

40.2.2 Classification of Protein Kinases

By attaching a phosphate group to a serine, threonine, or tyrosine residue of various proteins, the process called phosphorylation, protein kinases play a primary role in the complex signaling systems that transfer information between and within cells via switching on or off a cascade of cellular events. There are two main ways to categorize protein kinases.

(a) Based on their specificity for amino acid residues:
- Serine or threonine-specific kinases: catalyze the phosphorylation of serine or threonine residues.
- Tyrosine-specific kinases: catalyze the phosphorylation of tyrosine residue.
- Mixed function kinases: catalyze serine, threonine, or tyrosine phosphorylation.

(b) Based on their structure and cellular localization:
- Receptor kinases: contain an extracellular ligand-binding domain, a hydrophobic transmembrane domain, and a cytoplasmically located kinase domain. The extracellular ligand-binding domain is typically glycosylated and conveys ligand specificity. Epidermal growth factor receptors (EGFRs), platelet-derived growth factor receptors (PDGFRs), and vascular endothelial growth factor receptors (VEGFRs) are the three major families. Other well-known receptors include insulin-like growth factor 1 receptors (IGF-1Rs), Mast/stem cell growth factor receptor (SCFR, also known as proto-oncogene c-Kit or tyrosine-protein kinase KIT) and mutant FMS-like tyrosine kinase 3 (FLT-3) receptors.
- Non-receptor kinases: have no transmembrane or extracellular domains and may be associated with the cytoplasmic surfaces by membrane localization via a lipid modification that anchors them to the phospholipid bilayer or by non-covalent binding to a membrane receptor. Abelson tyrosine kinase (ABL), Janus kinase (JAK), focal adhesion kinase (FAK), and sarcoma (Src) kinases belong to this category.

40.2.3 General Mechanisms of Protein Kinase and Kinase Inhibitors

Protein kinases help transmitting information from a factor outside a cell into the cell plasma and nucleus while the initiating factor does not have to across the cell membrane. This mechanism allows the cellular function such as proliferation, cell–matrix adhesion, cell–cell adhesion, movement, apoptosis control, transcription, and membrane transport to be regulated by extracellular stimuli. There are two ways through which the signals from an extracellular factor can be transferred into the interior of the cell with the aid of kinases. First, ligand binding to receptor tyrosine kinases (RTKs) induces receptor dimerization or oligomerization, leading to the activation of kinases [8]. Secondly, non-receptor kinases are similarly activated in response to appropriate extracellular stimuli via interacting with other membrane-bound receptors such as G-protein coupled receptors; however, dimerization may or may not be necessary for activation [9]. In either case, the key step in transferring the signal across the membrane is the activation of the cytoplasmic kinase domain. The activated kinases then initiate a cascade of phosphorylation reactions resulting in the activation of other proteins, as well as the production of secondary messenger molecules that transmit the signal initiated by the extracellular factor to the nucleus [10].

Protein kinases play major etiologic roles in the initiation of malignancy and may contribute to the uncontrolled proliferation of cancer cells, tumor progression, and development of metastatic disease [11]. It is thought that cancer cells depend almost entirely on signaling by protein kinases for their continued proliferation [6], whereas normal cells rarely invoke these pathways [12]. Many protein kinases are mutated [13] or overexpressed [9] in tumor cells. Recent sequencing efforts in a wide variety of tumors have identified mutations in numerous RTKs, which are now collected in the COSMIC (Catalogue of Somatic Mutations in Cancer) database [14].

There are four main types of kinase inhibitors [15]. Type 1 inhibitors constitute the majority of ATP-competitive

inhibitors and recognize the active conformation of the kinases. Type 2 kinase inhibitors recognize the inactive conformation of the kinases and are still ATP-competitive. Type 3 kinase inhibitors bind outside the ATP-binding site, at an allosteric site, and modulate kinase activity in an allosteric manner. Therefore, this class of inhibitors is not competitive with ATP. Type 4 inhibitors are capable of forming an irreversible, covalent bond to the kinase active site, most frequently by reacting with a nucleophilic cysteine residue. A detailed description of these four types of kinase inhibitors was summarized in this excellent review article [15]. A very significant amount of drug research and development activities has been devoted to the discovery of small molecule inhibitors of the protein kinases thought to be important in the initiation and growth of tumors. These efforts have led to the approval of 33 kinase inhibitor drugs by the FDA. Most of these FDA-approved drugs and the drug candidates that are currently in clinical development are either type 1 or type 2 kinase inhibitors. We use the following examples to illustrate how small molecule kinase inhibitors as targeted cancer therapeutics were discovered.

40.2.4 BCR-ABL Inhibition: The Discovery of Imatinib (Gleevec™)

Being the first small molecule kinase inhibitor approved by FDA for treating cancers (approved in 2001 for chronic myeloid leukemia (CML) and in 2002 for gastrointestinal stromal tumors (GISTs)), imatinib (Gleevec™, Novartis) which is also known as STI-571, is widely acknowledged to be the classic example of kinase targeted drug discovery and the drug that validated the strategy of signal transduction inhibition. The molecular target of imatinib is BCR-ABL (breakpoint cluster region—Abelson), a result of genetic abnormality known for a long time as chromosomal translocation that creates an abnormal fusion protein (i.e., the BCR-ABL kinase) that signals aberrantly and leads to uncontrolled proliferation of the leukemia cells in CML [16].

CML is a malignant myeloproliferative disorder of hematopoietic stem cells [17]. It is characterized by a chromosomal abnormality, known as the Philadelphia chromosome, discovered by Nowell and Hungerford and named after the location of discovery [18], which results from a reciprocal translocation involving the Abelson (ABL) oncogene from chromosome 9 being transferred to a region on chromosome 22 termed the breakpoint cluster region (BCR) [19]. The resulting fused BCR-ABL gene produces a constitutively active tyrosine kinase that initiates multiple signaling pathways and causes perturbed interaction with extracellular matrix and bone marrow stroma, enhanced cell proliferation and reduced growth-factor dependence and apoptosis [16]. This leads to an increase in the number of granular leukocytes in the peripheral blood and bone marrow [20].

It has been well established that BCR-ABL is the causal to the pathogenesis of CML, and that constitutive tyrosine kinase activity is central to the capacity of BCR-ABL to transform hematopoietic cells in vitro and in vivo [21, 22]. The fact that it proved difficult to identify essential components downstream of BCR-ABL indicates that BCR-ABL is an attractive drug target from the therapeutic standpoint. The clear difference in the function of BCR-ABL between normal and leukemic cells further supports this view.

The discovery of imatinib represents an excellent example of rational drug design in cancer drug discovery [23, 24]. Starting in the late 1980s, scientists at Ciba Geigy (now Novartis), under the direction of N. Lydon and A. Matter, initiated projects on the identification of compounds with inhibitory activity against protein kinases. From a screen for inhibitors of protein kinase C (PKC), a phenylaminopyrimidine was identified as a hit (Fig. 40.1) [25, 26]. Although this compound had low potency and poor kinase selectivity, it had promising "lead-like" properties [27] and a high potential for structural modifications, allowing rapid generation of more potent and selective inhibitors. Adding a 3′-pyridyl group to the parent compound resulted in compound **1A** with significantly improved cellular activity. The introduction of a benzamide group on the phenyl ring (compound **1B**) provided inhibitory activity against tyrosine kinases such as BCR–ABL in addition to PKC. Further structure–activity relationships (SAR) exploration revealed that a substitution at the position 6 of the diaminophenyl ring abolished PKC inhibitory activity completely and the introduction of a simple flag-methyl at this position (compound **1C**) retained or even enhanced the activity against BCR–ABL. However, compound **1C** had poor oral bioavailability and low aqueous solubility. Further exploration of this series revealed that the attachment of a highly polar side chain such as *N*-methylpiperazine could significantly improve both solubility and oral bioavailability. In addition, the introduction of the CH_2 spacer between the phenyl ring and the nitrogen atom avoided the mutagenic potential of the aniline moiety. Compound **1D** (originally named as STI571, now known as imatinib), the most promising compound in this series, was selected for clinical development.

Binding of imatinib occurs at the ATP-binding site as indicated by docking studies [28] and X-ray crystallography [29]. It has also been shown from the crystal structure that imatinib inhibits the kinase by binding with high specificity to an inactive form of the kinase. Thus, imatinib is a type 2 kinase inhibitor. Binding to this unusual kinase conformation might contribute to the high selectivity of this compound. Surprisingly, the *N*-methylpiperazine group (added to increase aqueous solubility and oral bioavailability) was

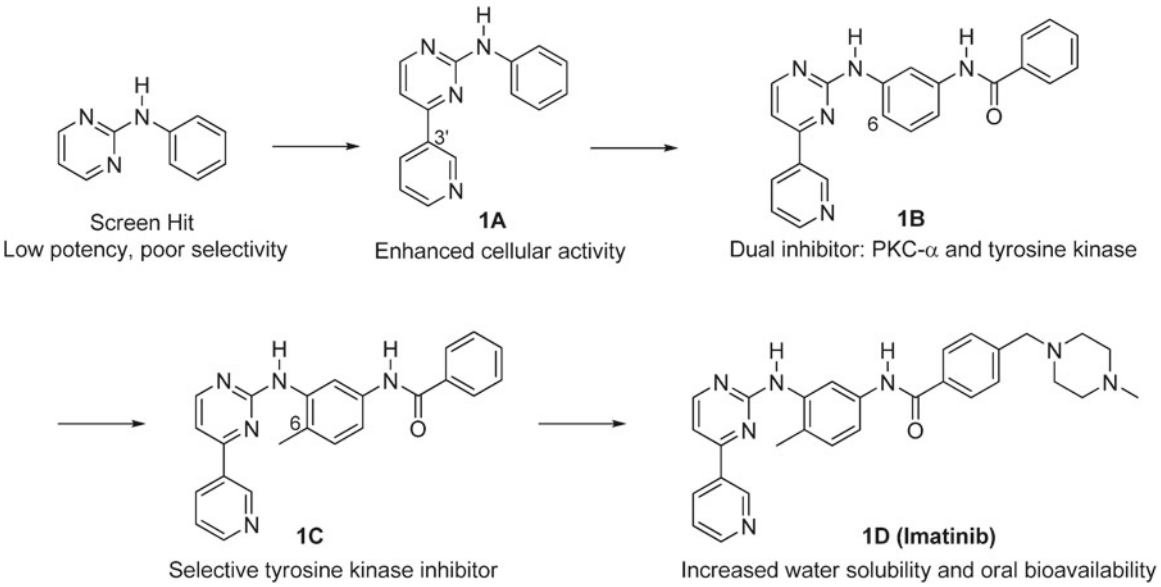

Fig. 40.1 Discovery of imatinib.

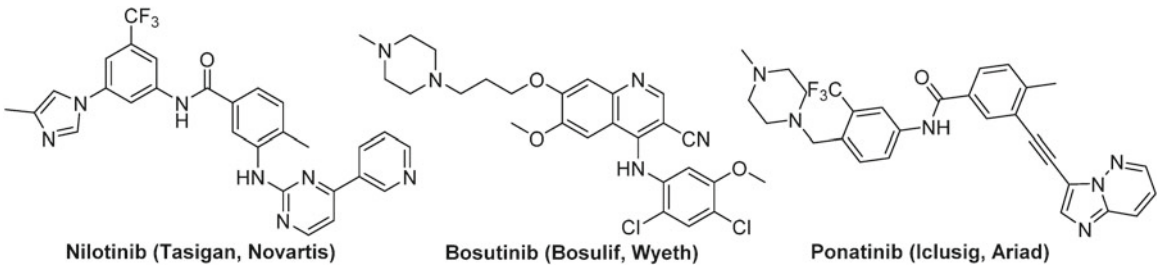

Fig. 40.2 FDA-approved BCR-ABL inhibitors.

found to have strong interaction with the protein via hydrogen bonds to the backbone carbonyl groups.

In addition to being orally bioavailable, thus more convenient for patients, imatinib lacks some of more serious side effects commonly observed with cytotoxic agents [30]. Imatinib has now been approved in numerous countries for treating the chronic phase of Philadelphia chromosome-positive CML. Through its use in clinic, it was discovered that, in addition to inhibiting BCR-ABL, imatinib effectively inhibited ABL, PDGFR, and SCFR (c-Kit) [31]. In particular, the activity against c-Kit manifested as remarkable clinical activity in c-Kit-positive unresectable or metastatic malignant GISTs, for which it is now also licensed.

In patients with newly diagnosed CML in the chronic phase, daily oral administration of imatinib has demonstrated impressive event-free survival (81%), freedom from progression (93%), and overall survival (86%) rates [32]. However, many patients eventually develop intrinsic or acquired resistance to this first-line therapy [33]. To overcome resistance in CML, a number of second generation inhibitors have been developed [34]. These include imatinib-like inhibitors nilotinib (Tasigna™, Novatis, Approved 2007) (Fig. 40.2) [35], dual SRC/ABL inhibitors dasatinib (Spreycel™, Bristol-Myers Squib, Approved 2006) [36], and bosutinib (Bosulif™, Wyeth, Approved 2012) [37], which have been approved for the treatment of adults in all phases of CML with resistance or intolerance to imatinib. Unfortunately, there are still subsets of mutants remain resistant even with these second-generation compounds, particularly a common BCR-ABL^{T315I} mutant at the gatekeeper position which represents ~15–20% of all clinically observed mutants [37–40]. To address this unmet need, several programs targeting development of potent BCR-ABL^{T315I} inhibitors have been established and the progress has been summarized in a number of reviews [41–44]. Ponatinib (AP24534, Iclusig™, Ariad) was developed as a "pan-BCR-ABL" inhibitor which is potently active against BCR-ABL^{T315I} and all other tested BCR-ABL variants and suppresses emergence of resistant mutations in a cell-based screen [45]. In addition, ponatinib was also found to be a multitargeted inhibitor with activity against FLT3, FGFR, VEGFR, c-Kit, PDGFR, Eph, Src family kinases, RET, and Tie2. Ponatinib was approved by FDA for the treatment of T315I positive CML and Philadelphia chromosome positive

ALL as well as CML or Philadelphia positive ALL that are resistant or intolerant to prior tyrosine kinase inhibitor therapy in December 2012 through FDA Accelated Approval program. Serious adverse reactions have been reported with ponatinib, with vascular occlusion, heart failure and hepatotoxicity prompting the US FDA to issue boxed warnings. Therefore, clinicians need to consider whether the potential benefits of therapy will outweigh the risks before starting treatment.

40.2.5 EGFR Inhibition

Because of their fundamental role in regulating key cellular functions including cell proliferation, differentiation, metastasis and survival, epidermal growth factor receptor (EGFR) signaling pathways have been a main focus of research for novel targeted anticancer agents [46]. EGFR is a member of the EGFR subfamily known as human epidermal growth factor receptor (HER) family, which contains 4 closely related receptors that include itself (as known as ErbB-1), HER2/neu (as known as ErbB-2), HER3 (as known as ErbB-3) and HER4 (as known as ErbB-4). EGFR is a 170-kDa glycoprotein that is expressed in most human tissues and is highly expressed in many human solid tumors [47].

EGFR is a receptor tyrosine kinase, which has an extracellular domain, a transmembrane domain and an intracellular tyrosine kinase domain. The activation of the EGFR pathway is initiated when an appropriate ligand (e.g., EGF, transforming growth factor-α or TGF-α, heparin-binding EGF, amphiregulin, betacellulin, epiregulin, or neuregulin G2b) [48] binds to the extracellular domain of the inactive single unit of the receptor. This causes receptor dimerization with another identical EGFR receptor to form a homodimer or with a nonidentical receptor from the same EGFR subfamily (e.g., HER2/neu) to give a heterodimer. This dimerization process activates the tyrosine kinase enzyme located in the intracellular domain, and that leads to the transphosphorylation of both intracellular domains. This, in turn, initiates a cascade of phosphorylation events that eventually results in a signal arriving at the nucleus [46]. The magnitude of EGFR signaling is influenced by several cellular mechanisms including receptor mutations, heterodimerization with other members of the HER family, increased expression of autocrine ligands, and alterations in molecules that control receptor signaling output [49].

The work from several research groups has provided strong rationales for EGFR as an anticancer target. EGF was first discovered by Stanley Cohen in the early 1960s [50]. As one of the first growth factors isolated, its discovery opened up a research field that has been crucial to the development of modern anticancer and other medical treatments. A decade later, human EGF4 was isolated [51]. It took another 5 years to demonstrate the link between EGFR and the malignant transformation of cells [52]. An autocrine mechanism was found to be involved in that transformation, involving autostimulation of EGFR in cancer cells by ligands such as EGF and TGF-α, which are produced by the cancer cells themselves. The ligand binding to EGFR activates a cyclic-AMP-independent phosphorylation system through an inherent tyrosine kinase located within the receptor [53]. This up-regulated EGFR-mediated signaling can help move cells into a continuous and uncontrolled stated of division, thus leading to greater numbers of malignant cells and an increase in tumor size. Additional compelling evidence for the role of EGFR in cancer pathogenesis came from reports that many human solid tumors, such as head and neck, lung, and colorectal tumors, express high levels of EGFR, which frequently correlates with poor prognosis [54], in particular, with an increased risk of metastasis and decreased survival. The high expression levels of EGFR can also protect cancer cells from hormone therapies, cytotoxic agents, and radiotherapy [55], thus reducing the effectiveness of these treatments. Furthermore, many tumors that express EGFR also produce one or more EGFR ligands, which further supports the hypothesis that autocrine growth-stimulatory mechanisms are involved in EGFR-mediated tumorigenesis [56]. In addition, it has been shown that EGFR signaling not only increases cell proliferation, but also regulates a range of processes that are essential for tumor progression, including cell motility, cell adhesion, tumor invasion, cell survival, and angiogenesis [57].

40.2.6 The Discovery of Gefitinib (Iressa™)

These strong target validation and disease association results have prompted the research community to pursue small molecule EGFR-TK (tyrosine kinase) inhibitors as potential anticancer therapeutics. These small molecule inhibitors can compete with ATP binding to the TK domain of the receptor, which inhibits TK activity and subsequently block signal transduction from the EGFR. Gefitinib (Iressa™), an 4,6,7-trisubstituted-4-quinazolinamine discovered by AstraZeneca in the mid- to late-1990s, was one of the first agents in this new family [49].

The discovery of gefitinib started from a phenylaminolquinazoline (compound **3A**, Fig. 40.3), which was discovered from the SAR study of the 4-anilinoquinazoline class as EGFR-TK inhibitors [58, 59]. This compound was found to be a potent inhibitor of EGFR-TK (IC_{50} = 5 nM) and EGF-stimulated human cell growth (IC_{50} = 50 nM (KB oral carcinoma cells)]. However, compound **3A** had a short half-life (approximately 1 h) and appeared to undergo rapid oxidative metabolism. Substitution of the methyl group with chlorine and introduction of fluorine at the *para*-position of

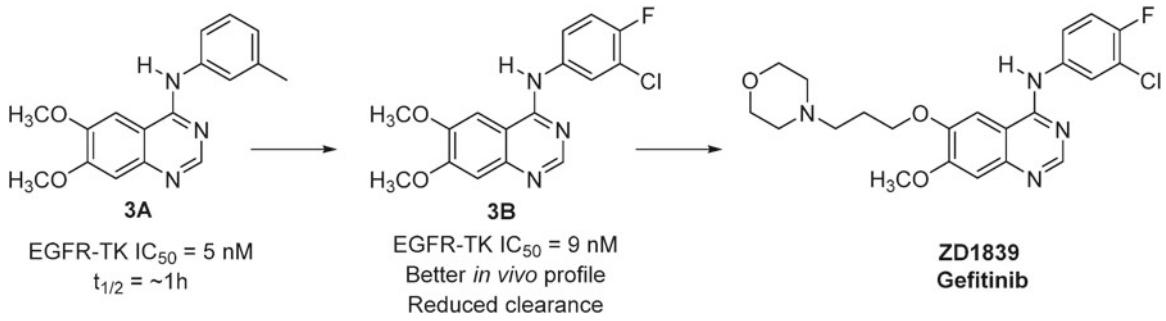

Fig. 40.3 Discovery of gefitinib.

the aniline gave compound **3B**, which was resistant to the oxidative metabolism. Although this compound showed a slight loss of potency in vitro (EGFR-TK, IC_{50} = 9 nM; EGF stimulated KB cell growth, IC_{50} = 80 nM) compared to compound **3A**, it had improved efficacy in in vivo models via oral dosing and better pharmacokinetic (PK) properties (e.g., reduced clearance, longer half-life—approximately 3 h). The approach aimed at further improving in vivo activity, which eventually proved successful, involved modification of the alkyl group of the methoxy side chain. Introduction of a basic group into the alkoxy side chain resulted in improved physical chemical properties such as solubility and further improved PK parameters. After profiling a series of compounds with different aminoalkoxy side chains, gefitinib (ZD1839) (Fig. 40.3) was chosen as a development candidate based on its excellent in vitro and in vivo profiles. Although gefitinib was not the most potent compound synthesized, it achieved high and sustained blood levels over a 24-h period and had good oral bioavailability in preclinical species [60]. Gefitinib is selective against structurally closely related ErbB2, the receptors of VEGF, FMS like tyrosine kinase (FLT1; VEGFR1), kinase insert domain-containing receptor tyrosine kinase (KDR; VEGFR-2), and a number of serine/threonine kinases [61]. Gefitinib inhibits the growth of a broad range of human solid tumor xenografts in a dose-dependent manner with marked regressions seen in some tumors. Treatment for up to 4 months in nude mice was well tolerated. Gefitinib has demonstrated a long half-life in humans compatible with once-daily oral dosing. The FDA approved gefitinib as a second-line treatment for non-small-cell lung cancer in May 2003.

40.2.7 The Discovery of Afetinib (Gilotrif™)

As exemplified by etitinib and erlotinib (Tarceva™, OSI), the first-generation small molecule EGFR tyrosine kinase inhibitors were shown to be effective against lung tumor cells harboring mutations in the kinase domain of EGFR, most commonly small in-frame deletions in exon 19 or the L858R missense mutation in exon 21 [62]. However, despite the initial response, patients almost invariably develop resistance to these inhibitors and relapse after several months [63]. A secondary mutation, T790M, in exon 20 of the EGFR kinase domain is account for about half of cases with acquired resistance to first-generation EGFR inhibitors [64, 65]. T790M EGFR exhibits elevated enzymatic and transforming activity, both alone and in combination with primary alterations in exon 19 or 21 [66–69], indicating a need for increased therapeutic efficacy of the next generation of EGFR inhibitors. Ideally, these new small molecule tyrosine kinase inhibitors should be more broadly active against ErbB receptor tyrosine kinases, yet retain the exquisite overall selectivity of first-generation EGFR TKIs within the human kinome that has afforded an acceptable drug safety and tolerability profile.

Irreversible inhibitors that covalently modify EGFR and/or HER2 exhibited increased efficacy against mutants resistant to gefitinib and erlotinib in cell-based assays [64, 69–73]. One such inhibitor, afetinib (BIBW2992) (Fig. 40.4), is a new irreversible dual EGFR/HER2 inhibitor derived from the anilino-quinazoline chemical series that was designed to covalently bind to Cys 773 of EGFR and Cys 805 of HER2 via a Michael addition [74]. Afetinib was found to potently suppress the kinase activity of wild-type and activated EGFR and HER2 mutants, including the most common mutations, L858R and deletion-19, and the exon 20 gatekeeper T790M mutations, albeit at lower potency [74, 75]. It has received regulatory approval for use as a treatment for non-small-cell lung cancer in 2013 although there is emerging evidence to support its use in other cancers such as breast cancer [76].

40.2.8 The Discovery of Lapatinib (Tykerb™)

Among the four members (EGFR, HER2, HER3, and HER4) of the EGFR family, only HER2 is unknown to bind ligands [77]. However, HER2 is the preferred heterodimerization partner for EGFR, HER3, and HER4. Ligand binding to the extracellular domain of members of this family causes receptor homodimerization or heterodimerization and tyrosine kinase activation. The resultant receptor autophosphorylation

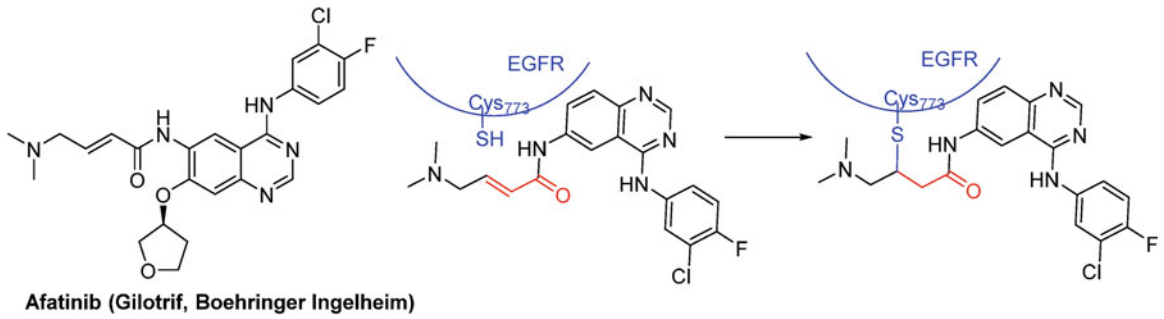

Fig. 40.4 Afatinib and its inhibitory mechanism.

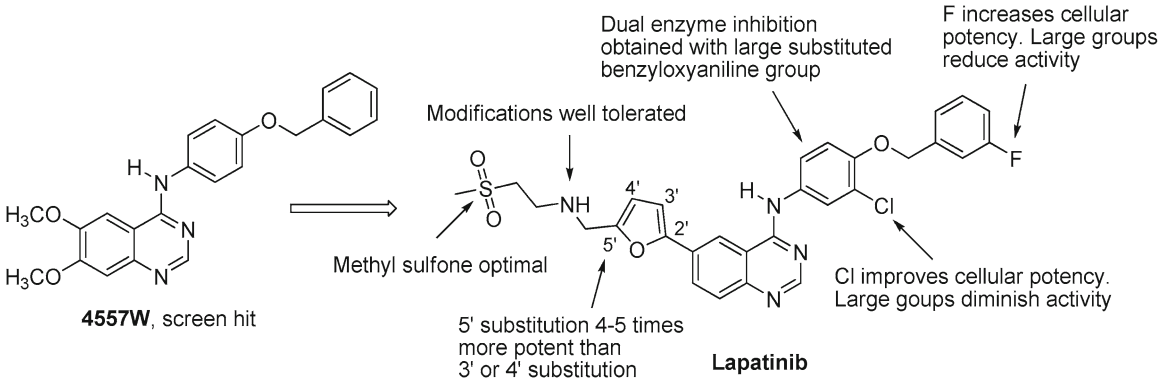

Fig. 40.5 Discovery of lapatinib.

leads to the activation of various signaling cascades that are involved in cell proliferation and survival [78].

EGFR and HER2 have been shown to promote the growth and survival of various types of epithelial malignancies. EGFR is overexpressed in up to 30 % of human breast cancers [79], and HER2 is amplified and overexpressed in up to 20–25 % of primary human breast cancers [80]. Importantly, overexpression of HER2 is associated with aggressive disease and shortened disease-free survival and overall survival [81]. Abundant evidence suggests that EGFR and HER2 work in synergy to produce oncogenic effects [82]. In particular, HER2 dimerization with EGFR increases the EGF binding affinity to EGFR [83], and the binding of EGF to EGFR subsequently increases the activation of HER2 [84]. It was therefore hypothesized that agents that inhibit both EGFR and HER2 might be more effective at inhibiting the activation of the PI3K-Akt and Ras-Raf-mitogen-activated protein kinase signaling cascades and could have more effective anticancer activity than those that target either kinase alone. Efforts on developing such molecules led to the discovery of lapatinib (Tykerb™, GlaxoSmithKline) [85].

The discovery of lapatinib (originally known as GW572016) started with the screen hit 4557 W (Fig. 40.5) [86], which was a potent inhibitor of both HER2 (IC_{50} = 0.079 μM) and EGFR (IC_{50} = 0.020 μM). Initial SAR study demonstrated that large anilino substitutions were needed to retain both EGFR and HER2 inhibition activity. The most potent dual enzyme inhibition could be obtained when the aryl group was the substituted benzyloxyaniline group, and the optimal substitution pattern involved a *para*-benzyloxy group. Other notable SAR include that although chlorine at 3-position afforded insignificant increases in enzyme potency, it improved cellular activity. Fluorine at 2′-position yielded compounds with greater potency in cellular assays. Larger groups at 3-position or 2′-position generally diminished activity.

For the left-hand side capping group, the simple methyl sulfone group appeared to be optimal. Study on the regiochemistry of the furan ring showed that the 5′ substituted analog was 4–5 times more potent against the tumor cell lines than the 3′ or 4′ regioisomer. In addition, a diverse set of amine substitutions was tolerated, presumably due to the binding mode of these inhibitors. However, the extra synthetic steps and increased molecular weight were deemed nonbeneficial for optimizing physical chemical properties.

The medicinal chemistry optimization ultimately led to the discovery of lapatinib, which possessed the desired enzyme potency, cellular activity in a panel of tumor cell lines, and excellent selectivity [87]. In March 2007, FDA approved lapatinib for treating breast cancer.

40.2.9 VEGFR Inhibition: The Discovery of Pazopanib (Votrient™) and Axitinib (Inlyta™)

Angiogenesis plays a critical role in the growth and metastasis of solid and hematologic malignancies [88]. It is considered as the rate-limiting step in tumor development because without blood supply, a solid tumor is limited to a maximum size of 1–2 mm [89]. This complex and highly regulated process involves numerous different cell types and mediators.

VEGF is the growth factor most often associated with angiogenesis [90]. Oxygen-deficient cells use VEGF in key signaling pathways to promote the growth of new blood vessels. VEGF interacts with VEGFRs on endothelial cell surfaces, directing them to build new blood supplies [91]. The cells respond to this message by producing specialized protease enzymes to penetrate the basal lamina, so that they can migrate to oxygen-deficient regions. Once there, the cells replicate and form into tubes, thus creating new capillary pathways. Elevate VEGF levels have been correlated with increased microvessel counts and poor prognosis in many cancer types [92].

As a principal subfamily of RTKs, VEGFRs are specifically expressed in vascular endothelial cells. They include FMS like tyrosine kinase-1 (FLT-1; VEGFR-1), kinase insert domain-containing receptor tyrosine kinase (KDR; VEGFR-2), and FLT-4 (VEGFR-3) [93]. Activation of VEGFR family RTKs and, in particular, VEGFR-2 by VEGF plays a primary role in tumor angiogenesis. VEGF mediated VEGFR-2 signaling induces a series of endothelial responses such as proliferation, migration, and survival and ultimately leads to new vessel formation and stabilization [94].

The therapeutic hypothesis that inhibiting the VEGF/VEGFR pathway can interrupt the angiogenesis process and subsequent tumor growth was first clinically validated by Bevacizumab (Avastin™; Genentech), a monoclonal antibody to VEGF, which is approved by FDA for the treatment of both metastatic colorectal cancer in combination of 5-fluorouracil [95], and for non-small-molecule lung cancer in combination with carboplatin and paclitaxel [96]. Efforts on discovering small molecule inhibitors of VEGFRs [97] led to the FDA approval of pazopanib (Votrient™, GlaxoSmithKline), N^4-(2,3-dimethyl-2H-indazol-9-yl)-N^4-methyl-N^2-(4 methyl-3sulfona midophenyl)-2,4-pyrimidinediamine, as an oral treatment for renal cell carcinoma (RCC).

The discovery of pazopanib started from a screening for agents active against VEGFR-2 [98]. Initial screening hit compound **6A** (Fig. 40.6), which inhibited VEGFR-2 with an IC_{50} of ~400 nM, was optimized to compound **6B** using a homology model of the kinase domain as the crystal structure was not known at that time. Compound **6B** inhibited VEGFR-2 with an IC_{50} of 6.3 nM, almost a 100-fold potency improvement compared to **6A**. In cellular assays, compound **6B** inhibited VEGF induced proliferation of human umbilical vein endothelial cells (v-HUVEC) with an IC_{50} of 0.54 μM. It also had an IC_{50} of 3.5 μM against basic fibroblast growth factor (b-FGF). However, the pharmacokinetic profile of this compound was poor (moderate to high clearances, 28–83 mL/min/kg, and low oral bioavailability, <11 %) in mice. Incorporation of a 3-methylindazole moiety into this series yielded indazolylpyrimidine (compound **6C**) with desired cellular potency, and selectivity in VEGF and bFGF driven HUVEC, with IC_{50}'s of 0.13 and 13 μM, respectively. **6C** had moderate plasma clearance (40 mL/min/kg) and oral bioavailability

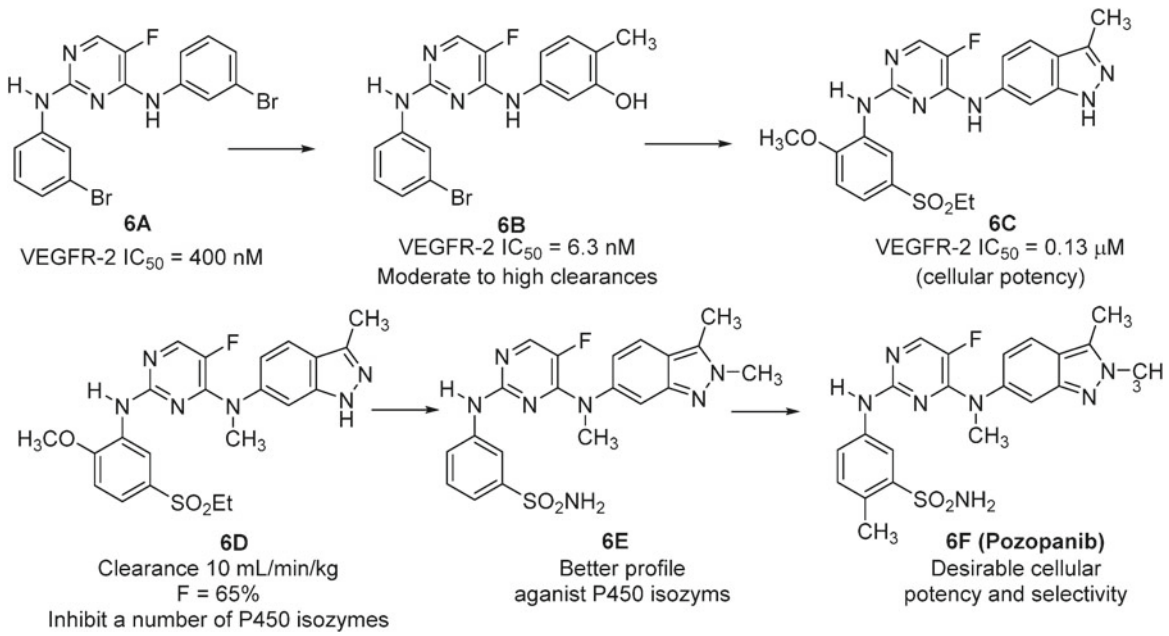

Fig. 40.6 Discovery of pozopanib.

(28 %) in rats. Introducing a methyl group into the C-4 amino nitrogen resulted in compound **6D**, which showed an improved PK profile with lower clearance (10 mL/min/kg) and higher oral bioavailability (65 %) while providing comparable enzymatic potency to its non-alkylated analog **6C**. Although compound **6D** possessed both good in vitro potency and cross-species PK profiles, significant inhibition ($IC_{50} < 10$ μM) was observed against a number of cytochrome P450 isozymes possibly due to the binding of the nitrogen on the indazole to the heme iron of the cytochrome P450 enzymes. Compound **6E** resulting from the addition of a methyl group at the 2-position of the indazole ring, which increases steric hindrance of the heterocycle ring, had an improved profile against the CYP2C19, CYP2D6, and CYP3A4 isozymes as well as improved cellular efficacy against v-HUVEC cells. With the preferred right-hand side moiety identified, a second aniline survey at the C-2 position of the pyrimidine resulted in the discovery of compound **6F** (pazopanib), which possesses a desirable combination of excellent in vitro potency, selectivity, cellular activities, PK, and developability properties. Pazopanib was potent against all human VEGFR receptors with a respective IC_{50} of 10, 30, and 47 nM for VEGFR-1, -2, and -3. Significant activity was also seen against the closely related tyrosine receptor kinases PDGFRα, PDGFRβ, c-Kit, FGF-R1, and c-fms with IC_{50}'s of 84, 74, 140, and 146 nM, respectively. In cellular assays, pazopanib had a desirable combination of cellular potency and selectivity in VEGF and bFGF driven HUVEC, with IC_{50}'s of 0.021 and 0.72 μM, respectively. It also potently inhibited VEGF induced phosphorylation of VEGFR-2 in HUVEC cells with an IC_{50} of 8 nM. Pazopanib had good PK parameters including low clearances and good oral bioavailability in preclinical species. The cytochrome P450 profile was also significantly improved with $IC_{50} > 10$ μM against the isozymes tested, with the exception of CYP2C9 ($IC_{50} = 7.9$ μM). On the basis of its favorable PK profiles and in vivo efficacies, the mono-HCl salt of compound **6F** (pazopanib) was progressed into clinical development [98] and approved by the FDA for the treatment of renal cell carcinoma in October 2009.

Axitinib (AG013736, Inlyta™, Pfizer) (Fig. 40.7), approved by FDA in January 2012, is another ATP-competitive VEGFR inhibitors for patients with metastatic renal cell carcinoma (mRCC) after failure of one prior systemic therapy [99]. This small molecule indazole derivative is a potent, orally bioavailable multitargeted tyrosine kinase receptor inhibitor, which selectively inhibits vascular endothelial growth factor receptors (VEGFR)-1, -2, and -3 at subnanomolar concentrations, in vitro [100]. The structure-based drug design of axitinib allows strategic optimization of critical binding elements, with the tight fit of axitinib into the deep pocket conformation of the kinase domain of VEGFRs resulting in high potency and selectivity (Fig. 40.7). In vitro, axitinib inhibits VEGFR-1, -2, and -3 autophosphorylation

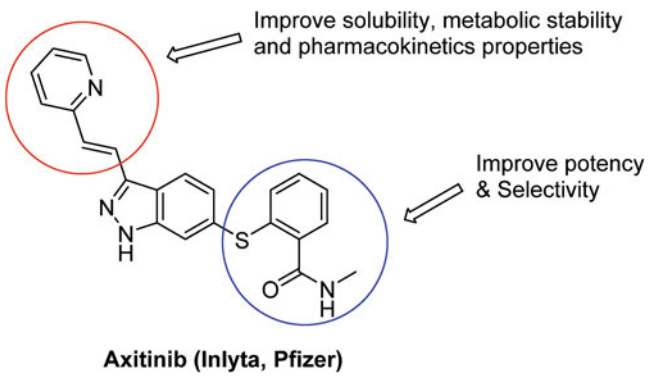

Fig. 40.7 Drug design strategy for axitinib.

at picomolar concentrations. Axitinib is tenfold more potent for the VEGF family receptors than for RTKs of other family receptors [100]. Additionally, axitinib did not significantly inhibit other receptor kinases including colony-stimulating factor (CSF)-1R, fms-like tyrosine kinase (Flt)-3, fibroblast growth factor receptor (FGFR)-1, ret proto-oncogene (RET), epidermal growth factor receptor (EGFR), and met proto-oncogene encoding hepatocyte growth factor (c-Met) [100].

Axitinib, orally administrated at a dose 2–10 mg twice daily, has been shown to reduce vascular permeability, tumor vascularization and tumor volume, and has demonstrated antitumor activity as a single agent in patients with cytokine- and/or sorafenib-refractory mRCC. The activity range of axitinib is the highest compared with other drugs currently approved for use in mRCC. Axitinib also has a favorable and non-cumulative tolerability profile associated with manageable adverse effects, which are generally mild to moderate in severity [101]. Based on the promising results from clinical trials, FDA approved axitinib for the treatment of mRCC after failure of one prior systemic therapy in 2012.

40.2.10 Multitargeted Tyrosine Kinase Inhibition

In search for more effective anticancer therapeutics, the multitargeted approach has emerged as a new paradigm [102]. Malignant tumors are complex tissues involving interplay between cancer cells and surrounding or supportive cells, thus a multitargeted therapeutic approach that affects supportive tissues and cancer cells may be of clinical benefit. Such agents can simultaneously target the tumor and surrounding or supportive cells and thereby interact with the complex multimolecular lesions that drive tumor growth and survival. A key advantage of the multitargeted approach is that it potentially reduces drug resistance. Due to mutations [72], overexpression of key components of signaling pathways [103], drug-efflux systems and/or signaling bypass

[104], tumors will likely develop resistance to single-targeted kinase inhibitors rapidly [105]. This drug resistance will be less likely to arise with multitargeted agents. In addition to multitargeted agents, the use of a combination of multiple kinase inhibitors has been investigated, which could offer similar benefits as multitargeted agents. In this section, we use sunitinib and dasatinib as examples to illustrate the success of multitargeted kinase inhibitor agents.

40.2.11 The Discovery of Sunitinib (Sutent™)

Growth factors including VEGFs and PDGFs are important pro-angiogenic factors. Their activity is mediated by binding to specific cell-surface receptor tyrosine kinases. There are four PDGF ligands (PDGFA to PDGFD), which bind to the receptor tyrosine kinases PDGFRα and PDGFRβ. PDGFB and PDGFRβ have been suggested to have crucial roles in tumor-vessel stability by recruiting pericytes to newly formed vessels [106]. The multitargeted tyrosine kinase inhibitor sunitinib (Sutent™, Pfizer) was designed to inhibit both VEGFRs and PDGFRs. Sunitinib, which demonstrated activity in RCC and other types of cancers, has been approved by the FDA for the treatment of kidney cancer and GISTs in January 2006.

Sunitinib (Sutent™, formerly SU11248, named from Schlessinger and Ullrich who created Sugen, a biotech company later acquired by Pharmacia then Pfizer) [107] is an orally active oxindol that has antiangiogenic and antitumor activities. It inhibits VEGFR-1, VEGFR-2, VEGFR-3, PDGFRα, PDGFRβ, KIT, FLT3, glial cell line-derived neurotrophic factor (GDNF) receptor, and colony stimulating factor 1 (CSF1) receptor (CSF1R) [108]. Sugen initially discovered SU5416 (Fig. 40.8) as a potent and selective VEGFR inhibitor [109]. Both in vivo and in vitro studies demonstrated its antiangiogenic potential [110]. Unfortunately, SU5416 failed in clinical trials due to its limited solubility and high toxicity. SU6668, a close analog of SU5416, was identified as a potent and selective PDGFRβ inhibitor [111, 112]. However, this compound had inadequate PK properties for clinical development. To broaden the kinase activity spectrum of this scaffold and to optimize PK properties, diversification at the C-4′ position on the pyrrole ring of SU5416 had been explored. It was found that modifications at the C-4′ position could lead to compounds with different kinase inhibition profiles for VEGFR2 and PDGFRβ. The cocrystal structure of SU6668 with the catalytic domain of fibroblast growth factor receptor 1 (FGFR1) kinase [111], which has high sequence similarity to the ATP-binding pocket of VEGFR-2, revealed that the substitution at the C-4′ position on the pyrrole ring was positioned close to the opening of the binding pocket and could be exposed to solvent. Thus, substitution at this position might serve as a handle for improving physical chemical properties of the core structure. Optimization of this region resulted in the discovery of sunitinib (SU11248), a more potent inhibitor of VEGFRs and PDGFRs. Comparing to SU6668, SU11248 was about 30-fold more potent against VEGFR-2 and PDGFRβ in biochemical assays, over ten-fold more potent in cellular kinase assays, and significantly more soluble under neutral (20-fold) and acidic (>500-fold) conditions [112]. Additional kinase selectivity study revealed that SU11248 was also a good inhibitor of KIT and FLT-3 [108, 113]. Furthermore, SU11248 had excellent oral bioavailability, was highly efficacious in a number of preclinical tumor models, and was well tolerated at efficacious doses [108]. Based on the satisfactory results from clinical trials, sunitinib was approved by the FDA for the treatment of RCC/GISTs in January 2006.

40.2.12 The Discovery of Dasatinib (Sprycel™)

Dasatinib (BMS-354825, Sprycel™; Bristol Myers Squibb) is a potent, second-generation, multitarget kinase inhibitor of BCR-ABL and the Src (sarcoma) family of kinases [114]. In addition to inhibiting BCR-ABL and Src kinases such as Fyn (Proto-oncogene tyrosine-protein kinase), Yes (Proto-oncogene tyrosine-protein kinase), Src, and Lyk (tyrosine-

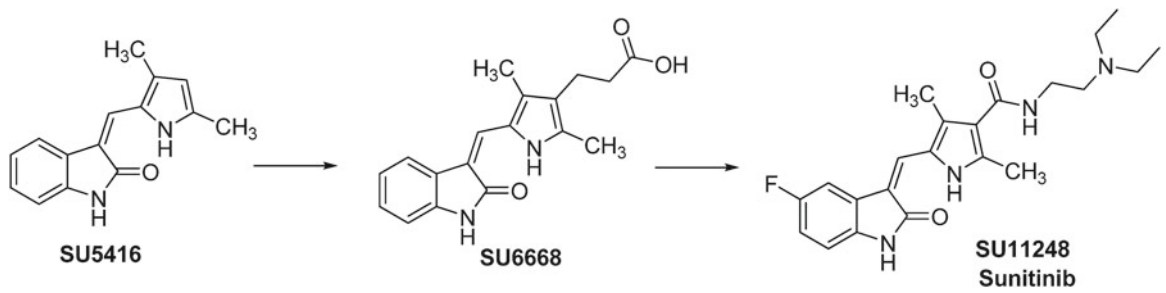

Fig. 40.8 Discovery of sunitinib.

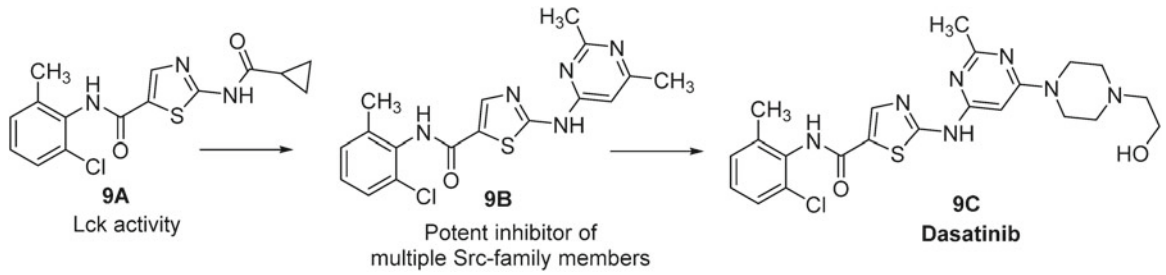

Fig. 40.9 Discovery of dasatinib.

protein kinase), dasatinib was found to inhibit ephrin receptor A2 (EphA2), PDGFRs, c-Kit, mitogen-activated protein kinases, and discoidin domain receptor 1 (DDR1) [115].

Src proto-oncogene is believed to play a role in the development of several human cancers, contributing to cellular proliferation, adhesion, invasion, and motility [116]. Src-family kinases such as Src and LYN (V-yes-1 Yamaguchi sarcoma viral related oncogene homolog) modulate signal transduction by phosphorylating tyrosine residues of molecules such as EGFRs, PDGFRs, fibroblast growth factor receptors (FGFRs), and VEGFRs. Src kinases have also been found to have oncogenic activities in cancer cell lines from tumors involving the colon, breast, pancreas, lung, and brain [117]. Thus, it was hypothesized that blocking signaling through the inhibition of the kinase activity of Src would be an effective means of modulating aberrant pathways that drive oncologic transformation of cells.

The discovery of dasatinib started from 2-acylamino-5-carboxamidothiazoles **9A** (Fig. 40.9), a Lck (lymphocyte-specific protein tyrosine kinase) kinase inhibitor [118]. Replacing the 2-acyl functionality with a variety of heterocycles led to the identification of compound **9B** [119], which was a potent inhibitor of multiple Src-family members including Lck, Fyn, Src, and Hck (hemopoietic cell kinase). In order to improve cellular activity of this series, a number of **9B** analogs were synthesized. These efforts resulted in the discovery of the piperazinyl ethanol **9C** (dasatinib), which has broad spectrum antiproliferative activity, favorable circulating plasma levels following oral dosing, long half-life, and favorable in vivo efficacy [120].

In addition to inhibiting multiple Src-family kinases including Lck, Fyn, Src, and Hck, dasatinib is a BCR-ABL inhibitor that blocks both the active and inactive conformations of ABL. Dasatinib is active against wild-type and almost all BCR-ABL mutant cell lines that are resistant to imatinib, except those carrying the T315I mutation [36]. The activity of dasatinib against ABL kinase mutations is likely due to the fact that it does not require interaction with some of the residues involved in those mutations. Dasatinib is also 325-fold more potent than imatinib against native BCR-ABL in in vivo studies [121] and is slightly more potent against Src family kinases ($IC_{50} = 0.5$ nM) compared to ABL ($IC_{50} = 1$ nM) [120]. It also inhibits c-KIT, PDGFR and EphA2 at nanomolar concentrations [115]. Potent Src inhibitory activity of dasatinib in CML progenitors involves BCR-ABL-dependent and BCR-ABL-independent Src activity [122]. Dasatinib also inhibits downstream signaling pathways in CML progenitors, as well as P-mitogen-activated protein kinase (MAPK), P-protein kinase B (Akt), and P-signal transducer and activator of transcription 5 (STAT5) levels in CML progenitors in the absence of growth factors. In addition, dasatinib significantly suppresses CML colony-forming cells and long-term culture-initiating cells [122]. In June 2006, the FDA approved dasatinib for the treatment of chronic phase, accelerated phase, or blastic phase CML, resistant or intolerant to imatinib, and for the treatment of Philadelphia chromosome-positive acute lymphoid leukemia that was resistant or intolerant to prior therapy.

40.2.13 Other Potential Kinase Targets

Encouraged by the rapid progress and tremendous success achieved in the fields of cancer molecular biology and kinase drug discovery to date, the academic research community and the pharmaceutical and biotech industry are targeting many other kinases for achieving potential clinical benefits. For examples, inhibitors of integrin-linked kinase (ILK), a focal adhesion serine–threonine protein kinase, are being developed for treating anaplastic thyroid cancer [123]. Focal adhesion kinase (FAK) has been shown to be an important mediator of cell growth, cell proliferation, cell survival, and cell migration [124]. Cell division cycle 7-related protein kinase (Cdc7) is a conserved serine–threonine kinase, which has been shown to be required for the initiation of DNA replication [125]. Other areas of research include the hepatocyte growth factor receptor (MET) [126], and the Ras/ERK1-2 (extracellular signal-regulated kinase 1-2) [127], Akt [128] and STAT (signal transducer and activator of transcription) [129] pathways. In this section, we describe the discovery of PD0325901, ARRY-142886, and trametinib (GSK1120212), three inhibitors of mitogen-activated protein kinase kinases (MEK), to highlight recent progress in this new area.

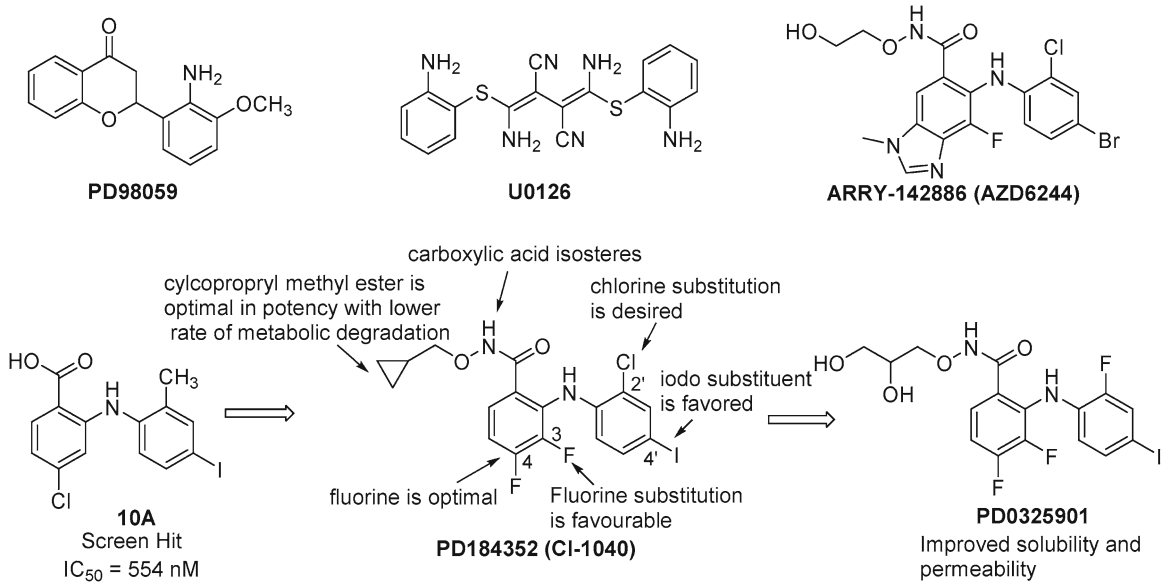

Fig. 40.10 Discovery of MEK inhibitors.

40.2.14 MEK Inhibition

The signaling pathway comprising mitogen-activated protein kinase (MAPK) kinases (MEK) /extracellular signal-regulated kinases (ERK) is activated in most human tumors [130]. Activation of the ERK pathway involves the guanosine triphosphate (GTP)-loading of Ras at the plasma membrane, and the sequential activation of a series of protein kinases. Initially, activated Ras recruits the Raf family of kinases such as Raf-1 to the plasma membrane, where it is then able to phosphorylate and activate MEK1/2 by serine phosphorylation. MEK1 and 2 then phosphorylate and activate their only currently known substrates, ERK1 and 2. When activated, ERK1 and 2 phosphorylate various downstream substrates involved in a multitude of cellular responses such as cell proliferation, cell differentiation, cell survival and cell motility [131].

Because the Raf-MEK-ERK kinase signaling module is activated as a consequence of several gene amplifications and genetic mutations identified in human cancer, it is an attractive target for small-molecule intervention [127]. Selective MEK1/2 inhibitors could be valuable tools to evaluate the role of this signaling axis because MEK1 and 2 have extremely unique characteristics among the components of the ERK pathway. Although Raf-1 is the major activator of MEK1/2, these kinases are activated also by several other kinases such as Mos, A-Raf, and B-Raf. However, no substrates for MEK1/2 have been identified other than ERK1 and ERK2. In addition, MEK1 and 2 are dual-specificity kinases that phosphorylate both tyrosine and threonine residues and can integrate many mitogenic signaling pathways into the ERK pathway. All these very prominent features including unusually restricted and unique substrate specificities and the integrating role of mitogenic signaling pathways highlight MEK1/2 as excellent targets for developing inhibitors against the ERK pathway [127]. Currently, a number of potent and selective MEK1/2 inhibitors have entered clinical development [132]. Most of them are ATP noncompetitive which means they do not directly compete for the ATP-binding site. Rather they bind to a unique allosteric site adjacent to the ATP site. This makes the noncompetitive MEK inhibitors highly specific [133].

From a screening campaign using an in vitro cascade assay, PD98059 (Fig. 40.10) was identified as the first pharmacological inhibitor of MEK1/2 [134]. Meanwhile, U0126 (Fig. 40.10) was discovered by screening a total of 40,000 compounds in a cell-based reporter assay [135]. Because of their poor PK and developability properties, these two early MEK1/2 inhibitors were not progressed into clinical development. Nevertheless, these two compounds were widely used as in vitro tools to elucidate the role of the ERK pathway in a variety of biological processes. The results from these studies have strengthened the hypothesis that the ERK pathway represents an attractive target for developing anticancer drugs.

The discovery of PD0325901 began with the high throughput screening hit **10A** (Fig. 40.10), a potent inhibitor of MEK with an IC_{50} of 554 nM [136]. However, this compound had poor cellular potency likely due to poor cell membrane permeability resulting from the carboxylic acid moiety. In order to improve cellular potency, carboxylic acid isosteres such as benzohydroxamic acid esters were investigated. A variety of small alkyl and cycloalkylmethyl esters showed comparable potency with cyclopropyl methyl ester

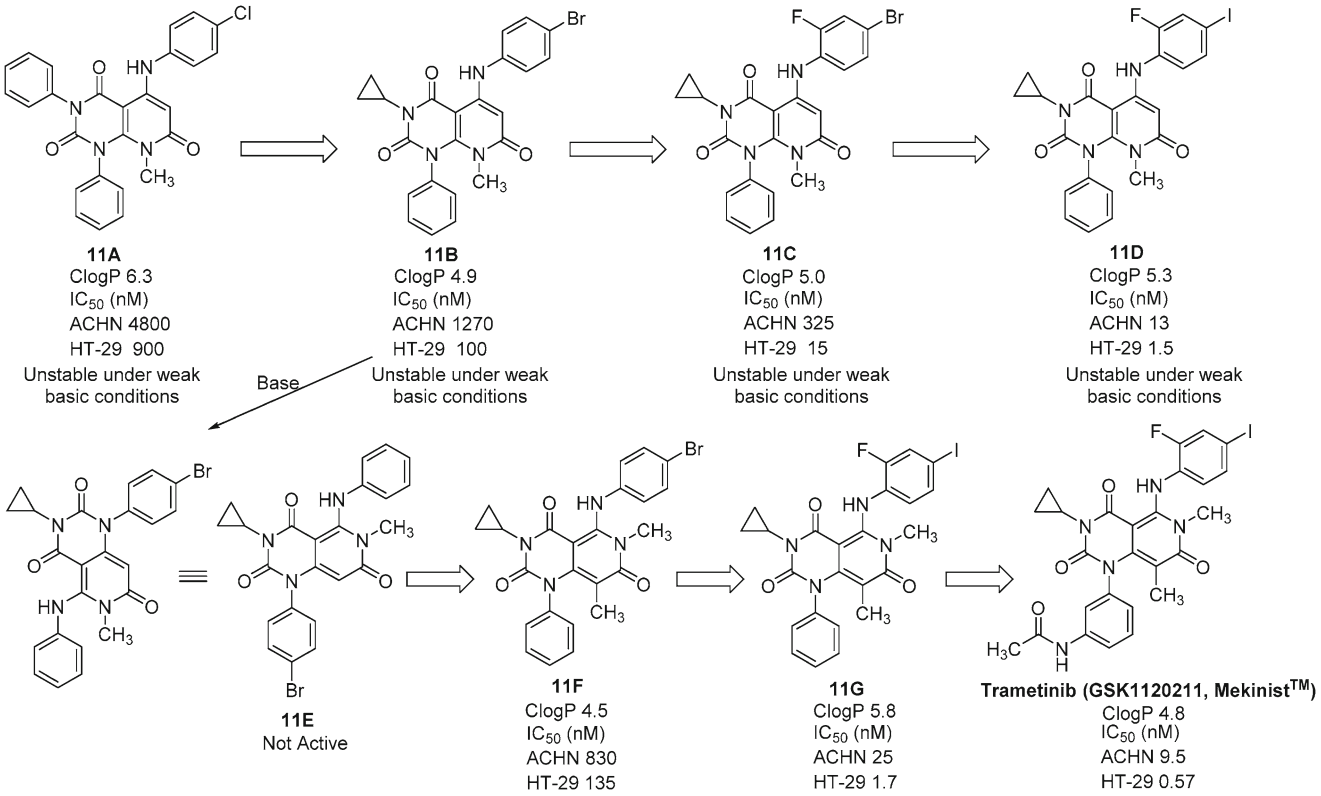

Fig. 40.11 Discovery of trametinib.

being the best. SAR studies also showed that the iodo substituent was favored at the 4′-position and a chloro substituent was desired at the 2′-position. Additionally, a halo substituent at the 4-position, in particular, a fluorine was optimal as the MEK1 X-ray cocrystal structure revealed that the fluorine had a dipolar interaction with the amide backbone [137]. Substitution of fluorine at 3-position gave moderate potency enhancement. These SAR studies resulted in the discovery of PD184352 (CI-1040), which demonstrated in vivo activity in a mouse tumor model following oral administration [138]. This compound was advanced into Phase II clinical trial, but failed for inadequate efficacy likely due to insufficient systemic exposure. The solubility of PD184352 is less than 1 μg/mL in pH 6.5 phosphate buffer, suggesting that low in vivo exposure is at least partly due to solubility limitations. In order to improve aqueous solubility of PD184352, replacing the cyclopropylmethoxy group with a (*R*)-dihydroxypropoxy group and the 2′-chloro substituent with a 2′-fluoro substituent led to the discovery of PD0325901, a second-generation MEK inhibitor. This compound has markedly improved potency, oral bioavailability, and half-life. Excellent anticancer activity has been demonstrated for PD0325901 against a broad spectrum of human tumor xenografts [136]. In an open-label, phase II study, patients with progressive, recurrent, or advanced NSCLC were treated with 15 mg PD-0325901 twice daily [139]. There were no objective responses during the trial period. Due to a lack of responses coupled with the safety issues, the trial was closed after the first stage [132].

In addition, ARRY-142886 (AZD6244, selumetinib, Fig. 40.10), a benzimidazole derivative of PD0325901, was discovered as a potent inhibitor of MEK1/2 with IC_{50} values of 12 nM in an in vitro assay and 8 nM in a cell-based assay [140]. ARRY-142886 is noncompetitive with ATP—potentially explaining its excellent selectivity for MEK1/2 as in the case of other MEK inhibitors. ARRY-14886, which is orally bioavailable and has low metabolic clearance, has been shown to exhibit promising antitumor efficacy in several human xenograft models [141]. Tumor growth inhibition by this compound correlates well with decreased phospho-ERK levels. ARRY-14886 is currently being evaluated in Phase III clinical trials for NSCLC.

Trametinib (GSK1120212, Mekinist™, GlaxoSmithKline) (Fig. 40.11), a selective inhibitor of MEK 1 and 2, has emerged as the first MEK inhibitor to show favorable clinical efficacy in a phase III trial [142] and has been approved by FDA for the treatment of Melanoma in May 2013.

Compound **11A** was identified as a hit via high throughput screening for compounds that can induce expression of the cyclin-dependent kinase (CDK) 4/6 inhibitor $p15^{INK4b}$ (Fig. 40.11) [143]. It was later confirmed that it had an antiproliferative activity against human cancer cell lines ACHN (renal adenocarcinoma) and HT-29 (colorectal adenocarcinoma) with IC_{50} values of 4800 and 990 nM, respectively

[144]. A medicinal chemistry campaign aiming at optimizing these antiproliferative effects led to the discovery of orally bioavailable GSK1120212 (trametinib), which has demonstrated selective inhibition of the proliferation in various BRAF mutant cancer cell lines. Later it was confirmed that this compound was a highly potent and selective inhibitor of MEK1/2 [144].

Compound **11A** has high hydrophobicity (ClogP 6.3). Therefore, the first step in chemical modification was to reduce the hydrophobicity of **11A** by replacing each aromatic ring with a small alkyl group. This resulted in compound **11B**, which contains a cyclopropyl group at the 3-position (upper left) instead of the phenyl group (Fig. 40.11). Compound **11B** exhibited reduced hydrophobicity (ClogP 4.9) and improved potency. Introducing a fluoro group at the 2-position of the aniline ring (compound **11C**) led to ca. four-fold potency improvement. Further exploration of the substitution at the 4-position at the aniline ring yielded compound **11D**, which was significantly more potent than compound **11C**.

Unfortunately, all the above compounds, possessing the pyrido[2,3-d]pyrimidinedione core, were unstable under weak basic conditions. For example, treatment of **11B** with potassium carbonate in methanol/chloroform at ambient temperature provided compound **11E**, which has a pyrido[4,3-d]pyrimidinedione core. Compound **11E** was totally inactive. However, it was hypothesized that compound **11F** could be chemically stable and highly active. Indeed, compound **11F** restored the inhibitory activity up to the level of **11B** but with much more chemical stability. Next, 2-F,4-I aniline moiety was introduced in the same substitution fashion as **11D** and the resulting **11G** had much improved potency as expected. To reduce high hydrophobicity of **11G**, polar substituents at the lower phenyl ring were investigated. GSK1120211, which has an acetamide group, was found to be the best compound.

40.3 Inhibitors Targeting DNA Repair

Numerous DNA repair mechanisms can protect DNA from damage by carcinogens, radiation, and viruses and therefore reduce the efficacy of DNA-interactive anticancer agents [145]. DNA repair is mediated by a remarkable set of enzymes that first recognize the damage and then signal to other enzymes to repair the lesion [146]. A number of distinct repair pathways have been identified with mechanisms ranging from simply removing an extra methyl group to completely excising the damaged segment of DNA and resynthesizing a new one [146]. Agents that target these pathways and mechanisms, thus inhibit DNA repair could potentially enhance the efficacy of DNA-interactive anticancer drugs [145].

40.3.1 Poly(ADP-Ribose) Polymerase Inhibition: ABT-888

Poly(ADP-ribose) polymerase-1 (PARP-1) is the most abundant and well characterized member of the PARP family of nuclear enzymes [147]. Among the 18 members of the PARP family identified and characterized to date, PARP-1 is the most thoroughly studied and PARP-2 has the highest homology to PARP-1 [148]. Highly evolutionarily conserved in all advanced eukaryotes, PARP-1 accounts for >90 % of the ADP-ribosylation within the cell [149]. Only PARP-1 and PARP-2 can be activated by DNA damage. The importance of these two family members in genomic integrity and cell survival has been indicated by the fact that PARP-1 knockout mice are viable, while double PARP-1 and PARP-2 knockout mice are embryonically lethal [150]. Because of the structural similarity between PARP-1 and PARP-2, most PARP-1 inhibitors also inhibit PARP-2.

By sensing and binding to breaks mainly in single-strand DNA, the zinc-finger DNA-binding enzyme PARP-1 becomes activated. It then initiates DNA repair by recruiting and ADP-ribosylating nuclear proteins, such as the scaffold protein X-ray repair cross-complementing 1 (XRCC1), which can, for example, direct DNA polymerase b (polb) to replace a damaged nucleotide. Nuclear proteins associated with apoptosis may also be recruited [151]. Therefore, the PARP-1 mediated poly(ADP-ribosyl)ation of nuclear proteins transforms DNA damage into signals that lead either to cell death or activation of the base excision repair pathway [150].

Since the discovery of PARP-1 about 40 years ago, many inhibitors have been developed both as potential adjuvants for use with DNA-interactive agents in anticancer therapies and as tools for investigation of PARP-1 function [152]. There is now convincing biochemical evidence at the cellular level, demonstrating that PARP inhibition can induce an enhanced sensitivity to ionizing radiation, topoisomerase I inhibitors, and DNA-alkylating agents [148]. The inhibition of PARP-1 has two potential therapeutic applications. The first application is as a chemopotentiator for many DNA targeting anticancer therapeutics as the PARP-1 mediated repair pathway is one major mechanism for the drug resistance and continued tumor growth [153]. Hence, PARP-1 inhibition together with DNA damaging chemotherapeutics or radiation would compromise the cancer cell DNA repair mechanisms, which results in genomic dysfunction and cell death [148]. The second application is as a standalone cancer therapy. It has been recently discovered that PARP-1 can be used as a mono-therapy for tumor types that are already deficient in certain types of DNA repair mechanisms [154, 155].

ABT-888 (Veliparib) was discovered starting from 3-aminobenzamide (**12A**, Fig. 40.12), a starting point for many PARP-1 inhibitors [156]. The very small size and good potency of the benzimiazole carboxamide core (**12B**,

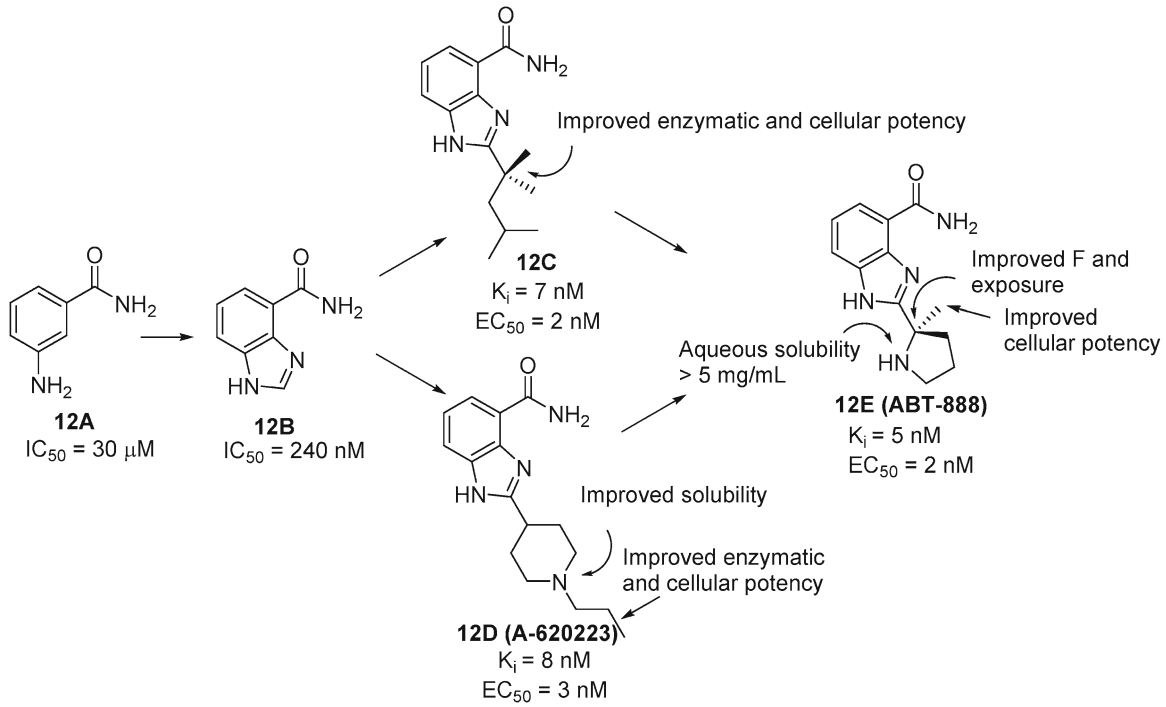

Fig. 40.12 Discovery of ABT-888.

IC_{50} = 240 nM, MW = 161) had attracted the Abbott group to synthesize several hundreds of 2-alkylamino derivatives. As a result, two closely related preclinical candidates **12C** (Ki = 7 nM) [157] and A-620223 (**12D**, Ki = 8 nM) [158] were identified. It was found that a quaternary carbon in the 2-alkyl side chain of the benzimidazole (**12C**) was beneficial for both enzymatic potency and cellular efficacy. Compound **12C** had a relatively short intravenous (iv) half-life across species (from 0.6 h in mice and monkeys to 2.8 h in dogs) and exhibited variable oral bioavailability (from 13 % in monkeys to 82 % in mice) [157]. Because of the variability of PK parameters, this compound was not advanced into human clinical trials. It was also found that adding an amino group provided adequate solubility for the core structure (>5 mg/mL for **12D**), and in the case of **12D**, also improved the cellular penetration and potency in a peroxide induced DNA damage cellular assay (EC_{50} = 3 nM). Compound **12D** showed good oral bioavailability across species (32–82 %) and half-lives of 1.2–2.7 h in the same species. This compound displayed excellent chemopotentiation activity with temozolomide (TMZ) and cisplatin in two subcutaneous, murine tumor models [158]. ABT-888 (**12E**, Ki = 5 nM, EC_{50} = 2 nM), was subsequently discovered from further optimization of this series [159]. The quaternary carbon adjacent to the benzimidazole ring was found to be necessary for high enzymatic potency and cellular efficacy and potency. While the enzymatic potency of **12E** and its (*S*)-enantiomer were identical (Ki = 5 nM), stereochemistry played an important role in both the oral bioavailability and exposure of the compounds. The (*R*)-enantiomer (ABT-888) was selected as the clinical candidate, which demonstrated excellent oral bioavailability across species (56–92 %) and a comparable half-life to preclinical leads **12C** and **12D** (1.2–2.7 h). Moreover, ABT-888 displayed moderate brain penetration (~1:3 brain/plasma ratio in rodents), a factor that influenced the eventual clinical path and its potential use in treating brain cancer. Based on its excellent chemopotentiation activity in preclinical xenograft models with TMZ and carboplatin [159], ABT-888 has been progressed to clinical development and is currently in several phase I, phase II and three phase III studies including neoadjuvant treatment of triple-negative breast cancer, non-small-cell lung cancer and HER2-negative, BRCA1, and/or BRCA2-positive breast cancer.

40.4 Inhibitors Targeting Epigenetic Mechanisms

Epigenetics is defined as heritable changes in gene function without modifications to the DNA sequence itself. Through modifications of chromatin that is primarily made up of DNA wrapped around octamers of histone proteins, these so-called epigenetic changes are present from birth to death and are involved in the first crucial steps that govern embryonic development, and also in influencing the expression and silencing of genes in human diseases [160].

The post-translational modifications of histones and DNA include: histone lysine methylation, arginine methylation,

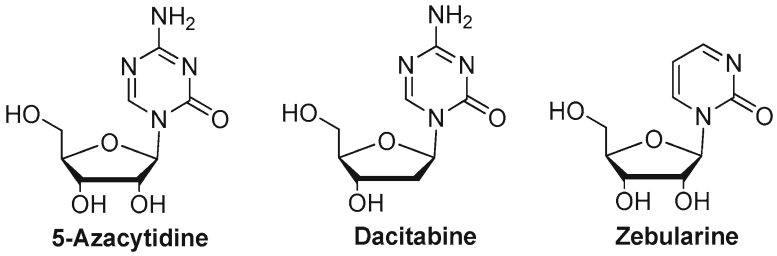

Fig. 40.13 Nucleoside DNMT inhibitors.

lysine acetylation, sumoylation, ADP-ribosylation, ubiquitination, glycosylation and phosphorylation, and DNA methylation [161]. Given the widespread importance of chromatin regulation to cell biology, the "writers" (the enzymes that produce these modifications), the "readers" (the proteins that recognize them), and the "erasers" (the enzymes that remove them) are critical targets for manipulation to further understand the histone code [162, 163] and its role in human diseases.

Epigenetic targets have been considered as attractive targets for therapeutic interventions because of the reversibility of epigenetic modifications [164]. Unlike genetic mutations, which are passively inherited through DNA replication, epigenetic mutations must be actively maintained. Therefore, faulty modification patterns could be corrected by pharmacologic inhibition of certain epigenetic modifications and thus directly change gene expression patterns and the corresponding cellular characteristics. Among the writers, readers, and erasers of the histone code, DNA methyltransferases and histone deacetylases have been studied most. In this section, we describe small molecule DNA methyltransferase inhibitors [165] and histone deacetylase inhibitors [166] approved by the FDA or in clinical development.

40.4.1 DNA Methyltransferase Inhibitors

DNA methylation can inhibit the binding of control proteins, such as transcription factors, to promoters, thus directly switching off gene expression. It is an essential epigenetic modification required for normal mammalian development, gene regulation, genomic imprinting, and maintaining chromatin structure [167]. However, human tumor cells frequently show altered patterns of DNA methylation, particularly at CpG islands, which are DNA sequences rich in CpG dinucleotides often found close to gene promoters [168]. Methylation within islands appears to be associated with transcriptional repression of the linked genes. Genes involved in all phases of tumor development and progression can become methylated and epigenetically silenced [169]. Re-expression of such silenced genes could lead to suppression of tumor growth or sensitization to anticancer therapies [170].

DNA methylation occurs at the C-5 position of cytosine and is carried out by a family of DNA methyltransferases (DNMTs): DNMT1, DNMT3A, and DNMT3B [171]. DNMT1 acts primarily as a maintenance methyltransferase by copying existing methylation patterns following DNA replication [172]. DNMT3A and DNMT3B exhibit de novo methyltransferase activity and are required for establishing new methylation patterns during embryonic development [173].

The prototypical inhibitor 5-azacytidine (5-AzaC; Mylosar™) (Fig. 40.13) has shown promising response rates in myelodysplastic syndrome (MDS) patients and has recently been approved by the FDA. It is a simple derivative of the nucleoside cytidine described more than 40 years ago [174]. Its demethylating activity was discovered later because of its ability to influence cellular differentiation [175]. Inside the body, 5-azacytidine can be chemically modified into a deoxyribonucleoside triphosphate and this triphosphate is able to be incorporated into DNA. When DNMTs methylate the 5-azacytosine residues in DNA, a covalent, irreversible protein–DNA adduct is formed between DNMTs and 5-azacytosine residues, which leads to DNMTs being trapped and inactivated [176]. Consequently, cellular DNMTs are rapidly depleted. As the DNA replication continues, the genomic DNA is demethylated. However, before converted into deoxyribonucleoside triphosphate, a portion of 5-azacytidine can be converted to a ribonucleoside triphosphate and incorporated into RNA, which affects a variety of RNA functions. Therefore, 5-azacytidine has cellular consequences independent of demethylation [177].

5-Aza-2′-deoxycytidine (decitabine, Fig. 40.13), a deoxyribose analog of 5-azacytidine, is another DNMT inhibitor [178]. Because this compound already possesses a deoxy sugar moiety and does not need to be modified before converting to the triphosphate form, it can be more directly incorporated into DNA. Therefore, Decitabine should be theoretically more specific and less toxic than 5-azacytidine. Indeed, greater inhibition of DNA methylation and antitumor activity in experimental models was achieved with this drug [177]. Decitabine, as a single agent, showed activity in myeloid malignancies [169, 179], including myelodysplastic syndrome (MDS), acute myelogenous leukemia, and chronic myelogenous leukemia and has been approved by the FDA for treating all MDS subtypes, though it is used most commonly to treat higher-risk MDS. However, substantial toxic effects were also found with Decitabine, in particular myelosuppression with neutropenic fever [180]. These toxic effects

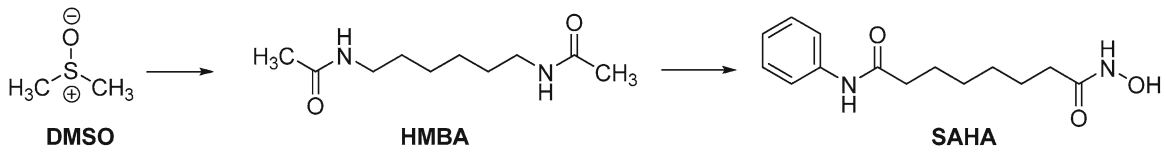

Fig. 40.14 Discovery of ™HDAC inhibitor SAHA.

are likely due to forming the covalent adducts between DNA and the trapped DNMTs [181].

More recently, zebularine (Fig. 40.13), another derivative of 5-azacytidine, has been discovered as a nucleoside DNMT inhibitor [182]. Similar to 5-azacytidine and Decitabine, Zebularine is incorporated into DNA as a cytosine analog after several chemical modifications. It is more stable than 5-azacytidine or decitabine. However, because of the low oral bioavailability in monkeys, Zebularine has not been evaluated in clinical trials [183]. Because of the similar mechanism of action as other nucleoside DNMT inhibitors, zebularine also sufferes from the toxicity resulting from covalent enzyme trapping.

The inherent cytotoxicity of nucleoside DNMT inhibitors poses considerable limitations on their use as therapeutic agents. Non-nucleoside DNMT inhibitors, on the other hand, are likely less toxic because they are not incorporated into DNA. A significant amount of research efforts are devoted to discovering non-nucleoside DNMT inhibitors [165]. Progress in this area is keenly awaited.

40.4.2 Histone Deacetylase Inhibitors

Histone deacetylases (HDACs) and histone acetyltransferases (HATs) control the level of acetylation of lysine residues in histone N-terminal tails [162]. The positive charge on histone lysine residues is masked by the addition of an acetyl group and therefore the affinity of the histones for DNA is decreased (e.g., chromatin opening), which generally facilitates transcriptional activation. Removal of the acetyl group by HDACs reconstitutes the positive charge of the lysine residues and consequently makes that the affinity of histones for DNA is increased, which leads to transcriptional repression (e.g., chromatin closing). HATs and HDACs exist in multi-protein complexes, where they work together to maintain fine control of transcriptional activation and repression [184].

HDACs have been pursued as anticancer targets based on results from numerous target validation studies [185]. It has been shown that aberrant recruitment of HDACs is associated with the development of certain human cancers [186]. By inhibiting the deacetylation of histone lysine residues, HDAC inhibitors (HDACIs) maintain the neutralized charge state on the histones to open up the phosphate backbone of the DNA and therefore facilitate the transcription of many genes, including tumor suppressor genes silenced in cancer. Moreover, acetylation of histones destabilizes DNA–nucleosome interaction and renders DNA more accessible to transcription factors [163]. In addition to inducing growth arrest and activating differentiation pathways, HDACIs have also been shown to be efficient inducers of apoptosis in several cellular systems [187].

There are four classes of HDACs in human with altogether 18 HDAC enzymes [188]. Class I (HDAC1, HDAC2, HDAC3, and HDAC8), class IIa (HDAC4, HDAC5, HDAC7, and HDAC9), class IIb (HDAC6 and HDAC10), and class IV (HDAC11) HDACs are zinc-binding enzymes [189]. The class III HDACs, the so-called Sir2 family, represent a structurally and mechanistically distinct class of NAD^+-dependent hydrolases [190]. Most of the HDACIs developed or being developed to date mainly target class I and II HDACs.

Suberoylanilide hydroxamic acid (SAHA, Vorinostat, Zolinza™) (Fig. 40.14) is the first HDACI approved by the FDA [191]. The discovery of HDACIs began with the initial observation by Charlotte Friend. When dimethylsulfoxide (DMSO) was placed with supertransfect murine erythroleukemia cells (MELCs) in culture, Charlotte Friend, in 1971, observed that many of these cancer cells turned red—suggesting the presence of hemoglobin [192]. Later on, it was found that the polar group of DMSO was required to induce the differentiation of MELCs, and simple polar amides were better than DMSO [193]. Compounds with two amides were found to be more potent, presumably because of the chelating effect that makes stronger binding. This led to the discovery of hexamethylene bisacetamide (HMBA), which was 6- to 20-fold more potent than simple acetamide [194]. HMBA was found to be able to induce growth arrest and differentiation of various transformed cells [195] and selectively alter gene expression [196, 197]. Extensive SAR study of this series led to the discovery of bishydroxamic acids with as much as two orders of magnitude more potent than HMBA in inducing transformed cell growth arrest and cell death [198, 199]. Among them, SAHA was active at low μM concentrations in causing MELC growth arrest and differentiation. The X-ray co-crystal structure of SAHA in complex with a histone deacetylase-like protein (HDLP) has revealed that SAHA binds to the catalytic site of the enzyme [200]. The hydroxamic acid group doubly coordinated to a zinc atom at the bottom of the catalytic cavity. The left-hand side

phenyl group of SAHA interacts with the hydrophobic surface of the enzyme while the polymethylene chain extends down a relatively narrow channel.

SAHA inhibits all class I and II HDACs at about 50 nM and arrests cell growth of a wide variety of transformed cells in culture at 2–5 μM [201–203]. It selectively alters the transcription of expressed genes in transformed cells, which includes the upregulation of pro-apoptotic genes and the downregulation of a constellation of anti-apoptotic genes [204–207]. In October 2006, SAHA was approved by the FDA for the treatment of cutaneous T cell lymphoma (CTCL).

Another FDA approved HDAC inhibitor is Romidepsin (Istodax™) [208] which is a natural product obtained from the bacteria *Chromobacterium violaceum* [209]. It was approved for the treatment of CTCL in October 2009. Most currently, two new HDAC inhibitors, belinostat (Beleodaq™, approved by FDA in July 2014) and panobinostat (Farydak™, approved by FDA in Feburary 2015) have also been approved for the treatment of peripheral T-cell lymphoma and multiple myeloma after at least 2 previous treatments, including bortezomib and an immunomodulatory agent respectively.

40.5 Inhibitors of Emerging Targets

Many emerging targets and novel approaches are being pursued by the academic research community and the pharmaceutical and biotech industry in order to develop novel, more effective targeted cancer therapeutics. In this section, we use the discovery of inhibitors of heat shock protein 90 (HSP90) [210] as an example to highlight the progress made in these novel approaches.

40.5.1 Inhibitors of Heat Shock Protein 90 (HSP90)

The function of the heat shock proteins (HSPs) is to fold and maintain the proper conformation of other proteins, called clients, so that they can function properly. HSPs are therefore molecular chaperones. They are overexpressed when a cell encounters transient temperature increase or other stresses, such as oxidants or radiations, to assist in refolding denatured client proteins [211]. In addition, HSPs play a routine homeostatic role in regulating client protein folding under non-stressed conditions [212]. They account for 5–10 % of all proteins in the cell, and are among the most abundant of cellular proteins. One protein of this type, HSP90, which even under basal, non-stressed conditions comprises approximately 1 % of the cellular protein population [213], is particularly important because it is a master protein that controls a series of other HSPs. It is also crucial for the folding of several client proteins, many of which are highly relevant to cancer including mutated p53 [214], BCR-ABL [214], HER2/neu, Raf-1, VEGFR, Cyclin-Dependent Kinase 4 (CDK4), c-Met, Polo-1, Akt, Src, FLT-3, human telomerase reverse transcriptase (hTERT), and steroid hormone receptors [215–220].

Inhibition of HSP90 causes client proteins to adopt aberrant conformations, and these abnormally folded proteins are rapidly eliminated by cells via ubiquitination and proteasome degradation. Because cancer cells typically have a large number of mutated proteins that might not fold properly, HSP90 is often overexpressed in cancer cells so that even mutated proteins can be folded sufficiently well to avoid disposal by the proteasomes, which allows cancer cells to survive [221]. In general, HSP90 inhibitors display remarkable selectivity for cancer cells compared to normal cells [222]. As HSP90 is involved in the correct functioning of so many oncoproteins and pathways (including signal transduction and transcription), inhibition of HSP90 should be able to block multiple oncogenic pathways in cancer cells, which is more preferable compared with targeting a single point of vulnerability [223]. Therefore, this type of "combinatorial blockade" of oncogenic targets has a greater chance to inhibit most if not all of the hallmark traits of malignancy, has the potential for broad-spectrum clinical activity across multiple cancer types, and could diminish the potential of the tumor acquiring resistance to any single therapeutic pathway.

Among all the 16 HSP90 inhibitors advanced to clinical trials to date [224], SNX-5442, an orally bioavailable and efficacious prodrug of SNX-2112, was developed by Serenex (acquired by Pfizer in 2008) and has been in clinical development since May 2007 [225]. The discovery of SNX-5442 started from compound **15A** (Fig. 40.15), a screening hit with low binding affinity to HSP90 (K_d = 3.7 μM) [226]. Although it was inactive in multiple cellular assays (IC_{50} > 50 μM), compound **15A** was considered a tractable starting point because of its relatively high selectivity for HSP90, high ligand binding efficacy, and chemically novel scaffold that is amenable to a broad range of structural modifications.

Initial SAR studies revealed that the C-2 (*ortho*) substitutions on the phenyl ring with an NH linker increased HSP90 binding affinity. By optimizing this 2-amino moiety, compound **15B** with much improved binding affinity was identified. However, this compound had poor cellular activity. To improve cellular potency, the indol-4-one moiety was modified. It was found that moving the C-2 methyl group to the C-3 position (**15C**) significantly improved cellular potency and activity. However, **15C** was neither orally bioavailable nor effective in mouse xenograft tumor models following intraperitoneal (ip) dosing. In addition, the electron rich trimethoxyaniline ring could potentially be metabolized to reactive quinone species. To address these problems, the tri-

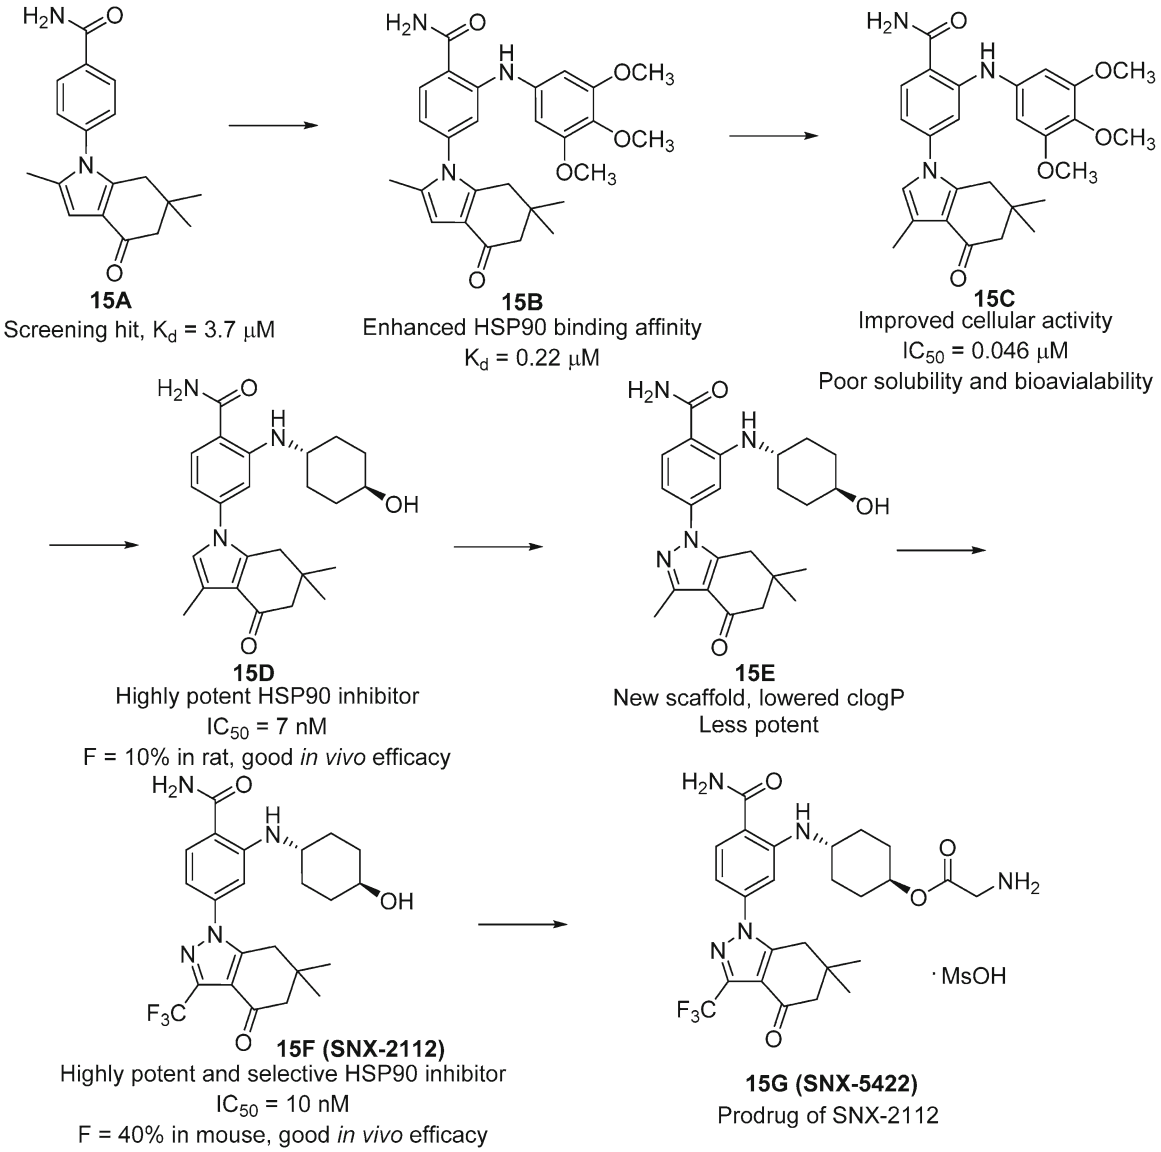

Fig. 40.15 Discovery of HSP90 inhibitor SNX-5422.

methoxyaniline ring was replaced with a trans-4-hydroxycyclohexylamino group, which resulted in compound **15D** with high potency, measurable oral bioavailability (ca. 10 % in rat), and good in vivo efficacy in mouse xenograft tumor models (ip dosing) [226]. Replacing the metabolically liable pyrrole moiety (**15D**) with the pyrazole moiety (**15E**) increased stability and polarity, thus aqueous solubility. However, compound **15E** was less potent than compound **15D**. Further exploration of this new scaffold afforded compound **15F** (SNX-2112), which was equally potent as **15D**. The amorphous form of compound **15F** displayed good oral bioavailability (40 %, mouse) and in vivo antitumor efficacy in mouse xenograft models following oral dosing. Compound **15F** was highly selective for HSP90 over a panel of 75 enzymes and receptors and did not exhibit significant inhibition against a panel of 9 cytochrome P450 enzymes. However, the crystalline forms of **15F** were not orally bioavailable, and their aqueous solubility at physiological pH (7.4) was reduced 25-fold to 6 μM. A simple ester prodrug strategy was explored and resulted in the discovery of the glycine ester **15G** (SNX-5442). SNX-5442 was crystalline, stable, and reasonably soluble (~1 mg/mL, pH 4–6). Excellent exposure of the parent compound **15F** can be achieved following oral and intravenous dosing indicating that the conversion of ester **15G** to alcohol **15F** was rapid and complete in vivo. SNX-5442 was selected as a clinical candidate based on its superior oral bioavailability and in vivo efficacy. Later, the development of SNX-5422 was discontinued during phase I clinical trial based on reports of ocular toxicity and the potential for irreversible retinal damage [227].

40.6 Conclusion

Over the last several decades, discovering and developing targeted cancer therapeutics has been one of the fastest growing areas in the cancer research field. The drug discovery examples described above illustrate the tremendous success in this exciting and fast moving area. As this field continues gaining momentum, one eagerly awaits the arrival of the next groundbreaking discoveries and lifesaving medicines.

Molecular Detection and Diagnosis of Cancer

41

Christos Patriotis, Padma Maruvada, and Sudhir Srivastava

41.1 Introduction

The incidence of cancer is increasing worldwide, owing to the trends toward increased lifespan and adaptation to western lifestyle [1]. Although progress has been made in therapeutic and diagnostic strategies contributing to a slight reduction in mortality, cancer still remains a serious health condition and is often fatal. Many cancer deaths occur because the disease is usually diagnosed at advanced stages and has spread to distant organs with lymph node involvement, where most of the treatment options fail. It has been well demonstrated that if the disease is detected earlier the chances of 5-year cancer-free survival and reduction in mortality are better. For example, colon cancer survival rates for localized disease are 82–93 %, compared with only 5–8 % for cases with distant disease [2]. Similarly, significant mortality reduction in cervical cancer cases is mainly due to the availability of effective screening strategies [3]. Some cancers such as ovarian, pancreatic, and lung remain asymptomatic and are diagnosed at advanced stages with poor survival [4–6].

Cancer detection and diagnosis is critical to population screening, cancer staging, prognosis, and consideration of appropriate measures for treatment. Current cancer diagnostic strategies rely mostly on imaging, tumor size, histology, lymph node involvement, and other clinical parameters. Unfortunately, imaging modalities suffer from lack of sensitivity and fail to detect tumors smaller than 1 mm. Mammography, used to screen breast abnormalities, suffers from lack of sensitivity and leads to a large number of false-positive rates [7]. Malignant tumors are repeatedly much smaller than can be detected by these approaches. For example, colonoscopy is commonly considered the gold standard for detecting colon cancer, yet it fails to detect some of the flat adenomas that are highly malignant [8–10]. Moreover, these approaches do not provide detailed information on molecular phenotypes of cancer. Breast cancer staging and mammography fall short of giving information on personalized treatment choices that are based on molecular analyses such as estrogen receptor expression or human epithelial growth factor receptor (Her-2) expression [11]. There is a clear need for better diagnostic tools that will enable improved prognostic prediction and therapeutic strategies.

41.2 Cancer Is a Molecular Disease

Cancer is a heterogeneous molecular disease and carcinogenesis is a multistep process wherein normal cells evade normal growth regulatory and inhibitory signals and enter a state of uncontrolled cell growth and proliferation leading to malignant transformation. The first step, termed initiation, involves changes at the genetic level and mutations leading to DNA malfunction. This is usually rapid and irreversible with no appreciable morphologic changes. However, it may involve mutational changes in oncogenes and tumor suppressor genes. The second step in the neoplastic transformation is promotion, which involves increased cell growth and proliferation. This step is typically reversible and involves a mixture of genetic and epigenetic cellular changes leading to alterations in protein expression and metabolic pathways. The third step, progression leads to ultimate malignant transformation with a carcinogenic phenotype. The process of progression is very long, often proceeding over many years, and disrupts cellular processes and communication pathways leaving unique cellular and molecular profiles for cancer. These molecular and cellular signatures present great opportunities for the development of clinical tools and assays to diagnose cancer and to complement existing diagnostic strategies.

The systematic study of the cancer genome has led to the discovery of mutations of key members of gene families involved in signal transduction, which are essential for the physiological regulation of gene expression, cell cycle progression, and programmed cell death, and associated with different stages of oncogenesis. The genome-wide analysis of the protein-encoding genes in breast and colorectal cancer has helped define the genetic landscape of these two types of human cancer [12] and such studies are currently extended to other types of human cancer. Pancreatic cancer is an aggressive disease with poor prognosis. The currently 5-year survival rate, despite aggressive therapy is still less than 5 %. Activating mutations of the K-Ras oncogene are highly prevalent in pancreatic cancer (>80 %) [13], and are assumed to occur during the initial stages in its development [14, 15]. Pancreatic cancer is also associated with high rate of inactivation of three tumor suppressor genes: TP53 (~50 %), $p16^{INK4A}$ (80–95 %), and SMAD4 (~50 %) [16–19]. Based on the understanding of the temporal sequence of acquisition of these mutations, a progression model of pancreatic cancer development emerges, in which genetic mutations occur in a temporally ordered sequence. While some function as gatekeepers in the initiation of neoplastic growth, such as the activating K-Ras mutation, others ($p16^{INK4A}$, TP53) allow tumor growth and malignant progression (Fig. 41.1). This illustration is provided only as an example and does not encompass many of the molecular pathways that are associated with different types of cancers and have been extensively studied and reported elsewhere [20–25]. The delineation of the different pathways whose function is altered in different types of cancer provides the scientific basis for the development of novel biomarkers (Table 41.1).

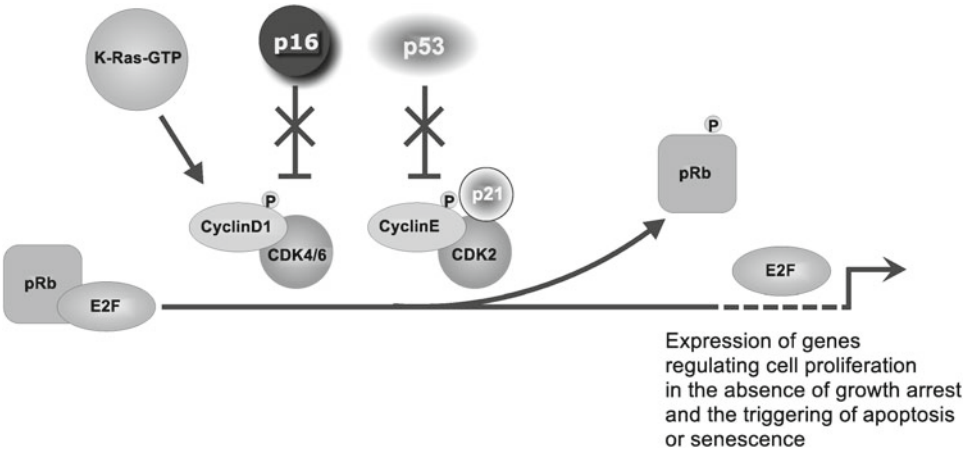

Fig. 41.1 Activating mutations in K-Ras occurring early on during pancreatic cancer development lead to higher proliferating rates of affected cells. While this may trigger the cell surveillance system that may cause cell growth arrest and apoptosis or senescence, the additional loss of expression of $p16^{INK4A}$ and/or mutation of TP53 allow the higher proliferating potential of the cells and the progression toward malignancy.

Table 41.1 Candidate biomarkers for cancer detection, risk assessment, and diagnosis

Type/marker name	Cancer type (organ)	Biospecimen	Utility	Reference
Epigenetic	Kidney	Tissue	Risk assessment	[97]
VHL	Pancreas	Pancreatic fluid	Risk assessment	[18]
$p16^{INK4a}$	Colon	Tissue	Disease recurrence	[98]
TIMP3	Lung	Sputum, Plasma	Diagnosis	[98]
Gene methylation panel				
Genetic	Pancreas	Pancreatic/bile fluids	Early detection	[99]
K-Ras (mutation, amplification)	Colon (HNPCC)	Tissue	Diagnosis	[97]
Bethesda microsatellite panel	Bladder	Urine	Early detection	[98]
Microsatellite assay (MSA)	Esophagus	Tissue	Disease prediction	[98]
FISH panel				
Genomic	Breast	Tissue	Disease prediction	[70]
OncotypeDx	Breast	Tissue	Disease prediction	[80]
Mammaprint				
Proteomic	Liver	Serum	Early detection	[94]
Des-γ-carboxyprothrombin (DCP)	Liver	Serum	Early detection	[94]
Alpha-fetoprotein (AFP)-L3	Liver	Serum	Early detection	[98]
MALDI 6-peak profile	Ovary	Serum	Early detection	[95]
Yale 6-protein marker panel	Breast	Tissue	Disease prediction	[84]
COX-2/Ki67/$p16^{INK4a}$	Breast	Tissue	Disease prediction	[100, 101]
MMP1/CEACAM6/HYAL1	Pancreas	Serum	Early detection	[98]
Mucin protein panel assay				

Identified new targets can be utilized for the design of novel strategies for screening for early cancer detection and molecular diagnosis, and for the development of novel preventive and therapeutic modalities.

41.3 Early Detection Versus Diagnosis

A cancer biomarker is defined as any molecular or biochemical alteration that can be measured and effectively used in a clinical scenario for cancer detection, diagnosis, prognosis, and prediction of therapeutic response. Cancer detection usually involves clinical testing of asymptomatic healthy subjects as in population screening or following stratified high-risk cohorts for the presence of preclinical/early disease. It has several implications in the clinical context, such as enabling further investigation to determine the extent of disease, or taking measures to contain the initial disease by surgical removal, limiting therapeutic treatment, or adapting preventive care. Ideally, a cancer biomarker for detection is present in easily accessible body fluids such as saliva, blood, urine, upper digestive tract effusion, and the material that can be extracted by fine needle aspirates and other minimally invasive procedures. It enables easy screening of a larger population without requiring extensive training and clinical expertise. However, biomarkers for diagnosis need to provide extensive information about the tumor and its microenvironment. For this reason, tissue biopsies and other invasive procedures are also used when necessary to enable critical decisions.

To be useful for detection, a cancer biomarker ideally should be able to distinguish normal individuals from cancer patients with 100 % accuracy. Sensitivity and specificity determine how accurately a biomarker can predict the presence of a disease and its ultimate utility in clinical practice. Sensitivity is defined as the ability of the biomarker to detect the cancer cases (true positive); while specificity is defined as the ability of the marker to identify the healthy cases (true negative). A useful biomarker should be able to detect cancer with high precision, allow early detection of the premalignant lesions and ultimately reduce mortality due to cancer. Unfortunately, most of the current biomarkers do not have sufficient diagnostic power to be clinically useful if used alone. The widely used clinical marker prostate-specific antigen (PSA) has only 70 % sensitivity and 59–97 % specificity [26–28]. When used in population screening, PSA, due to its low specificity, leads to many false positives and triggers unnecessary biopsies and clinical follow-up. CA-125, the biomarker for the detection of ovarian cancer, has only 70 % sensitivity and 87 % specificity and is not currently recommended for population screening [29–32].

In contrast, diagnosis of cancer requires more confirmatory tests with high precision and sensitivity to enable more critical decisions, such as surgical removal of vital organs, decisions related to suitable chemotherapy, preserving unaffected organs and follow-up. Moreover, it is important to differentiate different types of cancers that affect the same organ to enable additional diagnostic and efficient treatment strategies. *BRCA1* and *BRCA2* mutations affect the incidence of genetically predisposed breast cancers. Genetic screening of breast cancer patients for these mutations is complex and time-consuming owing to the large size of both genes. It is desirable to have more understanding of both the phenotype and the morphological and molecular characteristics of the tumors underlying these mutations. *BRCA1*-associated tumors are usually poorly differentiated, infiltrating ductal carcinomas and show frequent morphological features of atypical medullary carcinomas. *BRCA2*-associated tumors tend to be of higher grade than sporadic cancers. Additionally, *BRCA1* tumors are usually estrogen receptor and progesterone receptor negative and p53 positive, whereas such changes are not seen in *BRCA-2*-associated tumors. Both *BRCA1*-associated and *BRCA2*-associated breast tumors show a low frequency of Her-2 overexpression compared to sporadic cancers, in addition to various other molecular abnormalities [11]. Such information can be especially useful in making decisions in appropriate screening and therapeutic choices. However, the current imaging modalities only provide spatial resolution of tumors, but not their molecular composition. As such, there is a continuing need for multiple molecular markers to enable accurate detection and diagnosis of the disease.

41.4 Molecular Biomarkers of Cancer

The biology of carcinogenesis provides a large window of opportunity to study the range of molecular events that can provide information on malignant transformation. Over the last 30 years, there has been a tremendous explosion in the understanding of cancer biology. For example, it has been well characterized that Ras and Raf mutations and alterations in downstream MAP kinase pathways frequently form the early events in malignant transformation and have been explored as potential anticancer targets in a variety of cancers [33]. Epidermal growth factor receptor (EGFR) mutations have been implicated in the progression of breast, lung, and other cancers. Epigenetic changes and *P53* mutations have been indicators of late events of progression [33–35]. While many of the alterations in these pathways could provide molecular signatures that oncologists can reliably use in the detection and diagnosis of cancer, none of them have actually translated well into clinical application. One of the main problems in molecular diagnosis of cancer is that it is a cellular proliferation disease and many of the cancer-related proteins and changes are part of normal pathophysiological

phenomena and not specific to cancer. No abnormal molecular changes are effectively detected that indicate malignant transformation. Many of these events are viewed as part of the body's normal inflammatory responses. For example, it has been demonstrated that many of the initial changes are usually confined to the tumor microenvironment, making them inaccessible for noninvasive molecular diagnostic approaches [36]. The magnitude of the malignant changes associated with minute tumors by and large go undetected mainly because these changes are very small compared to variations in normal cellular and physiological processes. Confounding this problem is that most of the molecular detection approaches lack sufficient analytical sensitivity to detect such subtle changes. The detection sensitivity of currently used ELISA and other clinical assays is 1–2 pg/ml, which fails to detect molecular markers associated with cancer that are secreted at much lower levels (fg/ml) [37–40]. Detection systems with much lower detection limits (in Pico- and Femto-molar concentrations) are needed to detect such abnormal proteins.

41.5 New Technologies for Detection and Diagnosis Marker Discovery

Genome-wide DNA sequence analysis has led to a surge in the enthusiasm for the application of distinct high-throughput approaches to analyze multiple biomolecules giving rise to novel omic technologies. Using these technologies, it is now possible to analyze multiple molecular changes in DNA (genomics), RNA (transcriptomics), proteins (proteomics), or metabolites (metabolomics) in a limited sample size in a single platform, thereby saving time, efforts, and costs.

Current cancer research has taken a multidisciplinary approach to address the gaps in the translation of cancer molecular biomarkers into the clinic. This approach may lead to the identification of novel biomarkers that conventional approaches have long failed. High-throughput molecular analytical techniques combined with the latest tissue acquisition techniques, such as laser-aided microdissection enable global molecular profiling with very high precision. Both targeted and untargeted approaches are employed giving rise to information on either known molecular species or molecular profiles, such as in mass spectrometry. The resulting data are analyzed using state-of-the-art computational analytical tools for pattern recognition allowing the differential diagnosis of cancer. It is generally unnecessary to identify the molecular nature of the peaks (black box approach). With computational methods, it is possible to integrate the information from diverse markers to improve their clinical sensitivity and specificity for cancer detection and diagnosis. This has opened the door to a novel paradigm of cancer diagnosis in which a single marker for a single disease is no longer the norm. Instead, multiple markers for a single disease are the mode of choice. It is assumed that such a strategy allows accurate measurement of unique biological processes measured simultaneously and integrated for improved diagnosis.

41.6 Role of Specimens in Biomarker Development

Most of the molecular analysis approaches rely on the availability of freshly collected tissues as compared to fixed tissue and archived specimens. Some of the molecular approaches demand highly defined and precise cellular species. The introduction of laser scanning capture microdissection (LSCM) techniques into clinical specimen collection has improved the quality of the specimens for analysis. The need for immediate sample processing, fresh-frozen tissues, and concomitant specimen storage conditions, and the effect of the length of storage time make the molecular diagnostic approaches difficult to adapt in clinical practice. These issues undermine the utilization of existing repositories for biomarker development. However, some recent development efforts focused on the utilization of fixed tissues by high-throughput molecular approaches are improving this situation. The collection of specimens for molecular analysis, such as nipple aspirate fluid and ductal lavage for breast cancer detection and pancreatic effusion fluid for pancreatic cancer detection, poses further challenges in molecular diagnostics, and the development of special collection methods is needed.

41.7 High-Throughput Analysis and Biomarker Development

One of the main issues in high-throughput technological analysis is analytical sensitivity. Depending on the sensitivity of the technology employed, the numbers of molecular species resolved can vary widely. For example, 2D gel electrophoresis has a limited resolution of only 200–300 proteins per analysis and mainly focuses on the resolution of highly abundant proteins. More advanced mass spectrometric analyses, however, allow the resolution of hundreds to thousands of proteins ranging from MW 2000 to 30,000. As such, it may not always be possible to resolve both high-abundant and low-abundant proteins on the same technology platforms but it is usually difficult to compare proteins resolved on different platforms. It is possible to identify some of the low-abundant proteins (functional peptidomics), using more advanced mass spectrometric techniques combined with time-of-flight (TOF) techniques, and exoprotease digestion techniques [41]. Mass spectrometric techniques routinely suffer from inconsistencies in reproducibility mainly because of the nature of instrumentation, mass calibration shifts and

factors related to baseline correction in mass spectrometric analysis [42, 43]. Another confounding factor in reproducibility is the batch variations in protein chips; it is normally difficult to overlay the sets of features from different runs of the same specimens and to validate these molecular features as biomarkers.

High-throughput approaches, such as mass spectrometry, yield patterns and profiles that are subjected to computational analyses to simplify the dimensionality of the data and to identify meaningful patterns that may be clinically significant. Two major types of computational approaches, namely supervised and unsupervised methods, are applied to analyze the data. In the supervised methods, the information is organized in a predetermined fashion as to which molecular changes are expected to group together and the resulting patterns are analyzed collectively for their ability to differentiate cancers. When applying supervised approaches, it is difficult to analyze the patterns without established classification rules. Depending on the size of the training set, the test results give diverse patterns that may not be reproducible. With unsupervised methods, the data are grouped based on their inherent expression patterns and the resulting profiles are tested for their ability to group together and predict the outcome. Unsupervised approaches rely on imposition of algorithms that tend to fault depending on the method. Thus, the method of data analysis plays an important role in biomarker development. One of the confounding aspects with high-dimensional data analysis is the signal-to-noise ratio. Many genes undergo changes in expression that are not necessarily specific and related to cancer. These changes are recorded by microarray and other high-throughput approaches, thereby resulting into complex patterns and enormous volumes of data and leading to erroneous over-fitting of the data.

Another critical factor in the application of high-throughput technologies in biomarker development is that the platforms for discovery and development may not be the same as for clinical application, where more directed, simpler, and specific tests are needed. Typically, more than one approach can be applied to detect a molecular marker. For example, three molecular tests for human epidermal growth factor receptor-2 (Her-2/neu) oncogene expression have been approved by the Food and Drug Administration (FDA): one to monitor the treatment response of breast cancer with herceptin, a second to determine the sensitivity to doxorubicin therapy, and the third for the early detection of recurrence and to determine the prognosis of breast cancer [44–46]. Her-2 expression can be detected by various methods at the protein level (by immunohistochemistry; IHC), at the DNA level [using fluorescence in situ hybridization (FISH) analysis and polymerase chain reaction (PCR) amplification] or at the messenger RNA level. The FDA-approved tests include a FISH-based molecular assay and two antibody-based assays. However, a number of antibodies with varied sensitivity are commercially available, which together with kit to kit variability they make the detection of Her-2 a complicated task with many false-positive cases and misleading results. While FISH analysis is very sensitive, its high cost and marginally superior results make it less attractive as a routine monitoring tool [46]. Thus, the choice of the test method and its application depends on the analytical sensitivity and the cost-effectiveness.

The molecular profiles or signatures that arise from mass spectrometric and other high-throughput approaches may have clinical significance and could be successfully applied in the clinic if they have high sensitivity and specificity (even without prior knowledge of the molecular species contributing to the signatures). However, the negative results are difficult to interpret; hence, the absence of information on the peaks can often lead to inconclusive results. These molecules therefore should be further characterized using more specific analytical methods such as southern, northern, and western analyses or quantitative polymerase chain reaction (qPCR) and IHC, which can allow easier application of the molecular tests in a clinical setting [47].

Approaches to detect LMW proteins include the use of nanoparticles conjugated to molecular baits. These enable selective LMW protein binding and release on harvest platforms with nanoparticles such as nanobarcodes with distinct physicochemical properties [48].

One of the impediments in cancer biomarker development is that the tumor-specific proteins and cytokines are secreted at very low concentrations below the analytical sensitive range of most clinical methods. The real challenge is to identify such low abundant proteins that can provide critical information on the nature of a tumor. A variety of approaches are applied to detect such proteins either on sandwich arrays, where a pair of antibodies is used to detect each protein, or a label-based system, where target proteins are labeled to enable detection after they bind to the arrays. These approaches are highly sensitive and specific and assays are generally easy to develop [49, 50]. There are also other approaches that may significantly improve the sensitivity, accuracy, and reproducibility [50]. These include the two-color rolling-circle amplification antibody arrays, which amplify the signals from labeled proteins. Such methods allow detection of multiple proteins from two different sets of samples simultaneously. Two sets of samples are covalently labeled with biotin and digoxigenin individually and incubated with antibody arrays. The immobilized labeled proteins are detected using antibodies against biotin and digoxigenin that are covalently conjugated to two separate primers. The primers are amplified by complementary circular DNAs tagged to two different colors (cy5 and cy3) by DNA polymerase. This results in signal amplification in two colors for two different sets of proteins. These approaches allow acquisition of expression profiles of multiple proteins

from diverse samples and require very small biological specimens with minimal processing, making them attractive analytical tools. Although still in the developmental stage, these tools are beginning to show promising results when applied to clinical specimens [50].

Host immune systems play a critical role in surveying infectious and foreign bodies, including tumor antigens, and responding by eliciting antibodies, thereby paving the way for novel detection strategies for early detection of cancers. Autoantibodies are promising tools for detecting cancers as they are elicited in response to low concentrations of circulating tumor antigens; and the production of a large repertoire of antibodies makes the detection highly sensitive. Unlike tumor antigens, which are usually degraded by proteases, the antibody response persists for a long time even after the antigen has been removed from the circulation. They are more stable with a relatively long half-life in circulation. Assorted targeted antibody array approaches are attempting to identify cancer-specific autoantibodies that have promise for cancer detection, diagnosis, and therapeutics. These approaches make use of antigen libraries created on a variety of biological vectors such as phages, yeast, and others created from cancer cell lines, or by expressing protein in situ using DNA vectors and in vitro translation methods [51, 52]. The protein arrays are challenged with sera from healthy individuals and cancer patients to identify cancer-specific autoantibodies that interact with tumor antigens present on the arrays. Although the field is still emerging, growing evidence indicates that this approach may have important implications in cancer detection and diagnosis [51, 52]. Other emerging biomarker discovery modalities include the application of molecular species-specific flow cytometry to study pathological signal networks at the single cell level. Danna et al have used this approach to study molecular signaling alterations in acute myeloid leukemia [53].

MicroRNAs are small non-coding highly conserved RNAs that are derived from pre-miRNA precursors by cytosolic RNase action. They play an important role in diverse cellular functions including proliferation, differentiation, and death. Currently, more than 400 miRNAs have been identified. The relatively small numbers of miRNAs and their role in cellular functions make them promising candidates as biomarkers for diagnosis and detection. Despite the fact that the miRNA field is still in its infancy, evidence suggests miRNAs can provide critical information on the diagnosis, prognosis, and therapeutic targets of cancer [54]. Using miRNA microarray analysis, Bloomston et al identified several miRNAs that are differentially expressed among pancreatic adenocarcinoma, benign pancreatic tissue, chronic pancreatitis, and normal pancreas [55]. Using the Predictive Analysis of Microarrays method, they identified a subset of 21 miRNAs overexpressed and four miRNAs underexpressed that could discriminate pancreatic cancers from normal pancreatic tissue with 90 % accuracy. In the same study, they identified a set of 15 miRNAs overexpressed and eight miRNAs underexpressed which could identify pancreatitis from pancreatic cancers with 93 % accuracy. A set of 15 overexpressed miRNAs and two underexpressed miRNAs could differentiate pancreatitis from normal pancreas. These early results need further study, but these studies demonstrate the potential role of miRNAs as candidate diagnostic markers. miRNAs are being explored in many cancers for their diagnostic ability [54].

Other omic technologies that hold promise for the development of novel cancer biomarkers are metabolomics, the study of small molecules or molecular profiles in tissues or body fluids. Metabolomics broadly applies to nuclear magnetic resonance (NMR) and mass spectrometric technologies to measure a variety of metabolites or their profiles, which leads to enormous amounts of data. The relatively small number of metabolites compared to the number of proteins or genes present in the human body makes them attractive candidates for disease detection, diagnosis, and other clinical applications. However, the metabolome or metabolic profiles of a physiological system is dynamic and subject to influences such as environmental, pharmacological exposure, temporal, dietary, physiological, age, sex, and genetic predisposition. The technology has great promise and its potential is only beginning to be explored in cancer research. Recently, metabolomics technologies were applied to the differential diagnosis of ovarian cancer using differences in spectral patterns of healthy and affected women [56]. In this study, sera from 12 women with benign ovarian cysts, 38 ovarian cancer patients, 19 pre-menopausal, and 32 post-menopausal healthy women was subjected to ^{1}H-NMR spectroscopy and the resulting data were analyzed using both supervised and unsupervised methods. Demonstrating the promise it holds for future molecular diagnosis, researchers were able to identify a pattern that could discriminate between ovarian cancer and healthy subjects. Moreover, these patterns allowed discrimination between benign cases and ovarian cancer patients. Using fine needle aspirate biopsies from 140 patients with breast lesions analyzed by ^{1}H-NMR spectroscopy and pattern recognition analysis, Mountford et al were able to classify benign cases from malignant cases with 93 % sensitivity and 92 % specificity [57].

41.8 Molecular Imaging in Cancer Detection and Diagnosis

Functional magnetic resonance (MR) techniques such as dynamic contrast-enhanced MR imaging (DCE-MRI) and magnetic resonance spectroscopic imaging (MRSI) combine the virtues of conventional imaging with molecular profiling. Besides the spatio-temporal resolution of tumors, these enable additional novel molecular information on tumor metabolism, and provide more sensitive and accurate strategies for molecular diagnosis. Using this strategy, van Dorsten

et al have shown that the diagnostic sensitivity of prostate tumor regions can be significantly enhanced by adding metabolic profile information to the quantitative DCE-MRI [58]. It was shown that the ratio of (choline + creatine)/citrate was elevated in prostate cancer compared to healthy zones peripheral to the tumor and in the central gland. A ratio above 0.68 is a reliable indicator of cancer in determining the cancer-affected regions. Such an approach is feasible in clinical practice and has excellent clinical implications. Positron emission tomography (PET) imaging is another modality that has been approved by the FDA to determine cancer staging. It provides useful information on spatio-temporal resolution of the tumors. With the aid of specialized metabolic analogs, it is possible to visualize the tumor metabolism to distinguish between indolent and malignant cancers and normal tissues. The most frequently used PET agent is [^{18}F] fluorodeoxyglucose (FDG), a glucose analog taken up by highly metabolizing tumor cells, which allows the study of tumor metabolism. Many contrast agents have been approved by FDA for clinical applications that are used in molecular imaging. This approach has been approved for tumor staging of several cancers including breast, lung, and colon [59–62].

Other molecular imaging modalities for cancer detection utilize optical probes that can be triggered by cellular proteases that are specifically activated in cancers. Such approaches have been used in mouse models to detect lung tumors smaller than 1 mm diameter [63]. Similarly, fluorescent-based imaging agents in combination with endoscopic confocal microscopy allow detection of precancerous lesions that are not identified by conventional imaging methods [64]. Such imaging modalities have much higher sensitivity and provide high spatial resolution that is not possible with conventional modalities. The use of magnetic nanoparticles can provide information on cancer staging and have been applied to detect nodal metastasis in patients with occult cancers [65]. A functionalized nanoparticle-related approach allows the study of cellular functions, including cellular trafficking and receptor-based targets such as prostate-specific membrane antigen (PSMA), HER-2/neu, estrogen, progestin, and androgen receptors [65]. Animal models have been used extensively in molecular imaging for the evaluation of both the contrast agents and the imaging technologies [65].

41.9 Role of Animal Models in Biomarker Discovery

Animal models provide great biological tools for cancer biomarker development. Genetically, engineered mouse models based on genetic mutations mimic human disease conditions and provide a great deal of information on molecular pathogenesis. This provides a unique opportunity for the discovery of diagnostic biomarkers [63]. Animal models allow homogenous genetic background and controlled environmental exposures to reduce variability and control for other confounding factors among samples, thus providing samples from the same mice before and after onset of malignancy. Mouse models based on conditional activation of genetic mutations provide information on spatio-temporal regulation of carcinogenesis. These models can be explored further to identify novel blood-based biomarkers and to augment other strategies. Genetically engineered MIN mice, which harbor a germ-line truncation in the adenomatous polyposis coli (APC) gene, produce colon cancer similar to human colon cancers, and the genetically predisposed human condition known as familial adenomatous polyposis (FAP) syndrome. These mice have been used to study the novel optics technology of four-dimensional elastic light scattering finger printing (ELF) at several points in the neoplastic process. They have also been used to study the responsiveness of chemoprevention strategies and the efficacy of chemopreventive agents for the early detection of intestinal tumorigenesis before the clinical manifestation of the disease [66].

41.10 Translation of Cancer Biomarker Discovery to the Clinic

Cancer detection and diagnosis play a critical role in the management of disease treatment. Application of cancer biomarkers in clinical use will revolutionize cancer screening and open new avenues for personalized medicine. Recent molecular technologies offer great potential for discovery and development of novel biomarkers that will enable effective cancer screening and detection. Discovery is important, but for biomarkers to reach clinical application they need to be critically evaluated and validated both analytically and clinically. A five-phase biomarker development process has been proposed that lays out a systematic approach to bring putative biomarkers from discovery to ultimate clinical application for cancer detection (Fig. 41.2) [67]. These phases include: preclinical discovery, clinical and analytical validation, retrospective and longitudinal evaluation, prospective screening, and finally, cancer control for the utility of the marker. A similar approach can be adopted for validating diagnostic biomarkers. It is usually necessary to conduct pre-validation studies before determining the need for a successful validation study. Such an effort will help eliminate the gap between translational efforts.

Randomized prospective trials of biomarkers will prove their ultimate utility for clinical prediction of cancer detection and diagnosis. However, such trials are expensive and typically time-consuming. Validation of biomarkers requires a coordinated, multidisciplinary, and multi-institutional effort. Advances in novel methodologies of data analysis, data modeling, and integration of information from panels of

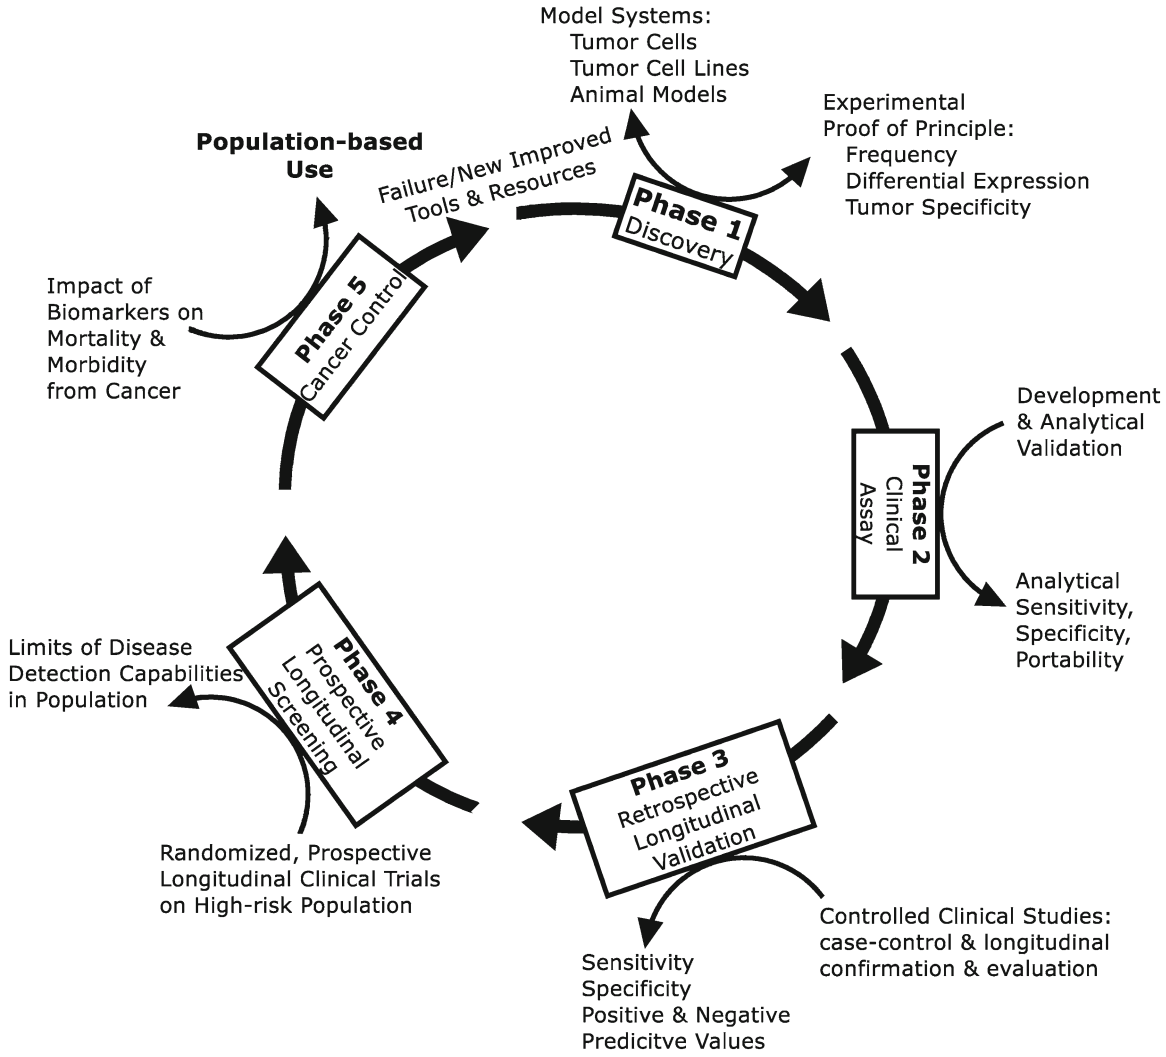

Fig. 41.2 A 5-phase, cyclic process of development of molecular markers for early detection and diagnosis. Adapted with modifications from [102].

biomarkers and algorithms to predict successful recognition patterns for biomarker profiles are necessary. Well annotated specimens and well characterized reference sets for triaging putative markers are critical. Novel high-throughput technologies require well developed standardized protocols and procedures and ways to translate them into clinically applicable assay methodologies.

While thousands of biomarkers are discovered, very few sustain the validation process to be approved by FDA for clinical use [68]. One reason for this is the discordance between academic investigators and diagnostic companies. It is considered that biomarker development is not as exciting as discovery. Conversely, efforts to advance potential markers into clinical application have been painstakingly slow even though the importance of biomarkers in cancer screening is highly recognized [69]. The general perception is that support from the federal agencies is essential to advance biomarkers across the translational architecture. To meet this challenge, the Department of Human Health Services has adapted many approaches. In 2002, FDA set up an exclusive regulatory unit, the Office of In vitro Diagnostic Devices, to expedite the approval process for biomarker and diagnostic devices. FDA and the National Cancer Institute (NCI) created a Critical Path Initiative to bridge the gaps in translational efforts in biomarker development. The Center for Medicaid and Medicare Services has been forthcoming in approving promising biomarkers and tests that can be applied in a research setting before they can be successfully approved by the FDA. For example, Oncotype DX™, a 21-gene panel which holds promise for predicting recurrence of breast cancer, was recently approved for use in a research setting [70]. NCI initiated the Early Detection Research Network (EDRN) program to coordinate translational biomarker developmental efforts [71–74]. The efforts are expected to expedite the validation process and fill a key gap in biomarker research [75, 76].

Cancer biomarkers will be able to detect early cancers and pave the way for personalized choices for cancer treatment and subsequently bring down the costs associated with it. Today, cancer detection and diagnosis strategies heavily depend on imaging modalities. Mammography is the method of choice for screening women above age 40 for breast cancer and colonoscopy is the screening strategy for people above 50 for colon cancer. It is unlikely that biomarkers will be able to eliminate existing imaging modalities. However, they will be able to complement them in providing additional information that may not be possible by current screening. The ultimate utility of the cancer biomarker is its ability to reduce cancer-associated mortality. The best biomarkers will be able to detect cancer early enough to allow intervention, reduce costs associated with cancer treatment, and reduce cancer-related mortality and morbidity. It appears that no single biomarker will have the necessary sensitivity and specificity to predict cancers accurately. Instead, panels of genes, proteins, or other candidate signatures obtained from novel high-throughput technologies will collectively provide useful information on cancer development and progression.

41.11 New Era of Molecular Detection and Diagnosis

Despite unresolved issues, high-throughput technologies are already providing evidence as promising tools for biomarker development. While few of these molecular tests have entered clinical practice, increasing evidence suggests they will play a critical role in aiding decisions related to personalized medicine for treating and managing disease. In this section, examples are discussed in which molecular diagnostic techniques may soon be applied in the clinic for numerous cancers to improve clinical diagnosis, monitoring of treatment, and management of disease. A small number have been approved for early detection of cancer and they provide excellent evidence and promise for the future development of molecular diagnostic tests.

41.11.1 Organ-Specific Biomarker Effort

Breast cancer is a heterogeneous disease with diverse clinical outcomes. Over the last two decades, there has been a documented decrease in mortality rate largely due to improvements in early detection and therapeutic strategies [77, 78]. However, the clinical outcome and the therapeutic course of an individual patient are customarily uncertain. Molecular profiling of breast cancer not only sheds light on different subtypes of breast tumors, but provides information clinically applicable for the prognosis. Several prognostic indicators based on clinical and histopathologic variables, such as tumor size, lymph node status, and hormone receptor status, already are used in clinical practice. Yet, these indicators still fail to determine the specific risk for recurrence associated with each patient. Several groups have developed a range of prognostic profiles using microarray approaches that provide specific information about breast cancer prognosis using both supervised and unsupervised analytical methods [79]. They have been validated using independent patient populations. Among them, the Amsterdam 70 gene profile popularly known as Mammaprint has been developed using microarray profiling of fresh-frozen tumors from two distinct populations, one with and one without distant metastasis. Using a supervised analytical approach, they identified a 70-gene set that appeared to correlate with the clinical outcome. The 70-gene panel, which was approved by FDA, was validated using retrospective analysis of 295 patients. It was able to predict prognosis regardless of lymph node involvement and acts as an independent risk factor for distant metastasis [80]. The 21-gene recurrence score indicator popularly known as Oncotype Dx, developed from a literature and database search, selected a 16-cancer-gene panel and a 5-reference-gene panel from 250 candidate genes. Their expression profiles were later established using fixed tumor samples and externally validated in patient samples collected for the National Surgical Adjuvant Breast and Bowel project, and then validated further in a number of studies [70]. The Recurrence Score provides reliable and reproducible information on the recurrence and therapeutic response. The Rotterdam 76-gene signature was developed by the expression profiling of more than 200 lymph node negative patients with both ER- and ER+ breast cancer, which outperformed clinical variables in predicting prognosis [81, 82]. Several other prognostic signatures still under study may be of high significance in clinical application. About 65,000 women are diagnosed annually with breast ductal carcinoma in situ (DCIS). All patients are treated similarly with lumpectomy and additional radiation or tamoxifen. However, only ~15 % of them will recur within 5 years and only half of the recurrent disease (~6.2 %) will be an invasive breast cancer (ICA) [83]. In a preliminary study, three protein markers were identified, whose individual expression pattern in DCIS lesions can provide information for patient risk stratification for a subsequent recurrent malignant event (ICA) [84]. While patients at a higher risk of ICA may undergo more aggressive preventive treatment, those at low risk may be spared the morbidity of unnecessary treatments. A large case–control study is currently being initiated by EDRN investigators at the University of California San Francisco to validate the clinical utility of the 3-marker panel.

Bladder cancer is the sixth leading cause of cancer deaths and as a matter of course it results in high recurrence rates. Cystoscopy, which is highly invasive, serves as the gold standard for monitoring the recurrence and diagnosing bladder

cancer with a sensitivity of 73 % and specificity of 37 % [85]. Urine cytology, another promising diagnostic tool, also suffers from low sensitivity and specificity leading to high number of false-positive rates. There is a need for a noninvasive, easy to administer test with reasonable performance characteristics that can either complement or be used alone. Numerous tests have been discussed in detail elsewhere, some of which have been recently approved by the FDA [85]. A variety of urinary proteins show promise as diagnostic biomarkers. Nuclear matrix protein 22 (NMP22) is a protein expressed by a variety of cell types and is found in the urine of bladder cancer patients at high levels. It has been approved by FDA as an inexpensive and sensitive tool that can be used as an adjunct to current diagnostic methods [86, 87]. Basement membrane antigen (BTA) has a sensitivity comparable to urine cytology and is approved as both qualitative and quantitative tests [88]. The ImmunoCyst test, based on sialylated carbohydrate on a mucin protein and 19A211 cell surface glycoprotein and the LDQ10 antigens by immunofluorescence microscopy, is also approved as an adjunct test for detecting bladder cancer. While tests are proposed and approved for diagnosing and managing bladder cancer, most suffer from low specificity and high false-positive rates, mainly because of interference due to other urological conditions such as inflammation and urinary infections and stones. Abnormal increased copy number of chromosomes 3, 7, and 17, and homozygous deletions of the p16 at 9p21 have been used to develop a FISH-based assay with high sensitivity (81 %) and specificity (96 %), which is approved by FDA as an adjunct diagnostic test. A microsatellite instability assay (MSA) has been recently developed by EDRN investigators at Johns Hopkins University, which can detect bladder cancer in urine sediment with an accuracy of >90 %, frequently 6–8 months prior to a positive cystoscopy [89, 90]. A large-scale validation study is currently being conducted to confirm the detection power of the MSA test.

Pancreatic cancer poses a serious health problem causing death in more than 98 % of the affected populations. Currently, pancreatic cancer is diagnosed at advanced stages. There are no approved diagnostic markers. CA-19-9, a sialylated Lewis blood group antigen, was approved for monitoring treatment, but it has very low specificity due to other confounding health conditions involving the pancreas. Efforts are underway to develop biomarkers for pancreatic cancer using a variety of approaches. Among them, global gene expression profiling of pancreatic cancer and normal pancreatic tissues has been used in identifying candidate markers. Efforts are underway to further characterize the candidate serum protein markers, namely macrophage migration inhibitory factor-1, osteopontin, and CA-242 [91, 92]. While none of them have been validated for clinical use, a strong indication exists that in combination they significantly improve the performance of CA-19-9.

Hepatocellular carcinoma (HCC) is one of the most common solid malignancies worldwide and its incidence in the United States is increasing [93]. Despite all advances in treatment, the 5-year survival of patients with HCC still remains at 5 %, which may be largely due to diagnosis at late stages of the disease. Hence, biomarkers for its early detection are really needed. Since 90 % of HCC patients have underlying cirrhosis, these are good candidates for HCC surveillance. Currently, HCC surveillance tests are ultrasound evaluation of the liver with or without measurement of serum alpha-fetoprotein (AFP). These tests are inadequately sensitive and specific (41–78 %) for use in screening. Various other biomarkers for HCC have been evaluated, including des-gamma carboxyprothrombin (DCP) and the fucosylated variant of AFP (AFP-L3). DCP was significantly better than total AFP or AFP-L3 in differentiating HCC from cirrhosis, with a sensitivity of 86 % and specificity of 93 % [94]. Currently, EDRN investigators at the University of Michigan Ann Arbor are conducting a large-scale study to confirm the validity of DCP alone or in combination with AFP or AFP-L3 as a test for early clinical diagnosis of HCC among cirrhotic patients.

Ovarian cancer is the fifth leading cause of cancer-related deaths in the United States. More than 20,000 women are diagnosed with ovarian cancer each year and more than 15,000 die annually from the disease. The high mortality rate of ovarian cancer is mainly due to the advanced stage at diagnosis of most cases and the current lack of a screening strategy for the detection of the disease at an early stage when treatment is more successful. Transvaginal ultrasound (TVS) and serial measurements of the biomarker CA-125 are being used for the surveillance of the high-risk population. The sensitivity and specificity of CA-125 are, however, very low (<60 % and PPV ~20 %) to justify its use as a population screening biomarker, given the overall relatively low incidence of ovarian cancer. Recently, a combination of six serum markers that also includes CA-125 was shown to detect early- and late-stage ovarian cancer significantly better than CA-125 alone. With sensitivity and specificity at 95.3 and 99.4 % respectively, the accuracy of the test is ~99 % [95]. The EDRN investigators together with LabCorp, Inc. are currently in the process of validating this test in Prostate-Lung-Colon-Ovarian (PLCO) screening trial sera of ovarian cancer patients and healthy controls that were collected up to 2 years prior to diagnosis. If its accuracy determined with clinical specimens is also validated with the PLCO pre-diagnostic samples, this test will be of great importance both for surveillance of the high risk as well as the general population.

State-of-the-art proteomic technologies are attempting to address issues in the management of common but not so life-threatening cancers. Thyroid cancer is on the rise in the United States in the last three decades and a large population

needs constant surveillance to manage the disease. The current test approved to monitor the disease, thyroglobulin, fails to accurately distinguish between benign and malignant tumors. The other diagnostic modalities tend to be highly invasive and expensive, and require more adaptable tests for making surgical decisions. Villanueva et al employed a serum peptidomic approach where serum peptides are captured and concentrated on magnetic, reverse-phase beads and analyzed with matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) mass spectrometer to generate a peptide signature [41]. They propose that the low molecular weight (LMW) peptide biomarkers are the result of ex vivo action by proteinase-mediated enzymatic cleavage as part of the coagulation and complement activation pathways. It is claimed that the fragments of endogenous blood proteins generated ex vivo serve as a substrate pool for disease-specific proteinases that arise from the tumor itself or from the tumor microenvironment. Using this approach, they identified a 12-member peptide panel thyroid cancer signature that was able to distinguish between thyroid cancers and normal subjects in an independent validation set, thus indicating that the technology indeed has promise for clinical application. Currently, they are characterizing the peptides in the panel and optimizing the set by expanding the study population. While this approach seems fascinating and may provide promising molecular markers, it calls for a tight coordination of efforts from nurses, phlebotomists, messenger service staff, and clinical technicians and for strict adherence to the standard protocol, which may be impractical in clinical application [41, 96].

41.12 Conclusion

Cancer detection and diagnosis efforts are constantly evolving because of recent applications of high-throughput omic technologies to cancer biology. Advances in bioinformatics and computational tools augment the process by allowing data analysis in myriad ways. These approaches may result in promising biomarkers that will enable personalized choices in cancer treatment. Potential biomarkers need to be critically validated both clinically and analytically before they can be successfully applied in the clinic. The actual value of a biomarker lies in its ability to reduce cancer-related mortality and morbidity by enabling cancer detection and subsequent early intervention and reducing the costs associated with late-stage treatment. A multidisciplinary, coordinated effort seems necessary to enable biomarker validation. Federal agencies are making provisions to expedite biomarker development. Molecular markers are likely to revolutionize the state-of-the-art in cancer detection and diagnosis and complement imaging strategies.

Acknowledgements The authors sincerely thank Dr. Paul Wagner for helpful discussions during manuscript preparation.

Gene Therapy in the Treatment of Human Cancer

42

Anand C. Annan, Paul B. Fisher, Paul Dent, Gene P. Siegal, and David T. Curiel

42.1 Introduction

Cancer can be considered a disease caused by mutations and/or epigenetic changes in tumor suppressor genes and oncogenes that populate the host genome [1, 2]. It is well established that most of the genetic events in cancer result from a series of accumulated, acquired genetic lesions [3, 4]. These genetic events either inactivate tumor suppressor genes or activate oncogenes. With an enhanced understanding of the genetic lesions associated with malignant transformation and progression in a wide variety of human cancers, different therapeutic approaches are being identified. In this regard, gene therapy is emerging as a method of preventive and therapeutic intervention against cancer targeted at the level of cellular gene expression [2]. In this approach, altering the complex cancerous pathophysiologic state is achieved by delivering nucleic acids into cells. These nucleic acids may be genes, portions of genes, oligonucleotides, or RNA. In conventional therapeutics, as in pharmacotherapy, altering a cell or tissue phenotype is accomplished by altering cell physiology or metabolism at the level of protein expression. In contrast, in gene therapy this is accomplished by changing the pattern of expression of genes whose products may correct defects in cellular phenotype.

42.2 Why Gene Therapy?

In the treatment of human disease, gene therapy strategies may offer the potential to achieve a much higher level of specificity of action than conventional drug therapeutics by virtue of the highly specific control and regulatory mechanisms of gene expression that may be targeted. Additionally, interceding at an earlier, upstream point in disease pathogenesis may offer greater potential to induce fundamental changes in phenotypic patterns of disease, with a more favorable clinical outcome. The availability of gene transfer systems, or vectors, for permanent or long-term genetic modification of cells and tissues allows for definitive therapeutic or preventive interventions. Furthermore, gene transfer can be accomplished in a limited loco-regional context, producing a high concentration of therapeutic molecules in the local area. Thus, potential undesired systemic effects of specific therapeutic molecules are avoided. Lastly, using the host to produce therapeutic proteins has a practical advantage of its own [5]. Briefly, limitations associated with manufacture, stability, and duration of effect after administration of drugs based on, for example, synthetic peptides are completely avoided. From the same pharmacological point of view, designer drugs designed from selective small molecules, currently under intensive investigation, cannot yet serve as an efficacious therapeutic alternatives or substitutes for the protein products of tumor suppressor genes.

Table 42.1 Potential contributions of gene therapy against the obstacles for curing cancer

Obstacles to curing cancer imposed by tumor cells	Potential contribution of gene transfer
1. Tumors are genetically unstable, and thus they are extraordinarily adaptable to environmental changes (This is arguably the biggest obstacle, and has never been approached directly)	Gene transfer of DNA repair or cell cycle checkpoint genes that restore DNA stability
2. Tumors are heterogeneous in many respects, including genetic mutations, expression of oncoproteins, immunogenicity, response to environmental changes, etc	Targeting of "genetically homogeneous" tissues, such as the tumor vasculature; genetic immunopotentiation
3. As a consequence of obstacles #1 and #2, tumors have, or acquire, resistance to cellular toxins and to many other therapeutically induced cellular insults	Strategies above, associated with chemotherapy or radiotherapy or with the transfer of genes that sensitize tumor cells to drugs or radiation
4. Tumors can have a low cellular growth fraction; therefore they are less susceptible to mitotic toxins and to gene transfer vectors that require dividing cells	Use of vectors that do not require cellular division for gene delivery and expression (adenovirus, herpesvirus, lentivirus, chimeric systems); repeated administration of non-immunogenic vectors
5. Tumors form metastases, which have to be reached systemically to eradicate the tumor	Use of targetable, injectable vectors (tropism-modified viruses, cellular vehicles); genetic immunopotentiation
6. Tumors do not express specific tumor antigens or immune costimulatory molecules; alternatively, tumors downregulate immune recognition, induce tolerance, and inhibit the immune response	Transfer of genes encoding costimulatory molecules and cytokines; genetic modification of antigen-presenting cells; induce inflammatory reactions that activate antigen presentation; transfer of genes blocking tumor-secreted inhibitors of the immune response
7. The spontaneous behavior of human tumors is somewhat different from that of malignant cells in vitro, and from that of experimental tumors in animal models	Development of better animal models, including tumor models in transgenic mice
8. Tumors are diagnosed in advanced stages, when billions of tumor cells exist in the body, frequently widely disseminated	Development of amplification vector systems (replicative viral vectors); use of targetable, injectable vectors; genetic immunopotentiation
9. The understanding and treatment of cancer requires the contribution of very diverse fields of basic knowledge, biotechnology, and medical practice	De facto multidisciplinary recruitment of gene therapy researchers

In the treatment of advanced human malignant tumors, several obstacles limit the effectiveness of currently available therapies preventing definitive cures (Table 42.1). It is apparent that new chemotherapeutic drugs, higher drug doses, cytokines, novel modalities of radiotherapy, and more ambitious and sophisticated surgeries can achieve incremental improvements in cancer treatment. But these therapies do not address critical biological obstacles, and thus will not bring the much-needed essential radical advances in the implementation and success of cancer treatments. Gene therapy, in contrast, offers an ability to overcome many of these fundamental barriers (Table 42.1).

42.3 Gene Therapy Vectors

Different vectors (both viral and nonviral) are employed for gene therapy. The six most frequently used viral vectors include those derived from adenovirus, retrovirus, poxvirus, adeno-associated virus, herpes simplex virus and lentivirus while the nonviral approaches includes calcium based molecular compounds, lipofection, and direct injection of naked DNA or RNA (Table 42.2). These vectors must meet certain basic criteria to be used to deliver therapeutic genes. In this regard, the vectors are based upon their fundamental ability to deliver therapeutic nucleic acids into relevant target cells. Further, the delivered genes must be expressed at an appropriate level and for an adequately prolonged period of time. Finally, the delivery and expression of the therapeutic genes must not be deleterious to the surrounding normal tissue, nor to the individual as a whole [6, 7]. In practice, two general approaches have been employed to meet these gene vector criteria: an ex vivo approach and an in vivo approach. In the former method, target cells are removed from the host and transduced with the genetic vector extracorporally, followed by reinjection or implantation. Though this approach has allowed reasonably efficacious transduction of target cells and has also allowed characterization of modified cells, the number and types of parenchymal cells that can be modified in this manner are quite limited. An alternate approach to achieve therapeutic gene delivery has been the in vivo administration of vectors into target parenchymal cells directly in their natural location. In this regard, both viral and nonviral vectors of diverse types have been employed to achieve in situ transduction of relevant target endodermal, ectodermal, and mesenchymal-derived cells (Table 42.2).

Table 42.2 Gene transfer systems used clinically against cancer[a]

Type	Vector system	Duration of expression	Distinguishing features
Nonviral	Liposomes	Transient	Repetitive and safe administration feasible, inefficient gene delivery, transient expression
	Naked DNA or RNA (injection, gene gun, electroporation)	Transient	Easy preparation, inefficient gene delivery, transient expression
	Molecular conjugates	Transient	Flexible design, inefficient gene delivery, transient expression, unstable in vivo
Viral	Retrovirus	Prolonged	Integrates into the chromosome of dividing cells, unstable in vivo
	Adenovirus	Transient	Highly efficient in vivo, production in high titer, tropism can be modified, induces potent inflammation and immunity, replicative vectors available
	Poxvirus (vaccinia)	Transient	Extensive clinical experience with parent virus, large insert capacity, induces potent inflammation and immunity
	Adeno-associated virus	Prolonged	Nonpathogenic, low insert capacity, difficult to scale up
	Herpes simplex virus	Transient	Highly efficient in vivo, large insert capacity, cytotoxic, replicative vectors available
	Chimeric vectors (e.g., Ad/Retro)	Prolonged	Combine features of component genetic vectors
	Lentivirus	Prolonged	Integrates into the chromosome of *both* dividing and nondividing cells, well-characterized production system not yet established

42.4 Gene Therapy Strategies

A number of strategies have been developed to accomplish cancer gene therapy. Broadly, these approaches include (1) mutation compensation, (2) molecular chemotherapy, (3) genetic immunopotentiation, and (4) virus-mediated oncolysis. Briefly, for mutation compensation, gene therapy techniques are designed to correct the molecular lesions that are etiologic of malignant transformation, or to avoid the contribution by tumor-supporting normal cells. For molecular chemotherapy, methods have been developed to achieve selective delivery or expression of a toxin gene in cancer or tumor stromal cells to induce their eradication. Also, attempts have been made to deliver genetic sequences that protect normal bone marrow cells from the toxic effects of standard chemotherapeutic drugs, thus allowing the administration of higher drug doses without reaching otherwise limiting myelosuppression. Genetic immunopotentiation strategies attempt to achieve active immunization against tumor-associated antigens by gene transfer methodologies. Both tumor cells and cellular components of the immune system have been genetically modified to this end. Viral mediated oncolysis is a relatively new therapeutic strategy in the treatment of cancer involving conditionally replicating viral vectors. As their name implies, these viruses conditionally replicate uniquely in tumor cells, thereby exhibiting oncolysis by direct cytopathic effects. These viral vectors are either genetically engineered (e.g., Herpes simplex virus type 1 or HSV-1, adenovirus), naturally attenuated (e.g., Newcastle disease virus), or nonpathogenic in humans (e.g., reovirus), so they replicate selectively in tumor cells, but do not harm normal tissues [8, 9]. Importantly, each of these strategies has been rapidly translated into human gene therapy clinical trials (Table 42.3).

In general, a common finding in many of these studies, including many clinical trials, has been the disparity noted between the in vitro and in vivo gene transfer efficiencies of these vector systems, and the suboptimal tumor transduction that presently available vector systems can achieve. In addition, the promiscuous tropism of current vectors may potentially allow for genetic modification of a number of normal non-transformed cells besides target cells. Furthermore, this non-selective gene transfer impedes the administration of vectors to tumor cells by the systemic route. Thus, important limitations of current approaches used for implementation of gene therapy for cancer have been noted. Although many potentially effective strategies exist to affect the molecular treatment of cancer, gene delivery issues currently limit the definitive evaluation of these methods.

In this regard, we examine the lessons learned from the results of the early attempts to apply gene therapy in human cancer. This will show both the rationale of gene therapy and the problems encountered in its development. We emphasize in our discussion the general biological concepts of each therapeutic strategy, and suggest comprehensive reviews for readers interested in detailed discussions. Finally, we illustrate prospects for overcoming the obstacles to gene therapy by novel methods that are currently being refined.

Table 42.3 Clinical trials of gene therapy for the treatment of cancer

Strategy	Clinical trials[a]	Molecular mechanism of anticancer effect
Mutation compensation	11	Inhibition of expression of dominant oncogenes, Augmentation of deficient tumor-suppressor genes, single chain antibodies, antisense, dominant negative mutation
Molecular chemotherapy	6	Pro-drug/HSV-TK and ganciclovir, chemoprotection of normal tissues during high-dose chemotherapy, radiotherapy
Genetic immunopotentiation	48	In vitro transduction—augmentation of tropism or cell killing capacity of tumor-infiltrating lymphocytes; genetic modification of irradiated tumor cells
	50	In vivo transduction—administration of costimulatory molecules or cytokines; immunization with virus encoding tumor-associated antigens
Viral-mediated oncolysis	14	Tumor cell lysis by viral vector replication

42.5 Mutation Compensation

Gene therapy techniques based on mutation compensation are designed to rectify either the molecular lesions in the cancer cell, the etiology of malignant transformation or the associated changes in stromal cells that support cancer progression. The genetic lesions in cancer cells that are linked to the pathogenesis of the malignancy may be thought of as a critical compilation of two general types; loss of expression of tumor suppressor genes (TSG) or aberrant expression of dominant oncogenes [3, 4]. In addition, contribution of other associated genes to either the individual cancer cell or its local microenvironment are critical during neoplastic progression. Angiogenesis, cellular motility, invasion, and metastasis are some examples of such phenotypic processes modulated by these associated genes. A knowledge of the major role that growth factors, signaling molecules, cell cycle regulators, and determinant factors of key steps along the metastatic cascade play, have positive implications for gene therapy, and therapeutic approaches have been proposed to achieve correction of each of these processes (Table 42.4).

42.5.1 Replacement of Tumor Suppressor Genes

Mutations of more than two dozen TSGs have been described in numerous cancers. Their functions are diverse and include maintaining cellular structure and signaling of intercellular junctions and receptors (*APC*, *DCC*, *DPC4*, *NF1*), components that regulate the transcription apparatus (*p53, VHL*, *RB1*, *WT1*), and DNA mismatch (*hML1*, *hMHS2*, *hPSM1*, *hPMS2*) or excision (*XPA*, *XPB*, *XPC*, *XPD*, *XPG*) repair. Thus, the inactivation of tumor suppressor genes contributes to the neoplastic phenotype by abrogating critical cell cycle checkpoints and DNA repair mechanisms. To approach this loss of function, a logical intervention is replacement of the deficient function with its wild-type counterpart gene [10]. Many of the TSGs have been shown to induce apoptosis or cell cycle arrest in cancer cells. Among these are p*53* [11], RB (Retinoblastoma) [11, 12], $p16^{INK4a}$, [13, 14], PTEN (Phosphatase and Tensin Homolog) [15], *mda7*/IL-24 (melanoma differentiation associated gene-7/IL-24^{New}) [16–21], BRCA1 (Breast Cancer 1 gene) [22], BRCA2 (Breast Cancer 2 gene) [23], APC (Adenomatosis Polyposis Coli gene) and OPCML (Opiod binding Protein/cell-adhesion molecule like) [24] genes, many of which are being targeted by gene therapy approaches (Table 42.4). Of these TSGs, *p53*, *RB1*, *BRCA1*, and *p16* ^{INK4a} have advanced to being administered in clinical trials as replacements for their mutated counterparts. *mda*-7/IL-24 represents a novel TSG that is not mutated in cancers, but when reintroduced into cancers of diverse origin induces programmed cell death (apoptosis) [16]. Additional attributes of *mda*-7/IL-24 that bode well for its therapeutic applications as a gene therapy for cancer include its ability to inhibit tumor blood vessel formation (angiogenesis), promote killing of distant tumor cells (a bystander anti-tumor effect), induce anti-tumor immune responses and synergize with other conventional modes of therapy (including chemotherapy, radiation and monoclonal antibodies) [16, 25]. Moreover, many of these properties have been persevered following intratumoral injection of a replication incompetent adenovirus expressing *mda*-7/IL-24 (Ad.*mda*-7; INGN 241) in advanced cancers including melanoma [26–29]. These studies confirmed that *mda*-7/IL-24 is safe and documented significant clinical anti-tumor activity.

Mutations in the p*53* tumor suppressor gene are observed in more than half of all malignancies [30]. Correction of such mutations may be particularly relevant due to the central role played by *p53* as guardian of the genome and regulator of apoptosis [31]. An additional antiangiogenic [32, 33] mechanism of action of *p53* has also been suggested. In this regard, *p53* has been the most frequently studied tumor suppressor gene [34] and is widely used in different gene therapy clinical trials. Replacement of the mutated p53 with its wild-type

Table 42.4 Mutations compensation strategies used clinically

Target[a]	Strategy	Vector	Tumor type
p53[b]	Replacement of tumor suppressor gene	Adenovirus	Varied cancer
RB[b] *(retinoblastoma)*	Replacement of tumor suppressor gene	Adenovirus	Bladder cancer
BRCA-1[b]	Replacement of tumor suppressor gene	Retrovirus	Ovarian cancer
Insulin-like growth factor 1[b]	Blockade by antisense	Cationic liposome complex	Glioblastomas
k-ras[b]	Blockade by antisense	Retrovirus	Non-small cell lung cancer
c-myc[b]	Blockade by antisense	Retrovirus	Breast and prostate cancers
TGFβ[b]	Blockade by antisense	Plasmid and electroporation	Glioblastoma
Bcl-2[a]	Blockade by antisense	Cationic liposome complex	Varied cancer
Clusterin[a]	Blockade by antisense	Cationic liposome complex	Prostate cancer
Telomerase[a]	Blockade by antisense	Cationic liposome complex	Varied cancer
erBb-2[b]	scFv	Adenovirus	Ovarian cancer

scFv single-chain intracellular antibody

counterpart allows phenotypic correction (usually with subsequent apoptosis) both in vitro and in vivo in a variety of tumors. In particular, several authors have shown, in murine models employing human cancer xenografts, that intratumoral delivery of the wild-type *p53* gene via recombinant viruses can prolong survival by inducing apoptosis in the tumor cell population [35]. Importantly, nontransformed cells can tolerate exogenous administration of *p53*, thereby providing an optimal therapeutic index for this intervention. It should be emphasized that restoration of wild-type *p53* expression in cells with a mutant or deleted gene has been shown to be sufficient to cause apoptosis or growth arrest, despite the presence of multiple additional genetic abnormalities in the tumor cell. This fact has established the rationale for human clinical gene therapy trials designed to achieve mutation compensation through restoration of *p53* in several cancers. In a pioneering study, Roth et al administered intratumoral injections of a *p53*-encoding retrovirus to patients with non-small cell lung cancer (NSCLC) [36]. One-third of patients in this group had tumor regression, while another third had stabilization; none presented high grade toxicity directly related to the treatment, thereby demonstrating the safety and feasibility of this gene therapy approach [37, 38]. In another trial involving 19 patients with chemoradiation resistant NSCLC, recombinant adenovirus was used to deliver the p*53* transgene; 63 % of these patients had no residual viable tumor by biopsy. Stated radiologically, 58 % showed partial response and 5 % showed complete response to treatment as evaluated by Computed Tomography (CT) and bronchoscopy [39]. Various Phase I and II clinical trials for carcinoma of the breast [40], esophagus [41], colorectum [42], and several other sites [43], have also shown similar clinical feasibility, low toxicity, and indications of tumor regression either alone or in combination with chemotherapy/radiotherapy.

Replacement of *RB1* and *BRCA1*, and forced expression of *mda-7*/IL-24 have shown similar preclinical experimental results, and are also currently undergoing clinical testing. Attempts to restore wild-type *RB* have been described in prostate, retinoblastoma, osteosarcoma, breast, bladder, and non-small cell lung cancers [44]. Of note, and perhaps not surprisingly, some *RB*-deficient tumors have shown persistent tumorigenicity and proliferation after successful restoration and expression of wild-type *RB*, a phenomenon referred to as tumor suppressor resistance [45]. Thus, restoration of the *RB* tumor suppressor gene in certain tumors may not effect complete reversion of the malignant phenotype. *BRCA1* is only occasionally affected in spontaneous tumors, and its function has not been completely characterized. Its clinical use has, therefore, been somewhat controversial [46]. In contrast, *mda*-7/IL-24 provoked apoptosis in human tumors with multiple genetic defects, including wild type, mutant or null for p53 and/or mutations in RB1 and Ink4a, and in patients that had received prior therapies (including radiation, chemotherapy and/or immunotherapy) and presumably contain multiple mutations.

42.5.2 Repression of Dominant Oncogenes

In addition to mutations and epigenetic mechanisms that cause the loss of normal tumor suppressor functions, most tumors exhibit dysregulated oncogenes. For dominant oncogenes, it is the aberrant expression of the corresponding gene product that elicits the associated neoplastic transformation. In this context, molecular therapeutic intervention is designed to ablate expression of the dominant

oncogene. Inhibition of oncogenic function has been attempted at all three levels of molecular regulation, i.e., transcription, translation, and post-translation. (1) At the first level, transcription of the oncogene can be inhibited using triplex-forming DNA binding antisense oligonucleotides. Also, transcriptional silencing by epigenetic regulation of CpG islands in the oncogene promoter has been attempted in vitro. (2) Translation of oncogene mRNA can be blocked by using sequence specific small interfering RNA (siRNA) or ribozymes. (3) And finally at the posttranslational level, (a) mobilization of the nascent oncoprotein to its final location can be blocked using intracellular antibodies that intercept and interfere with the processing of the oncoprotein or (b) its function inhibited at its final cellular location by the heterologous expression of mutant protein that can inhibit the function of the native oncoprotein. Oncogenes implicated in cancer and used as targets in clinical trials include genes encoding: (1) growth factors, such as insulin-like growth factor 1 (IGF-1), and transforming growth factor β1 (TGF-β1); (2) growth factor receptors, such as erbB-2; (3) proteins involved in cell signaling, such as K-ras; (4) and transcription factors, such as c-myc.

42.5.2.1 Transcriptional Inhibition of Genes

The most universally employed methodology to achieve proto-oncogene ablation is the utilization of antisense oligodeoxynucleotides (ODN) with sequences complementary to that of target genomic DNA. These molecules are thus designed to specifically target sense sequences to achieve blockade of the encoded genetic informational flow. In this approach, ODNs bind to genomic DNA by Hoogsteen hydrogen bonding which leads to the formation of non-functional triplex DNA, thereby blocking its transcription [47]. This technique has been utilized both in in vitro and in vivo model systems for targeting the c-*myc*, c-*ras*, *bcl-2, IGF-1,* and c-*erbB-2* oncogenes. Since there are no known naturally existing pathways to direct the ODNs to their target gene, the efficiency of inhibition of oncogenes by this technique is limited. Along with the discovery of the RNAi pathway, the utility of ODNs as a method to suppress an oncogene has largely been replaced with siRNAs.

Another method utilized to ablate dominant oncogenes is by inhibiting its promoter regulatory sequence. It has been shown, for instance, that the K1 mutant of the viral SV40 large T antigen inhibits the human c-erbB-2 promoter in human ovarian cancer cells. Moreover, liposome-mediated K1 gene transfer decreases the p185 erbB-2 protein level in these cancer cells, and significantly prolongs survival in an in vivo orthotopic animal model [48]. Although not a human gene, the E1A gene of adenovirus serotype 5 exhibits tumor suppressor functions in cancer cells over expressing the c-erbB-2 oncogene. E1A inhibits transcription of the human c-erbB-2 promoter by inhibiting the p300/CREB-binding protein (CBP) and accordingly suppresses the tumorigenicity and metastatic potential induced by the oncogene [49]. Studies have shown that both cationic liposomes and an adenoviral vector can efficiently deliver E1A into ovarian tumor cells in mice, resulting in suppression of tumor growth and significantly longer survival of treated animals [50]. A phase I clinical trial of intraperitoneal administration of a cationic lipid complex containing the E1A gene in patients with ovarian cancer showed the safety and efficacy of this approach [51]. Currently, phase II clinical trials are being undertaken for solid tumors overexpressing c-erbB-2.

42.5.2.2 Translational Inhibition of Genes

Specific antisense binding to transcribed RNA sequences may interrupt the flow of genetic information through several mechanisms including RNA degradation, translational arrest by steric hindrance and less probably through the impaired transport of target mRNA across the nuclear membrane. These inhibitory interventions may be accomplished by (1) an RNAi approach (siRNAs, miRNA), or by (2) ODNs that possess additional catalytic activity to accomplish cleavage of target sense sequences, called ribozymes [52, 53].

RNAi Approach

RNAi refers to a group of related gene silencing techniques with a terminal effector molecule of siRNA. Posttranscriptional inhibition of gene expression was revolutionized with the discovery of the RNAi pathway first in transgenic plants [54] and then in *Caenorhabditis elegans* [55]. Briefly, double stranded RNA (dsRNA) or a short hairpin RNA (shRNA) homologous to a gene, when introduced into a cell are processed by a cellular molecule, Dicer to generate short 19–26 nt RNA duplexes with 3′ overhangs called siRNA. The antisense strand of this siRNA is subsequently incorporated into an RNA-induced silencing complex (RISC) and guides the RISC complex to its complementary mRNA for cleavage. siRNA has been used to downregulate the oncoprotein product of the Philadelphia chromosome (BCR/ABL gene) found in almost all chronic myeloid leukemia (CML) patients and in one-third of acute lymphoblastic leukemia (ALL) patients. In vitro studies in K652 cells (a human CML cell line) showed the specificity of knocking down the BCR/ABL gene by siRNA without affecting other genes, yielding the desired phenotype of increased susceptibility to apoptosis [56, 57]. Similar in vitro studies of siRNAs for different oncogenes like *K-ras* [58] and *bcl-2* [59] as well as receptor including *EGFR* [60] and oncogenic fusion proteins like AML/MTG8 [57] and EWS/Fli-1 [61] have shown specific knock-down of respective genes. In vivo knockdown of oncogenes in tumor xenografts models using siRNA are currently being undertaken [62, 63] and a phase I clinical trial targeting safety and efficacy of siRNA treatment for CML is underway.

Ribozyme Approach

A variety of experimental models, both in vitro and in vivo, have demonstrated the potential utility of an ODN approach as an anticancer therapeutic [64–67]. ODNs can block the translation of mRNA by steric hindrance [68] while an RNA–DNA hybrid can be degraded by RNAase H [69]. ODNs used in a clinical setting have either a phosphorothioate [70] or morpholino [71] backbone modification to improve biodistribution and stability. The specificity of antisense molecules has been convincingly shown in the case of K-*ras*. ODN methylphosphonates directed at either normal human Ha-ras p21 or ras p21 mutated at a single base at codon 61 have been examined for their efficacy and specificity as inhibitors of p21 expression. Mixed cultures of cells expressing both forms of p21 have been treated with ODN complementary to the normal or point-mutated p21. Each of the ODNs specifically inhibited expression of only the form of ras p21 to which it was complementary and left the other form of p21 unaffected. Thus, in general the antisense approach offers the potential to achieve targeted disruption of specific genes in human cancer. Table 42.4 shows a list of clinical trials which use antisense oligonucleotides to treat various cancers. Several cancer associated molecules including *bcl-2, clusterin*, *survivin,* and *eIF4E* are being targeted using this antisense approach.

Despite the potentially novel therapeutic strategies offered by the antisense approach, this methodology in practice is associated with severe limitations [65, 72]. These practical constraints have limited wide employment of this technology in protocols of human anticancer gene therapy. What is most disconcerting is that, there are no universal rules for quantifying the efficacy of a given antisense oligonucleotide for achieving specific gene inhibition. An array with 1938 oligonucleotides ranging in length from monomers to 17-mers has been built to measure the potential of the oligonucleotides for heteroduplex formation with rabbit β-globin mRNA [73]. The oligonucleotides were complementary to the first 122 bases of the mRNA. Surprisingly, very few oligonucleotides gave significant heteroduplex yield and no obvious features in the mRNA sequence or the predicted secondary structure could explain this variation. In fact, despite the utility of antisense inhibition in selected contexts, attempts to achieve antisense blockage of many cancer-related genes have failed. In addition, delivery of the antisense molecules has been highly problematic. The tumor environment is deleterious to these unstable molecules, and it is often difficult to maintain effective intracellular levels. To circumvent this problem, a number of design modifications of the antisense molecules have been developed to enhance their in vivo stability. In addition, a number of vector approaches have been explored for effective cellular delivery. Despite these various maneuvers, the overriding limitations to the employment of this still promising therapeutic modality remain the idiosyncratic efficacy of specific antisense molecules for a given target gene and its suboptimal delivery to date.

42.5.3 Posttranslational Inhibition of Genes

42.5.3.1 Single-Chain Antibodies

Dominant oncogenes have also been targeted at the posttranslational level. Techniques have been developed to allow the derivation of recombinant molecules that possess antigen-binding specificities expropriated from immunoglobins [74]. In this regard, single-chain immunoglobin molecules, denoted by scFv, retain the antigen-binding specificity of the idiotypic region of the immunoglobin from which they were derived, but lack other functional domains characterizing the parent molecule. The encoded scFv may be expressed in the target cell and localized to specific, targeted subcellular compartments by incorporating appropriate signal molecules. Based on this, an approach leading to oncogene suppression has been developed in our laboratory. It was shown that if an anti-erbB-2 scFv was localized to the endoplasmic reticulum (ER) of cancer cells, the nascent, newly synthesized erbB-2 protein would be entrapped within the ER and therefore unable to achieve its normal cell surface localization. It was also shown that this intracellular entrapment would prevent the erbB-2 product, a transmembrane receptor, from interacting with its ligand, abrogating the autocrine growth factor loop driving malignant transformation in erbB-2 overexpressing cell lines. We showed that intracellular expression of anti-erbB-2 resulted in the following cellular effects: (1) downregulation of cell surface erbB-2 expression; (2) marked inhibition of cellular proliferation; (3) marked reduction in survival of neoplastic cell clones; and (4) selective cytotoxicity in tumor cells expressing the proto-oncogene target [75]. In addition, scFv-mediated erbB-2 ablation induced additional phenotypic alterations in tumor cells, including chemosensitization and radiosensitization [76]. In addition, the ability to accomplish selective abrogation of erbB-2 expression has been shown to be effective in the eradication of primary human ovarian cancer cells [77]. This shows the feasibility of such a therapeutic approach for tumor cell eradication by utilizing intracellular immunoglobulins to achieve targeted disruption of dominant oncogenes, thereby accomplishing reversion of the malignant phenotype, chemosensitization, radiosensitization, and initiation of cell death. To this end, we have translated the strategy into an approved human clinical gene therapy protocol for ovarian carcinoma [78, 79]. The feasibility of this strategy against other oncogenes including ras and c-myc has also been shown in animal models [80–82]. In spite of its rapid refinement in a relatively short time frame, scFv application in cancer gene therapy has not yet been fully realized. Although oncogenes have been the primary target of scFv therapy, targeting of the gene therapy

vectors to specific cell surface receptors are now first being attempted by the construction of bifunctional adapter proteins. Among these are sCAR-CD40 (the ecto-domain of the coxsackievirus-adenovirus receptor (sCAR) with an scFv against human CD40) for efficient transduction of dendritic cells [83] and sCAR-MFE (sCAR with an scFv against human CEA) for targeting selective cancer cells expressing high levels of CEA [84].

42.5.3.2 Transdominant Molecules

Alternatively, oncogenes can be inactivated at the protein level by the heterologous expression of mutant proteins that inhibit the function of the native version of oncoproteins, the so called dominant-negative mutation strategy. For instance, transdominant mutants of c-Jun have been shown in vitro to possess potent suppressive effect on colorectal cancer cells [85]. The feasibility of efficient delivery and production of adequate levels of mutant protein in vivo has been shown in a mouse model of human lung cancer in which the dominant negative mutant of mitogen activated protein kinase kinase 4 (MKK4) [86] has been delivered. Currently, further refinement of this strategy is underway to translate this approach into clinical practice.

42.5.4 Phenotypic Expression of Neoplastic Progression Dependent on Associated Genes

42.5.4.1 Angiogenesis

Folkman in 1971, proposed that angiogenesis is required for tumor growth [87]. The development of new blood vessels is now known to be a critical factor in the growth, progression, and metastatic spread of both solid and hematopoietic tumors. Despite heterogeneity in virtually all other respects, all tumors share a *universal* feature, i.e., they depend on the vasculature to maintain their viability and to sustain their growth and dissemination. Extensive experimental data supports this contention [88–91]. Furthermore, numerous clinical studies have shown the correlation between the development of intratumoral microvessels and the prognosis of individual cases in a variety of cancers [92–94]. Vessel targeting, therefore, should be useful for the treatment of most kinds of cancer [95–98]. Importantly in this regard, the genetic stability of endothelial cells, admittedly different one from the other, by site, should help minimize the appearance of resistance to molecular therapeutic interventions targeted to these cells [99]. This hypothesis has indeed been confirmed in a cancer animal model of treatment with a natural inhibitor of angiogenesis; endostatin [100]. An additional advantage of targeted killing of endothelial cells is the highly amplified killing effect over large numbers of tumor cells when deprived from its blood supply.

In the last decade, antiangiogenic drugs targeted to the proliferating endothelium of tumors and other diseases have been applied in the clinical setting and have entered clinical trials. In addition, the association of chemotherapy or radiotherapy with antiangiogenic agents has been shown to produce an enhanced antitumor effect in preclinical models. Notably, combined treatments can achieve cures that are not observed with either treatment alone [101]. Thus, molecular therapeutic interventions against the tumor and its vasculature are not only strongly appealing on theoretical grounds for their use in a variety of clinical contexts, but their utility is also being tested clinically [102]. Based on this, genetic modification of the endothelium lining the tumor vasculature has been proposed as an alternative therapeutic modality [103]. With this genetic strategy, many of the problems of previously failed tumor/vessel approaches can potentially be overcome. For instance, local production of high levels of therapeutic proteins can be induced, thus obviating or diminishing the difficulties associated with systemic toxicity while other pharmacological issues, such as large-scale manufacture, bioavailability, and the cost of ordinary drugs can be circumvented. In addition, the ability to continuously release a gene-encoded product may be relevant in certain cases, such as the appropriate antiangiogenic effect of interferon-γ against selected hypervascular solid tumors.

Both suppression of angiogenic cellular signals and augmentation of natural inhibitors of angiogenesis have proven to be feasible strategies in in vivo tumor models. Examples of effective genetic interventions for the suppression of angiogenesis factors include the downregulation of vascular endothelial growth factor (VEGF) by antisense [104], blockade of VEGF functionality by delivery of mutant versions of one of its cognate membrane receptors, Flk-1 (VEGF-R2) [105–107], or of a secreted soluble version of its other receptor, Flt-1 (VEGF-R1) [108–111]. Downregulation of VEGF receptor (VEGF-R) by siRNA [112, 113], or ODNs in models of glioma [114, 115] and liver cancer [116] have also shown similar effects. Conversely, the replacement or supplementation of inhibitors of angiogenesis has been tried by using vectors that encode soluble platelet factor 4 [117], angiostatin [118], and endostatin [119, 120]. However, none of these strategies has been clinically tested in patients using similar gene therapy approaches and major issues remain to be solved. Most obvious is the probable need to assure long-term expression of the therapeutic antiangiogenic genes to keep the tumor deprived of its growth-enabling vascularization. In addition, the current lack of targetable, systemically injectable vectors impedes the simultaneous application of anti-angiogenesis gene-based strategies to multiple foci of tumor that characterize disseminated cancer. Lastly, different combinations of endothelial growth factors and its receptors are altered in different tumors, and may even change in single tumors during different stages of progression. Thus,

despite its powerful rationale, the successful clinical implementation of antiangiogenesis gene therapy will require additional major advances.

42.5.4.2 Invasion and Metastasis

Increasingly, genes and proteins involved in phenotypic aspects of tumors, in addition to disordered proliferation, are being described and identified as potentially useful therapeutic targets. In this regard, besides angiogenesis, one fundamental component of the metastatic cascade is the local invasion of the extracellular matrix by tumor cells. Studies in animal models have begun to show that modulation by gene transfer of molecules involved in degradation of extracellular matrix (ECM), cellular motility, and cellular adhesion has the potential for inhibiting tumor cell spread [121]. Gene therapy approaches have targeted the inhibition of pro-metastatic genes like uPA, LIM kinase-2 and replacement of mutated anti-invasive, anti-metastatic genes like *p202*, PA-1 and 2, *MKK4/SEK1* have all been championed to prevent the invasion and metastasis of cancer cells.

Urokinase-type plasminogen activator (uPA) is a protease involved in the processes of tissue remodeling, tumor invasion and cell migration in vitro. Plasminogen activators are thought to degrade ECM proteins and cellular basement membranes and thus allow local tumor invasion and access to the vascular system for neoplastic cells destined for metastasis [122]. The inhibitors of plasminogen activation, PA-1 and PA-2, have also been described in association with different types of cancer. The levels of both uPA and its receptor uPAR are elevated in ovarian, prostate, glioma and other tumor cell types [123–125] and correlate with the clinical stage of disease [124–126]. Furthermore, it has been shown that inhibition of uPA receptor expression by siRNA [127] or ODNs can cause regression of preestablished tumor and abrogate the spread of human glioblastoma in both in vitro [128] and in vivo model systems [129, 130]. In an in vivo model of uveal melanoma, an adenoviral vector has been used for the transfer of plasminogen activator inhibitor type 1 (PAI-1) cDNA [131]. Intraocular injection of the vector resulted in a 50 % reduction in the number of animals developing liver metastases and a reduction in the metastatic tumor burden in animals that eventually developed metastases. These results support disruption of uPA function through gene transfer as an experimental strategy for preventing metastases and prolonging host survival. LIM kinase-2 is another such pro-metastatic gene which when inhibited by ribozyme caused a reduction in the metastatic potential of the cancer cell [132].

Metastatic suppressor genes by definition suppress tumor metastasis without affecting primary tumor growth. Among these metastatic suppressor genes are p202 [133], KAI1 [134] and MKK4/SEK1 [135]. When ectopically expressed in AT6.1 Dunning rat prostate cancer cells, these metastatic suppressor genes have been shown to reduce the lung metastatic capabilities of the cell line in xenograft mouse models in vivo. Multiple classes of metastatic suppressor genes are now in preclinical studies to assess their efficacy in reducing the invasion and metastatic potential of tumors.

42.5.5 Obstacles to Mutation Compensation

Although the strategies currently used for restoration and ablation of mutant genes have offered in-depth insights into the molecular biology involved in carcinogenesis and tumor progression of cancer, they face critical problems for allowing their use in the clinic. Human tumors are remarkably heterogeneous in the patterns of expression of relevant oncogenes. Thus, therapeutic targeting of a single molecular abnormality may have only an inconsequential impact on the management of the disease, both for the population as a whole and for individual patients. In addition, several mutated genes produce molecules with transdominant effects, thus requiring the blocking of their effects and not only the mere supplementation of the gene with a wild-type version. Furthermore, because these strategies modulate intracellular responses, nearly every tumor cell must be targeted for these approaches to be clinically effective. The current state of development of gene therapy vectors, both viral and nonviral, makes this feat unachievable within nontoxic margins of vector dose. Clearly, breakthrough developments in vector technology are needed for these obstacles to be overcome. Lastly, approaches such as molecular chemotherapy or immune system augmentation that exhibit an amplified regional or systemic effect hold the promise of tackling, by their own design, some of the aforementioned limitations.

42.6 Molecular Chemotherapy

A number of distinct approaches to accomplish molecular chemotherapy for cancer have been developed. These include the administration of (1) toxin genes to eliminate tumor cells and the stromal cells that support them, or (2) drug resistance genes to protect the bone marrow from myelosuppression induced by chemotherapy, or (3) genes that enhance the effect of conventional anticancer treatments. Initially, the molecular chemotherapy approach was designed to achieve selective eradication of neoplastic cells via expression of a toxin gene. This is similar to conventional chemotherapy, where pharmacological agents are employed. However, in order to effect a reduction in the neoplastic cell burden, patient's normal cells, tissues and organs have to be exposed to potentially harmful doses of the drug., Molecular chemotherapy is designed to circumvent this limitation by selectively targeting delivery of

the toxin into cancer cells on the basis of more specific tissue or transformation-associated marker targeting, thus reducing the potential for nonspecific toxicity.

42.6.1 Toxin Genes: Gene-Directed Enzyme Prodrug Therapy (GDEPT)

In this approach, a nontoxic prodrug which requires enzymatic activation to be transformed into a toxic metabolite is administered systemically. The gene for that enzyme is then selectively delivered and expressed in cancer cells, wherein the prodrug is locally converted to cytotoxically active drug that ultimately leads to cancer cell death [136–140]. This approach carries the moniker gene-directed enzyme prodrug therapy (GDEPT) or suicide gene therapy. A variety of prodrug–enzyme combination has been shown to work effectively both in in vitro and in vivo model systems with many of them being translated into multicenter phase III clinical trials [141]. Herpes simplex virus thymidine kinase/ganciclovir (HSV-*tk*/GCV), bacterial cytosine deaminase/5-fluorocytosine (CD/5-FC), bacterial nitroreductase/CB1954 (NTR/CB1954), and cytochrome P450/cyclophosphamide are all GDEPT systems which have been or are now in clinical trials. P450 reductase/tirapazamine, carboxypeptidase/CMDA, horseradish peroxidase/indole-3-acetic acid or paracetamol are some of the other GDEPTs which are currently in the preclinical experimental phase of development.

42.6.1.1 Thymidine Kinase

The most common molecular chemotherapy system utilized to date to accomplish cell killing has been the herpes simplex virus thymidine kinase (HSV-*tk*) gene given in combination with the prodrug ganciclovir (GCV) [142]. The selectivity of the HSV-*tk* system is based on the fact that, contrary to normal mammalian thymidine kinase, HSV-*tk* preferentially monophosphorylates GCV, rendering it toxic to the cell. GCV is then further phosphorylated by cellular kinases to triphosphates that are incorporated into cellular DNA. The incorporation of the triphosphate form of GCV causes inhibition of DNA synthesis and of RNA polymerase, leading to cell death [138]. In vitro studies have shown that the HSV-*tk* increases the sensitivity of the cell to GCV by up to 2000-fold [143] and thus, tumor cells (or any other cell undergoing mitosis) transduced to express the viral *tk* gene have enhanced sensitivity to cell killing after exposure to GCV. Normal cells transduced with HSV-*tk* after intravenous [144] or intrahepatic [145] administration of adenoviral HSV-*tk* vector have also shown high sensitivity to GCV, leading to liver degeneration and low survival in mice. The absence of toxicity of GCV after intravenous administration of a control adenovirus, or subcutaneous administration of an adenovirus encoding HSV-*tk,* suggests that the toxicity is specifically liver-associated. Phase I/II clinical trials for HSV-*tk* have demonstrated the safety and efficacy of this system in many tumors including ovarian cancer [146, 147], retinoblastoma [148], colorectal cancer [149], malignant gliomas [150–152], melanoma [153], and prostate carcinoma [154]. But the clinical efficacy of this system is still poor. A multicenter phase III clinical trial with HSV-*tk*/GCV in 248 glioblastoma multiforme patients showed no significant difference between conventional treatment (surgical resection followed by radiotherapy) and conventional treatment with adjuvant gene therapy [155]. Poor transduction of the cancer cells and the use of non-migratory fibroblasts as retroviral delivery vehicles were considered to be the possible reason for the trial failure. Approaches of increasing the transduction efficiency using an adenoviral vector system have shown an improved mean survival time of patients with recurrent glioblastoma tumors [156].

42.6.1.2 Bystander Effect

While the benefits of selectively eradicating tumor cells are obvious, an important limitation associated with molecular chemotherapy (as noted earlier) is the inability to target 100 % of the tumor cells with the toxin gene. However, this may prove not to be as severe a limitation as initially believed due to the phenomenon known as bystander effect, whereby eradication of HSV-*tk* transduced cells elicits a killing effect upon the surrounding non-transduced tumor cells. That not all of the tumor cells need to contain the HSV-*tk* gene for obtaining complete eradication of the tumor was an observation of early experiments employing the relatively inefficient retroviral vectors in brain tumors [157]. This occurrence was later confirmed in a variety of other tumor model systems [158–161]. Our laboratory has previously established the necessary biological properties to elicit bystander-mediated cell killing in a murine model of ovarian cancer [162].

Both local and distant bystander effects have been described in in vitro and in vivo models. In this regard, the basic biological mechanisms that underlie the bystander effect have been hypothesized. They include (1) exchange of toxic metabolites through gap junctions between cells [163, 164], (2) phagocytosis of apoptotic bodies containing toxic metabolite by neighboring cells [158, 161], (3) tumor vasculature necrosis due to toxicity of the active drug to dividing endothelium [165–168], and (4) an immune response to GCV-exposed HSV-*tk* transduced tumor cells [167, 169, 170]. Both the local and distant bystander effects, observed in vivo in distant foci of untreated tumors, are accompanied by the regional induction of cytokines [169] and an immune cellular response against the tumor [170–173]. A phase I/II clinical trial showed this bystander effect in human glioma patients and a better prognosis (time of progression of disease, survival) in patients who had a bystander effect than those who did not [150]. Nevertheless, the authors were

guarded in considering it as an indicator for treatment effectiveness and outcome because the patients with bystander effect had other favorable prognostic factors including a younger age and smaller tumor volume.

42.6.1.3 Other Toxins

In addition to the HSV-*tk*/GCV system, several additional combinations of enzyme/prodrug have been developed to improve the efficacy of molecular chemotherapy (Table 42.5). Features of these combinations have caused investigators to hypothesize that they might overcome the limitations of HSV-*tk*/GCV. For example, some of them induce toxic effects not only in cycling but also in non-cycling cells (carboxypeptidase G2, nitroreductase, purine nucleoside phosphorylase). With others, the bystander effect is stronger (purine nucleoside phosphorylase) or does not require cell contact (cytosine deaminase, nitroreductase) (Table 42.5).

The combination of cytosine deaminase (CD) and 5-fluorocytosine (5-FC) has been the first of these alternative systems to be tested clinically [174]. Studies both in vitro and in vivo have shown that transfer of the microbial CD gene sensitizes cells to the innocuous antifungal drug 5-FC. This effect is induced by metabolizing 5-FC into the toxic antitumor agent, 5-fluorouracil (5-FU) [175]. By administering high doses of the nontoxic 5-FC, intratumoral activity of the enzyme can provide increased intratumoral concentrations of the active drug, without its accompanying systemic toxicity. Potential weaknesses of the system are its dependence on cellular proliferation, and its complex metabolism, which facilitates acquired resistance by selective tumor cell population.

With some notable exceptions, single drugs in standard chemotherapy do not cure cancer. Historically, effective treatments were developed when drugs with different mechanisms of action were used in combination. Extending this concept to molecular chemotherapy, several combinations of enzyme/prodrug have been shown to induce synergistic killing effects in vitro [176, 177]. Combination schemas have also achieved higher rates of tumor regression and cure in animal models [178, 179]. The application of classical principles for designing drug combinations would recommend the use of prodrug/enzymes that target both dividing and nondividing cells, that elicit different mechanisms of bystander effect, and that have nonoverlapping toxicities.

42.6.2 Drug-Resistance Genes

In a second molecular chemotherapy approach, the host's tolerance to higher doses of standard chemotherapeutic drugs is increased by transducing bone marrow cells, known to be highly sensitive to chemotoxicity, with genes that confer drug resistance [180, 181]. In this context, retroviral vectors have been the vectors of choice for the in vitro derivation of stably transduced cells, due to their capacity for integration in host cell chromosomes. It was shown that when mice transplanted with bone marrow cells containing a transferred multiple drug resistance (MDR1) gene were treated with the

Table 42.5 Prodrug–enzyme combinations for molecular chemotherapy

Enzyme (origin)	Prodrug system		In vitro bystander effect	Target cell	Reference
	Prodrug	Release drug			
Thymidine kinase (herpes simplex virus)	Ganciclovir and other modified pyrimidine nucleosides	Monophosphate nucleotide analogs	Yes	Dividing cells	[138]
Cytosine deaminase (*E. coli*)	5-fluorocytosine	5-fluorouracil	++ (Independent of cell contact)	Dividing and possibly nondividing cells	[174, 175, 352]
Nitroreductase (*E. coli*)	CB1954 and analogs	Alkylating agents, pyrazolidines	+++ (Independent of cell contact)	Dividing and nondividing cells	[353–356]
Cytochrome P-450 isoenzyme (rat liver)	Cyclophosphamide, isophosphamide	Alkylating agents	Yes	Dividing cells	[357]
Carboxylesterase (rabbit liver)	CPT-11 (irinotecan)	SN-38	+++	Dividing cells	[358, 359]
Carboxypeptidase G2 (bacterial)	CMDA	CMBA	+++	Dividing and nondividing cells	[360]
Deoxycytidine kinase (human)	Cytosine arabinoside	Cytosine arabinoside monophosphate	+ (Dependent on cell contact)	Dividing cells	[361, 362]
Purine nucleoside phosphorylase (*DeoD* gene of *E. coli*)	Purine nucleosides, flutarabine	6-Methylpurine, 2-fluoroadenine	+++	Dividing and nondividing cells	[363]
Xanthine-guanine phosphoribosyl transferase (*gpt* gene of *E. coli*)	6-thiopurines	6-thiopurine nucleoside	++ (Independent of cell contact)	Dividing cells	[364–366]

CB1954: 5-(aziridin-1-yl)-2,4-dinitrobenzamide; CMBA: 4-[(2-chloroethyl)(2-mesyloxyethyl)aminobenzoic acid; CMDA: 4-[(2-chloroethyl)(2-mesyloxyethyl)amino]benzoyl-L-glutamic acid; SN-38: 7-ethyl-10-hydroxy-(20S)-camptothecin. Transduced cells needed for complete cell growth inhibition in cell mixing experiments: 10 % or less: +++; from 10 to 50 %: ++; more than 50 %: +

cytotoxic drug taxol, a substantial enrichment of transduced bone marrow cells was observed [180, 181]. The MDR1 gene encodes an ATP dependent plasma membrane efflux pump called P-glycoprotein (P-gp). Hydrophobic drugs like vinca alkaloids, taxol, anthracyclines, colchicine, actinomycin D, taxotere, and the epipodophyllotoxins are pumped out of the cell by P-gp, thereby rendering the cell resistant to these drugs. The demonstration of positive selection in an in vivo model system established the ability to amplify clones of transduced hematopoietic cells and suggested possible applications for human therapy. Patients with breast cancer [182–184], lymphoma [185], other advanced neoplasms [186], and germ cell tumors [187] have undergone clinical trials with autologous CD34 expressing hematopoietic cells transduced with retroviral encoded MDR1 [183]. Taken as a whole, this series of work has shown a selective expansion of MDR1 transduced hematopoietic cells in patients treated with drugs which can be effluxed out by P-gp. Another study [187] observed the expression of a drug resistance transgene for more than 1 year in 4 out of 9 patients in the trial. Currently a phase I clinical trial utilizing another drug resistance gene, methyl-guanine methyl transferase (MGMT) whose product O^6-alkylguanine-DNA-methyltransferase (AGT) provides resistance to O^6-benzylguanine (BG) is underway for patients with advanced solid tumors or non-Hodgkin's lymphoma. Some potential problems with this strategy are, however, apparent. These include (1) failure to demonstrate that higher chemotherapy doses translate into improved patient survival, (2) very low transduction efficiency of the target human hematopoietic cells with retrovirus vectors, (3) the dose-limiting effects determined by other non-hematological toxicities, and (4) the fact that cancer cells in the marrow could be transduced with the drug-resistance gene, which could rapidly give rise to clones of treatment-resistant tumor cells.

42.6.3 Chemosensitization and Radiosensitization

A third molecular chemotherapy approach seeks to modulate the level of expression of a variety of genes that influence the sensitivity of the cell to toxic stimuli, including conventional chemotherapeutic drugs and radiotherapy. Genetic chemosensitization can be achieved by modulating apoptosis, inhibiting tumor cell resistance, or enhancing the intratumoral production of cytotoxic drugs. To facilitate apoptosis, genes such as *p53* may be administered to tumor cells to enhance the mechanisms of apoptosis induced by chemotherapeutic agents [188]. In vitro studies with the human oral squamous cell carcinoma cell lines HSC4 and SAS have shown that replacement of wild type *p53* concomitantly with X-irradiation had a better cell killing effect than either of the two approaches separately [189]. A phase II clinical trial with Ad-*p53* and radiotherapy in patients with non-small lung cell cancer showed that 63 % of the patients showed no viable tumor 3 months post-therapy [39]. Our group has also shown that downregulation of Bcl-2 protein levels by an intracellular anti-Bcl-2 single-chain antibody increased drug-induced cytotoxicity [190]. Analogously, genetic downregulation of cellular factors related to chemoresistance has been shown to enhance chemosensitivity. Again, our group has been able to show that single-chain antibody-mediated abrogation of the c-erbB-2 oncoprotein can significantly mitigate intrinsic chemoresistance in erbB-2 overexpressing ovarian cancer cells. This allows for augmented sensitivity to the DNA-damaging drug cisplatin [76]. Alternatively, genes can be administered intratumorally that enhance metabolic conversion of conventional chemotherapeutic agents. Studies have shown that transfer of a liver cytochrome P450 gene, CYP2B1, into human breast cancer cells greatly sensitized these cells to the cancer chemotherapeutic agent cyclophosphamide as a consequence of the acquired capacity for intratumoral drug activation. This effect produced a substantially enhanced antitumor activity in vivo [191]. Lastly, combinations of conventional chemotherapeutic agents and molecular chemotherapy can serve the established rule of administering cytotoxic drugs with different mechanisms of action and toxicities.

Several drugs are proven radiosensitizers, a fact that is commonly exploited in the clinic. One of these drugs is 5-fluorouracil (5-FU), which is the product of the CD suicide gene. In this regard, molecular chemotherapy based on CD has been shown to enhance the effects of radiation therapy in animal models of gliosarcoma [192] and cholangiocarcinoma [193]. Thus, strategies to alter both chemosensitivity and radiosensitivity by gene transfer appear to have potentially wide applicability in many tumor contexts.

42.6.4 Obstacles to Molecular Chemotherapy

With all of its promise, molecular chemotherapy also bears some practical limitations. To date, the strategy of molecular chemotherapy has been mainly used in loco-regional disease models. In these in situ schemas, a vector encoding the toxin gene is administered intratumorally or into an anatomically closed compartment containing the tumor mass. The goals of this delivery method are to achieve high local vector concentration in order to favor tumor transduction and to limit vector dissemination. However, transduction efficiencies of presently available vectors have been shown to be inadequate. Even in closed compartment delivery contexts, it has not been possible to modify a sufficient number of tumor cells to achieve a relevant tumoral response in clinical models [194–198]. Furthermore, although transduction with HSV-*tk* followed by ganciclovir treatment reduces tumor burden and prolongs survival in various model systems, including those

utilizing intratumoral and intraperitoneal administration, the required increased doses of viral vector needed for obtaining quantitative tumor cell transduction is associated with limiting toxicity. In fact, substantial toxicity and experimental animal death have been noted [144, 145, 197]. Thus, the small therapeutic index of currently available vectors in the context of in situ administration is a critical limiting factor for the purpose of gene therapy of cancer. Furthermore, and most importantly, a well-known limitation of conventional chemotherapy is also to be expected with the use of molecular chemotherapy, i.e., the appearance of drug-resistant tumor subpopulations (Table 42.1). In conclusion, vector limitations and well-known barriers to classical cytotoxic maneuvers impede the full exploitation of the promise of a more selective eradication of carcinoma cells via expression of a toxin or protective genes.

42.7 Genetic Immunopotentiation

The development of clinically evident tumors in patients implies the obvious failure of the host immune system to recognize and eliminate tumor antigen(s). Involvement of the immune system or lack thereof, in the development of cancer has been known for eons with the earliest record of cancer immunotherapy in its rudimentary form being attempted in ancient Egypt around 2600 BC [199]. Simply stated, cancer cells have or acquire the ability to escape the immune system. Factors that can explain this failure of the immune system to recognize nonself in the cancer patients include: (1) inadequate immunogenicity of the tumor or (2) a deficiency of the immune system to recognize, respond, and reject. Genetic immunopotentiation strategies attempt to achieve active immunization against tumor-associated antigens by gene transfer methodologies applied either directly to tumor cells to increase their immunogenicity or to cellular components of the immune system to recognize the tumor cells more efficiently. To this end, insights into the pathophysiology of tumor escape from the immune system surveillance offer guidance for designing new therapeutic strategies [200].

42.7.1 Genetic Modification of Tumor Cells

One of the strategies for augmenting the antitumor immune response is to genetically modify tumor cells, or to manipulate their components, to facilitate a robust immune response. Thus, it has been hypothesized that a formerly tolerant host may revert from its immune status resulting in either tolerance or anergy, ultimately leading to tumor rejection. In other words, it is hypothesized that the host can be vaccinated against the tumor by exposing tumor antigens to the immune system in a more favorable context [201–203]. Most clinical experience with antitumor vaccines to date has been obtained with melanoma patients. For years, irradiated tumor cells, either autologous or allogeneic, have been administered in combination with different adjuvants, such as Bacille Calmette-Guérin (BCG) back into stricken patients. Later, as our molecular knowledge of tumor-associated antigens progressed, this allowed the testing of vaccines based on individual antigenic determinants delivered to the patient in the form of peptides or DNA. More recently, tumor cells themselves have been genetically modified to increase their immunogenicity by transfer of a variety of genes, including cytokines such as IL-1, IL-2, and GM-CSF, along with MHC molecules, costimulating signal molecules such as B7, and tumor associated antigens themselves. A common requirement, not yet adequately accomplished, is to introduce the gene of interest into tumor explants or cultured cells with high efficiency.

42.7.1.1 Cytokine Gene Transfer

The utility of antitumor vaccines based on whole tumor cells has been poor when analyzed in all (randomized) clinical trials to date. However, it has been argued that the genetic modification of tumor cells with carefully selected cytokine genes will eventually lead to an augmentation of the immune response against the tumor [204]. One possible intervention is to induce, by intratumoral gene transfer, cytokines that, once secreted by the tumor cell, can activate directly the response of cytotoxic T-lymphocytes (CTL), and thus increase the awareness of the immune system cells to tumor cells in the microenvironment. Cytokines tested to this end include: IL-1, IL-2, IL-4, IL-6, IL-7, IL-10, IL-12, IFN-γ, TNF, G-CSF, and GM-CSF [205–219]. In some cases, intense inflammatory infiltrates have been observed surrounding cytokine-secreting tumor cells, with the type of infiltrate varying with the particular cytokine utilized. In animal models, immune-mediated tumor regressions are consistently observed with this strategy. Also, specific immunity mediated by CTLs against subsequent exposure to unmodified tumor cells is commonly observed in treated animals. A phase I clinical trial using adenoviral vector to deliver IL-12 intratumorally in patients with advanced gastrointestinal tumors showed the safety of the approach [220]. Under the experimental conditions, tumor growth was seen to stabilize in 30 % of the patients in this clinical trial. Another phase I clinical trial using IL-2 showed similar effects in patients with prostate cancer. The tumors were excised and pathological analysis showed intense necrosis and T-lymphocyte infiltration [221]. Other clinical trials using IL-24 (melanoma differentiation antigen gene-7 [*mda*-7]) [26, 27, 29], GM-CSF [222–224], TNF-alpha [225, 226] and γ-IFN [227, 228] have also shown the safety and efficacy of the approach in phase I clinical trials. Even though phase I trials have been successful, cytokine gene therapy as a single treatment approach for cancer has not advanced given the recognized

complexity of immunological intervention and its potential host toxicities.

42.7.1.2 Induction of MHC Expression and Transfer of Allogeneic MHC

Recognition of a tumor-associated antigen by CTLs requires its simultaneous presentation with major histocompatibility complex (MHC) class I molecules on the surface of tumor cells. Hindering this approach is the evidence for a decrease in MHC class I expression levels in numerous tumors samples derived from patients [229]. To complicate matters further, in vitro co-culture experiment of cancer cell with CTLs demonstrated the evasion of these cancer cells (with low MHC class I molecule levels) from cytotoxicity [230, 231]. In this regard, gene therapy approaches directed at replacing the MHC class I antigen on the tumor cells surface have been attempted. Interestingly, tumor transfer of allogeneic MHC genes can generate CTLs reactive not only against the treated tumor mass, but also against non-modified tumor cells. This results in widespread tumor regression [232]. On this basis, phase I and II clinical trials have been performed by transferring the HLA-B7 gene, by intratumoral injection into tumors that do not express the molecule [233, 234]. The results of a recent multicenter phase II trial utilizing plasmid DNA expressing HLA-B7/β2-m mixed with cationic lipid has shown minimal adverse effects while exhibiting biological activity at the given dose (9.1 % of the patients had a complete or partial response and another 23.4 % had stable disease) [235]. Other cytokines like Interferon-γ (IFN-γ) and tumor necrosis factor (TNF) also stimulates the expression of MHC molecules, and can, therefore, make tumor cells more recognizable to the immune system [236]. In vitro studies have confirmed that the transfer of the interferon-γ gene increases MHC expression. These results were the foundation for establishment of a phase I clinical trial using this approach [237]. A theoretical risk of upregulating MHC class I antigen is the inhibition of the antitumor activity of NK cells, which recognize and attack specifically MHC class I-negative cells.

42.7.1.3 Costimulatory Molecules

Rejection of a tumor by CTLs requires not only the presence of cell surface tumor antigens and their appropriate display in association with MHC class I molecules (signal 1) but also an array of *costimulatory signals*, provided by antigen-presenting cells (APCs) (signal 2). A costimulatory signal promotes the clonal expansion of antigen-specific T cells, cytokine release and their differentiation into effector and memory cells. These costimulatory signals also reduce the threshold for T-cell activation especially when recognizing weak antigens like tumor associated antigens [238]. The efficacy of increased costimulation of T lymphocytes for antitumor immunotherapy has been shown in mice vaccinated with tumor cells expressing genes encoding several costimulatory molecules. For instance, tumor cells transfected with B7.1 (also known as CD80, a ligand of CD28 in lymphocytes and distinct from HLA-B7) potently stimulate an immune response, which is not observed with unmodified cells. When injected into syngeneic animals, B7.1 expressing cells are rejected, whereas unmodified cells are not. Furthermore, B7.1 expressing cells induce a potent immune response against unmodified cells in distant regions. The reason is that the presence of B7.1 increases the activation of T lymphocytes, but the cytolytic activity of differentiated CTLs does not depend on B7.1. These results in animals led to the development of clinical trials, in which tumors from patients were cultured, genetically modified, irradiated, and finally reintroduced into the same patient as vaccines. This strategy, although time-consuming, technically demanding, and costly, could be effective even when no tumor antigens had been identified. A phase I clinical trial utilizing recombinant vaccinia virus to deliver B7.1 for the treatment of melanoma showed only minimal side effects, i.e., low grade fever, myalgia, and vitiligo. Of the 12 patients in the trial, partial response to treatment was observed in one patient and disease stabilization in two more. Local immunity at the tumor site suggested tumor regression and an increase in the expression of CD8 and IFN-γ. Immune ignorance of primary tumor sites due to a lack of mobilization of activated T lymphocytes towards the original tumor localization can severely limit the utility of strategies based on costimulatory molecules and may thus explain the lack of effectiveness to date in patients treated by this methodology.

Other molecules involved in costimulation are formed by the intercellular adhesion molecules ICAM-1, ICAM-2, ICAM-3 and the lymphocyte functional antigen (LFA-1). Many tumors do not express ligands of the ICAM family efficiently, thus decreasing their ability to costimulate or be targets of the immune response. Again, the transfer of the corresponding gene could conceivably be useful to augment the effect of antitumor vaccines, and that seems to have been the case in several animal models [239, 240]. CD40, present in APCs, and its ligand in lymphocytes, CD40L, form a third system of costimulatory molecules of unclear importance with respect to the systems mentioned above.

42.7.1.4 Vaccination with Tumor-Associated Antigens

There are five general *categories of tumor antigens*. First, antigens coded by genes that are silent in normal cells and expressed almost uniquely in tumors, such as the MAGE family of antigens in melanomas. Second, antigens resulting from mutations in normal proteins, such as p53, MUC-1, MUM-1, CDK4, and beta-catenin. Third, differentiation antigens, present normally in the cells from which the tumor is thought to originate, such as melanoma antigen recognized by T cells (MART-1), gp75, gp100, and tyrosinase, again in melanoma and melanocytes. The fourth category includes antigens encoded by normal genes that are dysregulated in

tumor tissues, such as erbB-2. Finally, antigens encoded by genomes of oncogenic viruses, such as the human papillomavirus E6 and E7 gene products round out the tumor antigen family.

Antitumor vaccines have been developed based on tumor-associated antigens. Patients have been vaccinated with these tumor-associated antigens combined with adjuvants that increase their immunogenicity. The rationale is the probability that existing T-lymphocytes with antitumor specificity can be activated and specifically stimulated by the vaccine. Immunization could further be performed by direct administration of the peptides, by viral vectors encoding the antigens, by cellular lysates obtained after infection of tumor specimens with vaccinia vectors encoding the antigens, or by naked DNA.

One limitation of vaccines based on peptides is that it is improbable that these peptides could efficiently replace other non-immunogenic peptides already present and associated with MHC molecules in the surface of tumor cells in the patient. Furthermore, extracellular proteins are presented to the immune system via MHC class II molecules, which activate $CD4^+$ helper lymphocytes but not cytotoxic $CD8^+$ lymphocytes. In contrast, DNA vaccines are better stimulators of CTLs resulting in expression of antigens from within cells, where they are associated with MHC class I molecules and are thus presented in the appropriate manner at the tumor cell surface.

The MUC-1 mucin is a transmembrane glycoprotein expressed by both normal and malignant cells. Hypoglycosylated forms of MUC-1 are associated with adenocarcinomas having exposed the cryptic epitopes which are recognized by the immune system of the host [241]. Unlike other tumor associated antigens, the CTLs specific for MUC-1 exhibit both MHC restricted and unrestricted recognition of cancer cells expressing MUC-1, thereby making it an excellent target for immunotherapy [242, 243]. Phase I clinical trials with MUC-1 in combination with IL-2 in patients with advanced prostate cancer [244] and other MUC-1 positive advanced forms of cancer [245] showed its safety and efficacy. Four of the 13 patients in the latter study had stabilization of their disease for approximately 6–9 months. Other particularly attractive candidate antigens (as they are shared by multiple tumors) include the melanoma antigens MAGE-1, MART-1, and gp100, which are currently being used in several ongoing clinical trials.

42.7.2 Genetic Modification of Immune Effector Cells

So far we have seen gene therapy approaches targeting tumor cells to increase their immunogenicity and thereby facilitating the immune system to clear the tumor cells from the host. Alternatively, the host immune effector cells themselves can be modulated by gene therapy techniques to effectively increase their efficiency in removing cancer cell populations from the patient.

42.7.2.1 Tumor Infiltrating Lymphocytes (TIL)

Several therapeutic maneuvers have been based in trying to modify the cells of the immune system. Tumor infiltrating lymphocytes (TIL) are derived from mononuclear cells obtained from leukocytes infiltrating solid tumors. In the early 1990s, it was hypothesized that TILs could be an enriched source of NK cells and CTLs specific for tumor antigens and could also have tropism towards systemic tumor foci. On this basis, technology for their expansion in culture was developed and TILs were the first immune cells to be genetically modified and applied in a human gene therapy clinical trial against cancer [246]. It was soon observed that while TILs do include CTL and NK activated cells, only a few of these cells in these mixed populations are specific against the tumor from which they are isolated. Furthermore, reinfused TILs localized poorly into tumors.

Three strategies have been applied to improve treatments based on TILs [247]. First, the IL-2 gene has been transferred into TILs to increase lymphocyte number and survival when in the host. Second, to boost antitumoral efficacy, the tumor necrosis factor (TNF) gene has been transferred into TILs ex vivo previous to reinfusion. Thirdly, to improve localization into tumor foci several novel cellular receptors have been engineered in lymphocytes by genetic and immunological means. In this regard, Steven Rosenberg, who pioneered clinical trials with TILs at the National Cancer Institute, has reported rare clinical responses, with notable toxicity from the IL-2 treatment frequently added to maintain the requisite number and functionality of TILs. Localization of TILs in tumor biopsies is, as mentioned, modest. Targeted lymphocytes expressing chimeric T-cell receptors against tumor antigens have been developed with the aim of improving that barely exploitable tropism, and are currently undergoing clinical testing in colorectal and ovarian cancer, and melanoma.

42.7.2.2 Dendritic Cell (DC) Targeted Gene Therapy

Dendritic cells, with their unique ability to prime naïve T cells to initiate immune response are the most powerful antigen presenting cells (APC) identified to date [248]. In contrast to T cell stimulation, which is based on distinction between self and nonself antigens, DC stimulation has been hypothesized to be dependent on a danger signal as perceived by DCs [249]. For e.g., pro-inflammatory signals associated with microbes will lead to DC activation which in turn activates specific T cells, while a steady state condition would not cause activation of DCs and hence would maintain a state of peripheral tolerance. The tumor microenvironment comes under the latter category with no

DC activation, as the immune system does not perceive it as possible threat [250].

DC Maturation Strategies

Poor DC differentiation and maturation has been observed in many tumors, and a decrease in DC infiltration of the tumor microenvironment is considered as a poor prognostic factor among different cancers [251, 252]. Therefore gene therapy approaches targeted to correct the DC maturation in cancer are underway. Different cytokines are known to modulate the differentiation and maturation of DCs. The most commonly used cytokine in this regard is GM-CSF, which stimulates DC maturation [253]. In vivo studies in mouse models of cancer showed an increase in the anti-tumor immunity following GM-CSF transfer [254–257]. Other cytokines used for this purpose include IL-4 [258], TNF-α [259], IFN-α [260], and IL-18 [261].

DC Targeted Polynucleotide Immunization

Alternatively, the mature DCs are transferred with the genes for tumor associated antigens (TAA) either ex vivo or in vivo to potentiate the immune response of the host T cells to TAAs and to eliminate the tumor. The most common ex vivo approach involves the generation of DCs in vitro from monocytes, followed by TAA transduction and adoptive transfer. Though the transduction efficiency can be controlled by this approach, it is a tedious, time consuming procedure and also may serve as a possible source of infection when introduced into the patient. In vivo targeted delivery of TAA to DCs has, however, demonstrated tumor rejection in mouse studies. But the route of administration has to be considered carefully to target DCs, with intradermal injection of the vector with TAA being the preferred route. Also, the efficacy of this approach depends on the DC-mediated activation of CTLs. Targeted transduction of DCs in vivo is being attempted by using different targeting molecules including DC-SIGN [262–265], CD1 molecules [264], TNF and TNF receptor superfamilies. A number of phase I clinical trials utilizing viral vectors to deliver different TAA to DCs have shown the safety of this method, but there was no objective clinical response reported [266–268].

42.7.3 Obstacles to Genetic Immunopotentiation

The main advantage of genetic immunopotentiation is the possibility of enlisting physiological mechanisms for a potentially vast amplification of the therapeutic maneuver. To this end, even modest levels of gene transfer can theoretically be followed by clonal expansion and systemic spread of effector immune cells and mediators. Thus, efficiency of gene transfer here is not critical, given the relatively low amounts of cells and gene products needed to obtain a potentially powerful response from the immune system. There are, however, other more important obstacles that perhaps explain the *poor* results obtained to date by tumor immunotherapy in humans. Antigenic heterogeneity and plasticity, redundancy of immune system regulation, and well-established tolerance to natural tumors are the more evident barriers.

42.7.3.1 Antigenic Heterogeneity and Plasticity

During the last two decades numerous reports have confirmed both in vitro and in vivo that expression of tumor cellular antigens in different tumor types is heterogeneous, with variability being found not only between different patients with the same tumors, but between different regions of a single tumor and even in single cell clones [269, 270]. Moreover, this variability changes with time. This fact, first confronted by monoclonal antibody therapists, may clearly limit the impact of vaccines against single tumor-associated antigens, including those based on cultured, homogeneous populations of tumor cells.

42.7.3.2 The Redundant Phenomenology of the Immune System

The destructive power of the immune system, occasionally needed in its entire exuberance, obligingly requires a complex network of balances and counterbalances to control the pathways of activation and termination of the immune response. Interventions directed to supplement or inhibit single mediators will most probably obtain partial physiological and therapeutic results in the best case, may frequently yield no result at all, and occasionally will produce effects opposed to those desired. Increasingly, combinations of cytokines are being used to try to control the complexity of the immune response against tumors. Current therapeutic interventions for inducing organ graft tolerance successfully prolong organ survival by blocking multiple effector cells and mediators of the adaptive and innate immune systems. Similarly, it is conceivable that breaking tumor tolerance will require a strategy of multiple interventions against several simultaneous target cells and cytokines.

42.7.3.3 Lack of an Immune Response (Tumor Tolerance)

Current knowledge in tumor immunobiology establishes that T cells able to recognize tumor-associated antigens can be found in vivo and are inducible (with varying degrees of difficulty) in vitro. Thus, the lymphocyte repertoire against these epitopes has not been fully defined. However, either tolerance to these (tumor) self-antigens has been induced or,

in the absence of costimulatory signals, peripheral T cells simply have ignored these antigens [271]. This phenomenon should be an early event in tumor progression [272], but may have been totally missed in many animal models employed to date, which are based on tumor grafts. In this regard, studies with transgenic mice that develop spontaneous tumors have shown that vaccination with tumor cells transduced with cytokines fail to inhibit tumor onset and progression, whereas the same cells are able to immunize non-transgenic mice subsequently grafted with tumors [273]. Thus, the failure of naturally established tumors to efficiently present antigens, and to attract and activate tumor-specific T cells at the tumor site may impede successful vaccination against cancer antigens. Furthermore, ignorance by the immune system can abort most of the immunotherapy maneuvers being tested.

42.8 Oncolytic Viruses for Cancer Therapy

The anticancer effects following natural viral infections have been recognized for more than a century. Numerous examples of remission of cancers, including acute lymphoblastic leukemia [274] and Burkitt's lymphoma [275], following varicella or measles virus infections have been documented since the 1950s. However, due to the toxicity associated with using wild type virus [276] and lack of techniques to upscale and purify viruses, this approach for treating cancer did not take off until 1990s, when recombinant DNA technology revolutionized the field of molecular biology. Oncolytic viruses (Onco: cancer, lysis: killing) are replication competent viruses, which can selectively replicate and hence kill the cancer cells by their cytopathic effects. The cancer cell selective replication of these viruses may be due to genetic engineering of wild type virus (e.g., HSV-1, adenovirus), attenuation of natural virus (e.g., Newcastle disease virus) or use of nonpathogenic viruses in humans (e.g., reovirus) that replicate specifically in tumor cells [8]. Since the first description of genetically engineered conditionally replicating virus (CRV) 15 years ago [277], the field of oncolytic virotherapy has significantly advanced with the approval of H101—an oncolytic adenovirus treatment for head and neck cancer in China [278]. Table 42.6 shows the list of oncolytic viruses which are currently being used in a clinical setting. We shall briefly discuss the tumor selective replication mechanism for oncolytic Herpes Simplex Virus (HSV) and conditionally replicative adenovirus (CRAds) and also discuss double-armed CRVs which are essentially oncolytic viruses carrying additional therapeutic genes (such as pro-apoptotic genes) to enhance cell killing.

Table 42.6 Conditionally replicating oncolytic viruses commonly used in clinical trials

	Parental strain	Agent name	Genetic alteration in virus resulting in selectivity	Target molecules in cancer cells rendering virus replicative
Engineered virus	Adenovirus	ONYX-015	(1) Δ E1b-55K, (2) Δ E3b deletion	Mutated *p53* molecule
		Ad-Δ24	Δ Amino acids 121–128 of E1a gene	Mutated *Rb* gene product
		H101	(1) Δ E1b-55K, (2) Δ E3	Mutated *p53* molecule
		CN706	E1a gene under PSE element	Prostate tissue specific expression of E1a gene product
		AvE1a041	E1a gene under AFP promoter	HCC and testicular carcinoma specific expression of E1a gene product
	Herpes simplex virus (HSV)	G207	(1) Δ ICP6 (ribonucleotide reductase subunit), (2) Δ *γ34.5* gene	Activated Ras pathway and decreased PKR
		1716	Δ *γ34.5* gene	Loss of neurovirulence
		G47Δ	(1) Δ ICP6 (ribonucleotide reductase subunit), (2) Δ *γ34.5* gene, (3) Δ *α47*	Activated Ras pathway, decreased PKR and upregulation of MHC I molecules with HSV-1 antigens
		G92A	*ICP4* gene under albumin enhancer/promoter	Liver tissue (HCC) selective replication
Non-engineered virus	Reovirus		None	Activated Ras pathway
	Newcastle disease virus (NDV)	NDV (73-T)	Unknown (serial passage in cancer cells)	IFN resistance of tumors
	Vesicular stomatitis virus		None	IFN resistance of tumors

AFP α-fetoprotein, *HCC* hepatocellular carcinoma, *ICP4, ICP6* infected cell protein 4 and 6, *IFN* interferon, *MHC I* major histocompatibility complex I, *PKR* protein kinase R, *PSE* prostate-specific enhancer

42.8.1 Oncolytic Herpes Simplex Virus

HSV is a naturally occurring neurotropic virus which initially was genetically engineered to have a single mutation in a nonessential gene associated with either viral virulence or viral DNA synthesis, to make it conditionally replicative in cancer cells [279, 280]. This first generation vector was shown to be an effective oncolytic agent, but concerns that a further single mutation could revert it to wild-type phenotype led to the development of second and third generation oncolytic HSVs that have more than one mutation. G207, a second generation oncolytic HSV, with deletion of both copies of the γ34.5 gene—the major determinant of neurovirulence [281], showed its selective oncolytic potential. The *γ34.5* gene antagonizes the double stranded RNA-dependent protein kinase R (PKR) response seen following HSV-1 infection that, in turn, leads to the shut down of cellular protein machinery [282]. Since Ras signaling is activated in tumor cells with inhibition of PKR, the *γ34.5* gene deleted G207 could be seen to replicate selectively in tumor cells [283, 284].

There is another insertional mutation of the *Escherichia coli lacZ* gene, in the infected-cell protein 6 (ICP6) coding region, which inhibits ribonucleotide reductase—a key enzyme for viral DNA synthesis in nondividing cells [285]. These double mutations (the *γ34.5* gene deletion and *lacZ* gene insertion) greatly minimizes the chances of G207 reverting to the wild type phenotype. Additionally, the presence of the *lacZ* gene can be utilized to detect G207 infected cells histochemically. R3616, 1716, and NV1020 are other second generation oncolytic HSVs with the same *γ34.5* gene deletion [281, 286]. Preclinical in vitro and in vivo studies have shown the selective replication of G207 in cancer cells with inhibition of tumor growth and prolonged survival in mouse models of human glioma [287, 288]. Since HSVs are neurotropic viruses, G207's neurotoxic effects were evaluated in nonhuman primates. Results showed normal brain tissues at necropsy with no infectious particles or viral DNA detected outside the brain [289, 290]. These safety profile data led to phase I clinical trials using G207 and 1716 oncolytic viruses. The dose escalation phase I trial for G207 in patients with recurrent gliomas showed a maximum tolerated dose of 3×10^9 plaque forming units (pfu) [291]. Of the 21 patients studied at two centers, two of them had seizures and one patient had brain edema. All patients showed disease progression but histology of the brain samples at autopsy in five patients showed no evidence of encephalitis or other inflammatory changes and all tissues were negative for HSV-1 immunoreactivity. NV1020, another oncolytic HSV was used in a phase I clinical trial in patients with colorectal cancer with liver metastasis. It showed similar tolerable doses with minimal adverse effects [292]. G47Δ is a third generation oncolytic HSV, which has an additional mutation in the *α47* gene, is also being currently tested in both in vitro and in vivo studies. The *α47* gene product normally inhibits a key transporter associated with antigen presentation and hence the G47Δ virus infected cells present higher levels of MHC I molecules and were better at stimulating cytotoxic T-lymphocytes. However, since the interaction of the *α47* gene product with the transporter is species specific, it is not possible to test this virus in in vivo tumor models [293].

42.8.2 Oncolytic Adenovirus

When a cell is infected with adenovirus (Ad), the cellular *p53* and *Rb* genes activate the cell's apoptotic pathway and inhibit cellular proliferation respectively, to contain the viral spread to other cells. Adenovirus in turn has evolved to antagonize the function of these TSGs by expressing certain proteins, which interact with the components of the *p53* and *Rb* protein pathway, thereby promoting cellular proliferation and inhibiting apoptosis. E1a, E1b, E4-orf6/7, and E4-orf6 (viral early proteins) are the major proteins encoded by Ad for this purpose. E1a [294, 295] and E4-orf6/7 [296] inhibits the *Rb* protein product, thereby promoting cellular proliferation, while the E1b 55K protein [297] and E1b 19K protein [298] in a *p53* dependent pathway, and E4-orf6 protein product [299–301] in a *p53* independent pathway prevents the premature apoptosis of the infected cell. In this regard, genetically engineered Ads with mutations in either of these genes can replicate only in cells with a defective *p53* or *Rb* pathway (cancer cells). E1a and E1b are the most commonly modified viral genes in derived CRAds.

ONYX-015 is a E1b-55K gene deleted virus [302] and was shown to be selectively replicative in tumor cells with a dysregulated *p53* pathway. Subsequently it was determined that the deletion of the E1b-55K gene affected the late viral protein synthesis regardless of the *p53* status of the cell [303, 304]. This led to the development of other mutants which did not affect the late stage of viral replication (e.g., ONYX-051 with a R240A point mutation in the E1b-55K region of ONYX-015). Irrespective of that observation, ONYX-015 was tested in a number of phase I/II clinical trials and shown to have a very good safety profile [305–311]. Ad-Δ24, an oncolytic adenovirus which has a deletion of amino acids 121–128 in the E1a region has also been shown to be effective in inducing cytopathic effects selectively in cells with a dysregulated *Rb* pathway [294]. Table 42.6 provides a list of the most commonly used oncolytic viruses currently being used in clinical studies.

42.8.3 Double Armed Conditionally Replicative Virus

In spite of their great potential, oncolytic viruses do not achieve complete lysis of all cells within a tumor tissue because of tumor cell heterogeneity. The introduction of a therapeutic gene, be it one that codes for a cytokine or a pro-apoptotic gene

greatly enhances their oncolytic potential. But therapeutic genes selected should not interfere with the replicative properties of the virus they exist within. Further, they should be expressed in the late phase of the viral replication. In this way the local concentration of the therapeutic gene product is increased many fold due to the replication capacity of the vector, when compared to its delivery via a replication defective virus. Cytokines like IFN [312, 313] and TNF [314], pro-apoptotic genes like *Bcl-xs* [315], *p53* [316], and *mda*-7/IL-24 [317, 318], and prodrug conversion enzymes like HSV-*tk* [319, 320] and CD/uracil phosphoribosyl transferase [321] have all been used within CRAds, complementing their effects both in vitro and in vivo while demonstrating a greater cytopathic effect than seen with either of them alone.

42.8.4 Obstacles to Oncolytic Viral Cancer Therapy

One of the major issues for achieving an acceptable therapeutic index in patients is the selective replication of oncolytic virus in tumor cells avoiding nonspecific replication in noncancer cells. Adenoviruses, due to their natural hepatotropism, have to be untargeted from liver to avoid hepatotoxicity. To achieve this liver-off, tumor-on replication pattern, different approaches including transductional targeting (redirecting Ad away from its natural coxsackie-adenovirus receptor [CAR] to different receptors [322], transcriptional targeting (transcription of E1a gene under tumor or tissue specific promoters [323, 324], translational targeting (translation of E1a gene only in tumor cells [325]) and liver-untargeting by hexon swapping (which decreases coagulation factor X binding to Adenovirus and hence decreased liver tropism) [326] have been attempted. Our Center had recently undertaken the first phase I clinical trial in the USA utilizing a CRAd, specifically the Ad-Δ24, which has a RGD (Arginine–Glycine–Aspartic acid) peptide modification in its fiber [327] that binds integrins overexpressed in cancer cells (transductional targeting), for the treatment of patients with ovarian cancer [328]. Transcriptional targeting of oncolytic viruses utilizing different tissue or tumor specific promoters (such as CXCR4, survivin, midkine [329], rodent progression elevated gene-3 [330], or modified E2F-1 promoter [331]) are also being evaluated in both in vitro and in vivo model systems for their tumor specific oncolytic functions. Our lab has also recently shown the ability to target the replication of CRAd by translational regulation of E1a in addition to its transcriptional control [325]. A long and highly structured 5′ untranslated region (5′ UTR) element from fibroblast growth factor-2 (FGF-2) mRNA was inserted upstream of the E1a region. Eukaryotic translation initiation factor (eIF4E) which is over-expressed in solid tumors is needed to unwind this highly structured 5′ UTR element upstream of the E1a transcript. This leads to the regulation of translation of E1a mRNA only in cells over expressing eIF4E (cancer cells) and thereby allowing replication in cancer cells only [325].

42.9 Novel Strategies to Overcome Current Limitations of Gene Therapy

Gene transfer therapies are remarkably successful in in vitro and in vivo animal model systems. In effect, we already know that the malignant phenotype can be reverted in tumor cell lines by knocking out or knocking in certain genes; that tumors can be eradicated by delivery of cytotoxic genes followed by treatment with appropriate prodrugs; and that tumors can be cured in murine models by making the tumor cells either more immunogenic or by making the immune system cells more responsive, via the expression of cytokines, costimulatory, or immunogenic molecules. However, overriding limitations have been made apparent in preclinical experiments and in the first human gene therapy clinical trials against cancer, as emphasized by the Orkin and Motulsky Report to the NIH [332]. Most difficulties in obtaining clinically relevant benefits come from the inefficiency of current gene vectors in transducing tumor or immune cells and their inability to access selectively target cells distributed systemically. In this regard, each of these limitations undermines the implementation of a particular gene therapy strategy. Several avenues for improvement have been proposed, and some will be succinctly reviewed.

42.9.1 A Successful Gene Therapy Approach Requires Targeting

Less than optimal transduction levels of vectors may require the employment of gene vectors at higher magnitudes of infectivity, leading to target cell cytotoxicity. Thus, for direct in situ infection of selected organs, improvements in basic gene transfer efficiency may be required. In addition, and more specifically, the promiscuous tropism of the vector may potentially allow ectopic transduction of non-tumor cells with therapeutic genes. Therefore, strategies to enhance the efficiency of the vector as well as methods to enhance the specificity of target cell transduction will be necessary to render gene delivery optimal for cancer gene therapy purposes. In this regard, studies have demonstrated the feasibility of creating tropism-modified retroviral and adenoviral vectors to achieve cell-specific targeting (Table 42.7). To this end, immunological and genetic strategies for retargeting vectors to nonviral specific cellular receptors have been designed. Modifications of the adenovirus vector to alter native viral tropism in order to achieve selective transduction of target cells have proved to be feasible [333–336], in contrast with the more structurally demanding characteristics

Table 42.7 Targeting of cancer gene therapy

Principle	Basis	Strategies	Examples of applications
Selective delivery (transductional targeting)	Anatomically directed administration	Intratumoral, intravascular, or body compartment injection of vector	Injection of a plasmid encoding the immunostimulatory molecule B7 in foci of malignant melanoma [367]; intra-arterial infusion of a plasmid encoding VEGF in an ischemic vascular tree [368]; intraperitoneal administration of adenovirus expressing the suicide gene *tk* in model of ovarian cancer [369]
	Target cell physiology	Exploit cell cycle differences: gene transfer by retroviruses occurs only in dividing cells	Brain tumors (tumors are surrounded by neural cells, which are non-mitotic) [370]
		Exploit cell cycle differences: Herpes virus deleted in *tk* or other genes replicates only in cells undergoing division	Injection of virus is followed by lytic replication in liver metastasis [371] and brain tumors [372] (tumors are surrounded by cells that are non-mitotic)
		Exploit differences between transformed and normal cells: adenovirus deleted in E1B gene replicates selectively in p53 defective tumor cells	Injection of virus is followed by lytic replication in head and neck tumor cells [297]
	Specific receptors in target cells	Retrovirus: pseudotyped retroviruses (built with heterologous envelope proteins that confer novel tropism); retroviruses with genetically, chemically, or immunologically modified envelope proteins	Retrovirus with the genome and core of murine leukemia virus and the envelope protein of vesicular stomatitis virus have wider tropism [373] Retrovirus with modified envelope protein that includes a fragment of erythropoietin [374] or a single-chain variable region directed against known epitopes such as MHC class I molecules [375] or CEA [376]
		Adenovirus: genetic modifications in the fiber; immunologically mediated attachment of cellular ligands	The modification of the adenovirus fiber is feasible [377, 378]. Adenovirus with folate [378] or the fibroblast growth factor (FGF) attached to the virus via anti-knob Fab antibody fragments in ovarian tumors
		Molecular conjugates that combine a DNA binding domain and a cellular ligand	Asialoglycoprotein-based conjugates target hepatocytes [379]; adenovirus enhances transduction efficiency of conjugates [380] transferrin-based conjugates target leukemic cells [381]
		Liposomes modified with antibodies specific against cellular receptors	Liposomes coupled with antibody G22-MCA against glioma cells have higher transduction efficiency [382]
Selective expression (transcriptional targeting)	Tumor specific promoters	A suicide gene is administered under the control of a promoter sequence that is active on tumor cells	Adenoviruses expressing *tk* under the alpha-fetoprotein promoter in hepatoma [340], or DF3 (MUC1) in breast cancer [337]. Also shown with cells stably expressing the CD gene under the CEA promoter in colon cancer [341], and with cells transfected with the SLPI promoter, which is expressed in several carcinomas, to direct transcription of *tk* [338]. Same principle shown with promoter of erbB-2, overexpressed in breast and pancreatic tumors [339]. PEG-Prom displays broad spectrum cancer-specific expression [330]
	Tissue specific promoters	A suicide gene is administered under the control of a promoter sequence that is active in a particular tissue	Tyrosinase (melanocytes) directs expression of *tk* into malignant melanoma [343] and other melanocytes; surfactant protein-A drives *tk* expression in lung cancer cell lines [342]

CD cytosine deaminase, *SLPI* secretory leukoprotease inhibitor, *tk* thymidine kinase, *VEGF* vascular endothelial growth factor

of retroviruses. Apart from the transductional targeting, the expression of the transgene can be transcriptionally targeted by the use of tissue or tumor specific promoters. These novel constructs have been used in in vitro and in vivo studies and shown to be effective [337–343].

42.9.2 Prolonged Transgene Expression: Immune Tolerance to Viral Vectors

Under certain conditions as with mutation compensation strategies, the expression of the therapeutic gene is needed for an extended duration. However, gene delivery via adenoviral vectors has been associated with the induction of both characteristically intense inflammatory and immunological responses when employed in vivo. A number of specific cellular and humoral immune effector mechanisms, together with nonspecific defense mechanisms, eliminate the infecting virus [344–346]. This process has been associated with attenuation of expression of the transferred therapeutic gene based, at least in part, on loss of the vector transduced cells. Based on an understanding of the biology of this phenomenon, specific strategies have been developed to mitigate this process.

Maneuvers to minimize the immune response against viral vectors include manipulations of both the vector and the host. Firstly, recombinant viral vectors are genetically engineered to delete viral genes encoding highly immunogenic or cytotoxic viral proteins. New generations of deleted viral vectors are, however, more difficult to propagate while still not completely devoid of immunogenic properties. Alternatively, different serotypes have been employed or, in regard to adenoviruses, either chimeras composed of mixed fiber and knob components of different serotypes or unique viruses from of other species such as canine [347, 348] or ovine Ads [349] have been proposed to minimize the stimulus for an immune response. Secondly, vectors have been modified to *express* immunomodulatory molecules. It has been hypothesized that this could create a locally privileged environment for the vector. Some of these engineered molecules are viral genes that interfere with the apparatus of antigen presentation, such as the adenoviral glycoprotein 19K or the herpes simplex virus (HSV) immediate early protein ICP47. Others are recombinant molecules designed to abrogate antigen presentation, such as antisense oligonucleotides or single-chain antibodies against MHC class I and II proteins, or have the ability to block costimulation, such as CTL4IgG.

Intervention of the immune system of the host has been adopted from common practices in the field of organ transplantation. In this regard, virally transduced cells have been considered to behave, to some extent, as allogeneic cell transplants. Thus, antibodies or drugs are employed that inhibit the cellular immune response, among these are anti-CD4 antibodies, cyclosporine, dexamethasone, and FK 506. In addition, drugs that decrease the humoral immune response, including cyclophosphamide and deoxyspergualin, have been used. Several groups have shown transient and more specific immune blockade with inhibitors of T cell costimulation, such as anti-CD40 ligand, CTL4IgG, and anti-LFA-1. Unfortunately, the required chronic administration of these immunosuppressive drugs affects systemic immune function and results potentially in a number of complications, not the least of which are life-threatening infection and malignancy. This makes them markedly less attractive in principle for clinical application, although short-term treatment in patients should be feasible. Lastly, induction of tolerance to adenovirus vectors by oral ingestion of adenoviral antigens has been described, but this approach needs further characterization. Thus, although inflammatory and immunological issues have limited the overall utility of vectors for gene therapy applications, many of the aforementioned strategies appear promising and may ultimately allow overcoming these limitations.

42.10 Conclusion

The delineation of the molecular basis of cancer provides unique opportunities for specific intervention at the molecular level for therapeutic purposes. To this end, four main gene therapy approaches have been developed to treat cancer: mutation compensation, molecular chemotherapy, genetic immunopotentiation, and viral oncolysis. For each of these conceptual approaches, human clinical protocols have entered testing in Phase I and II to assess dose escalation, safety, and toxicity issues, and more recently to evaluate efficacy, respectively. In fact, the People's Republic of China has conducted a phase III clinical trial with oncolytic virus (H101) for the treatment of head and neck cancer [350]. However, major problems remain to be solved before these approaches can become effective and a common place strategy for the treatment of neoplasia. Principal among these issues is the basic inability to deliver therapeutic genes quantitatively, and specifically, not only into tumor cells but also into tumor supporting tissues and effector cells of the immune system. As vector technology more fully fulfills these stringent requirements, it is anticipated that the promising results already observed in preclinical studies will translate quickly into the clinic for the amelioration of life-threatening disease. In addition, the complex heterogeneity of cancerous tissues should call for a multimodality approach whereby combinations of gene therapy with conventional therapies including chemotherapy and radiotherapy exist to effectively eradicate the transformed cells in the host. That is where the future of gene therapy stands with regard to anticancer therapy.

Personalized Medicine for the Treatment of Human Cancer

43

Scott A. Turner and Gregory J. Tsongalis

43.1 Introduction

The concept of personalized medicine is being introduced into routine patient care at all levels of healthcare. The Human Genome project has been a catalyst for this new age of medicine by fulfilling initial promises to provide better tools for diagnostic, prognostic, and therapeutic interventions [1, 2]. New and more rapid drug development, reclassification of tumor types, better diagnostic assays, and novel technologies are a few of the benefits we are now experiencing from this heroic effort [3–6]. For the cancer patient, these new diagnostic approaches will improve such things as tumor classification, mechanisms for monitoring disease, evaluations for susceptibility to cancer, prognostic markers, indicators of tumor cell response to therapeutics with less adverse reactions, and the development of novel therapeutics. As all of this comes to fruition, preventive medicine through our understanding of pharmacogenomics will lead to more personalized therapy and better overall outcomes.

Pharmacogenomics, as an underlying principle, represents the role that genes play (pharmacogenetics) in the processing of drugs by the body (pharmacokinetics) and how these drugs interact with their targets to give the desired response (pharmacodynamics) [7–9]. While other environmental factors also play a role in this selection, an individual's genetic makeup provides new insights into the metabolism and targeting of commonly prescribed, as well as, novel targeted therapies. Current medical practice often involves a trial-and-error approach to select the proper medication and dosage for a given patient. This can lead to adverse drug reactions and more often decreased efficacy of a therapeutic management strategy. While this may be the standard of practice, this approach cannot be sustained by our healthcare system at a time when the cost of novel therapeutics can exceed $10,000 per cycle of treatment and knowing that only a subset of the patient population will experience substantial benefit from that therapy. The overall aim of pharmacogenomic testing is to decrease adverse responses to therapy and increase efficacy by ensuring the appropriate selection and dose of therapy.

43.2 Historical Perspective

Although Fredrich Vogel did not coin the term pharmacogenetics until 1959, the concept of pharmacogenetics existed long before [10]. The concept was recognized and first documented in 510 BC by Pythagoras who observed that some individuals developed hemolytic anemia with fava bean consumption [11]. In 1914, Garrod expanded upon these early observations by documenting the fact that enzymes detoxify foreign agents so that they may be excreted harmlessly and that some people lack these enzymes and experience adverse effects [12]. Hemolytic anemia due to fava bean consumption was later determined to occur in glucose-6-phosphate dehydrogenase deficient individuals [11].

Pharmacogenomics evolved throughout the twentieth century as investigators combined Mendelian genetics with observed phenotypes. In 1932, Snyder performed the first global study of ethnic variation and deduced that taste deficiency was inherited. As such, the phenylthiourea non-taster phenotype was an inherited recessive trait and the frequency of occurrence differed between races [13]. Subsequently, genetic deficiencies in other enzyme systems were documented and shown that metabolism of drugs played a critical role in a patient's response as well as risk for development of

adverse drug reactions (ADRs) [14–16]. The introduction of molecular technologies to examine an individual's DNA for genetic variants that are responsible for these phenotypes propelled the field of pharmacogenomics forward. Genotype:phenotype correlations could now confirm ones predisposition to adverse events and allow simpler and more rapid analysis of patient samples in a clinical setting.

43.3 Genotyping Technologies

The evolution of molecular technologies and their introduction into the clinical laboratory setting has been a remarkable transformation for diagnostic testing. Our ability to detect single base variants in any region of the three billion base human genome has set an unprecedented paradigm for technical, clinical, and social implications of a laboratory test. From a technical perspective, we can now identify many different types of genetic variants, including copy number variants (CNV), insertions/deletions, chromosomal rearrangements, and single nucleotide variation, with a high degree of sensitivity and specificity using various available technologies, including quantitative PCR, Sanger sequencing, pyrosequencing, PCR/RFLP, allele-specific PCR, high-resolution melting curves, somatic mutation arrays, chromosomal microarrays, and others [17–22]. Recent advancements in next-generation DNA sequencing technologies have allowed for parallel sequencing of multiple genomic targets from multiple patients in one clinical test. The rapid incorporation of this technology into the clinic has resulted in the development of a variety of applications ranging from the detection of common mutations in tumor-specific genes (hotspot panels) to the detection of all variations across the entire genome. The ability to readily identify all relevant genomic variations in one clinical test has the potential to revolutionize the personalized treatment of the modern-day cancer patient.

Genotyping methods are generally easier to perform and more cost-effective than the more traditional phenotyping methods. Because an individual's genotype is not expected to change over time or during the course of treatment, most genotyping applications need only be performed once in an individual's lifetime. This is commonly the case with variants associated with drug metabolism and transportation. However in cancer the disease-causing (oncogenic) mutation may change over the course of the disease requiring the need for repeated genotyping depending on responsiveness of initial treatment.

43.4 Pharmacogenomics and Drug Metabolism

Many of the enzymes involved in drug metabolism are members of the cytochrome P450 (CYP450) superfamily [23, 24]. CYP450 enzymes are mainly located in the liver and gastrointestinal tract and include greater than 30 isoforms. The most polymorphic of these enzymes responsible for the majority of biotransformations are the CYP3A, CYP2D6, CYP2C19, and CYP2C9 isoforms. Benign genetic variants in these genes, including single nucleotide polymorphisms (SNPs), insertions/deletions and duplications, can lead to the following phenotypes. Poor metabolizers (PM) have no detectable enzymatic activity; intermediate metabolizers (IM) have decreased enzymatic activity; extensive metabolizers (EM) are considered normal and have at least one copy of an active gene; ultra-rapid metabolizers (UM) contain duplicated or amplified gene copies that result in increased drug metabolism. The following are several examples of polymorphic drug metabolizing enzymes that can affect response to therapy.

In an effort to standardize genetic polymorphism annotation of pharmacologically important genes, star allele nomenclature is used. Briefly, *1 is usually the first sequence described that codes for a functional protein, and all other alleles are compared to this sequence. Each novel functional variant identified is assigned a unique number. Nonfunctional variants thought to be associated with a named star allele are not given new numbers but are defined by additional letters, and the principal star-allele is designated with an "A" (e.g. CYP2D6*14A, CYP2D6*14B) [25].

43.4.1 CYP2D6

CYP2D6 is the most widely studied member of this supergene enzyme family. The CYP2D6 gene is localized on chromosome 22q13.1 with two neighboring pseudogenes, CYP2D7 and CYP2D8 [26]. More than 50 alleles of CYP2D6 have been described of which alleles *3, *4, *5, *6, *7, *8, *11, *12, *13, *14, *15, *16, *18, *19, *20, *21, *38, *40, *42, and *44 were classified as nonfunctioning and alleles *9, *10, *17, *36, and *41 were reported to have substrate-dependent decreased activity. CYP2D6 alone is responsible for the metabolism of 20–25 % of prescribed drugs. Screening for CYP2D6*3, *4, and *5 alleles identifies at least 95 % of poor metabolizers in the Caucasian population. Based on the type of metabolizer, an individual can determine the response to a therapeutic drug. The U.S. FDA has approved the Luminex xTAG® CYP2D6 assay for clinical genotyping.

CYP2D6 has become an enzyme of interest for a specific oncology application in regards to the metabolism of one of the more commonly used therapies for breast cancer. All newly diagnosed breast cancers are evaluated for the expression of the estrogen receptor (ER) (Fig. 43.1). ER-positive breast cancers are then treated with hormonal therapies that mimic estrogen. One of these estrogen analogs is Tamoxifen (TAM), which itself has now been shown to have altered metabolism due to CYP450 genetic polymorphisms [27, 28]. TAM is used to treat all stages of ER-positive breast cancers

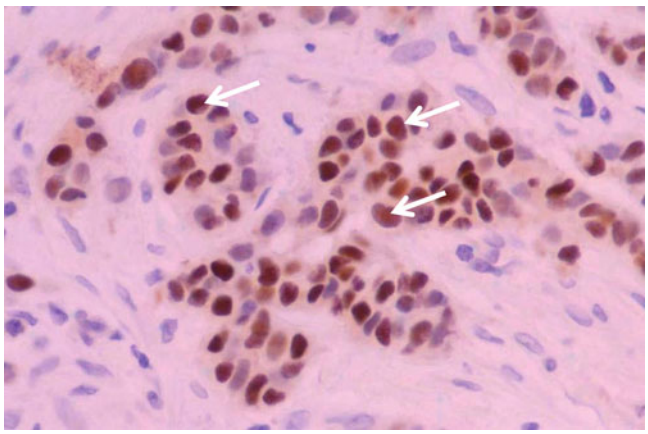

Fig. 43.1 *Immunohistochemical staining for the estrogen receptor (ER) in breast cancer.* The ER is detected as a *brown* color in the nucleus of the tumor cells (*arrows*).

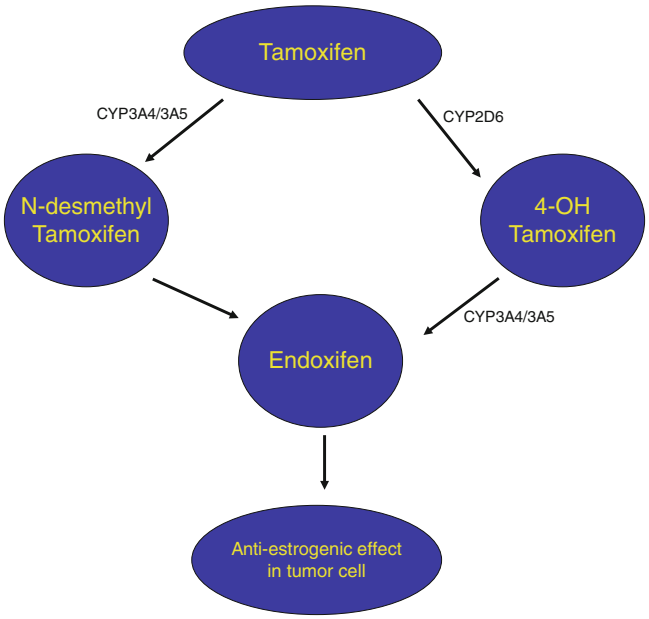

Fig. 43.2 Simplified schematic diagram showing metabolism of tamoxifen by CYP450 enzymes with the resulting production of the active metabolite, endoxifen.

yet it is not effective in all ER-positive breast cancer patients and it is frequently associated with side effects, such as hot flashes. TAM and its metabolites compete with estradiol for occupancy of the estrogen receptor, and in doing so inhibit estrogen-mediated cellular proliferation. Conversion of TAM to its active metabolites occurs predominantly through the CYP450 system (Fig. 43.2). Conversion of TAM to primary and secondary metabolites is important because these metabolites can have a greater affinity for the estrogen receptor than TAM itself. For example, 4-OH *N*-desmethyl-TAM (endoxifen) has approximately 100 times greater affinity for the estrogen receptor than tamoxifen. Activation of tamoxifen to endoxifen is primarily due to the action of CYP2D6. Therefore, patients with defective *CYP2D6* alleles may derive less benefit from TAM therapy than patients with functional copies of *CYP2D6*. The most common null allele among Caucasians is *CYP2D6*4*, a splice site mutation (G1934A) resulting in loss of enzyme activity and therefore, lack of conversion of TAM to endoxifen. Patients with lower CYP2D6 activity and lower levels of endoxifen have been shown to have a significantly shorter time of disease-free progression [29]. This would result in significantly decreased response to this commonly used anti-hormonal therapy. Common polymorphisms such as this make it feasible to accurately genotype patients so that treatments may be optimized.

43.4.2 UGT1A1

The uridine diphosphate glucuronosyl transferases (UGT) superfamily of endoplasmic reticulum-bound enzymes is responsible for conjugating a glucuronic acid moiety to a variety of compounds, thus allowing these compounds to be more easily eliminated. A member of this family catalyzes the glucuronidation of bilirubin, allowing it to be excreted in the bile.

As irinotecan therapy for advanced colorectal cancers became more widely used, it was observed that patients who had Gilbert syndrome (defects in UGT leading to mild hyperbilirubinemia), suffered severe toxicity [30]. Irinotecan is converted to SN-38 by carboxylesterase-2, and SN-38 inhibits DNA topoisomerase I activity [31, 32]. SN-38 is glucuronidated by uridine diphosphate glucuronosyl transferase (UGT), forming a water-soluble metabolite, SN-38 glucuronide, which can then be eliminated (Fig. 43.3). The observation made in Gilbert syndrome patients revealed that SN-38 shares a glucuronidation pathway with bilirubin. The decreased glucuronidation of bilirubin and SN-38 can be attributed to polymorphisms in the *UGT1A1* gene. The wild-type allele, *UGT1A1*1*, has six tandem TA repeats in the regulatory TATA box of the *UGT1A1* promoter. The most common polymorphism associated with low activity of *UGT1A1* is the *28 variant, which has seven TA repeats. Severe diarrhea and myelotoxicity can be found in those individuals who are homozygous for the *28 allele [33, 34]. In August 2005, the FDA amended the irinotecan (Camptosar®) package insert to recommend genotyping for the UGT1A1 polymorphism and suggested a dose reduction in patients homozygous for the *28 allele.

43.4.3 TPMT

Thiopurine S-methyltransferase (TPMT) is a cytosolic enzyme that inactivates thiopurine drugs such as 6-mercaptopurine and azathioprine through methylation. Thiopurines are frequently used to treat childhood acute lymphoblastic leukemia and

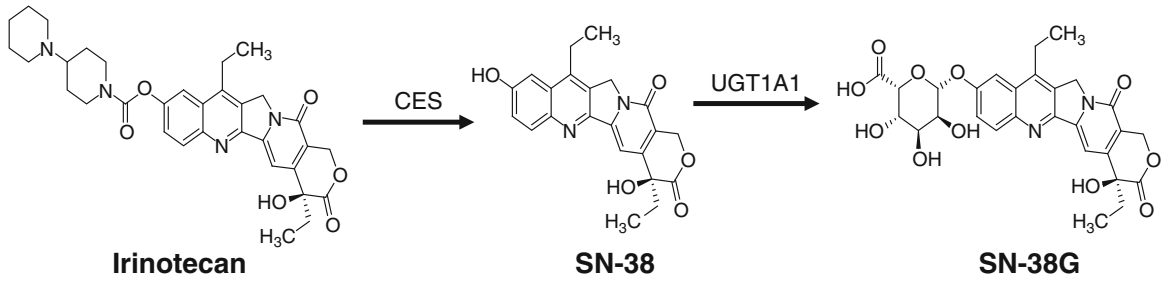

Fig. 43.3 *Schematic diagram of irinotecan metabolism.* The prodrug is converted to the active metabolite, SN-38, which is inactivated by UGT1A1.

various other diseases including inflammatory bowel disease (IBD), and rheumatoid arthritis [35, 36]. They are also used as immunosuppressants in solid organ transplants. Thiopurines are metabolized partly by TPMT whose gene contains polymorphisms that result in null or decreased enzyme activity. These polymorphisms have been associated with increased risk of myelosuppression and toxicity.

Variability in activity levels of TPMT enzyme function exists between individuals, and it has been found that this variability can be attributed to polymorphisms of the *TPMT* gene [37, 38]. The most common variant alleles, *TPMT*2*, *TPMT*3A*, and *TPMT*3C*, account for 95 % of TPMT deficiency. Molecular technologies provide an accurate method for assessment of TPMT enzyme function in patients before treatment with thiopurines. Approximately 90 % of patients have the *TPMT**1/*1 (wild-type) genotype and thus have normal *TPMT* enzyme activity. Up to 14 % of patients have been shown to be heterozygous for a *TPMT* genotype and possess one *TPMT* variant allele with lower enzyme activity. These patients may experience moderate to severe myelosuppression such that drug dose reduction may be warranted. Low TPMT activity levels could put a patient at risk for developing toxicity, since too much drug would be converted to 6-thioguanine nucleotides (6-TGNs), the cytotoxic active metabolite incorporated into DNA. On the other hand, a patient with high TPMT activity levels would need higher than standard doses of a thiopurine drug to respond well to the therapy, since a large amount of the drug is being inactivated before it can be converted to 6-TGNs. TPMT genotyping represents yet another example where molecular techniques can provide adequate information to assess drug-related risk of toxicity.

43.5 Pharmacogenomics and Drug Transporters

Although the genes that code for drug metabolizing enzymes have received more attention in recent years as markers for pharmacogenomic testing, the genes that code for proteins used to transport drugs across membranes also need to be considered when discussing a genetic basis of drug efficacy. These drug transporter proteins move substrates across cell membranes, bringing them into cells or removing them from cells. These proteins are essential in the absorption, distribution, and elimination of various endogenous and exogenous substances including pharmaceutical agents.

Several groups of drug transporters that may be significant in the field of pharmacogenomics exist, including multidrug resistance proteins (MDRs), multidrug resistance-related proteins (MRPs), organic anion transporters (OATs), organic anion transporting polypeptides (OATPs), organic cation transporters (OCTs), and peptide transporters (PepTs). ABCB1 (MDR1) is a member of the multidrug resistance protein family and is one example of a drug transporter protein important in the field of cancer pharmacogenomics.

43.5.1 ABCB1

ABCB1 is a member of the ATP-binding cassette (ABC) superfamily of proteins. Also known as P-glycoprotein (P-gp) or MDR1, it is a 170 kDa glycosylated membrane protein expressed in various locations including the liver, intestines, kidney, brain, and testis [39]. Generally speaking, ABCB1 is located on the membrane of cells in these locations and serves to eliminate metabolites and a wide range of hydrophobic foreign substances, including drugs, from cells by acting as an efflux transporter [40, 41]. Due to the localization of ABCB1 on specific cells, ABCB1 aids in eliminating drugs into the urine or bile and helps maintain the blood–brain barrier.

Like other eukaryotic ABC proteins, the ABCB1 protein is composed of two similar halves, each half containing a hydrophobic membrane-binding domain and a nucleotide-binding domain ([39]. The membrane-binding domains are each composed of six hydrophobic transmembrane helices and the two hydrophilic nucleotide-binding domains are located on the intracellular side of the membrane where they bind ATP. ABCB1 was first identified in cancer cells that had developed a resistance to several anticancer drugs because of an overexpression of the transporter. When expressed at normal levels in noncancerous cells, ABCB1 has been shown to

transport other classes of drugs out of cells including cardiac drugs (digoxin), antibiotics, steroids, HIV protease inhibitors, and immunosuppressants (cyclosporin A).

Genetic variations in the ABCB1 gene expressed in normal cells have been shown to have a role in interindividual variability in drug response [39]. Although many polymorphisms have been detected in the ABCB1 gene, correlations between genotype and either protein expression or function have only been described for a few of the genetic variants. Most notable among these is the 3435 C>T polymorphism, found in exon 26, which has been found to result in decreased expression of ABCB1 in individuals homozygous for the T allele. The possible importance of the 3435 C>T is particularly interesting considering the mRNA levels are not affected by this polymorphism which is found within a coding exon. Although the correlation between the 3435 C>T polymorphism and ABCB1 protein levels may be due to linkage of this polymorphism to others in the ABCB1 gene, a recent study showed that this polymorphism alone does not affect ABCB1 mRNA or protein levels but does result in ABCB1 protein with an altered configuration. The altered configuration due to 3435 C>T is hypothesized to be caused by the usage of a rare codon which may affect proper folding or insertion of the protein into the membrane, affecting the function, but not the level of ABCB1 [42]. Genetic variations affecting the expression or function of drug transporter proteins, such as ABCB1, could drastically alter the pharmacokinetics and pharmacodynamics of a given drug.

43.6 Pharmacogenomics Applied to Oncology

Cancer represents a complex set of deregulated cellular processes that are often the result of underlying molecular mechanisms. While there is recognized inter-individual variability with respect to an observed chemotherapeutic response, it is also apparent that there is considerable cellular heterogeneity within a single tumor that may account for this lack of efficacy. It is becoming clear that molecular genetic variants significantly contribute to an individual's response to a particular therapy and part of this response is due to polymorphisms in genes coding for drug-metabolizing enzymes as previously described. However, in the cancer patient the acquired genetics of the tumor cell must also be taken into account. Unlike traditional pharmacogenomic testing, testing for the cancer patient must be able to identify acquired or somatic genetic alterations that deviate from the underlying genome of the individual.

Cancer patients exhibit a heterogeneous response to chemotherapy with only 25–30% efficacy. Pharmacogenomics can improve on chemotherapeutic and targeted therapy responses by providing a more informative evaluation of the underlying molecular determinants associated with tumor cell heterogeneity and by integrating information on drug responsiveness due to alterations in molecular biomarkers. The advancement of genotyping methods (i.e. next-generation sequencing) has allowed for the simultaneous identification of this heterogeneity. In large part these methods have illuminated genotyping as a major pharmacogenomics limitation. However, to date, only a handful of these mutations are deemed clinically actionable and have FDA-approved therapy associated with improved patients outcomes (Fig. 43.4) [20]. As research in clinical pharmacogenomics identifies more genotype specific therapies, the potential of these advanced genotyping methods in personalized medicine will be fully realized. Thus, the therapeutic management of the cancer patient can be tailored to include a specific therapy or a combination of therapies targeted to the patient's tumor genotype.

Most therapeutic drugs act on targets to elicit the desired effects. These targets include receptors, enzymes, or proteins involved in various cellular events such as signal transduction, cell replication, etc. Knowing if the target is present or being able to identify polymorphisms in these targets that

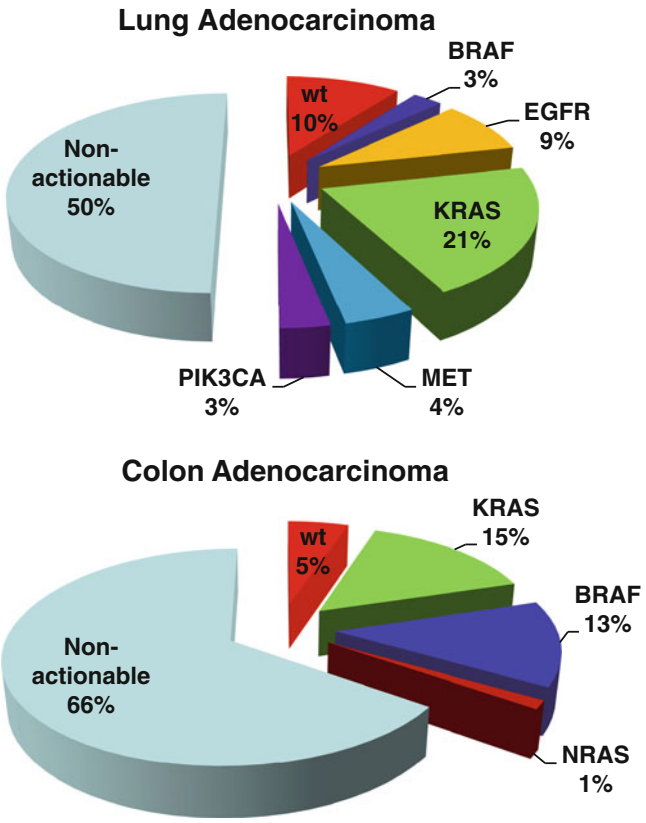

Fig. 43.4 *Next-generation sequencing of cancers identifies actionable mutations.* Types of mutations (actionable and non-actionable) identified in (**a**) lung adenocarcinomas and (**b**) colon adenocarcinomas by next-generation sequencing.

either sensitize or render them resistant to the particular therapeutic agent is critical to patient management (Table 43.1). The following sections highlight several examples of characterized drug targets whose presence in a normal or variant form could affect the outcome of the therapeutic response.

43.6.1 FLT3

FLT3 is a receptor tyrosine kinase expressed and activated in most cases of acute myeloid leukemia (AML) which has a relatively high relapse rate due to acquired resistance to tra-

Table 43.1 List of common mutation associated with the activation or resistance to FDA-approved pharmacogenomic therapies

Cancer type	Activity	Genes	Mutation	Therapeutic agent

ditional chemotherapies. An internal tandem duplication (ITD) mutation in the *FLT3* gene is found in up to 30 % of AML patients while a point mutation at D835 has been shown to account for approximately 5 % of refractory AML [43, 44]. The *FLT3*-ITD induces activation of this receptor and results in downstream constitutive phosphorylation in STAT5, AKT, and ERK pathways. This mutation in *FLT3* is a negative prognostic factor in AML.

FLT3-ITD-positive AML has become a clinical dilemma due to the poor results obtained with standard chemotherapy. One potential therapeutic option for patients who are at risk for relapse is allogeneic stem cell transplant [45]. In addition, randomized phase III trials using *FLT3* inhibitors in combination with chemotherapy in patients with *FLT3*-positive AML are ongoing. Two promising multitargeted receptor tyrosine kinase inhibitors (TKIs), sorafenib and ABT-869, have been developed to suppress signal transduction from constitutively expressed kinases such as a mutated *FLT3* [46]. The investigational FLT3-specific TKIs, quizartinib (AC220) and crenolanib, have also shown some recent success in a phase II trial in patients with FLT3-ITD+ AML with some evidence for increased activity against the D835 resistance mutation [47].

43.6.2 ALK

The fusion of the anaplastic lymphoma kinase (*ALK*) gene with the echinoderm microtubule-associated protein-like 4 (*EML4*) gene was first identified in 2007 in Japanese non-small-cell lung cancers (NSCLCs) [48]. The *EML4-ALK* fusion gene is the result of an inversion on the short arm of chromosome 2 that joins exons 1–13 of *EML4* to exons 20–29 of *ALK* [49]. The fusion gene can be detected by use of break-apart probes and FISH technology (Fig. 43.5).

The *EML4-ALK* fusion gene represents a novel biomarker and potential molecular target in NSCLC and translocations or rearrangements of the *ALK* gene with other genes have been reported in several other human cancers [49, 50]. Approximately 3–5 % of NSCLCs found in North America harbor the *EML4-ALK* fusions. The fusion of these two genes results in constitutive ALK tyrosine kinase activity which has significant oncogenic function. Because of its oncogenic role, the EML4-ALK fusion product has been a target for tyrosine kinase inhibitors. Several ALK kinase inhibitors have been developed and FDA-approved for treatment of NSCLC, such as crizotinib (Xalkori) and certitnib (Zykadia) [49, 51]. Crizotinib is a first-line oral inhibitor of ALK tyrosine kinase activity which has shown high response rates in patients with *EML4-ALK*-positive NSCLC [52]. However, a large number of patients treated with crizotinib develop resistance to treatment, many by acquiring secondary mutations in the *ALK* tyrosine kinase domain, driving relapse [53]. These patients are now eligible for treatment with a newly approved ALK TKI, ceritinib, which has exhibited a response rate of greater than 70 % in those patients resistant to crizotinib [54]. In addition, there are numerous phase II trials investigating the efficacy of heat shock protein 90 (HSP-90) inhibitors to treat patient who are positive for ALK fusions. Early results suggest a significant response to treatment with these HSP-90-targeted inhibitors [55]. The identification of these resistance mutations and the successful development of second- and third-generation therapies to combat them exhibit the utility in fully characterizing the genotypes of therapy-resistant tumors.

43.6.3 BCR-ABL1

Chronic myelogenous leukemia (CML) is a myeloproliferative disorder characterized by three distinct clinical courses and a well characterized chromosomal translocation. CML consists of a chronic indolent phase, an accelerated phase, and a terminal blast crisis. In addition to this heterogeneous clinical presentation, CML represents one of the most significant human malignancies with respect to characterization of a disease-causing genetic variant and now biomarker for targeted treatment options. The Philadelphia chromosome represents a reciprocal translocation between chromosomes 9 and 22, t(9;22), which creates a fusion gene product between the *ABL1* gene on chromosome 9 and the *BCR* gene on chromosome 22. This results in constitutive activation of the ABL tyrosine kinase which is thought to induce the leukemia [56].

The management of CML with small-molecule drugs began with the introduction of the TKI imatinib (Gleevec), which significantly improved outcomes for Philadelphia chromosome-positive CML patients [57]. The progression of CML patients receiving this first-line TKI therapy is measured by evaluation of hematologic response, cytogenetic response, and molecular response. It became evident that the sensitivity of molecular monitoring would be needed to follow patients through their treatment course and for the detection of minimal residual disease as traditional cytogenetics and FISH testing are not capable of this level of sensitivity. Using real-time quantitative PCR assays, clinical laboratories can monitor the level of Philadelphia-positive leukemic cells in bone marrow and peripheral blood samples [58]. A major molecular response (MMR) is defined as at least a 3-log reduction in the *BCR-ABL1* level relative to a control gene. After achieving MMR, the goal is to achieve a complete molecular response (CMR), defined as undetectable *BCR-ABL1* levels.

Despite these improved outcomes observed in CML patients, a significant percentage of patients can show partial response and/or drug resistance due to secondary mutations

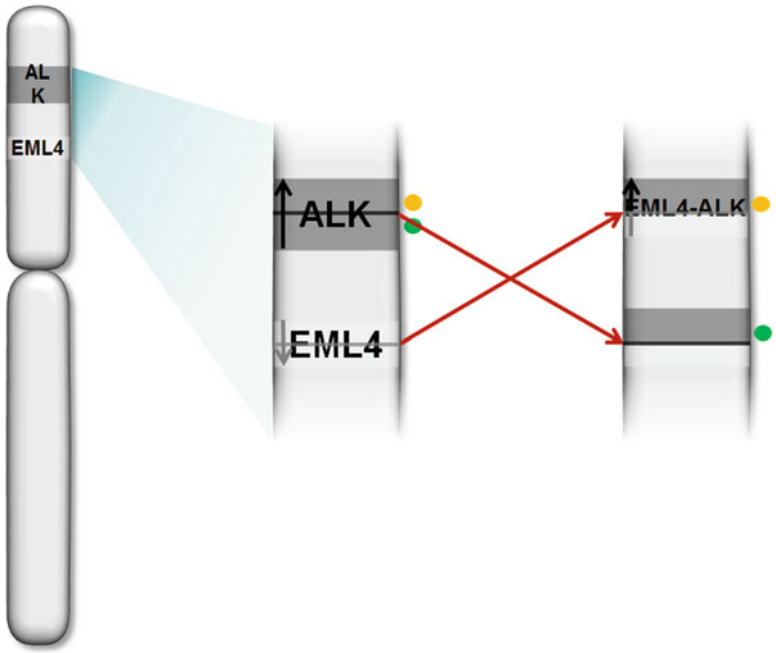

Fig. 43.5 *EML4-ALK FISH.* Diagram of translocation and location of break-apart probes (*colored dots*).

in the fusion gene [59]. This led to the development of new TKIs of BCR-ABL1, including dasatinib, nilotinib, ponatinib, and bosutinib [60–62]. These second- and third-generation TKIs have been shown to have an increased potency against BCR-ABL1 kinase activity and have varying effectiveness in treating CML after the accusation of imatinib-resistant mutations. The National Cancer Comprehensive Network (NCCN) now provides tailored treatment guidelines based on the BCR-ABL1 secondary mutations present in an individual's cancer. Therefore, in addition to monitoring *BCR-ABL1* levels, it has become important to screen imatinib-resistant CML cases for mutations in the fusion gene.

43.6.4 HER2

The human epidermal growth factor receptor 2 (ERBB2 or HER2) is the second member of the EGFR gene family. This gene is amplified and/or overexpressed in up to 30 % of all breast cancers [63, 64]. While this gene can be expressed in low levels in a variety of normal epithelia, amplification of the HER2 gene is the primary mechanism of HER2 overexpression that results in increased receptor tyrosine kinase activity. HER2 amplification is an indicator of poor prognosis and predicts resistance to hormonal therapies and other chemotherapeutic agents. HER2 status can be utilized to determine sensitivity to anthracycline-based chemotherapy regimens. However, its main clinical utility is as the first FDA-approved companion diagnostic for Trastuzumab (Herceptin). As the first humanized monoclonal antibody against the HER2 receptor, this therapeutic was approved by the FDA in 1998. Introduction of this therapeutic into routine use made it necessary for laboratories to determine the HER2 status in breast cancer cells before patients would be eligible for treatment (Fig. 43.6). In addition to trastuzumab, in 2007 the FDA approved lapatinib for use in combination with capecitabine for treatment of advanced HER2-positive breast cancers. Thus, there is increasing need for accurate HER2 testing strategies for appropriate management of breast cancer patients.

The importance of accurate HER2 status determination was highlighted again in October 2010, when the FDA approved trastuzumab for use in combination with cisplatin and either capecitabine or 5-fluorouracil in patients with metastatic gastric or gastro-esophageal junction cancer (GC/GEJ) who had not previously received treatment for metastatic disease. This approval was granted following the results of the ToGA (Trastuzumab for Gastric Cancer) phase III, international, randomized controlled trial which were published in 2010 [65].

Several FDA-cleared tests for immunohistochemical detection of HER2 protein and fluorescence in situ hybridization (FISH) detection of gene amplification are commercially available and approved as companion diagnostics for Herceptin therapy [66]. An approved set of guidelines have been published and recently updated for performing and interpreting HER2 testing [67–69]. These guidelines attempt to standardize HER2 testing by addressing pre-analytical, analytical, and post-analytical variables that could lessen result variability due to technical and interpretative subjectivity.

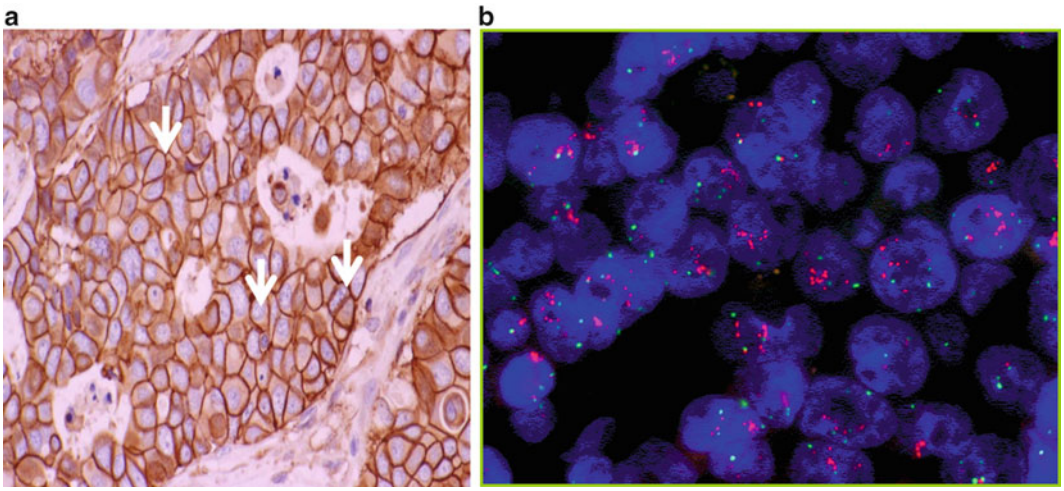

Fig. 43.6 *Assessment of HER2 status in breast cancer.* Determination of HER2 status in breast cancer cells using immunohistochemistry for detection of membranous HER2 receptor staining (*arrows*) (**a**) and by fluorescence in situ hybridization (FISH) to detect gene amplification (*orange* signal) (**b**).

43.6.5 EGFR

The epidermal growth factor receptor (EGFR or HER1) is one of the best-characterized receptors and signal transduction pathways to date. As a member of the ErbB family of tyrosine kinases, EGFR joins HER2, HER3, and HER4 as unique proteins that undergone homo- or hetero-dimerization upon binding of their respective ligands. Once activated, these receptors initiate signaling to downstream pathways such as PI3K/AKT and RAS/RAF/MAPK, which in turn regulate cell proliferation and apoptosis [70].

Recently, the EGFR TK has been the target of both monoclonal antibody and tyrosine kinase inhibitor therapies as it is expressed in many human cancer types, including lung cancer [71]. It has been shown that tumors that respond to these TKIs contain somatic mutations in the EGFR TK domain [70–72]. The most common of these mutations found in non-small-cell lung cancers (NSCLC) include in-frame deletion within exon 19 and a single-point mutation in exon 21 (T2573G). These mutations are known as activating or sensitizing mutations as they are associated with a favorable response to the new TKIs. However, other EGFR mutations are associated with a poor response and resistance to these new therapeutics [70, 73].

Mutation analysis of the EGFR gene represents a new application for molecular diagnostics as some mutations confer response to therapy while others confer resistance. It has become routine practice for all NSCLC to be tested for these mutations so that the management of the NSCLC patient can be optimized.

43.6.6 BRAF

The *BRAF* gene, located on chromosome arm 7q34, is a member of the *raf* family of serine/threonine protein kinases in the RAS/RAF/MAPK signaling pathway [74] (Fig. 43.7). With respect to the signaling cascade, *BRAF* is found downstream of *KRAS*. Once activated, BRAF phosphorylates and activates MEK and ERK. The *BRAF* gene consists of 18 exons and the most common activating mutation is found in exon 15. The T1799A point mutation is a transversion that replaces valine with glutamic acid at amino acid 600 ($BRAF^{V600E}$) (c.1799T>A[p.Val600Glu]) and results in constitutive activation of the kinase activity. BRAF and KRAS signal through the same pathway and thus far there is mutual exclusivity to their mutation status.

The $BRAF^{V600E}$ mutation has been shown to be present in greater than 60 % of melanomas. Because of this high prevalence, selective BRAF inhibitors have been explored. Sorafenib was one of the first multi-kinase inhibitors which targeted BRAF but showed minimal activity in melanoma. Vemuranfenib (Zelboraf) was later developed to selectively inhibit the V600E mutant BRAF. In 2011, the FDA approved vemuranfenib for treatment of late-stage metastatic melanoma alongside a companion diagnostic detecting the activating BRAF V600E mutation. This was largely due to the fact the clinical trials showed up to 70 % objective response rates in patients with BRAF mutant positive [75, 76]. Clinical studies examining the efficacy of this therapy in additional tumor types harboring the V600E mutation are ongoing.

In colorectal cancer, *BRAF* mutation testing is also used to differentiate sporadic colon cancer from Lynch Syndrome,

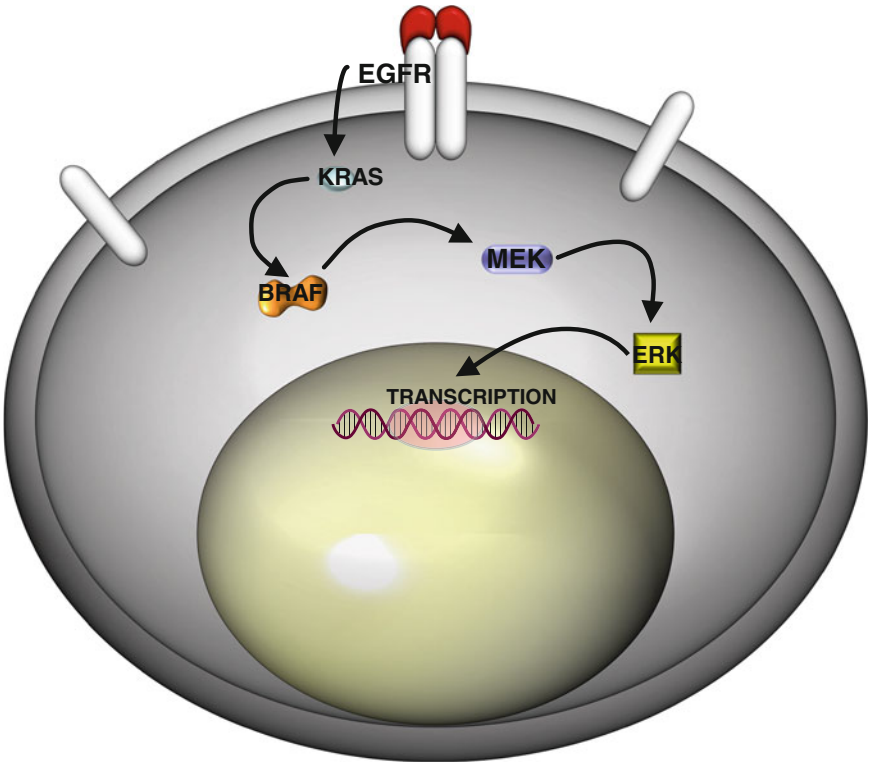

Fig. 43.7 Schematic of the RAS/RAF/MAPK signal transduction pathway.

to identify those tumors that are BRAF mutation negative and thus more likely to respond to EGFR tyrosine kinase inhibitors, and as a prognostic indicator in microsatellite stable colorectal cancers [77]. Several investigators have shown that the V600E mutation is associated with shorter progression-free survival and overall survival in metastatic colon cancer chemorefractory patients treated with anti-EGFR mAbs [78–80]. So while the presence of the BRAF V600E mutation results in improved efficacy of some BRAF TKIs, it can also be indicator of resistance for alternative therapies in a tumor-specific manner.

43.6.7 KRAS

The *KRAS* gene is one of the most commonly mutated proto-oncogenes in human cancers. *KRAS* is a signaling molecule downstream of the epidermal growth factor receptor (EGFR), a transmembrane receptor for extracellular signaling, and upstream of RAF in the RAS/RAF/MAPKs signaling pathway [81, 82] (Fig. 43.7). Wild-type KRAS regulates signal transduction through its GTPase activity by switching the GDP bound inactive form to the GTP bound active form. Point mutations at codons 12 or 13 in exon 2 of *KRAS* convert its GTPase activity into a constitutively expressed active form, irrespective of upstream signaling [82].

Mutations in *KRAS* occur in approximately 35–40 % of all colorectal cancers. In patients with colorectal cancer carrying one of seven known point mutations in *KRAS* codons 12 or 13, inhibition of upstream EGFR activation with monoclonal therapeutics against EGFR, such as cetuximab, will not affect the constitutively activated mutant *KRAS*. Its effects on the downstream signaling pathways will continue to lead to the uncontrolled proliferation of tumor cells.

Target-specific treatments, such as cetuximab and panitumumab, monoclonal antibodies directed against EGFR, improve progression-free survival and the quality of life in patients with colorectal cancer that have not responded to traditional chemotherapies. However, patients with metastatic or recurrent colorectal cancers harboring *KRAS* mutations do not benefit from these anti-EGFR therapies [83–87]. In 2010, De Roock et al. showed that those colorectal cancers that harbor a specific codon 13 mutation (p.G13D) showed better overall survival when treated with cetuximab than those with other KRAS mutations [88]. This demonstrates the need not only to identify a tumor as positive or negative for mutation but also to identify accurately which mutation is present. It is clear that the routine detection of KRAS mutations in colorectal cancer patients is of critical importance to the management of these patients.

43.7 Conclusion

Our knowledge base of pharmacogenomics and applications to clinical oncology are progressing at record speeds. Technology is allowing us to perform these tests routinely in the clinical laboratory from specimen types that include

whole blood, bone marrow, and formalin-fixed paraffin-embedded tissues. In the cancer patient, our ability to detect polymorphisms and mutations associated with responses to newly developed small-molecule targeted therapies is critical to patient management. The ultimate goal of these efforts is to truly provide a personalized medicine approach to patient management for the purpose of eliminating ADRs, selecting more efficacious therapeutics, and improving the overall well-being of the patient.
