The information contained in this textbook describes the ever-expanding field of cancer biology and our contemporary understanding of the pathology, pathogenesis, and pathophysiology of the diverse collection of diseases representing human cancer. Hence, this work represents the culmination of innumerable small successes that emerged from the ceaseless pursuit of new knowledge by countless clinical, experimental, and translational cancer biologists working around the world on all aspects of human cancer. Their ingenuity and hard work have dramatically advanced the field of cancer pathobiology over time, and particularly during the last 25 years. This book is a tribute to the dedication, diligence, and perseverance of individual scientists who contributed to the advancement of our understanding of the molecular basis of human cancer, especially graduate students, laboratory technicians, and postdoctoral fellows, whose efforts are so frequently taken for granted, whose accomplishments are so often unrecognized, and whose contributions are so quickly forgotten.

We especially dedicate this book to the loving memory of Chris Helms Austin who passed away far too young on August 17, 2014 after a long battle with breast cancer. Chris was cherished by her family and friends, and was a gifted teacher who made significant impressions on her students, their parents, and her colleagues. She did so much good in her short lifetime and that goodness continues through the lives of her students and everyone else she touched. Chris' journey through breast cancer showed us the realities associated with a cancer diagnosis, treatment, and disease progression. Her obstinate optimism and resolve in the face of an unrelenting disease provides a lesson and example for all of us on how to attack life's challenges no matter how insurmountable the odds of success.

We also remember people we have known and loved, that taught us through example about dignity, positivity, strength, courage, and tenacity in the fight against cancer – Samuel Apostola, Dr. Bobby G. Bell, Jeffery A. Bell, Dr. Sharon Ricketts Betz, Linwood Braswell, Bobbie Coleman Clark, William B. Coleman, Jr., Anne Griffin Clawson, Jewell T. Coleman, George G. Gerding, Evelyn B. Hadden, Shayne Snyder Hall, Dr. Eugene F. Hamer, Jerry S. Harris, Effie H. Helms, Larry Hendley, Joel C. Herren, Jean G. Herren, Kathleen M. Jackson, Jerry W. Kirkman, Gloria Morin, John Panu, Dr. Kathleen Rao,

Dr. Rhonda Simper Ronan, Alexandria Rucho, Peter Rucho, Beverly Clark Tice, Ruth E. Trull, Josephine Caccavallo Vasquez, and W. Kenneth Weatherman. This book is also dedicated to the cancer survivors and those who continue to live with cancer, for their bravery and determination, for the inspiration that they provide, and for reminding us that there is far too much left to be done to rest on our accomplishments.

We also dedicate The Molecular Basis of Human Cancer – Second Edition to the many people that have played crucial roles in our successes. We thank our many scientific colleagues, past and present, for their camaraderie, collegiality, and support. We especially thank our scientific mentors for their example of dedication to research excellence. We are truly thankful for the positive working relationships and friendships that we have with our faculty colleagues, for the mentoring we received from our elders and for the opportunity to mentor those that follow us. We also thank our undergraduate students, graduate students, and postdoctoral fellows for teaching us more than we might have taught them. We thank our parents for believing in higher education, for encouragement through the years, and for helping make dreams into reality. We thank our brothers and sisters, and extended families, for the many years of love, friendship, and tolerance. We thank our wives, Monty and Nancy, for their unqualified love, unselfish support of our endeavors, understanding of our work ethic, and appreciation for what we do. Lastly, we give special thanks to our children, Tess, Sophie, Pete, and Zoe. Their achievements and successes as young adults are a greater source of pride for us than our own accomplishments. As when they were children, we thank them for providing an unwavering bright spot in our lives, for their unbridled enthusiasm and boundless energy, and for giving us a million reasons to take an occasional day off from work just to have fun.

William B. Coleman
Gregory J. Tsongalis

Preface

The practice of medical oncology has been in a period of sustained significant positive change over the last two decades that is primarily due to advances in the basic science of cancer biology. In recent years, developments in molecular biology techniques have substantially increased our ability to detect and characterize genetic defects in human cells, resulting in significant increases in our understanding of the normal molecular mechanisms controlling cellular proliferation and differentiation. The advancement of our comprehension of these basic molecular mechanisms has been paralleled by comparable increases in our understanding of the molecular basis of the processes involved in neoplastic transformation and tumorigenesis. Information gleaned from studies conducted in basic molecular research laboratories is being applied with unprecedented speed to the development of new molecular tests for cancer detection, diagnosis, and prediction of clinical outcomes, as well as to the development of new strategies for cancer prevention and treatment through therapies that target specific molecular pathways in the cancer cell. Basic scientists, clinical scientists, and physicians have a need for a source of information on the current state-of-the-art of the molecular biology of human neoplastic diseases. In this Second Edition of *The Molecular Basis of Human Cancer* we attempt to provide such a source of current information, as well as providing a look to the future of the discipline and the potential impact of scientific advances on the practice of medical oncology. This book is directed primarily to advanced graduate students and medical students, postdoctoral trainees, and established investigators having basic research interests in the molecular basis of human neoplastic disease. However, this book is also well suited for the non-expert with similar interests since it provides a broad overview of general themes in the molecular biology of cancer. To be sure, our understanding of the many processes of neoplasia and their molecular basis is far from complete, but numerous areas of thematic or conceptual consensus have developed. We have made an effort to integrate accepted principles with broader theoretic concepts in an attempt to present a current and comprehensive view of the molecular basis of human cancer. We hope that this book will accomplish its purpose of providing students and researchers who already possess strong but diverse basic science backgrounds with unifying concepts, so as to stimulate new research aimed at furthering our understanding of the array of diseases that represent human cancer.

Cancer Epidemiology: Incidence and Etiology of Human Neoplasms

1

William B. Coleman and Gregory J. Tsongalis

1.1 Introduction

Cancer does not represent a single disease. Rather, cancer is a myriad collection of diseases with as many different manifestations as there are tissues and cell types in the human body, involving innumerable endogenous or exogenous carcinogenic agents, and various etiological mechanisms. What all of these disease states share in common are certain biological properties of the cells that compose the cancer, including unregulated (clonal) cellular growth, impaired cellular differentiation, invasiveness, and metastatic potential. It is now recognized that cancer, in its simplest form, is a genetic disease, or more precisely, a disease of abnormal gene expression. Recent research efforts have revealed that different forms of cancer share common molecular mechanisms governing uncontrolled cellular proliferation, involving loss, mutation, or dysregulation of genes that positively and negatively regulate cell proliferation, migration, and differentiation (generally classified as proto-oncogenes and tumor suppressor genes). Essential to any discussion of the molecular mechanisms that govern disease pathogenesis for specific cancers is an appreciation for the distribution of these diseases among world populations, with consideration of specific risk factors and etiologic agents involved in disease causation. This introduction will describe cancer incidence and mortality for the major forms of human cancer, and will briefly review some of the known risk factors and/or causes of these cancers for specific at-risk populations.

1.2 Cancer Incidence and Mortality

Cancer is an important public health concern in the USA and worldwide. Due to the lack of nationwide cancer registries for all countries, the exact numbers of the various forms of cancer occurring in the world populations are unknown. Nevertheless, estimations of cancer incidence and mortality are generated on an annual basis by several domestic and world organizations. Estimations of cancer incidence and mortality for the USA are provided annually by the American Cancer Society (ACS—www.cancer.org) and the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program (http://seer.cancer.gov/data/). Global cancer statistics are provided by the International Agency for Research on Cancer (IARC—http://globocan.iarc.fr/), the World Health Organization (WHO—http://www.who.int/en/), and Cancer Research UK (http://info.cancerresearchuk.org/cancerstats/world/). Monitoring of long-range trends in cancer incidence and mortality among different populations is important for investigations of cancer etiology. Given the long latency for formation of a clinically detectable neoplasm (up to 20–30 years) following initiation of the carcinogenic process (exposure to carcinogenic agent), current trends in cancer incidence probably reflect exposures that occurred many years (and possibly decades) before. Thus, correlative analysis of current trends in cancer incidence with recent trends in occupational, habitual, and environmental exposures to known or suspect carcinogens can provide clues to cancer etiology. Other factors that influence cancer incidence include the size and average age of the affected population. The average age at the time of cancer diagnosis for all tumor sites is approximately 65 years [1, 2]. As a higher percentage of the population reaches age 60, the general incidence of cancer will increase proportionally. Thus, as the life expectancy of the human population increases due to reductions in other causes of premature death (due to infectious and cardiovascular diseases), the average risk of developing cancer will increase.

W.B. Coleman, G.J. Tsongalis (eds.), *The Molecular Basis of Human Cancer*, DOI 10.1007/978-1-59745-458-2_1

1.3 Cancer Incidence and Mortality in the USA

1.3.1 General Trends in Cancer Incidence

The American Cancer Society estimates that 1,658,370 new cases of invasive cancer were diagnosed in the USA in 2015 [3]. This number of new cancer cases reflects 848,200 male cancer cases (51 %) and 810,170 female cancer cases (49 %). The estimate of total new cases of invasive cancer does not include carcinoma in situ occurring at any site other than in the urinary bladder, and does not include basal and squamous cell carcinomas of the skin. In fact, basal and squamous cell carcinomas of the skin represent the most frequently occurring neoplasms in the USA, with an estimated occurrence of >1 million total cases in 2015 [3]. Likewise, carcinoma in situ represents a significant number of new cancer cases in 2015 with 60,290 newly diagnosed breast carcinomas in situ and 63,440 new cases of melanoma carcinoma in situ [3].

Estimated site-specific cancer incidence for both sexes combined is shown in Fig. 1.1. Cancers of the reproductive organs represent the largest group of newly diagnosed cancers in 2015 with 329,330 new cases [3]. This group of cancers includes prostate (220,800 new cases), uterine corpus (54,870 new cases), ovary (21,290 new cases), and uterine cervix (12,900 new cases), in addition to other organs of the genital system (vulva, vagina, and other female genital organs; testis, penis, and other male genital organs). The next most frequently occurring cancers originated in the digestive tract (291,150 new cases), respiratory system (240,390 new cases), and breast (234,190 new cases). The majority of digestive system cancers involved colon (93,090 new cases), rectum (39,610 new cases), pancreas (48,960 new cases), stomach (24,590 new cases), liver and intrahepatic bile duct (35,660 new cases), and esophagus (16,980 new cases), in addition to the other digestive system organs (small intestine, gallbladder, and others). Most new cases of cancer involving the respiratory system affected the lung and bronchus (221,200 new cases), with the remaining cases affecting the larynx or other components of the respiratory system. Other sites with significant cancer burden include the urinary system (138,710 new cases), lymphomas (80,900 new cases), melanoma of the skin (80,100 new cases), leukemias (54,270 new cases), and the oral cavity and pharynx (45,780 new cases).

Estimated cancer incidence by cancer site for males and females are shown in Fig. 1.2. Among men, cancers of the prostate, respiratory system (lung and bronchus), and digestive system (colon and rectum) occur most frequently. Together, these cancers account for 61 % of all cancers diagnosed in men. Prostate is the leading site, accounting for 220,800 new cases and 26 % of cancers diagnosed in men (Fig. 1.3). Among women, cancers of the breast, respiratory system (lung and bronchus), and digestive system (colon and rectum) occur most frequently. Cancers at these sites

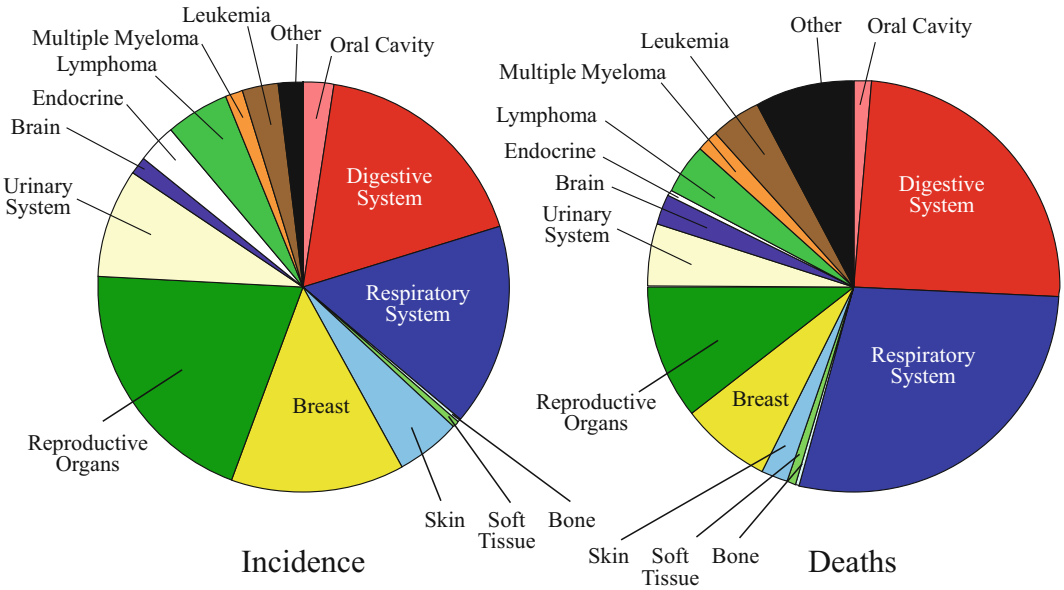

Fig. 1.1 Cancer incidence and mortality by site for both sexes (USA, 2015). The relative contributions of the major forms of cancer to overall cancer incidence and cancer-related mortality (both sexes combined) were calculated from data provided by Siegel et al. [3]. Cancers of the reproductive organs include those affecting the prostate, uterine corpus, ovary, uterine cervix, vulva, vagina, testis, penis, and other organs of the male and female genital systems. Cancers of the digestive system include those affecting esophagus, stomach, small intestine, colon, rectum, anus, liver, gallbladder, pancreas, and other digestive organs. Cancers of the respiratory system include those affecting lung, bronchus, larynx, and other respiratory organs.

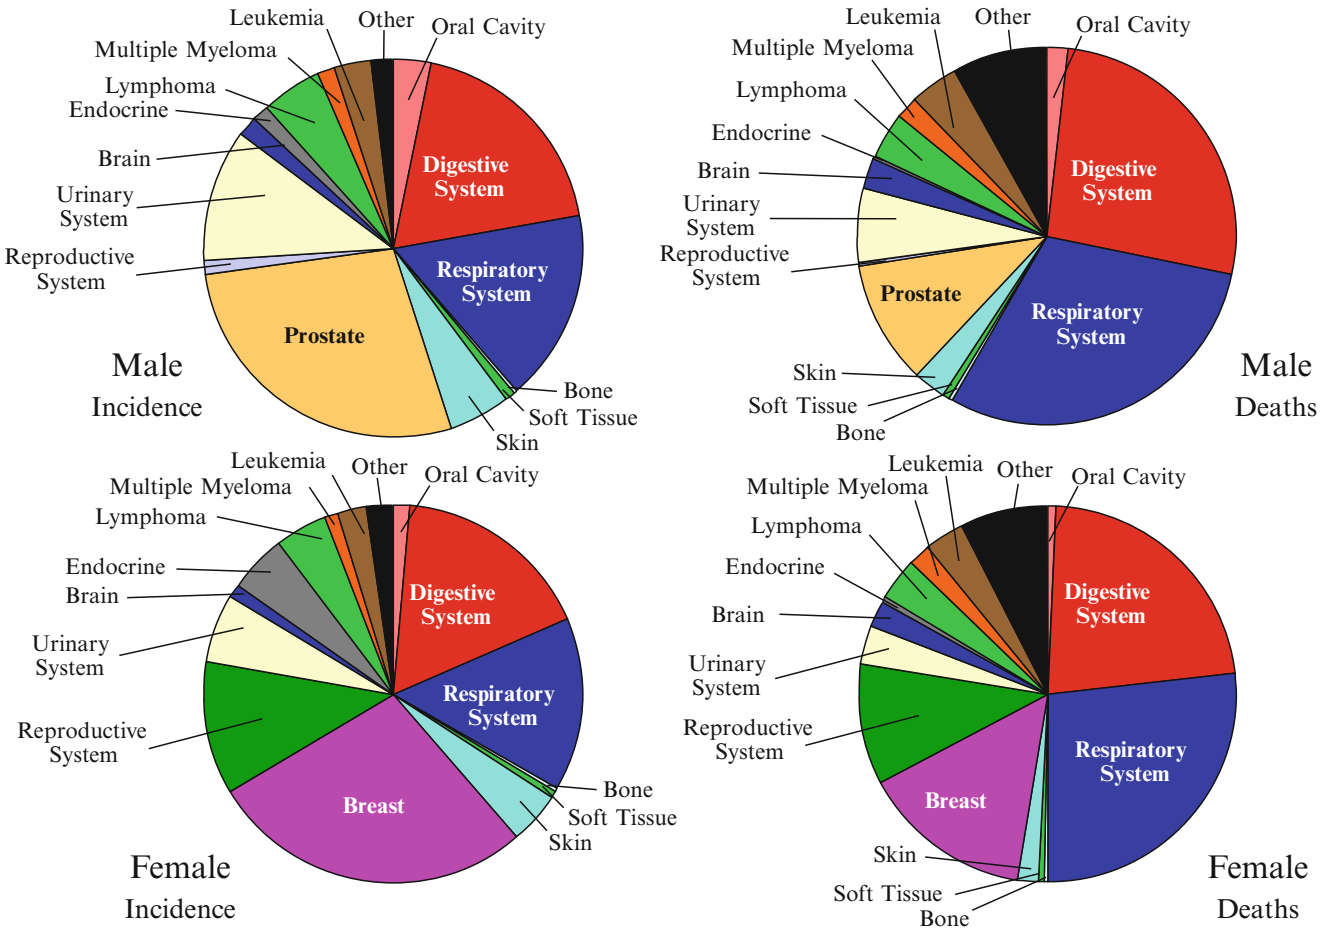

Fig. 1.2 Cancer incidence and mortality by site (USA, 2015). The relative contributions of the major forms of cancer to overall cancer incidence and cancer-related mortality for males and females were calculated from data provided by Siegel et al. [3]. Cancers of the male reproductive organs include testis, penis, and other organs of the male genital system. Cancers of the female reproductive organs include those affecting the uterine corpus, ovary, uterine cervix, vulva, vagina, and other organs of the female genital systems. Cancers of the digestive system include those affecting esophagus, stomach, small intestine, colon, rectum, anus, liver, gallbladder, pancreas, and other digestive organs. Cancers of the respiratory system include those affecting lung, bronchus, larynx, and other respiratory organs.

combine to account for 58 % of all cancers diagnosed in women. Breast is the leading site for cancers affecting women, accounting for 231,840 new cases and 29 % of all cancers diagnosed in women (Fig. 1.3).

1.3.2 General Trends in Cancer Mortality in the USA

Mortality attributable to invasive cancers produced 589,430 cancer deaths in 2015. This reflects 312,150 male cancer deaths (53 % of total) and 277,280 female cancer deaths (47 % of total). Estimated numbers of cancer deaths by site for both sexes are shown in Fig. 1.1. The leading cause of cancer death involves tumors of the respiratory system (162,460 deaths), the majority of which are neoplasms of the lung and bronchus (158,040 deaths). The second leading cause of cancer deaths involve tumors of the digestive system (149,300 deaths), most of which are tumors of the colorectum (49,700 deaths), pancreas (40,560 deaths), stomach (10,720 deaths), liver and intrahepatic bile duct (24,550 deaths), and esophagus (15,590 deaths). Together, cancers of the respiratory and digestive systems account for 53 % of cancer-associated death.

Trends in cancer mortality among men and women mirror in large part cancer incidence (Fig. 1.2). Cancers of the prostate, lung and bronchus, and colorectum represent the three leading sites for cancer incidence and cancer mortality among men (Fig. 1.3). In a similar fashion, cancers of the breast, lung and bronchus, and colorectum represent the leading sites for cancer incidence and mortality among women (Fig. 1.3). While cancers of the prostate and breast represent the leading sites for new cancer diagnoses among men and women (respectively), the majority of cancer deaths in both sexes are related to cancers of the lung and bronchus (Fig. 1.3). Cancers of the lung and bronchus are responsible

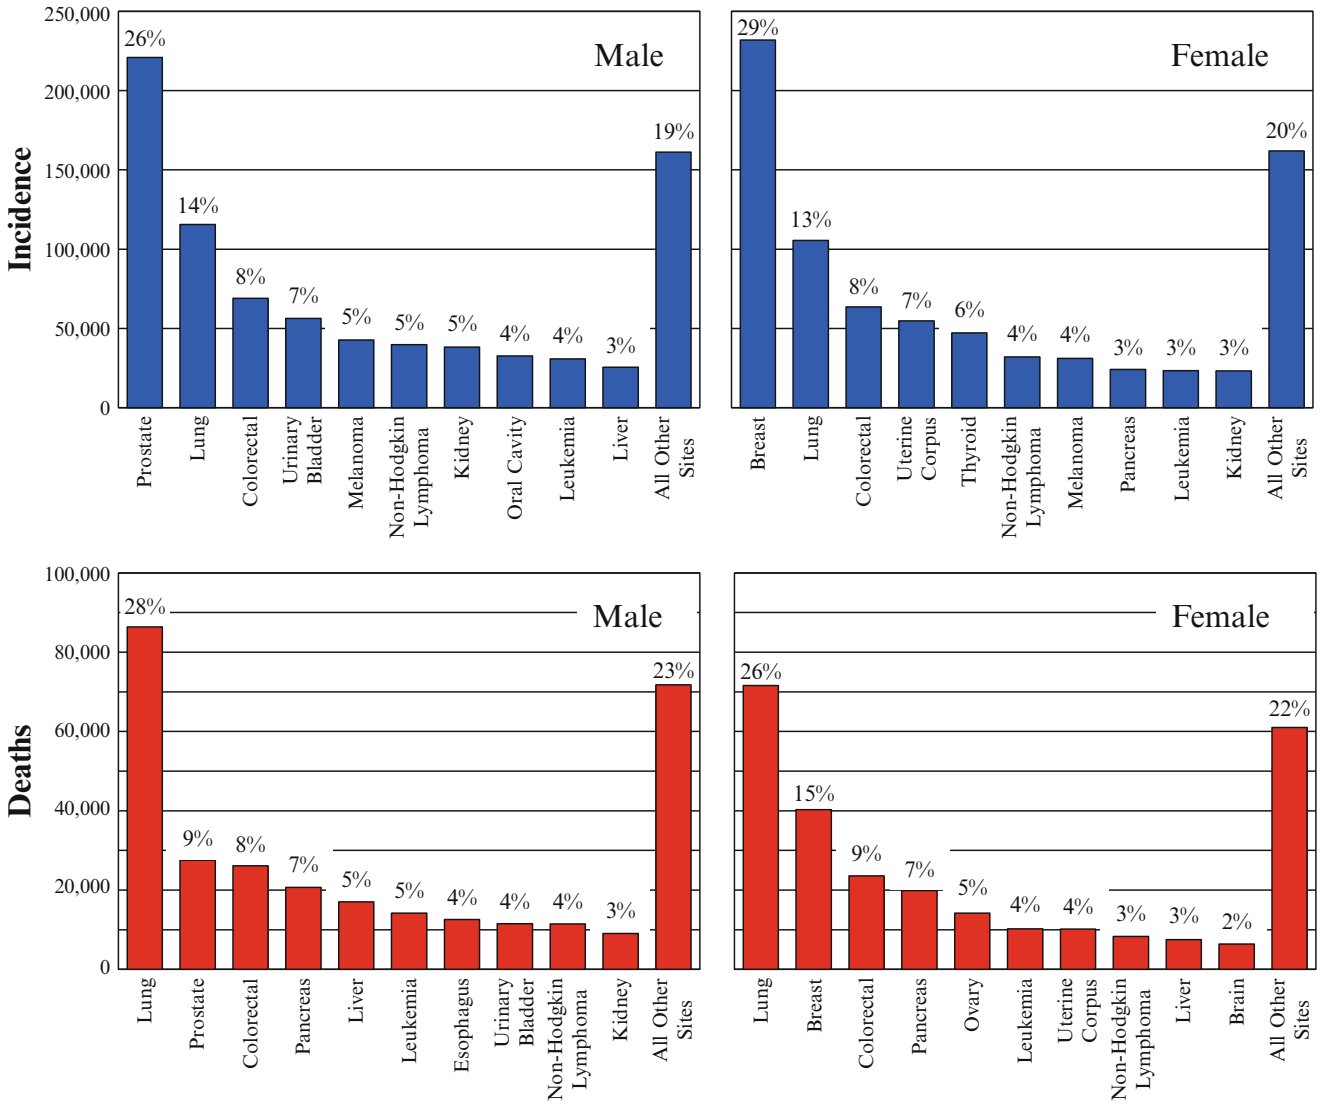

Fig. 1.3 Cancer incidence and mortality by leading site (USA, 2015). The numbers of cancers (and percentage of total cancers) and numbers of cancer-related deaths (and percentages of cancer-related deaths) for the leading sites for males and females were calculated from data provided by Seigel et al. [3]. The numbers provided for lung include tumors of the lung and bronchus, and numbers for colorectal cancer include tumors of the colon and rectum.

for 28 % of all cancer deaths among men and 26 % of all cancer deaths among women (Fig. 1.3). The age-adjusted death rate for lung cancer among men increased dramatically during the six decades between 1930 and 1990, while the death rates for other cancers (like prostate and colorectal) remained relatively stable (Fig. 1.4). However, since 1990, the age-adjusted death rate for lung cancer among men has decreased, although it remains very high compared to all other cancers. The lung cancer death rate for women increased in an equally dramatic fashion since about 1960, becoming the leading cause of female cancer death in the mid-1980s after surpassing the death rate for breast cancer (Fig. 1.4).

1.4 Global Cancer Incidence and Mortality

1.4.1 Current Trends in Cancer Incidence and Mortality Worldwide

The IARC estimates that 12,667,500 new cancer cases were diagnosed worldwide in 2008 [4]. This number of new cases represents 6,629,100 male cancer cases (52 %) and 6,038,400 female cancer cases (48 %). Mortality attributed to cancer for the same year produced 7,571,500 deaths worldwide [4]. This reflects 4,225,700 male cancer deaths (56 %) and

3,345,800 female cancer deaths (44 %). The leading sites for cancer incidence worldwide in 2008 included cancers of the lung (1,609,000 new cases), breast (1,383,500 new cases), colorectum (1,233,700 new cases), stomach (989,600 new cases), and prostate (903,500 new cases; Fig. 1.5). The leading sites for cancer mortality worldwide in 2008 included cancers of the lung (1,378,400 deaths), stomach (738,000 deaths), liver (695,900 deaths), colorectum (608,700 deaths), and breast (458,400 deaths; Fig. 1.5). As can be seen, lung cancer accounted for the most new cancer cases and the most cancer deaths among men and women combined during this period of time (Fig. 1.5). The leading sites for cancer incidence among males worldwide included cancers of the lung (1,095,200 new cases), prostate (903,500 new cases), colorectum (663,600 new cases), stomach (640,600 new cases), and liver (522,400 new cases). Combined, cancers at these five sites account for nearly 48 % of all cancer cases among men [4]. The leading causes of cancer death among men included tumors of the lung (951,000 deaths), liver (478,300 deaths), stomach (464,400 deaths), colorectum (320,600 deaths), and esophagus (276,100 deaths). Deaths from these cancers account for 59 % of all male cancer deaths [4]. The leading sites for cancer incidence among females included breast (1,383,500 new cases), colorectum (570,100 new cases), cervix uteri (529,800 new cases), lung (513,600 new cases), and stomach (349,000 new cases). The leading causes of cancer death among females directly mirrors the leading causes of cancer incidence: breast (458,400 deaths), lung (427,400 deaths), colorectum (288,100 deaths), cervix uteri (275,100 deaths), and stomach (230,000 deaths). Combined, these five cancer sites accounted for approximately 55 % of all female cancer cases and 51 % of female cancer deaths [4].

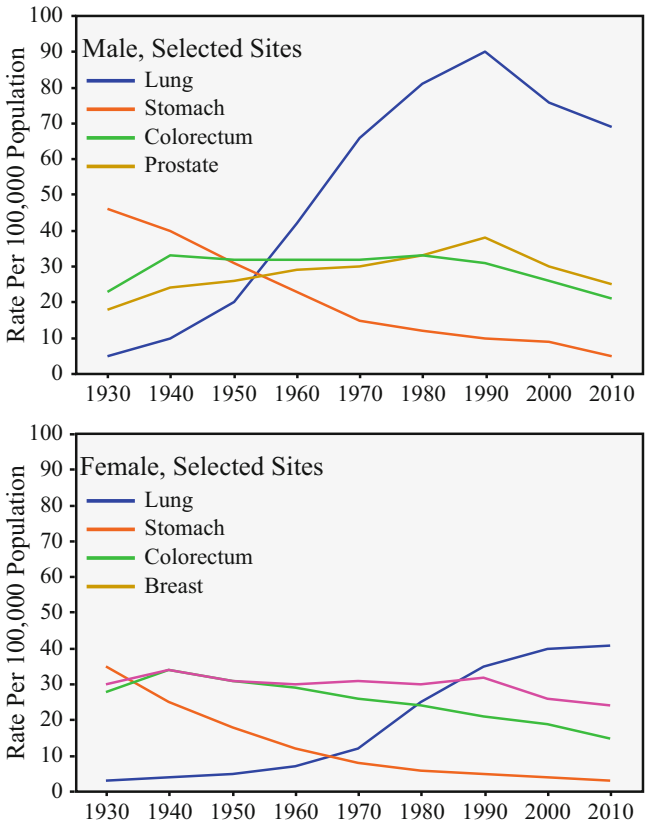

Fig. 1.4 Age-adjusted cancer mortality by site. The age-adjusted death rates for males and females for selected sites were adapted from the data provided by Seigel et al. [3]. Death rates are per 100,000 population and are age-adjusted to the 2000 standard population of the USA.

1.4.2 Geographic Differences in Cancer Incidence and Mortality

Cancer incidence and mortality differs between developed and developing countries [4]. In 2008, developed countries accounted for 43.9 % of new cancers (5,560,000 cases) and 36.3 % of cancer deaths (2,751,400 deaths), whereas developing countries accounted for 56.1 % of new cancers (7,107,600 cases) and 63.7 % of cancer deaths (4,820,100 deaths). The leading sites for cancer occurrence among men from developed countries include prostate (648,400 new cases), lung (482,600 new cases), and colorectum

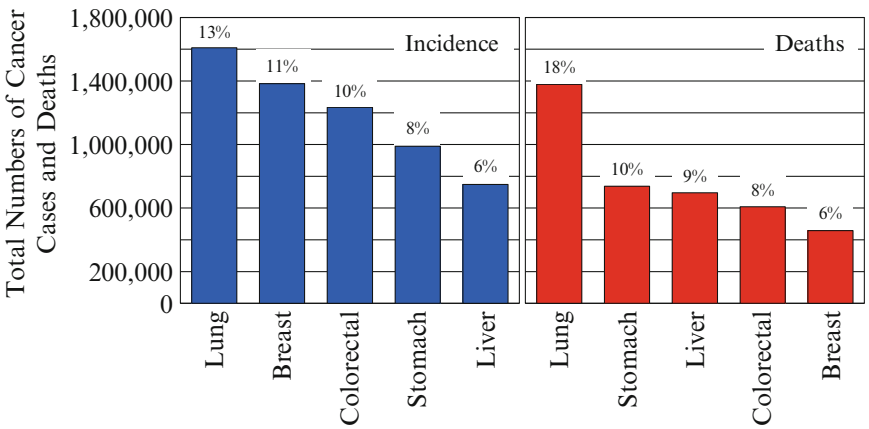

Fig. 1.5 Worldwide cancer incidence and mortality by leading site. The numbers of cancers (and percentage of total cancers) and numbers of cancer-related deaths (and percentages of cancer-related deaths) for the leading sites worldwide were calculated from data provided by Jemal et al. [4]. The numbers provided for lung include tumors of the lung and bronchus and the numbers for colorectal cancer include tumors of the colon and rectum.

(389,700 new cases). In contrast, the leading sites for cancer occurrence among men from developing countries include lung (612,500 new cases), stomach (466,900 new cases), and liver (440,700 new cases). The incidence of prostate cancer and liver cancer provide excellent examples of differences in incidence between men from developed and developing countries. In 2008, prostate cancer affected 648,400 men in developed countries (ranked first for cancer incidence in this cohort) compared to 255,000 men in developing countries (ranked sixth for cancer incidence in this cohort). Likewise, in 2008, liver cancer affected 440,700 men in developing countries (ranked third for cancer incidence in this cohort) compared to 81,700 men in developed countries (ranked tenth for cancer incidence in this cohort). While incidence rates vary, lung cancer represents the most frequent cause of cancer death among men from both developed and developing countries. Among women, breast cancer is the most frequent site of cancer in both developed (692,200 new cases) and developing countries (691,300 new cases) in 2008. Likewise, lung cancer occurs frequently in both groups—241,700 new cases in developed countries (ranked third for cancer incidence) and 272,000 new cases in developing countries (ranked third for cancer incidence). However, significant differences in cancer incidence among women from developed and developing countries can be seen for cancer of the cervix. Women from developing countries develop cervical cancer frequently (453,300 new cases, ranked second for cancer incidence), while women in developed countries develop cervical cancer less often (76,500 new cases, ranked tenth for cancer incidence).

New cancer incidence and cancer-related mortality can differ tremendously from world area to world area, country to country, and even from region to region within a single country. The leading world areas for new cancer cases includes Eastern Asia/China (17.3 % of new cases), North America (14.9 % of new cases), South Central Asia (11.6 % of new cases), Eastern Europe (10.4 % of new cases), and Western Europe (8.3 % of new cases). Collectively, Asia accounted for approximately 40 % of all new cancer cases worldwide in 1990 [5]. Recognizing the significant contribution of the population density of China and other regions of Asia to these numbers of cancers, it is appropriate to consider the cancer burden of these countries after correction for population. The numbers of cases/deaths and the incidence/mortality rates for these world regions in 1999 are given in Fig. 1.6. It is evident from the data contained in Fig. 1.6 that there is a marked disparity between total numbers of cancer cases/deaths and the incidence/mortality rate for specific world regions [5]. In 2012, men from Australia/New Zealand exhibit the highest cancer incidence rate worldwide (365 cases per 100,000 population), followed closely by men from North America (344 cases per 100,000 population) and

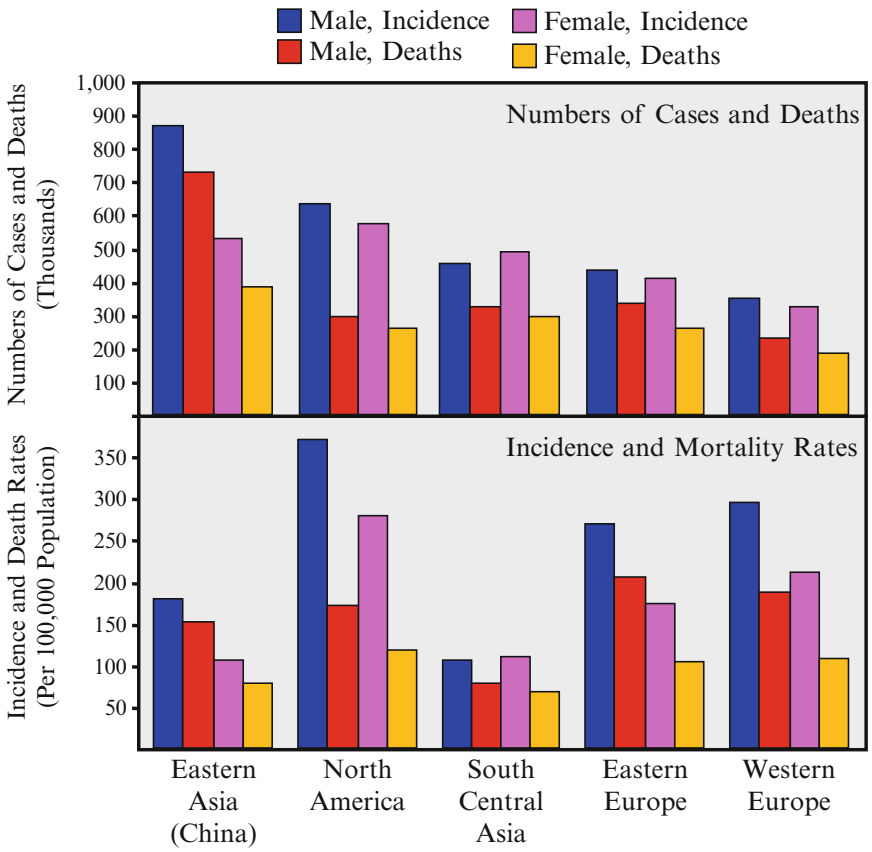

Fig. 1.6 Worldwide cancer incidence and mortality for both sexes by world region. The total numbers of cancers and cancer-related deaths, and the total incidence of cancer and cancer-related mortality rates for selected world regions were calculated from data provided by Parkin et al. [5].

Western Europe (344 cases per 100,000 population), while the lowest cancer incidence rate is found among men from Western Africa (79 cases per 100,000 population) [6]. While demonstrating the highest cancer incidence rate worldwide, the male populations of Australia/New Zealand, North America, and Western Europe rank 13th, 9th, and 5th (respectively) for cancer mortality rate, possibly reflecting the relative quality and availability of healthcare and treatment options among the various world regions [6]. The highest cancer mortality rate for men is found in Central/Eastern Europe (173 deaths per 100,000 population), followed by Eastern Asia (159 deaths per 100,000 population), Southern Europe (138 deaths per 100,000 population), Southern Africa (137 deaths per 100,000 population), and Western Europe (131 deaths per 100,000 population), while the lowest mortality rate is found among men from West Africa (69 deaths per 100,000 population) [6]. The North American female population shows the highest cancer incidence rate worldwide (295 cases per 100,000 population), followed by Australia/New Zealand (278 cases per 100,000 population), Northern Europe (264 cases per 100,000 population), and Western Europe (264 cases per 100,000 population), while the lowest incidence rate is found among women from South/Central Asia (103 cases per 100,000 population) [6]. The highest mortality rate for females worldwide is found in Melanesia (119 deaths per 100,000 population), followed by Eastern Africa (111 deaths per 100,000 population), Southern Africa (99 deaths per 100,000 population), Northern Europe (94 deaths per 100,000 population), and Polynesia (93 deaths per 100,000 population), while the lowest mortality rate is found among women from Micronesia (56 deaths per 100,000 population) [6].

1.5 Population Factors Contributing to Cancer Incidence and Mortality

1.5.1 Age-Dependence of Cancer Incidence and Mortality

Cancer is predominantly a disease of old age. Most malignant neoplasms are diagnosed in patients over the age of 65, making age the most important risk factor for development of many types of cancer [7, 8]. The age-specific incidence and death rates for cancers of the prostate, breast (female), lung (both sexes combined), and colorectum (both sexes combined) for the period of 1992–2012 [2] are shown in Fig. 1.7. The trends depicted in this figure clearly show that

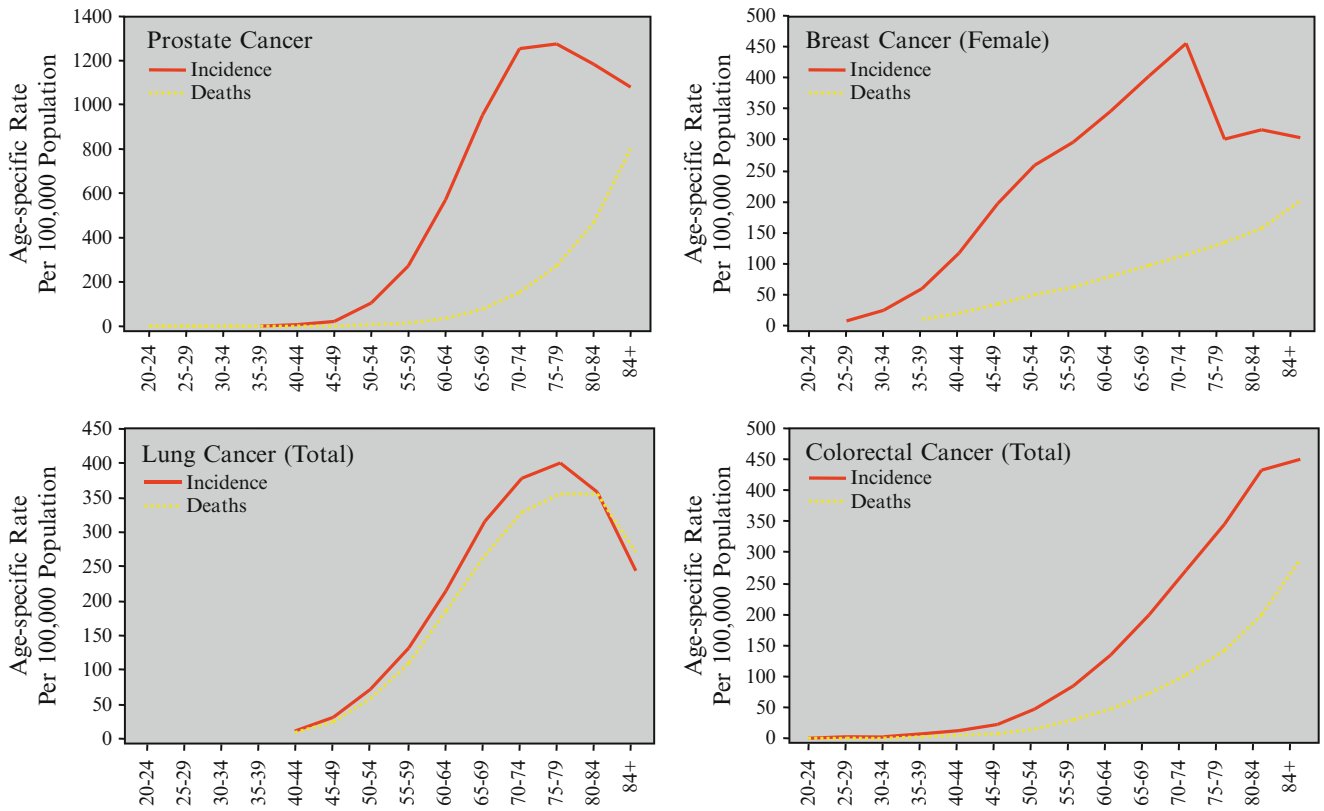

Fig. 1.7 Age-specific incidence and mortality rates for selected sites, 1992–2012. The age-specific rates for breast cancer incidence and mortality are for females only. The age-specific rates for lung cancer and colorectal cancer are combined for both sexes. These data were adapted from Howlander et al. [2]. Rates are per 100,000 population and are age-adjusted to the 2000 standard population of the USA.

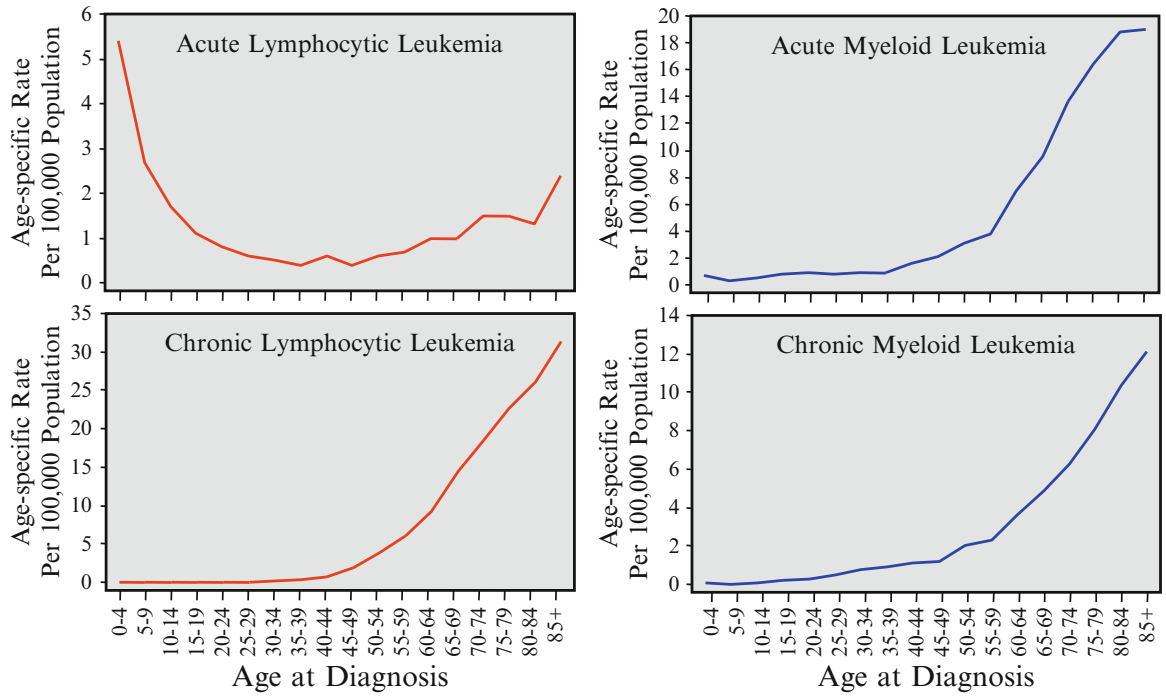

Fig. 1.8 Age-specific incidence rates for acute and chronic leukemias, 1992–2012. The age-specific rates for incidence and mortality for the major forms of leukemia are combined for both sexes. These data were adapted from Howlander et al. [2]. Rates are per 100,000 population and are age-adjusted to the 2000 standard population of the USA.

the majority of each of these cancer types occur in individuals of advanced age. In the case of prostate cancer, 86 % of all cases occur in men over the age of 65, and 99.5 % occur in men over the age of 50. Likewise, 97 % of prostate cancer deaths occur in men over the age of 65 (Fig. 1.7). In contrast, female breast cancer occurs much more frequently in younger individuals. Nonetheless, 63 % of cases occur in women over the age of 65, and 88 % of cases occur in women over the age of 50 (Fig. 1.7). A notable exception to this relationship between advanced age and cancer incidence involves some forms of leukemia and other cancers of childhood. Acute lymphocytic leukemia (ALL) occurs with a bimodal distribution, with highest incidence among individuals less than 20 years of age, and a second peak of increased incidence among individuals of advanced age (Fig. 1.8). The majority of ALL cases are diagnosed in children, with 40 % of cases diagnosed in children under the age of 15, and 45 % of cases occurring in individuals under the age of 20. Despite the prevalence of this disease in childhood, a significant number of adults are affected. In fact, 32 % of ALL cases are diagnosed in individuals over the age of 65 years of age. In contrast to ALL, the other major forms of leukemia demonstrate the usual pattern of age-dependence observed with solid tumors, with large numbers of cases in older segments of the population (Fig. 1.8). Among 54,270 new cases of leukemia in 2015, 88 % (48,020 new cases) represent forms of leukemia that primarily affect older individuals (acute myeloid leukemia, chronic myeloid leukemia, or chronic lymphocytic leukemia), with the remainder (6250 new cases) reflecting childhood ALL.

1.5.2 Cancer Incidence and Mortality by Race and Ethnicity

Cancer incidence and mortality can vary tremendously with race and ethnicity [9]. In the USA, African Americans and Caucasians are more likely to develop cancer than individuals of other races or ethnicities (Fig. 1.9). African Americans demonstrated a cancer incidence for all sites combined of approximately 443 cases per 100,000 population, and Caucasians exhibited a cancer incidence rate of 403 cases per 100,000 population. In contrast, American Indians showed the lowest cancer incidence among populations of the USA with 153 cases per 100,000 population for all sites combined. Mortality due to cancer also differs among patients depending upon their race or ethnicity. Similar to the cancer incidence rates, mortality due to cancer is higher among African Americans (223 per 100,000 population) and Caucasians (167 deaths per 100,000 population) than other populations, including Asian/Pacific Islanders, American Indians, and Hispanics (Fig. 1.9). For both cancer incidence and mortality, racial and ethnic variations for all sites combined differ from those for individual cancer sites. African

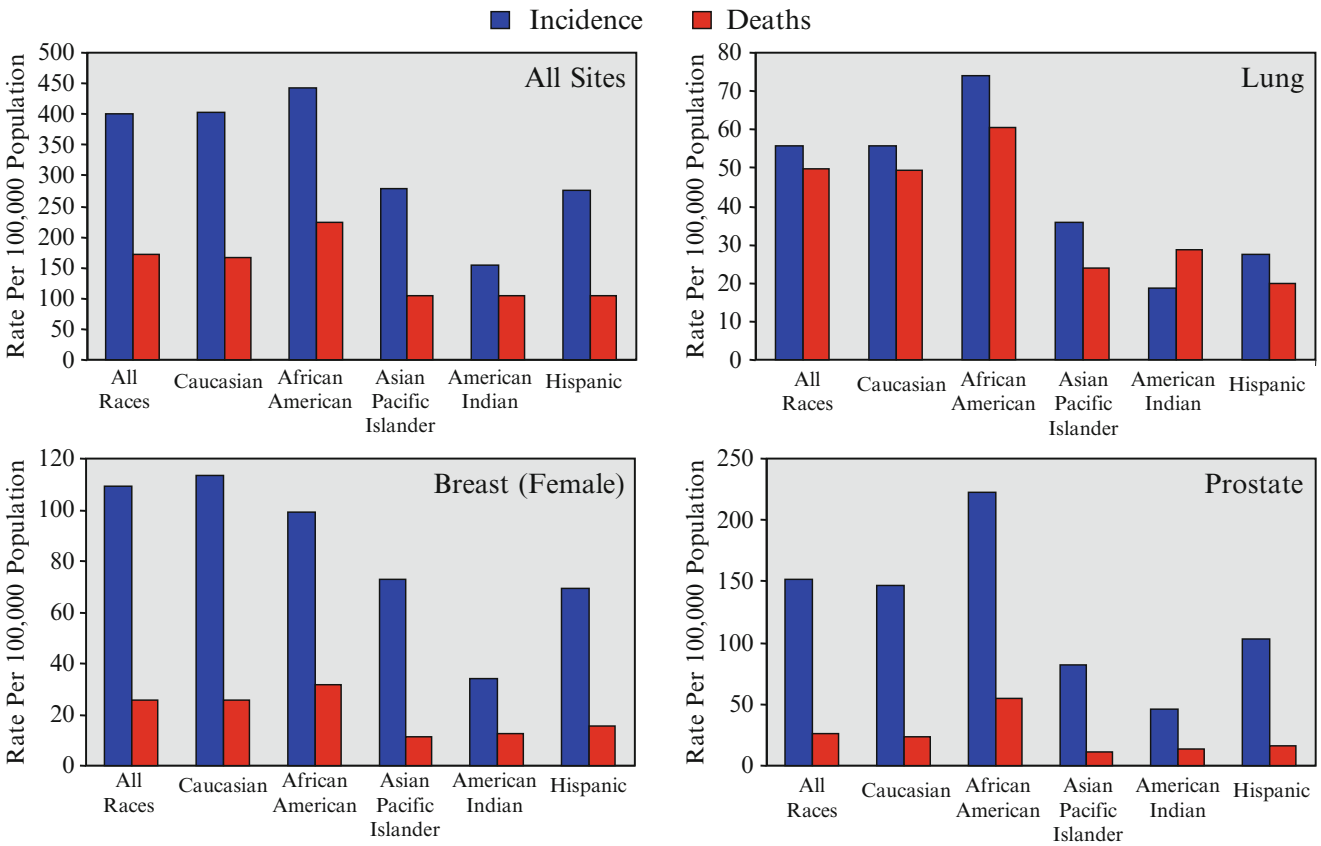

Fig. 1.9 Cancer incidence and mortality by race and ethnicity (USA, 1990–1996). The age-specific rates for cancer incidence and mortality for all races and select ethnicities residing in the USA are given for all cancer sites and select organ-specific cancer sites. The rates for all sites and lung cancer are for both sexes combined. These data were adapted from Reis et al. [9]. Rates are per 100,000 population and are age-adjusted to the 1970 standard population of the USA.

Americans and Caucasians demonstrate an excess of cancer incidence compared to the general population for a number of primary sites. African Americans exhibit high incidence rates for cancers of the prostate (223 cases per 100,000 population), lung (74 cases per 100,000 population for both sexes combined), colorectum (50 cases per 100,000 population), pancreas (13 cases per 100,000 population), oral cavity and pharynx (13 cases per 100,000), stomach (12 cases per 100,000 population), cervix uteri (12 cases per 100,000 population), and esophagus (8 cases per 100,000 population). The cancer incidence rates for lung, prostate, pancreas, and esophagus among African Americans are 33 %, 47 %, 50 %, and 115 % (respectively) higher than those rates for the general population. Caucasians exhibit high incidence rates for cancers of the breast (113 cases per 100,000 population), uterine corpus (23 cases per 100,000 population), urinary bladder (18 cases per 100,000), ovary (16 per 100,000 population), and melanoma (14 cases per 100,000 population). The excess of melanoma in the Caucasian population compared with populations possessing darker skin pigmentation is clearly shown in Fig. 1.10. The Asian/Pacific Islander population exhibit high rates of liver cancer (11 cases per 100,000 population) and stomach cancer (15 cases per 100,000 population), which are 173 % and 97 % (respectively) higher than the rates for the general population (Fig. 1.10). The Hispanic population demonstrates high rates of incidence for cancers of the cervix uteri (16 cases per 100,000 population) and stomach (11 cases per 100,000 population). These rates are 78 % and 36 % (respectively) higher than rates for these cancers in the general population (Fig. 1.10).

1.6 Trends in Cancer Incidence and Mortality for Specific Sites

1.6.1 Lung Cancer

Approximately 221,200 new cases of lung cancer were diagnosed in the USA in 2015, with 115,610 new cases among men and 105,590 new cases among women, and 13 % of all invasive cancer diagnoses [3]. The relative lung cancer incidence for all races and genders was estimated to be 56 cancers per 100,000 population in 2012 [2]. The relative lung

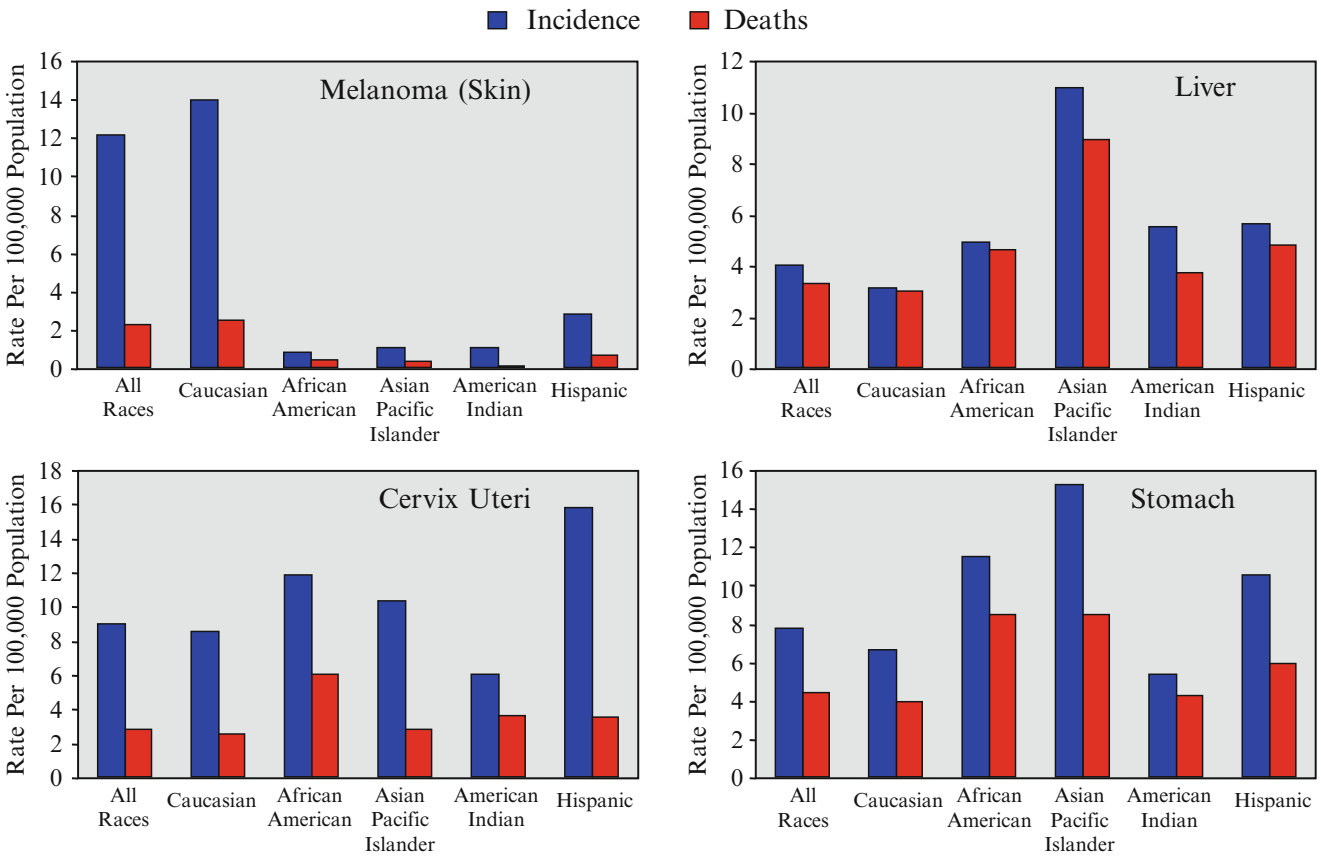

Fig. 1.10 Cancer incidence and mortality by race and ethnicity (USA, 1990–1996). The age-specific rates for cancer incidence and mortality for all races and select ethnicities residing in the USA are given for all cancer sites and select organ-specific cancer sites. The rates for melanoma, and cancers of the liver and stomach are for both sexes combined. These data were adapted from Reis et al. [9]. Rates are per 100,000 population and are age-adjusted to the 1970 standard population of the USA.

cancer incidence for men (all races) was estimated to be 65 cancers per 100,000 population in 2012, down from the all-time high of 102 cases per 100,000 population in 1984 [2]. African-American men exhibit a higher incidence of lung cancer (90 cancers per 100,000 population in 2012) compared to Caucasian-American men (64 cancers per 100,000 population in 2012). However, lung cancer incidence has declined among both groups from their all-time highs (159 cancers per 100,000 population for African-American men in 1984, and 101 cancers per 100,000 population for Caucasian-American men in 1987). The relative lung cancer incidence rate among women increased to 54 cancers per 100,000 population in 2007, but has been declining since that time, reaching approximately 50 cases per 100,000 population in 2012 [2]. Cancer of the lung and bronchus accounted for an estimated 158,040 deaths in 2015, which represents 27 % of all cancer deaths [3]. Furthermore, lung cancer is the leading cause of cancer deaths among men (86,380 deaths, 28 % of cancer deaths) and women (71,660 deaths, 26 % of cancer deaths) (Fig. 1.3).

Cancers of the lung and bronchus represent 92 % of all respiratory system cancers [3]. The remainder of respiratory system cancers include tumors of the larnyx and nasal cavities. The majority of lung cancers are histologically classified as either small cell lung carcinoma (SCLC, 13 % of all lung cancers) or non-small-cell lung carcinoma (NSCLC, 83 % of all lung cancers). The NSCLC class includes the morphologic subtypes of squamous cell carcinoma (SCC), adenocarcinoma, and large cell undifferentiated carcinoma. Squamous cell carcinomas (SCC) account for approximately 35 % of lung cancers [10]. This histologic subtype of lung cancer is closely correlated with cigarette smoking and represents the most common type of lung cancer among men. SCCs display varying levels of differentiation, from tumors consisting of well-differentiated keratinized squamous epithelium to tumors consisting of undifferentiated anaplastic cells. Adenocarcinomas have increased in frequency in recent years and now account for nearly 35 % of lung cancers [10]. These tumors grow faster than SCCs and frequently metastasize to the brain. Lung adenocarcinomas can present as well-differentiated tumors consisting of well-differentiated glandular epithelium, or as undifferentiated tumors composed of highly mitotic anaplastic cells. Large cell undifferentiated carcinomas account for approximately 15 % of all

lung cancers [10]. These tumors lack squamous or glandular cell characteristics and are typically composed of large anaplastic cells with frequent mitotic figures. Clinically, these tumors metastasize early and have a poor prognosis. Small cell lung carcinomas (SCLC) make up the majority of the remaining cancers (13%) [3, 10]. These cancers are also associated with smoking history. SCLCs tend to produce a variety of neuroendocrine substances that can cause symptoms related to the biological activity of the hormonal substance. About 10% of SCLCs display a paraneoplastic phenotype related to production of these neuroendocrine effectors [11]. These cancers grow rapidly, metastasize early, and have a very poor prognosis.

The majority of lung cancers are attributable to exposure to known carcinogenic agents, particularly cigarette smoke. Several lines of evidence strongly link cigarette smoking to lung cancer. Smokers have a significantly increased risk (11- to 22-fold) for development of lung cancer compared to non-smokers [12], and cessation of smoking decreases the risk for lung cancer compared to continued smoking [12, 13]. Furthermore, heavy smokers exhibit a greater risk than light smokers, suggesting a dose-response relationship between cigarette consumption and lung cancer risk [12, 13]. Numerous mutagenic and carcinogenic substances have been identified as constituents of the particulate and vapor phases of cigarette smoke, including benzo[*a*]pyrene, dibenza[*a*]anthracene, nickel, cadmium, polonium, urethane, formaldehyde, nitrogen oxides, and nitrosodiethylamine [14]. There is also evidence that smoking combined with certain environmental (or occupational) exposures results in potentiation of lung cancer risk. Urban smokers exhibit a significantly higher incidence of lung cancer than smokers from rural areas, suggesting a possible role for air pollution in development of lung cancer [15]. Occupational exposure to asbestos, bis(chloromethyl) ether, chromium has been associated with increased risk for development of lung cancer [16, 17]. Exposure to the radioactive gas radon has been suggested to increase the risk of lung cancer development. This gas is ubiquitous in the earth's atmosphere, creating the opportunity for exposure of vast numbers of people. However, passive exposure to the background levels of radon found in domestic dwellings and other enclosures are not sufficiently high to increase lung cancer risk appreciably [18, 19]. High level radon exposure has been documented among miners working in uranium, iron, zinc, tin, and fluorspar mines [20, 21]. These workers show an excess of lung cancer (compared to non-miners) that varies depending upon the radon concentration encountered in the ambient air of the specific mine [20, 21].

Therapy for lung cancer varies depending upon the tumor type and other clinical variables (tumor stage, grade, location, and size). Surgery is the preferred treatment choice for SCC and adenocarcinoma, whereas SCLC is generally treated with chemotherapy. In some cases special treatment modalities are employed, such as chemotherapy followed by surgery or surgery followed by radiation treatment. Despite the variety of treatment modalities that can be applied to lung cancer management, the overall survival rates for affected individuals are not good (Fig. 1.11). The average 5-year survival rate for all patients and all stages of disease is only 17% [3, 9, 22].

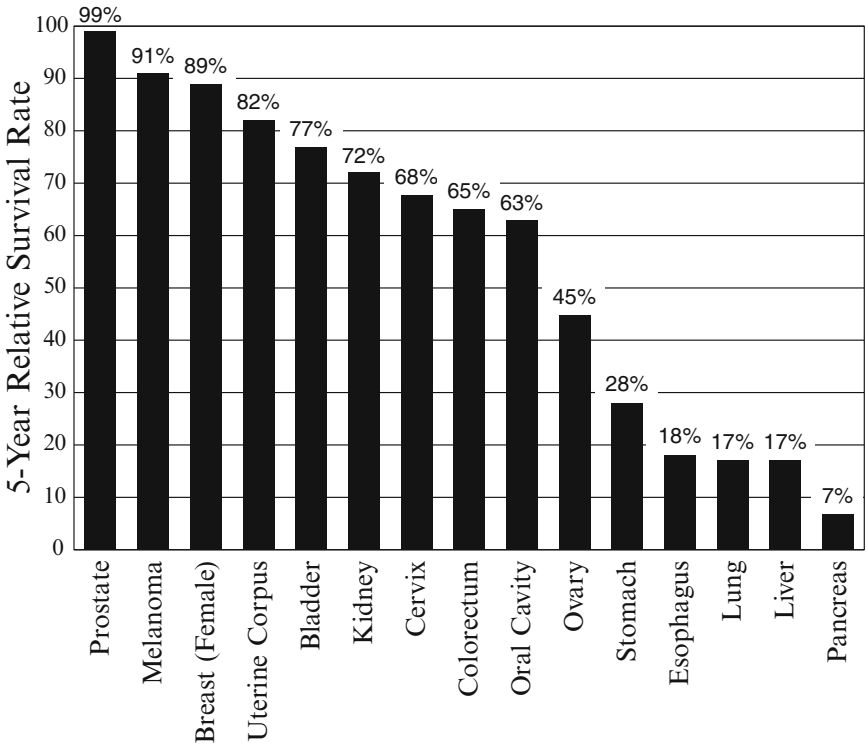

Fig. 1.11 Five-year relative survival rates for invasive cancers (all stages, 2004–2010). The average 5-year survival rates for select invasive cancers (including cancers diagnosed at all stages) among affected individuals residing in the USA for 2004–2010 are shown. These data were adapted from Seigel et al. [3].

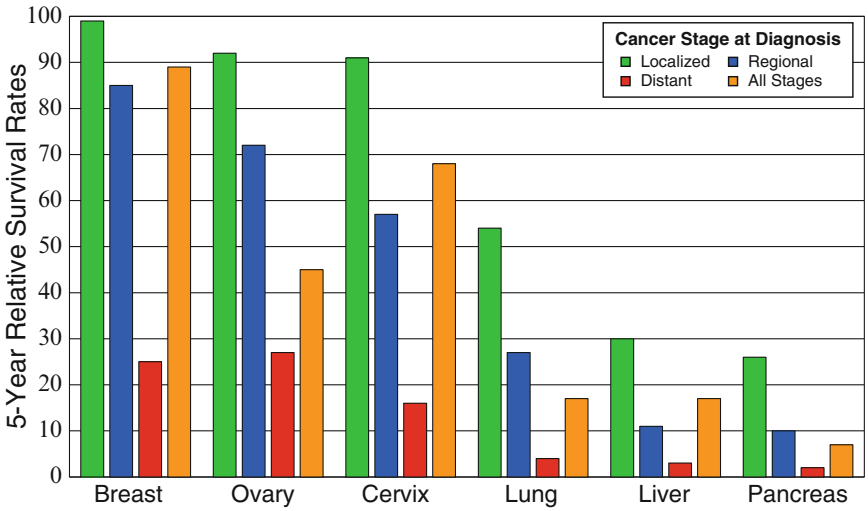

Fig. 1.12 Five-year relative survival rates for selected sites by stage at diagnosis. The percentage of tumors for select invasive cancers according to tumor stage at diagnosis and the corresponding 5-year survival rates among affected individuals residing in the USA for 2004–2010 are shown. These data were adapted from Seigel et al. [3].

The survival rate increases to 54 % if the disease is detected early (localized), but few lung cancers (15 %) are discovered this early (Fig. 1.12). The majority of lung cancer cases are not detected until after the development of regional spread (27 %) or distant metastases (58 %). The 5-year survival rate for patients with regional disease is 27 %, and this drops to 4 % in patients with distant metastasis (Fig. 1.12). The overall poor probability of surviving lung cancer probably reflects the difficulty with early detection of this tumor (or the failure to detect tumors while localized) and the ineffectiveness of traditional therapies (radiation and chemotherapy). However, over the last decade or so, a variety of targeted drugs have received market approval for treating NSCLC [23]. These new drug modalities for early stage or advanced NSCLC include inhibitors of the epidermal growth factor receptor (gefitinib, erlotinib, and afatinib), the anaplastic lymphoma kinase inhibitor crizotinib, and the antivascular endothelial growth factor receptor monoclonal antibody, bevacizumab [23]. In parallel, molecular alterations of the epidermal growth factor receptor (EGFR) and the anaplastic lymphoma kinase (ALK) have been characterized, enabling the development of molecular diagnostics of discrimination of lung cancer patients that are more likely to benefit from specific targeted therapies versus those patients that will not respond to a specific drug [23].

1.6.2 Colorectal Cancer

Approximately 132,700 new cases of colorectal cancer were diagnosed in the USA in 2015 (approximately 8 % of all cancers), with 69,090 new cases among men and 63,610 new cases among women [3]. Colorectal cancer represent 46 % of all digestive system tumors, and is the third leading site for cancer diagnosis among men (8 % of new cases among men) and women (8 % of new cases among women). In 2012, the relative incidence rate for colorectal cancer was 45 cancers per 100,000 population for men (all races) and 35 cancers per 100,000 for women (all races) [2]. However, colorectal cancer incidence rates vary by race (as well as gender). The overall incidence rates for colorectal cancer among Caucasians in 2012 was 39 cancers per 100,000 population compared to 48 cancers per 100,000 population among African-Americans. African-American men exhibit the highest incidence rate for colorectal cancer at 57 cancers per 100,000 population (versus 43 cancers per 100,000 population for Caucasian men), and colorectal cancer incidence rates for African-American women (41 cases per 100,000 population in 2012) exceed that for Caucasian women (34 cases per 100,000 population in 2012) [2]. Colorectal cancer accounted for an estimated 49,700 deaths in 2015, which represents 8 % of all cancer deaths [3]. Colorectal cancer is the third leading cause of death among men and women, accounting for 8 % and 9 % of all cancer deaths, respectively (Fig. 1.3).

Colorectal tumors are often first recognized as a polyp protruding from the wall of the bowel, which may be either hyperplastic (non-dysplastic) or dysplastic (adenomatous). Hyperplastic polyps consist of large numbers of cells with normal morphology that do not have a tendency to become malignant [24]. Adenomatous polyps contain dysplastic cells that fail to show normal intracellular and intercellular organization. Expanding adenomas become progressively more dysplastic and likely to become malignant. The majority of malignant neoplasms of the colon are thought to be derived from benign polyps. The malignant nature of colorectal tumors are defined by their invasiveness. The major histologic type of colorectal cancer is adenocarcinoma, which account for 90–95 % of all colorectal cancers [25, 26], although other rare epithelial tumor types do occur, including squamous cell carcinomas, adenosquamous carcinomas, and undifferentiated carcinomas which contain no glandular structures or features such as mucinous secretions [25, 27].

There are several recognized risk factors for development of colorectal cancer, some of which are genetic or related to benign pathological lesions of the colorectum, and others that are related to lifestyle or environment. Approximately 5–10 % of colorectal cancers are thought to be related to an inherited predisposition. Familial colorectal cancer can arise in presence or absence of polyposis, which is characterized by the occurrence of multiple benign polyps lining the walls of the colon. Several polyposis syndromes have been described, the major form of which is familial adenomatous polyposis (FAP) [28]. The hereditary nonpolyposis colorectal cancer (HNPCC) syndrome predisposes affected individuals to the development of colorectal cancer, as well as tumors at other tissue sites [29, 30]. These two hereditary syndromes account for a large percentage of familial colorectal cancers. Individuals affected by these syndromes carry mutations in one or more genes that function as tumor suppressor genes or that encode critical components of the DNA repair mechanisms that protect the genome from mutation [28]. Patients with inflammatory bowel disease (ulcerative colitis) or Crohn's disease (granulomatous colitis) exhibit an increased risk for development of colorectal cancer [28, 31]. Epidemiologic studies indicate that individuals consuming diets that are high in animal fat and red meat [32–34], or low in fiber [35, 36] are associated with increased risk for development of colorectal cancer. In addition, there is some evidence that alcohol intake and cigarette smoking can increase the risk for colorectal cancer [37, 38].

Treatment for colorectal cancer may include surgery, radiation therapy, chemotherapy, or a combination of these treatment modalities. Chemotherapy alone is not very effective, but some drug combinations that are now employed show promise. In general, survival of colorectal cancer is closely correlated with early detection of localized disease, and the mortality due to this disease has been declining in recent years [3, 39]. The average 5-year relative survival rate for colorectal cancer is 65 % (Fig. 1.11). The relative survival rate increases to 90 % if the cancer is detected early (localized), and remains relatively high (71 % survival) when detected with regional metastasis (Fig. 1.12). In contrast, the 5-year survival is only 13 % when the cancer is detected after development of distant metastases [3, 9]. Most colorectal cancers are now detected while localized (40 % of tumors) or with limited regional spread (37 % of tumors), which contributes to the generally favorable probability of survival for this form of cancer. Several screening methods are available for surveillance of patients that are at high risk for development of colorectal cancer, and some screening strategies are now routinely applied to the general population. These screening methods include digital rectal examination, fecal occult blood testing, and various forms of colonoscopy [40].

1.6.3 Liver Cancer

Hepatocellular carcinoma (HCC) is a relatively rare neoplasm in the USA, with 35,660 new cases diagnosed in 2015 [3]. However, liver cancer occurs at high incidence when the world population is considered. In 2008, there were 748,300 new cases of liver cancer worldwide [3], which represents 5.9 % of all cancers and the fifth leading site for cancer incidence (Fig. 1.5). Deaths attributed to liver cancer for the same year totaled 695,900, which represents 9.2 % of all cancer deaths and the third leading site for cancer mortality (Fig. 1.5). The prevalence of primary liver cancer varies greatly from world region to world region (Fig. 1.13).

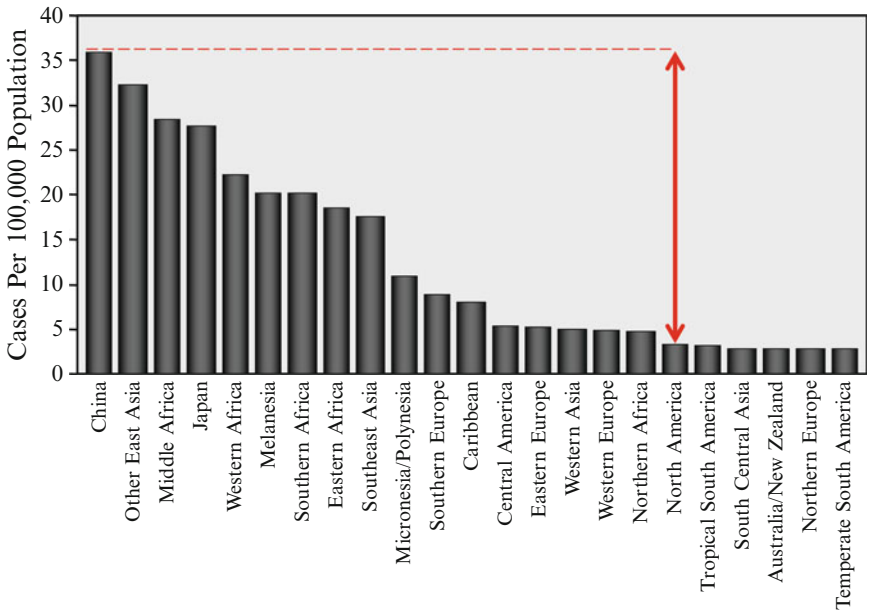

Fig. 1.13 Incidence of liver cancer among men by world region. The primary liver cancer incidence for 1990 for males residing in select world regions is shown. These data were adapted from Parkin et al. [5], and are expressed per 100,000 population.

Approximately 85 % of all liver cancers worldwide occur in regions of Asia and Africa [41, 42]. The highest incidence of liver cancer worldwide is found in China [41, 42], where men exhibit an incidence rate of approximately 36 cases per 100,000 population (Fig. 1.13). In fact, >50 % of liver cancers worldwide occur in China [41, 42]. High rates of liver cancer incidence are found throughout large portions of Asia and Africa, with much lower incidence rates for this cancer found in Europe and the Americas (Fig. 1.13). Early studies called attention to the extremely high incidence of hepatocellular carcinoma among black males in Mozambique [43, 44], which demonstrate the highest incidence worldwide at 113 cases per 100,000 population [45]. In fact, the incidence of this tumor among black Mozambican males aged 25–34 years is over 500-fold higher than the incidence for comparably aged while males in the USA and UK [44, 46]. These statistics strongly suggest that factors related to genetic background and/or environmental exposure contribute significantly to the incidence of this tumor among world populations. Whereas the incidence rate for primary HCC in the USA has remained fairly low compared to other world regions, the occurrence of this neoplasm has been increasing dramatically over the last two decades (Fig. 1.14). As shown in Fig. 1.14, the incidence of primary liver cancer in the USA has increased from approximately 15,000 new cases in 2000 to >35,000 new cases in 2015 (233 % increase in 15 years). Likewise, deaths associated with liver cancer have increased from approximately 15,000 in 2005 to nearly 25,000 in 2015 (159 % increase in 10 years). The likely cause of this dramatic increase in liver cancer incidence in the USA is the increase in HCV infection prevalence. Increased incidence of liver cancer has been observed in a number of developed countries during the last decade [41, 42]. There has also been a dramatic rise in HCC incidence among Japanese men during the last 30 years [47], possibly reflecting some significant change in risk factors or environmental exposures.

Liver cancer affects men more often than women. The ratio of male to female incidence in the USA is approximately 2:1 [2], and worldwide is approximately 2.6:1 [4]. However, in high incidence countries or world regions, the male to female incidence ration can be as high as 8:1 [48, 49]. This consistent observation suggests that sex hormones and/or their receptors may play a significant role in the development of primary liver tumors. Some investigators have suggested that hepatocellular carcinomas overexpress androgen receptors [50], and that androgens are important in the promotion of abnormal liver cell proliferation [51, 52]. Others have suggested that the male predominance of liver cancer is related to the tendency for men to drink and smoke more heavily than women, and are more likely to develop cirrhosis [53].

The etiology of HCC is clearly multifactorial [54]. HCC is usually associated with chronic hepatitis [55–58], and 60–80 % of HCC occurring worldwide develop in cirrhotic livers [55, 58–61], most commonly nonalcoholic posthepatitic cirrhosis [62]. Numerous causative factors have been identified that are suggested to contribute to the development of HCC in humans, including exposure to naturally occurring carcinogens, industrial chemicals, pharmacologic agents, and various pollutants [63, 64]. In addition, viral infection, genetic disease, and life-style factors (like alcohol consumption) contribute to the risk for development of HCC [41, 63, 64]. The most well studied hepatocarcinogen is a natural chemical carcinogen known as aflatoxin B_1 that is produced by the *Aspergillus flavus* mold [41, 65, 66]. This mold grows on rice or other grains (including corn) that are stored without refrigeration in hot and humid parts of the

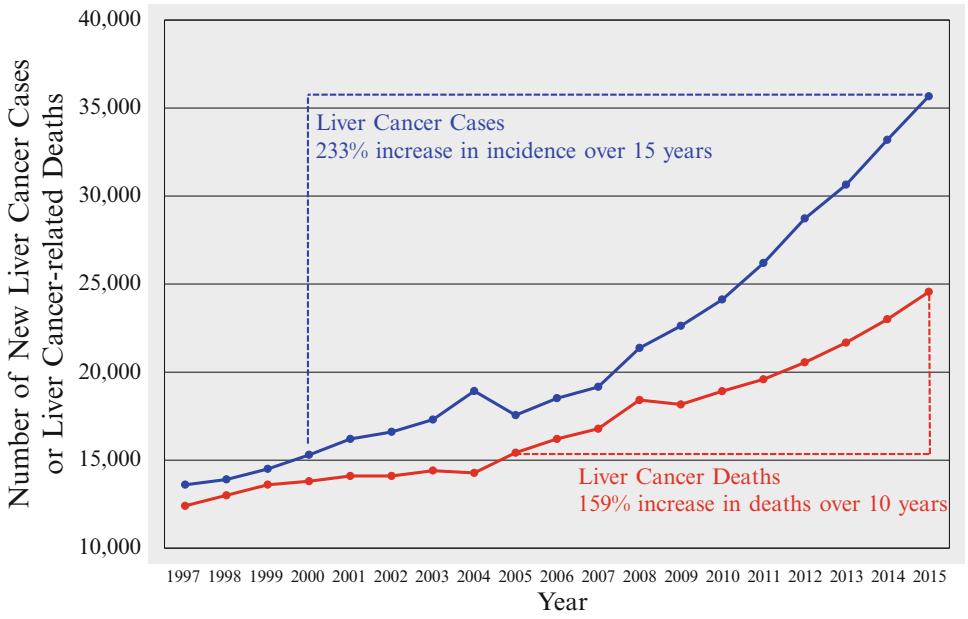

Fig. 1.14 Increasing incidence of primary liver cancer in the USA, 1997–2015. Numbers of new primary liver cancer cases (*blue trend line*) and deaths (*red trend line*) are provided. These data were assembled from the annual cancer statistics reviews for 1997–2015 from the American Cancer Society (www.cancer.org).

world. Ingestion of food that is contaminated with *Aspergillus flavus* mold results in exposure to potentially high levels of aflatoxin B_1 [67]. Aflatoxin B_1 is a potent, direct-acting liver carcinogen in humans, and chronic exposure leads inevitably to development of HCC [66]. Numerous studies have shown a strong correlation between hepatitis B virus (HBV) infection and increased incidence of HCC [45, 68–70]. More recently, an association between chronic HCV infection and HCC has been recognized [70–73]. In certain geographic areas (such as China), large portions of the population are concurrently exposed to aflatoxin B_1 and HBV, which increases their relative risk for development of liver cancer [68]. Pharmacologic exposure to anabolic steroids and estrogens can lead to development of liver cancer [74]. Several genetic diseases that result in liver pathology can increase the risk of development of a liver cancer, including hemochromatosis, hereditary tyrosinemia, glycogen storage disease types 1 and 3, galactosemia, Wilson's disease, and others [75]. Chronic alcohol consumption is associated with an elevated risk for HCC [76–79]. Alcohol is not directly carcinogenic to the liver, rather it is thought that the chronic liver damage produced by sustained alcohol consumption (hepatitis and cirrhosis) may contribute secondarily to liver tumor formation [80]. Other lifestyle factors may also contribute to risk for development of HCC, including tobacco smoking [81, 82]. Several chemicals, complex chemical mixtures, industrial processes, and/or therapeutic agents have been associated with development of HCC in exposed human populations [64]. These include therapeutic exposure to the radioactive compound thorium dioxide (Thoratrast) for the radiological imaging of blood vessels [83, 84], and exposures to certain industrial chemicals, such as vinyl chloride monomer [85].

Treatment of hepatocellular carcinoma may include surgery, chemotherapy, radiotherapy, or some combination of these treatments. The overall 5-year survival rate for HCC is only 5 % (Fig. 1.11). The poor survival rate for HCC primarily reflects both the lack of effective treatment options and the advanced stage of disease at diagnosis. HCC is diagnosed as localized disease in approximately 21 % of cases, with region spread in 23 % of cases, and with distant metastases in 22 % of cases [9]. The 5-year survival for patients diagnosed with distant metastases is only 1.2 %, and survival improves to only 14.7 % when the patient presents with localized disease [9]. Most patients with HCC also have underlying cirrhosis which makes surgical resection of the tumor very difficult. Furthermore, cirrhosis itself is a preneoplastic condition, which opens the possibility for development of additional secondary neoplasms in the unresected tissue after surgery. In fact, the recurrence rate after surgery for HCC was found to be 74 % within 5 years [86]. However, orthotopic liver transplantation can afford a complete cure for HCC if surgery is carried out prior to tumor spread from the liver [87]. While the application of liver transplant in the treatment of HCC is not favored by transplant surgeons, the results emerging from such treatment are very encouraging in some cases. In one study of 17 patients [88], liver transplant was performed to correct metabolic disorders of the liver (such as tyrosinemia) and small HCCs (without invasion or local spread) were incidentally discovered in the resected specimens. Of these patients, 90 % survived >5 years without recurrence of the HCC [88]. Other studies have not produced such favorable results [89], but it appears that certain types of HCC (such as fibrolamellar carcinoma) do very well after transplant, with >50 % survival 5 years after transplant [90]. A number of chemotherapeutic agents and combinations of these agents have been used to treat HCC. However, chemotherapy for HCC is generally not very effective and the response rates are very low, particularly when a single agent is used [91]. Nonetheless, there are occasional reports of dramatic responses using systemic chemotherapy, and some reports of complete remission [92], suggesting that responsiveness of HCC to chemotherapy is totally unpredictable [62]. Radiation therapy for HCC can be effective at reduction of tumor size, but produces a number of serious side effects, including progressive atrophy of the liver parenchyma which leads to fulminant liver failure in some patients [62]. More recent developments in radiation therapy have resulted in treatment modalities that limit collateral damage to the liver and surrounding tissues but are effective at reducing tumor burden [93].

1.6.4 Skin Cancer

There are several major forms of skin cancer, including basal cell carcinoma, squamous cell carcinoma, and malignant melanoma [94]. Non-melanoma skin cancer represents the most frequently occurring tumor-type in the USA, with several million total cases in 2015 [3]. These types of skin cancer tend to be slow growing, minimally invasive, not readily metastatic, and usually curable (given appropriate treatment). Thus, these forms of skin cancer are not typically included in cancer statistics for incidence, mortality, and survival rates (and these cancers are not reported to cancer registries making it difficult to quantify the magnitude of the disease). Nonetheless, the common occurrence of these tumors among the human population suggests that it is an important group of diseases to consider. Basal cell carcinoma accounts for most cases of non-melanoma skin cancer and is the most frequently occurring form of skin cancer. Squamous cell carcinoma is the second-most common form of skin cancer. Basal cell carcinoma accounts for at least 75 % of non-melanoma skin cancers diagnosed each year in the USA, while squamous cell carcinomas account for approximately 20 % [95]. In contrast to the other forms of

skin cancer, malignant melanoma of the skin is an aggressive and invasive cancer that can metastasize to many tissue locations. The incidence of melanoma has been rising about 4 % per year in the USA. In 2015, there were 73,870 new cases of malignant melanoma, representing 5 % of all male cancers (42,670 new cases) and 4 % of all female cancers (31,200 new cases) (Fig. 1.3). Mortality due to malignant melanoma accounted for 9940 deaths in 2015 [2].

Basal cell carcinoma is a malignant neoplasm of the basal cells of the epidermis and this tumor occurs predominately on sun-damaged skin. The carcinogenic agent that accounts for the neoplastic transformation of the basal cells is ultraviolet (UV) radiation. Thus, sun bathing and sun tanning using artificial UV light sources represent significant lifestyle risk factors for development of these tumors. Basal cell carcinoma is now diagnosed in some people at very young ages (second or third decade of life) reflecting increased exposures to UV irradiation early in life. The incidence of this tumor increases with increasing age and increasing exposure to sunlight. Some researchers have suggested that the increasing frequencies of skin cancer can be partially attributed to depletion of the ozone layer of the earth's atmosphere [96], which filters out (thereby reducing) some of the UV light produced by the sun. Squamous cell carcinoma is a malignant neoplasm of the keratinizing cells of the epidermis. It tends to occur later in life and is diagnosed more frequently in men than in women. Like basal cell carcinoma, extensive exposure to UV irradiation is the most important risk factor for development of this neoplasm. When left untreated, squamous cell carcinoma can metastasize to regional lymph nodes and/or distant sites. Development of malignant melanoma occurs most frequently in fair-skinned individuals and is associated to some extent with exposure to UV irradiation. This accounts for the observation that Caucasians develop malignant melanoma at a much higher rate than individuals of other races and ethnicity's (Fig. 1.10).

The preferred treatment of skin cancer is surgery. In fact, many, if not most, cases of basal cell carcinoma and squamous cell carcinoma are treated with minor surgery in the setting of the physician's office. In the case of malignant melanoma, surgery is employed for localized disease, with radiotherapy used in the palliative treatment of metastasis to the central nervous system and bone. Chemotherapy is employed for metastatic disease, but clinical responsiveness is limited to 15–20 % of patients [97]. More recently, targeted therapies and immunotherapy has been employed to treat advanced melanoma. The 5-year survival rate for malignant melanoma is 91 % (Fig. 1.11), reflecting the high rate of diagnosis (82 %) of localized disease where survival is high (98 %) [3, 9]. The 5-year survival of this disease drops precipitously with increasing spread of the cancer. Patients diagnosed with region disease exhibit a 5-year survival of 63 % and this drops to 16 % with distant metastasis [3, 9].

1.6.5 Prostate Cancer

An estimated 220,800 new cases of prostate cancer were diagnosed in the USA in 2015 [3], representing approximately 150 cases per 100,000 population (Fig. 1.9), and 26 % of all cancers in men (Fig. 1.3). The incidence rate for prostate cancer has been increasing in the last several decades at a rate of approximately 4 % per year, and this increase is paralleled by an increase in the mortality rate (Fig. 1.4). These increases are probably related to the increasing average age of the male population, increased reporting, and increased screening of older men [98]. Detection of prostate cancer can be achieved through the application of the digital rectal examination, screening based upon detection of the prostate specific antigen (PSA) in serum, and using ultrasonography. Elevations of PSA can be detected in both benign prostatic hypertrophy and in prostate cancer, but levels of this protein in the serum are markedly elevated in cancer. While the serum PSA assay is extremely sensitive, it lacks specificity which limits its usefulness as a definitive diagnostic for prostate cancer. However, when used in combination with the digital rectal exam and ultrasonography, PSA increases the ability to detect occult prostate cancer [99].

Cancer of the prostate provides a dramatic example of the age-dependent cancer development (Fig. 1.7). Cancers at this site occur with negligible frequency in men that are less than 55 years of age, and the vast majority of cases (56 %) occur in men over the age of 65 (Fig. 1.7). Almost all prostate cancer cases (97 %) occur in men older than age 50 [3]. In addition, prostate cancer occurs with greatly varied frequency among men of different races and ethnicity (Fig. 1.9). In the USA, African-American men exhibit a significantly higher incidence of this cancer than Caucasian men, whereas American Indians demonstrate the lowest incidence of all groups (Fig. 1.9). The reason for these dramatic differences in prostate cancer incidence are not readily apparent. However, differences in the levels of circulating testosterone among men from these different groups has been suggested as one factor contributing to the observed variations in prostate cancer occurrence. The incidence of prostate cancer also varies widely from world region to world region, with the highest incidence among men living in North America (Fig. 1.15). It is notable that the incidence of prostate cancer among men from the various regions of Africa are significantly lower than the rates for African-American men living in the USA.

Treatment for prostate cancer includes surgical removal of the prostate, radiation therapy for locally invasive tumors, and hormone therapy. Strategies for hormone therapy in the treatment of prostate cancer include both administration of estrogenic hormones (such as diethylstilbesterol) or ablation of androgenic hormones through surgical or chemical castration methods. The 5-year survival rate for prostate cancer has

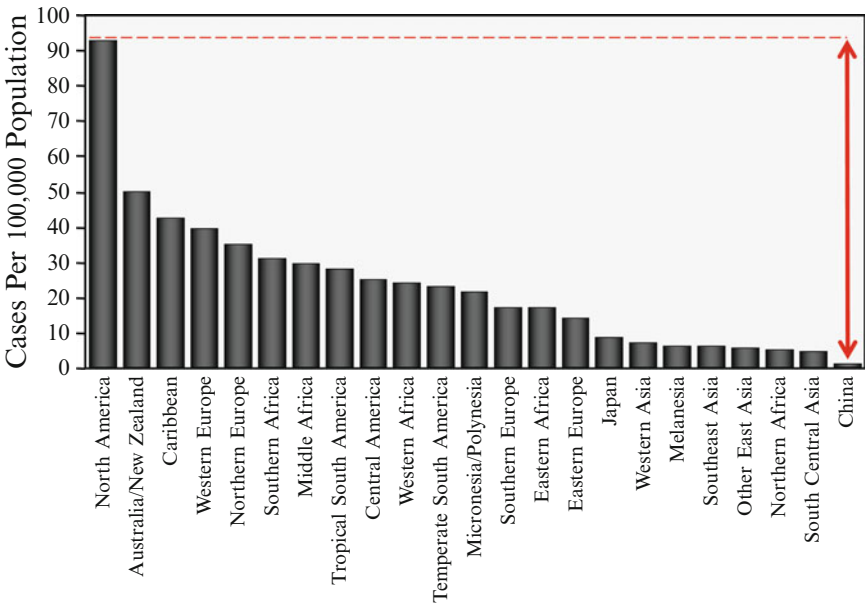

Fig. 1.15 Incidence of prostate cancer by world region. The incidence of prostate cancer for 1990 for individuals residing in select world regions is shown. These data were adapted from Parkin et al. [5], and are expressed per 100,000 population.

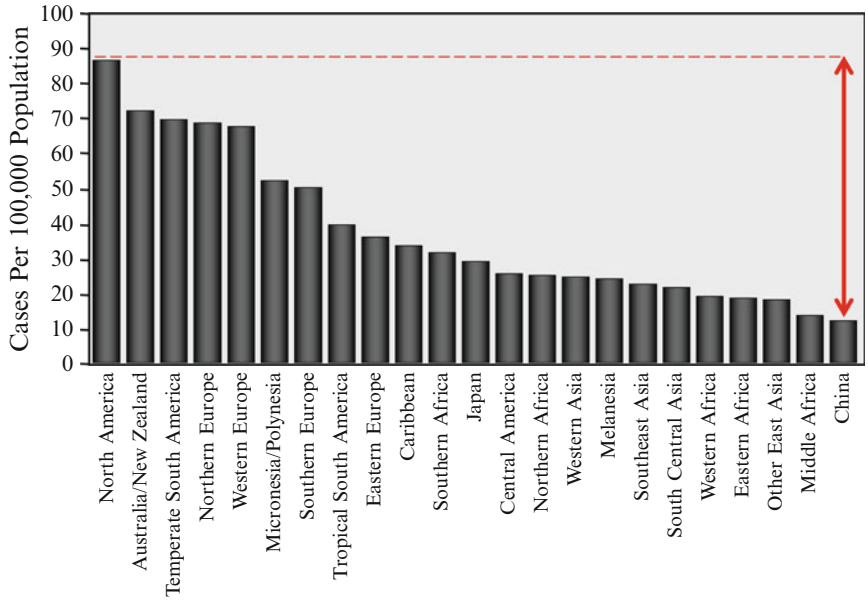

Fig. 1.16 Incidence of breast cancer among women by world region. The incidence of breast cancer for 1990 for individuals residing in select world regions is shown. These data were adapted from Parkin et al. [5], and are expressed per 100,000 population.

increased from 50 % in the years 1963–1965 to 93 % in the years 1989–1995 to 99 % in the years 2004–2010 [3, 9]. This dramatic improvement in survival can be attributed to advances in early detection of this cancer. Currently, approximately 79 % of prostate cancers are detected while they are still localized with minimal regional spread, and the 5-year survival among this group >99 % [9]. While the overall survival of prostate cancer is excellent (Fig. 1.11), early diagnosis and treatment are essential. This point is highlighted by the observation that the 5-year survival among prostate cancer patients that have distant metastasis at the time of diagnosis drops to 9 % [9].

1.6.6 Breast Cancer

An estimated 231,840 new cases of breast cancer among women were diagnosed in the USA in 2015 [3], accounting for 29 % of all female cancers diagnosed (Fig. 1.3). Breast cancer occurs more frequently among women in North America than among women from other parts of the world, while women in Asia have the lowest occurrence of breast cancer worldwide (Fig. 1.16). During the 1980s the number of new cases of breast cancer among women each year rose at a rate of about 4 % per year [9]. The incidence of breast cancer among women (all races) in the USA in the mid-1970s

was approximately 100 cancers per 100,000 population, and rose to 142 cancers per 100,000 population by 1999 [2]. In 1999, the incidence rate for breast cancer among Caucasian women peaked at 147 cases per 100,000 population and has since declined [2]. In contrast, the incidence rate for breast cancer among African-American women has increased steadily since 1976 when it was 86 cases per 100,000 population [2]. Since 1999, the incidence rate for breast cancer among women (all races) has declined somewhat and is now apparently stabilized at approximately 130 cases per 100,000 women [2]. The relative incidence of breast cancer is similar between Caucasian women (132 cases per 100,000 population in 2012) and African-American women (132 cases per 100,000 population in 2012) [2]. The increases in breast cancer incidence that were observed in the 1980s and 1990s have been suggested to reflect increased early diagnosis as mammography screening became an established standard for surveillance of the general female population. Evidence supporting this suggestion includes the fact that the average primary breast tumor at diagnosis is of smaller size and earlier stage than those diagnosed more than a decade ago. The 5-year survival for breast cancer patients diagnosed in the 1975 was approximately 75 %, compared to approximately 85 % for patients diagnosed in 1990 [9], and 89 % for patients diagnosed from 2004–2010 [3]. Nonetheless, the overall mortality rate for breast cancer has not changed substantially during this same period (Fig. 1.4), suggesting that earlier diagnosis has not significantly impacted patient outcome for this cancer. These observations suggest that the earlier diagnosis of smaller (and lower stage) cancers has impacted on the 5-year survival, without affecting the overall survival for breast cancer patients. In fact, it has been documented that breast cancer can recur after long periods of time, well after 5-years from the initial diagnosis. There are also differences in mortality rates associated with breast cancer depending upon the race of the patient. In 2012, the breast cancer-associated death rate for all women (all races) was 21 deaths per 100,000 population, which is closely mirrored by the breast cancer-associated death rate for Caucasian women (21 deaths per 100,000 population in 2012, down from the high of 33 deaths per 100,000 population in 1977). In contrast, African-American women exhibit higher death rates from breast cancer—29 deaths per 100,000 population in 2012 (down from 38 deaths per 100,000 population in 1995). An estimated 40,290 women died as a result of breast cancer during 2015 [2], making breast cancer the second leading cause of cancer death among women, accounting for 15 % of all cancer deaths (Fig. 1.3).

Risk factors for development of breast cancer include, advancing age (over 50 years of age), early age at menarche, late age at menopause, first childbirth after age of 35, nulliparity, family history of breast cancer, obesity, dietary factors (such as high-fat diet), and exposure to high dose radiation to the chest before age 35 [100–104]. In addition, fibrocystic breast disease is recognized as an established risk factor for breast cancer, especially when accompanied by cellular proliferation and atypia [105]. Epidemiologic evidence has consistently pointed to family history as a strong and independent predictor of breast cancer risk. A substantial amount of research has led to the discovery of several breast cancer susceptibility genes, including *BRCA1*, *BRCA2*, and *p53* [106], which may account for the majority of inherited breast cancers. It has been estimated that 5–10 % of breast cancers occurring in the USA each year are related to genetic predisposition [107]. Despite the recognition of multiple genetic and environmental risk factors for development of breast cancer, approximately 50 % of affected women have no identifiable risk factors other than being female and aging [108].

Treatment of breast cancer includes surgery, radiation therapy, chemotherapy, and hormone-modification therapy. Overall 5-year survival rates for breast cancer are very good—89 % irrespective of stage at diagnosis (Fig. 1.11). Localized disease can very often be cured by partial mastectomy (lumpectomy) alone or in combination with localized radiation treatment. Hence, survival of early stage (localized) breast cancer is 99 % (Fig. 1.12). Total mastectomy remains a treatment of choice for more extensive localized disease, but breast-conserving surgery has been used with increasing frequency in recent years [109]. Outcome data indicate that patients that undergo more conservative surgery with radiation therapy demonstrate survival rates that are similar to patients that are treated with total mastectomy for localized disease [110]. Five year survival rates for breast cancer patients with regional disease is 85 % (Fig. 1.12). Patients presenting with metastatic spread to regional lymph nodes are typically treated with chemotherapy, and the 5-year survival rate drops to 25 % (Fig. 1.12). The antiestrogenic drug tamoxifen is effective when used as a single agent or when used in combination with other chemotherapeutic agents in patients that are postmenopausal, have positive regional lymph node involvement, and whose tumors express estrogen or progesterone receptors [111]. Patients that receive adjuvant chemotherapy respond better to regimes that employ multiple drugs in combination. Commonly employed combinations include cyclophosphomide, methotrexate, and 5-fluorouracil (CMF), adriamycin plus cyclophosphomide, adriamycin followed by CMF, or one of these combinations with the addition of tamoxifen [109]. The decision to use adjuvant chemotherapy depends upon several variables (patient's age and general health), including the patient's estimated risk for recurrence. Typically, patients with a risk for recurrence of less than 10–15 % are spared adjuvant chemotherapy, while all others are expected to benefit from the adjuvant treatment [109].

1.6.7 Ovarian Cancer

An estimated 21,290 new cases of ovarian carcinoma were diagnosed in the USA in 2015 [3], accounting for 3 % of all female cancers (Fig. 1.3). The majority of these cancers are diagnosed in postmenopausal women. Recognized risk factors for development of ovarian cancer include advancing age (>60 years-old), infertility, use of fertility drugs (such as clomiphene), history of breast cancer and other genetic predispositions, as well as some lifestyle and dietary factors [112–119]. Pregnancy decreases the risk for ovarian cancer and multiple pregnancies increase the protective effect [120]. In addition, the use of oral contraceptives in nulliparous women reduces the risk for ovarian cancer to that for parous women [121].

Treatment for ovarian cancer typically involves surgical removal of the ovaries, the uterus, and fallopian tubes. This is usually accomplished as part of a comprehensive staging laparotomy, after which the clinical findings and histologic evaluation of the tumor are used to select appropriate postoperative therapy. A subset of patients (stage IA or IB, with well-differentiated or moderately well-differentiated tumors) exhibit excellent long-term disease-free survival in the absence of adjuvant therapy [122]. Several options exist for treatment of early-stage ovarian cancer with unfavorable prognosis, including radiation (external beam radiotherapy or intraperitoneal radioisotope) and chemotherapy. However, it is a matter of controversy whether treatment should be immediate or delayed until the disease begins to progress. The generally accepted therapy for advanced ovarian cancer is surgery followed by chemotherapy. The standard chemotherapy combination consist of paclitaxel and one of several platinum compounds (such as cisplatin or carboplatin).

Ovarian cancer accounted for 14,180 deaths in 2015 [3], making this the leading cause of death among the cancers of the female reproductive tract (Fig. 1.3). Contributing to the significant mortality associated with this cancer is the fact that there are no obvious symptoms in affected patients until late in the disease. This is reflected in the poor 5-year survival rate among patients with distant metastases at the time of diagnosis (27 %) (Fig. 1.12). In contrast, the 5-year survival rates for patients diagnosed with localized disease or regional disease are 92 % and 72 %, respectively (Fig. 1.12). However, most patients are diagnosed after development of distant metastases; 34 % of cases are diagnosed as localized/regional disease, while 60 % of cases present with distant metastases [9]. The overall 5-year survival rate for ovarian cancer is 45 % (Fig. 1.11). Successful screening for ovarian cancer would be expected to decrease mortality by increasing the percentage of affected individuals that are diagnosed early in the progression of the disease. However, the currently available screening techniques (ovarian palpation, transvaginal ultrasonography, and serum CA125 measurements) lack sufficient specificity and sensitivity to allow for routine screening [123].

1.6.8 Leukemia

Approximately 54,270 new cases of leukemia were diagnosed in the USA in 2015 [2]. These new cases were divided between myeloid (51 %) and lymphocytic (38 %) forms of the disease, with chronic forms of the disease representing 39 % of all leukemias versus acute disease representing 50 % of all leukemias [3]. The major types of leukemia include acute lymphocytic leukemia (ALL), chronic lymphocytic leukemia (CLL), acute myeloid leukemia (AML), and chronic myeloid leukemia (CML). AML represents the most common form of leukemia (20,830 new cases), followed by CLL (14,620 new cases), CML (6660 new cases), and ALL (6250 new cases). Rarer forms of leukemia include monocytic, basophilic, eosinophilic, and erythroid leukemia (combining for approximately 11 % of all leukemias). Although it is commonly regarded as a childhood cancer, leukemia affects more adults than children on an annual basis [3, 9]. Development of leukemia has been linked to certain environmental and genetic risk factors, including exposure to radiation (such as atomic bomb radiation), toxic chemicals (such as benzene), previous exposures to chemotherapeutic agents (mutagenic drugs), Down's syndrome, genetic disorders associated with chromosomal instability (Fanconi's anemia, Bloom syndrome, ataxia telangiectasia), and some viral infections [124–129]. Cigarette smoking has also been linked causally to development of leukemia, particularly in patients of advancing age [130, 131]. Exposure to electromagnetic radiation or fields has been suggested as a risk factor for development of leukemia [132], but a causal relationship has not been firmly established [129].

Acute leukemia is relatively rare, representing approximately 1.6 % of all cancers [3]. However, the acute leukemias are the leading cause of cancer-related mortality in the USA for persons less than 35 years of age [133, 134]. In 1993, leukemias accounted for 3.9 % of total cancer-related deaths among men in the USA [135]. However, leukemias were responsible for approximately 37 % of cancer-related deaths among men less than 15 years of age, and approximately 22 % of cancer-related deaths among men less than 35 years of age [135]. Likewise, in 1997, leukemia was responsible for approximately 33 % of all cancer-related deaths (both sexes combined) among individuals <20 years of age [136]. Figure 1.8 shows the age-specific incidence rates for the major forms of leukemia. ALL occurs with an incidence of >5 cases per 100,000 population for children that are less than 4 years-old, declining with increasing age to approximately one case per 100,000 population in individuals over 15 years of age [9]. In fact, ALL accounts for

the majority (approximately 76 %) of childhood leukemias (individuals <20 years-old). In contrast, AML is rare in individuals less than 40 years of age, but increases with advancing age from approximately 1.6 cases per 100,000 population at age 40 to >13 cases per 100,000 at age 70 [9]. Likewise, CML occurs very rarely in individuals less than 40 (≤1 case per 100,000 population), but increase to >6 cases per 100,000 population in individuals over age 70 [9]. The incidence of CLL is strictly age-dependent, occurring only rarely in individuals less than 45 years of age, increasing with advancing age to six cases per 100,000 population by age 65 years, and to >31 cases per 100,000 population in individuals over 85 years [6]. As can be seen in Fig. 1.8, >90 % of all leukemias occur in individuals >20 years of age [3].

Conventional treatment of leukemia involves aggressive chemotherapy. Post-remission therapy can involve bone marrow ablation (through high dose chemotherapy or whole body radiation) with allogeneic bone marrow transplant. A variety of drugs and drug combinations have been evaluated for treatment efficacy in various forms of leukemia [137, 138]. Appropriate drug regimens are chosen based upon various diagnostic and prognostic factors, including the nature of chromosomal rearrangements in the leukemic clone [139]. Improvements in chemotherapeutic drugs and drug regimens for leukemia have dramatically improved treatment success rates for several forms of leukemia. Whereas childhood ALL was nearly uniformly fatal in the 1950s, today the majority (90–95 %) of affected children achieve complete remission, and long-term survival (5-year survival) for patients diagnosed at <45 years of age is approximately 69 % [9]. The overall 5-year survival rate for patients with CLL is approximately 71 %, but is somewhat lower (58 %) among older patients (diagnosed at ≥75 years of age). In contrast, the overall 5-year survival rates for AML (approximately 15 %) and CML (approximately 32 %) remain dismally low despite improvements in treatments during the last 25 years [9]. With the exception of CLL, the long-term survival of older leukemia patients is dramatically lower than that of younger patients. In fact, most adult patients with acute leukemia ultimately succumb to their disease [140]. The 5-year survival of patients older than 65 years of age is approximately 6 % for ALL, compared to 63 % for patients younger than 65 years of age [9]. Likewise, the 5-year survival of patients older than 65 years of age is approximately 3 % for AML, compared to 25 % for patients younger than 65 years of age, and 35 % for patients younger than 45 years of age [9].

1.6.9 Lymphoma

Approximately 80,900 new cases of lymphoma were diagnosed in the USA in 2015 [3]. The majority of lymphomas are classified as non-Hodgkin lymphoma (71,850 new cases), representing 89 % of all lymphomas diagnosed [3], and the remaining cases are classified as Hodgkin lymphoma. Non-Hodgkin lymphoma is a broad category consisting of several distinct lymphoid neoplasms [141], 85 % of which are B-cell lymphomas (including follicular lymphoma, diffuse large B-cell lymphoma, mantle cell lymphoma, and several others), and 15 % of which are T-cell lymphomas (including peripheral T-cell lymphoma, anaplastic large-cell lymphoma, and several others). Risk factors associated with non-Hodgkin lymphoma include immunodeficiency associated with congenital diseases (such as ataxia telangiectasia, severe combined immunodeficiency, and X-linked lymphoproliferative disorder), acquired immunodeficiency (related to HIV infection, bone marrow transplant, or organ transplant with iatrogenic immunosuppression), various autoimmune disorders, infectious agents (Epstein-Barr virus, HTLV-1, and others), and chemical and physical agents (diphenylhydantoin, certain herbicides, radiation) [141]. Hodgkin lymphoma is a unique form of neoplasm consisting of small numbers of putative neoplastic cells (known as Reed-Sternberg cells) in an inflammatory background [142]. Most immunophenotypic and genetic data suggest that Reed-Sternberg cells represent some form of altered B-cell [142], while other evidence supports the suggestion that these cells represent a novel lymphoid cell type [143]. Risk factors for development of Hodgkin lymphoma have not been definitively characterized. However, increased incidence of this disease is associated with HIV infection, other immunodeficiency syndromes (such as ataxia telangiectasia), autoimmune disorders (such as rheumatoid arthritis), certain genetic factors, and viral infections (such as Epstein Barr virus) [144–147].

Therapeutic approaches for the treatment of non-Hodgkin lymphoma are based upon a number of factors, including the specific lymphoid neoplasm, cancer stage, prognostic factors, and the physiologic status of the patient. Treatment options include radiotherapy alone, single-agent chemotherapy, or combination chemotherapy (mild or aggressive). The majority of patients with aggressive forms of non-Hodgkin lymphoma require aggressive combination chemotherapy, often with additional radiotherapy. Treatment of Hodgkin lymphoma involves radiation therapy, radiation and chemotherapy, or chemotherapy alone. The results from a large number of randomized trials suggest some advantages of combine modality radiation/chemotherapy in the treatment of Hodgkin lymphoma over radiation alone [148]. However, there was no significant difference in the overall survival of patients between these approaches to treatment [148, 149]. Chemotherapy is effective against Hodgkin lymphoma. However, the use of drugs in combination is essential to effect complete and lasting remission of the disease [150–152].

Approximately 20,940 deaths were attributed to lymphoma in 2015, including 1150 deaths related to Hodgkin lymphoma and 19,790 deaths related to non-Hodgkin lymphoma [3].

Lymphoma affects more men than women on an annual basis, and non-Hodgkin lymphoma represents a leading site for cancer-related mortality among men. Non-Hodgkin lymphoma is the leading site for cancer-related mortality among men 20–39 years of age, accounting for 13 % of cancer deaths [136]. Furthermore, non-Hodgkin lymphoma accounts for significant numbers of cancer-related deaths among men <20 years-old (7 % of cancer deaths), and 40–79 years-old (5 % of cancer deaths). The overall 5-year survival rate for non-Hodgkin lymphoma is 72 % [2]. In general terms, long-term survival among non-Hodgkin's lymphoma patients does not differ with age. Despite an overall 5-year survival of 88 % (all races/genders) [2], there is a clear age-related difference in long-term survival among patients with Hodgkin lymphoma. Hodgkin lymphoma patients under the age of 65 display a 5-year survival rate of nearly 87 %, whereas patients older than 65 have a 5-year survival rate of only 45 %, and patients older than 75 exhibit a 5-year survival of only 31 % [9].

Essential Concepts and Techniques in Molecular Biology

2

Claudine L. Lefferts and Joel A. Lefferts

2.1 Biology of Nucleic Acids

Deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) are macromolecules that convey genetic information. Both DNA and RNA are made up of nucleotides, molecules that in turn are composed of a nitrogenous base, a sugar, and one or more phosphate groups. There are five nitrogenous bases found in nucleic acids: adenine, guanine, cytosine, thymine, and uracil. Adenine, guanine, and cytosine are found in both DNA and RNA; thymine is found only in DNA and uracil is found only in RNA. A second difference between DNA and RNA is the sugars that are incorporated into the nucleotides. The sugar in the nucleotides of DNA is deoxyribose, RNA nucleotides contain ribose. Finally, DNA molecules are double-stranded, while RNA molecules are usually single-stranded.

2.1.1 Composition and Structure of DNA

DNA is formed by the linear polymerization of nucleotides. The four nitrogenous bases found in DNA are either purines (adenine or guanine) or pyrimidines (cytosine or thymine), and the backbone of the DNA polymer is formed by linkage of these bases via deoxyribose and phosphate groups (Fig. 2.1). The informational content of DNA is governed by the sequential arrangement and primary structure of the nucleotide polymer. The DNA strand is polar, with no nucleotide attached to the 5′ position of the deoxyribose at one end (referred to as the 5′ end), and no nucleotide attached to the 3′ hydroxyl group at the other end (referred to as the 3′ end).

The DNA within the eukaryotic nucleus is arranged in a double-stranded helix composed of two strands of opposing polarity. The helix is stabilized by the formation of hydrogen bonds between complementary bases (A-T and G-C), by pi bonding that occurs when the bases are stacked together, and by the association of proteins [1, 2]. In eukaryotic cells, most of the DNA is in the B-form, a right-handed helix with bases on the inside where they are protected from damage by oxidating or alkylating agents. The Z-form of DNA occurs when a left-handed helix is formed, and is usually associated with portions of the DNA that are highly methylated and are not transcribed actively. Enzymatic reactions within the nucleus are responsible for conversion of DNA from the B-form to the Z-form and vice versa [3].

The DNA comprising the human genome is segmented into 46 discrete structural units, termed chromosomes. The DNA in each eukaryotic cell must be compressed to fit within the nucleus, which is only about 10 μm in diameter. Chromosomal DNA is condensed by the formation of nucleosomes, which consist of a group of small basic proteins (histones) with 160–180 base pairs of DNA wrapped around them [4]. Formation of nucleosomes is not sequence-dependent and it occurs in mammalian, bacterial, and viral DNA [5]. Nucleosomes are wound into a left-handed helix for further condensation of the DNA, and higher orders of structure include supercoils and/or rosettes [2]. Ultra-condensed DNA (heterochromatin) is inactive metabolically, and is found primarily in the periphery of the nucleus, while less condensed DNA (euchromatin) is readily accessible by transcription machinery and is located in the center of the nucleus [6].

2.1.2 Gene Organization

The majority of genes that are transcribed into mRNA and translated into cellular proteins exist as two copies in the nucleus of each cell, one maternal and one paternal copy. Some genes are present at a high copy number (100–250 copies) within the genome, including the genes that encode transfer RNA (tRNA), ribosomal RNA (rRNA), and the histone proteins [7]. These tandemly repeated genes are present

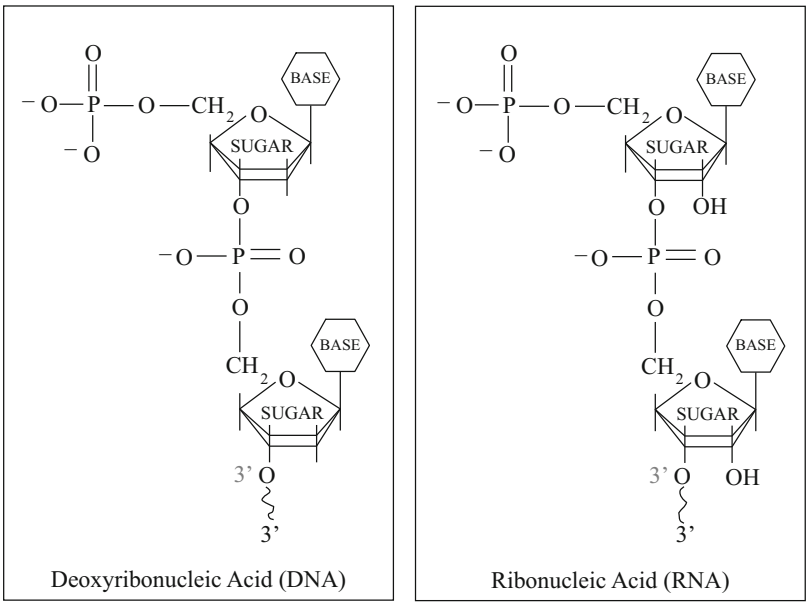

Fig. 2.1 Chemical structures of DNA and RNA.

on several chromosomes and associate in the nucleus to form a nucleolus [8, 9]. Highly repetitive sequences with thousands of copies, called satellite DNAs, are found at the telomeric ends of chromosomes and around the centromeres [10]. It is likely that the centromeric sequences play a role in the establishment and maintenance of chromosome structure. Telomeric repeats are involved in completing replication of chromosome ends [11], and it has been demonstrated that the length of the telomeric repeat sequences decreases with life-span of cultured human cells [12]. The evidence of telomeric shortening in normal cells along with observations that immortalized or transformed cells display limited telomere degeneration has led to the hypothesis that telomeric shortening is involved in the cellular aging process [12]. Other repetitive sequences, such as the *Alu* sequences, are found throughout chromosomes; their function is largely unknown, but a role in regulation of gene function has been proposed [13].

Simple polymorphic repetitive elements composed of dinucleotide or trinucleotide repeats are present in the human genome and have been associated with cancer and other diseases such as myotonic dystrophy, Fragile X syndrome, Huntington disease, and spinocerebellar ataxia [13, 14]. Symptomatic problems arise when the affected DNA is inappropriately methylated and inactivated (as in Fragile X syndrome) [15], or when the repeats cause detrimental changes in the encoded protein (as in Huntington disease) [16].

2.1.3 DNA Replication and Cell Division

In order for the DNA in a cell to be replicated prior to cell division it must be single-stranded. This is accomplished by an enzyme (helicase), which denatures the DNA and allows DNA-binding proteins to associate with the DNA and prevent reformation of the DNA helix [17]. A small strand of RNA 10–20 nucleotides in length acts as a primer, initiating synthesis of new complementary strands of DNA from multiple replication starting points. Deoxynucleotide triphosphates (dNTPs) are added to the primer by DNA polymerase, the RNA primers are removed, the gaps are filled in with dNTPs by DNA polymerase, and the nucleotide strands are joined by DNA ligase. The enzymatic action of topoisomerase removes twists generated during denaturation of the helix and allows the helix to re-form [18]. DNA replication is complete when the telomerase enzyme has added the nucleotide repeats to the telomeres at the 5′ end of the DNA strands.

As a new strand of DNA is synthesized, dNTPs are selected based on hydrogen bonding to complementary dNTPs in the template strand, which results in an error rate of 1 in 10^4–10^5 [2]. Eukaryotic cells employ a proofreading mechanism that removes mispaired dNTPs in the strand before the next dNTP is added, which decreases the error rate to 1 in 10^6–10^7 [2, 19]. Prior to cell division, another error correction system recognizes and repairs mismatched nucleotides and decreases the error rate further to 1 in 10^8–10^9 [2, 19]. Several inherited disorders are due to dysfunctional DNA damage-repair, including ataxia telangiectasia, Fanconi anemia, and xeroderma pigmentosum [20].

The DNA within the nucleus of a eukaryotic cell can be replicated completely in about 8 h, during the S phase of the cell cycle. Resting cells (G_0) receive a mitotic stimulus, which causes transition into the G_1 phase, where the cell prepares for DNA synthesis (S phase). The G_2 phase occurs after replication but before division, and mitosis (M) involves actual nuclear and cellular division. The cell cycle is pivotal in cellular and organismal homeostasis, so it is tightly controlled by phosphorylation and dephosphorylation of kinases and cyclins, and by two major checkpoints [21,

22]. The first checkpoint occurs between G_1 and S, and can prevent cells with damaged or unrepaired DNA from entering S phase. The second checkpoint occurs between G_2 and M, and can prevent the initiation of mitosis [21].

2.1.4 Structure and Composition of RNA

RNA, or ribonucleic acid, is a linear polymer of ribonucleotides linked by 5′–3′ phosphodiester bonds (Fig. 2.1). RNA differs from DNA in that the sugar group of RNA is ribose, rather than deoxyribose, thymine is replaced by uracil (U) as one of the four bases, and RNA molecules are usually single-stranded. The extra hydroxyl group present on the ribose causes RNA to be more susceptible to degradation by nucleases than DNA. Single-stranded RNA molecules form complex secondary structures, such as hairpin stems and loops, via Watson–Crick base pairing between adenine and uracil, and between guanine and cytosine.

RNA molecules are classified by function and cellular location, and there are three major forms of RNA in eukaryotic cells. Ribosomal RNA (rRNA) is the most stable and most abundant RNA. rRNA is highly methylated, and complexes with proteins to form ribosomes upon which proteins are synthesized [23]. In eukaryotic cells, two major species of rRNA are present, 28S and 18S, as well as two minor species of 5.8S and 5S. Transfer RNA (tRNA) is responsible for carrying the amino acid residues that are added to a growing protein chain during protein synthesis. All tRNAs form secondary structures consisting of four stems and three loops, and many bases found in tRNA are modified by methylation, ethylation, thiolation, and acetylation [24, 25]. Messenger RNA (mRNA) mediates gene expression by carrying coding information from the DNA to the ribosomes, where the mRNA molecule is translated into protein. Messenger RNA is the most heterogeneous type of RNA, and also has the shortest half-life.

Many other RNA species exist in eukaryotic cells. Heterogeneous nuclear RNAs (hnRNA) are the precursors to mature mRNA [26]. Small nuclear RNAs (snRNAs) associate with proteins to form small nuclear ribonucleoprotein particles, which participate in RNA processing [27]. Small interfering RNAs (siRNAs) and microRNAs are double-stranded RNAs 21–25 nucleotides in length involved in regulation of gene expression at the translational level [28].

2.1.5 Transcription of RNA

Even simple eukaryotic organisms, such as yeast, contain a large number of genes (~2000), and higher eukaryotes, such as mammals, have ~20,000–25,000 protein encoding genes [29]. Clearly, the proteins encoded by all genes are not expressed simultaneously at any given time. Transfer of genetic information from DNA to protein begins with synthesis of RNA molecules from a DNA template by RNA polymerase, a process termed transcription. The RNA polymerase holoenzyme works processively, building an RNA chain with ribonucleoside triphosphates (ATP, GTP, CTP, UTP) [30]. Initiation of transcription involves association of the transcription machinery (RNA polymerase and transcription factors) with the DNA template and the synthesis of a small ribonucleotide primer from which the RNA strand will be polymerized [31]. Initiation of transcription is not random, but occurs at specific sequences called promoters that are located at the 5′-end of genes. Every gene initiates transcription independently at its own promoter, therefore the efficiency of the process varies greatly depending on the strength of the promoter. Once RNA polymerase binds to a promoter, the DNA helix is opened and an RNA primer is synthesized. Elongation occurs as the RNA polymerase moves along the DNA strand, opening the DNA helix and conducting DNA-directed RNA synthesis until the gene is transcribed [30]. Termination of transcription is poorly understood in eukaryotes, but takes place at sites that include a stretch of Ts on the non-template strand of the gene [32].

2.1.6 RNA Processing

The majority of eukaryotic RNAs require extensive modifications before they attain their mature structure and function. RNA strands may be modified by (1) the removal of RNA sequences, (2) the addition of RNA sequences, or (3) the covalent modification of specific bases. The long, relatively unstable mRNA precursor strand (hnRNA) is synthesized and remains in the nucleus where it is subjected to several stability-enhancing processes. With the exception of mitochondrial mRNAs, the 5′-ends of eukaryotic mRNA precursor molecules are capped, which involves removal of the terminal phosphate group of the 5′-nucleoside triphosphate and subsequent linkage of the 5′-diphosphate group to a GTP molecule [33]. The cap structure is covalently modified by methylation of the newly added guanine. The hnRNA is also modified at the 3′ end by the addition of a poly-A tail, a string of 50–250 adenine residues. The poly-A tail serves to extend the life of the mRNA by protecting the 3′-end of the molecule from 3′-exonucleases, and may also act as a translational enhancer [34]. The mRNA molecule is stabilized further by the association of a ~70 kDa protein with the poly-A tail [35].

The majority of protein-encoding eukaryotic genes contain intervening sequences, termed introns, which do not encode any portion of the protein. These introns, which may be between 65 and 10,000 nucleotides in length, are maintained during transcription of the hnRNA molecule, resulting in production of a long hnRNA that must be modified in order to become a continuous template for synthesis of the encoded protein. Maturation of the hnRNA requires a splicing event in which the introns are removed in conjunction with the joining

of the coding sequences, termed exons. Three short consensus sequences are necessary for splicing to occur; two are found at the intron–exon boundary at both the 5′ and 3′ of the intron and the third is found within the intron near the 3′-end [36]. The consensus sequences mark splice sites and act as targets for the spliceosome, a large multisubunit protein complex comprised of 45 proteins and thousands of snRNA [36]. The spliceosome catalyzes removal of introns and rejoining of exons, ultimately resulting in the formation of a protein-encoding mRNA. Some genes encode for more than one protein, which is accomplished by alternative splicing of the primary hnRNA transcript. One mechanism of alternative splicing involves removal of one or more exons during splicing when the spliceosome ignores one or more intron–exon boundaries [37]. Alternative transcripts may also be generated by the use of a secondary polyadenylation site [38].

RNA processing is not limited to mRNA. Eukaryotic tRNAs are modified posttranscriptionally, as are eukaryotic rRNAs [39]. Introns present within rRNAs are classified as Group I or Group II introns. Group I introns are removed as linear molecules by a self-splicing mechanism that requires magnesium and guanosine as cofactors [40]. Group II introns are also self-splicing, are removed as a lariat structure, and require spermidine as a cofactor [41].

2.2 Basic Molecular Analysis and Interpretation

Investigations into the molecular mechanisms of disease depend on the analysis of cellular and often times microbial DNA and RNA to identify and characterize the genes involved. Target genes can be identified, localized to specific chromosomes, amplified by cloning, and subjected to sequence analysis. DNA analyses are used practically in the identification of individuals for forensic or parentage testing, detection of gene mutations, amplifications, and deletions, associated with disease and RNA analyses to characterize gene expression in various forms of human cancer.

2.2.1 Isolation of Nucleic Acids

In theory, nucleic acids can be isolated from any tissue that contains nucleated cells. Common starting material for nucleic acid isolations include blood and other body fluids, cultured cells, buccal swabs, and a variety of fresh, frozen, or formalin-fixed, paraffin-embedded (FFPE) tissue specimens. Although isolation may need to be optimized for any particular tissue type or sample and application, there are basic steps in the extraction process that are universal: the cells must be lysed, proteins and cellular debris must be removed, and the nucleic acid must be made available in solution.

FFPE tissue is the most common specimen type used when interrogating solid tumors for somatic changes in the clinical setting. FFPE tissue is readily available following tumor resection or biopsy, is easily stored at room temperature and the tissue being used for molecular analysis can be viewed microscopically to determine the precise histological diagnosis and to determine the adequacy of the specimen (percent tumor cells, exclude excessive necrosis, etc.). Nucleic acid derived from FFPE tissue, however, can be very problematic because the fixation process degrades nucleic acid and creates cross-links between nucleic acids and proteins. Molecular analysis of FFPE tissue, therefore, requires special attention during isolation and the design of downstream molecular applications. For example, the majority of an FFPE DNA sample is fragmented to 100-200 bp and will not work at all in most assays designed for high quality DNA. Assays specifically designed to detect these smaller fragments must be used in when FFPE-derived DNA is needed.

Before nucleic acids can be separated from the rest of the cellular contents, the cells must be lysed. This is often accomplished in some type of lysis buffer that can contain agents such as proteinase K and sodium dodecyl sulfate which are needed to digest structural proteins and to disrupt the cellular and nuclear membranes. Some samples such as solid tissues often require additional steps first, such as mincing, homogenization, or freezing the sample in liquid nitrogen followed by pulverization with a mortar and pestle to obtain a complete lysis. After the sample has been adequately lysed, the protein component in the sample must be removed. This can be accomplished in several ways, including: (1) adding a phenol–chloroform–isoamyl alcohol mixture to the sample which contains an organic phase and an aqueous phase whereby proteins and lipids dissolve into the organic phase and nucleic acids are retained in the aqueous phase of the mixture; (2) precipitation of proteins; (3) absorbance of nucleic acids to a column or magnetic bead and washing away proteins.

After the DNA has been separated from the rest of the other cell components, it must be transferred to a suitable buffer such as tris–EDTA (TE) or deionized water. This can be accomplished by adding ethanol or isopropanol which causes the DNA to precipitate out of solution. The DNA can then be pelleted by centrifugation, and resuspended in deionized water or a buffer. Alternatively, nucleic acids can be eluted directly from columns or magnetic beads in some of the more automated methods.

Due to the time involved and the toxicity and waste disposal issues associated with phenol, many laboratories choose other isolation protocols that remove proteins by other means. After lysis of the cells a protein precipitation solution can be added followed by centrifugation to separate the DNA from the cellular proteins. DNA can then be further purified by the use of silica gel particles in suspension or bound in a column. These silica columns can be purchased from numerous companies and are available in a wide range of formats and sizes, including the popular spin columns which rely on centrifugation to move solutions through the column. DNA binds to the silica gel as it passes through the column, allowing unwanted

salts and contaminants to wash through. After the DNA is bound to the column it can be washed and then eluted off the column with water or a low salt buffer such as TE. Similar methods have been developed using magnetic beads capable of binding DNA in solution. DNA can be purified by binding it to these beads in a tube. When these tubes are placed next to a magnet, the beads can be held in place on the side of the tube while the original solution and contaminants are removed. This process can then be repeated with wash solutions and finally an elution buffer that is often heated to facilitate removal of the DNA from the beads.

Although these alternative methods can be faster, they are often more expensive and can result in lower yield and slightly lower quality DNA. However, this is not generally a problem for most molecular techniques commonly used today. Another improvement on traditional nucleic acid isolation methods has been the introduction of automated isolation systems which can greatly reduce the hands-on time needed for isolating DNA. Once loaded, these instruments can go through the entire DNA isolation procedure, often using some form of magnetic separation. Although these automated systems are much more expensive than manual methods, the time they save will often make these systems a valuable investment for laboratories that process larger numbers of samples.

RNA isolation methods are similar to those for DNA. However, when isolating RNA extra care must be taken to avoid RNA degradation due to its susceptibility to RNA-digesting enzymes (RNases). To avoid RNase digestion of the sample, it is often necessary to work quickly and to work in a clean area. Care should be taken to ensure that all solutions purchased for use in these extractions have been designated as "RNase-free" or treated with special chemicals such as diethylpyrocarbonate (DEPC) that inactivate RNases.

2.2.2 Use of Enzymes in Molecular Biological Techniques

DNA or RNA isolation techniques only produce the starting material needed for molecular evaluation of nucleic acid. Almost every method used to examine DNA or RNA relies heavily on the use of enzymes, often isolated from various microbial species. These enzymes can be exploited to perform various tasks such as selectively cutting DNA or RNA into smaller pieces or digesting them completely, modifying the ends of DNA strands to remove or add phosphate groups, ligating two strands of DNA together to form one, and replicating nucleic acids.

2.2.2.1 Nucleases

Nucleases make up a diverse group of enzymes that are able to cleave or digest nucleic acids. This group of enzymes can be divided into various classifications based on the type of nucleic acid they use as substrates and the way in which they digest. Exonucleases begin digesting nucleic acids at the ends while endonucleases make internal cuts in a nucleic acid molecule. Restriction endonucleases make up a very large group of enzymes found in bacteria that recognize very specific sequences of DNA, often six base pairs in length. For example, the restriction endonuclease EcoRI (isolated from *E. coli*) recognizes the sequence GAATTC and makes a single cut within this recognition site. If the sequence of a particular piece of DNA is unknown, observing the digestion patterns of various restriction enzymes can provide valuable information about its sequence. For example, if a particular mutation occurs within the recognition sequence of a specific restriction enzyme, that enzyme may not cut when the mutation is present.

When complete digestion of DNA or RNA is desired, for example when DNA is being isolated and contaminating RNA is not desirable, RNase can be used to selectively digest the RNA, leaving a pure population of DNA. In the same way, DNases can be used to digest unwanted DNA molecules in an isolation of RNA.

2.2.2.2 DNA Ligases, Kinases, and Phosphatases

In addition to digesting DNA, enzymes are also available which facilitate the joining or ligation of two or more DNA fragments. Enzymes with this capability are called DNA ligases and commercially, T4 DNA ligase is widely available and most often used in molecular laboratories. Since DNA ligases work by creating a phosphodiester bond between the 5′ phosphate and 3′ hydroxyl termini of two DNA strands, the presence of the 5′ phosphate is essential. DNA phosphatases, such as calf intestinal phosphatase or shrimp alkaline phosphatase, remove the phosphate group on the 5′ end of a DNA strand, preventing ligation; a DNA kinase, T4 polynucleotide kinase, can restore the 5′ phosphate in order to allow ligation.

2.2.2.3 Polymerases

DNA and RNA polymerases are enzymes that synthesize new strands of DNA or RNA, normally using a preexisting strand of DNA (or RNA) as a template. Reverse transcriptase is another polymerase that is unique in its ability to use RNA as a template for synthesizing DNA. DNA polymerases are essential for the polymerase chain reaction (PCR), a technique described below that has revolutionized molecular biology.

2.2.3 Electrophoretic Separation of Nucleic Acids

Gel electrophoresis of DNA is widely used in procedures such as Southern blotting and PCR in which separation or sizing of a population of DNA fragments is an essential step in the analytical process. In some cases, a significant amount of information can be gleaned from relatively simple electrophoretic procedures that take advantage of the various properties of DNA molecules (i.e., charge, size, and conformation).

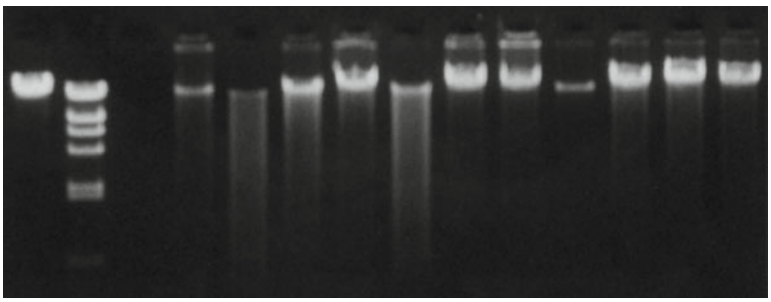

Fig. 2.2 Agarose gel electrophoresis of human genomic DNA.

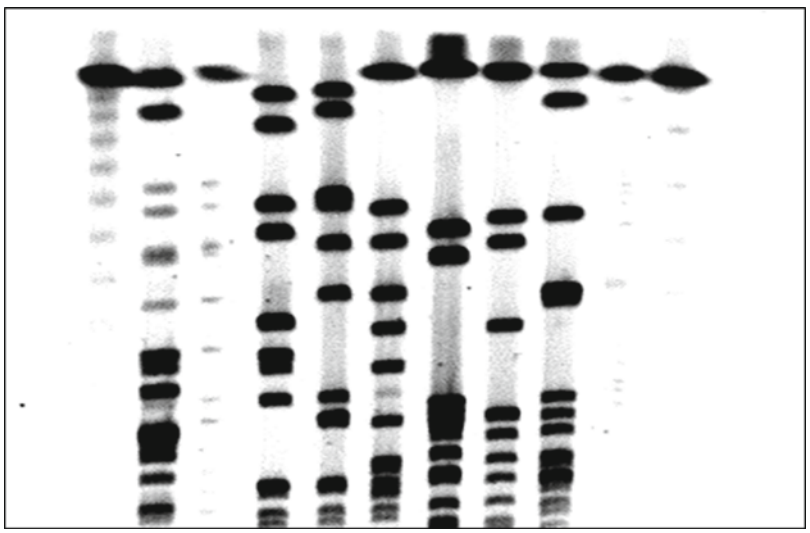

Fig. 2.3 Pulse field gel electrophoresis for strain typing of *Staphylococcus aureus.*

Gels employed in electrophoretic techniques are generally composed of agarose or polyacrylamide, which act as a matrix through which DNA (or RNA) will travel when an electric current is passed through the gel. Generally, larger fragments of DNA will migrate more slowly through the gel and smaller fragments will migrate more quickly. DNA of a given size will travel through the gel at the same rate and form a band that is visualized by staining the gel with a dye such as ethidium bromide, which binds to DNA and fluoresces when viewed under UV light (Fig. 2.2). Agarose gels are useful in most traditional molecular techniques for visualizing DNA greater than 100 base pairs. However, when smaller DNA fragments are to be analyzed, special agarose formulations or polyacrylamide gels are needed for proper resolution and visualization.

When larger fragments of DNA need to be resolved, a technique called pulsed-field gel electrophoresis can be utilized. Conventional gel electrophoresis techniques are not useful for separation of extremely long pieces of DNA, because the constant current eventually unravels the DNA strands completely so that they travel, end first, through the gel at a rate that is independent of their length. Pulsed-field gel electrophoresis (PFGE) overcomes this challenge by periodically switching the orientation of the electric fields with respect to the gel, thus preventing the DNA strands from losing secondary structure and allowing long strands to be size-differentiated [42]. PFGE is often used in the identification of pathogens [43], i.e., differentiating between strains of bacteria (Fig. 2.3). Other applications include chromosomal length polymorphism analysis, and large-scale restriction and deletion mapping in DNA that is hundreds or thousands of kb in length. The effectiveness of PFGE is dependent on high-integrity starting material, and DNA that is degraded or sheared will not yield informative results. High quality DNA is often generated by embedding the cells of interest in agarose plugs, lysing cell membranes with detergent, and removing proteins enzymatically, leaving intact DNA which can be digested by restriction enzymes in situ and easily loaded into a gel apparatus [42, 44]. In a typical analysis, PFGE will produce a pattern of DNA fragments that range in size from 10 to 800 kb.

Electrophoresis of RNA to check the quality of a sample or for blotting techniques is typically accomplished by electrophoresis through a 1–2 % agarose gel containing formaldehyde, which maintains the denatured state of the RNA strands. When secondary structure of an RNA molecule is to be investigated, samples are subjected to non-denaturing polyacrylamide gel electrophoresis.

2.2.4 Denaturation and Hybridization

The majority of techniques used in molecular analyses require single-stranded nucleic acids as starting material. Prior to hybridization with a complementary nucleotide sequence such as an oligonucleotide primer or a nucleic acid probe, double-stranded DNAs and single-stranded RNAs must be denatured to generate single strands and eliminate secondary structure. Denaturation of nucleic acids is rapid, and can be induced by various conditions, including extremes of pH (pH < 4 or pH > 10), hydrogen-bond disrupting agents (such as urea or formamide), or heat [45]. Heat is the most commonly used means of disrupting the hydrogen bonds that occur between complementary strands of double-stranded DNA to produce single-stranded DNA. The melting temperature (T_m) of a specific double-stranded DNA sequence is reached when the disruption of the hydrogen bonding in a population of DNA causes 50 % of the DNA to become single-stranded. Since more hydrogen bonding occurs between G and C as compared to A and T, the T_m will be greater for DNA containing a larger percentage of G and C nucleotides. The denaturation process is easily monitored by spectrophotometry, since the absorbance of the DNA at 260 nm increases as denaturation progresses [45].

Hybridization of nucleic acid strands is a relatively slow process and the rate is governed by the relative concentration of strands with complementary sequences and by the temperature. When two complementary strands are aligned properly, hydrogen bonds form between the opposing complementary bases and the strands are joined. Target nucleic acid sequences can hybridize to a complementary DNA (cDNA) or RNA strand, or to other complementary sequences such as oligonucleotide primers or nucleic acid probes. Hybridization between two complementary RNA molecules is strongest, followed by RNA–DNA hybrids, and DNA–DNA hybrids [46].

2.2.5 Concepts and Applications of Southern Blotting

Southern blotting is a technique that relies heavily on the concepts of denaturation and hybridization of DNA. Southern blotting has been used in clinical or forensic settings to identify individuals, determine relatedness, and to detect genes associated with genetic abnormalities or viral infections. Southern blot analysis is also used in basic scientific research to confirm the presence of an exogenous gene, evaluate gene copy number, or to identify genetic aberrations in models of disease. Although this technique has been replaced to a large extent by newer, faster techniques, it still has its place in a molecular laboratory.

The first step in successful Southern blotting is to obtain DNA that is reasonably intact (Fig. 2.4). DNA that has been degraded by excessive exposure to the elements or mishandling will not produce a good quality Southern blot because it cannot be fragmented uniformly prior to the blotting procedure. The test DNA must be fragmented with restriction enzymes, which cut the double strands of DNA at multiple sequence-specific sites, creating a set of fragments of specific sizes which represent the regions of DNA between restriction sites. The fragmented DNAs are size-fractionated via agarose gel electrophoresis and are subsequently denatured, which enables them to later be hybridized to complementary nucleic acid probes. The DNA from the gel is transferred to a solid support such as a nylon or nitrocellulose membrane via capillary action or electrophoretic transfer and is bound permanently to the membrane by brief UV crosslinking or by prolonged incubation at 80 °C. Blots at this stage may be stored for later use or may be probed immediately. For detailed protocols, the reader is referred to other sources [46, 47].

Interpretation of the Southern blot is easy when the question is whether or not a gene is present in a particular sample, as long as appropriate positive and negative controls are included (a sample of DNA known to be positive and a sample of DNA known to be negative). The presence of multiple copies of a gene indicates gene amplification, which may occur in oncogenes during cancer development [48, 49]. Amplifications are obvious on a Southern blot as a band or bands that are more intense than the normal single-copy control; numerical values that reflect intensity may be assigned to bands using a densitometer. Structural aberrations in a gene of interest can be detected by Southern blotting, including the insertion or deletion of nucleotides or gene rearrangements (Fig. 2.4). When nucleotides are mutated, inserted, or deleted, the ladder of fragments produced may be abnormal due to the obliteration of restriction sites, the generation of novel restriction sites, or alterations in fragment size due to an increase or decrease in the number of nucleotides between restriction sites. The majority of these aberrations are apparent on Southern blots as abnormal banding patterns. The Southern blot remains a useful and reliable way to obtain definitive data on gene structure.

2.2.6 Polymerase Chain Reaction (PCR)

The development of PCR has increased the speed and accuracy of DNA analysis, and has resulted in the rapid development of new and creative techniques for detecting, replicating, and modifying DNA. Since it was described originally [52, 53], PCR has evolved to encompass an enormous array of specific applications. This section will cover the basic concepts of PCR and several applications that are useful in molecular analyses of cancer. For a complete technical description of PCR techniques, the reader is referred to a more detailed source [50].

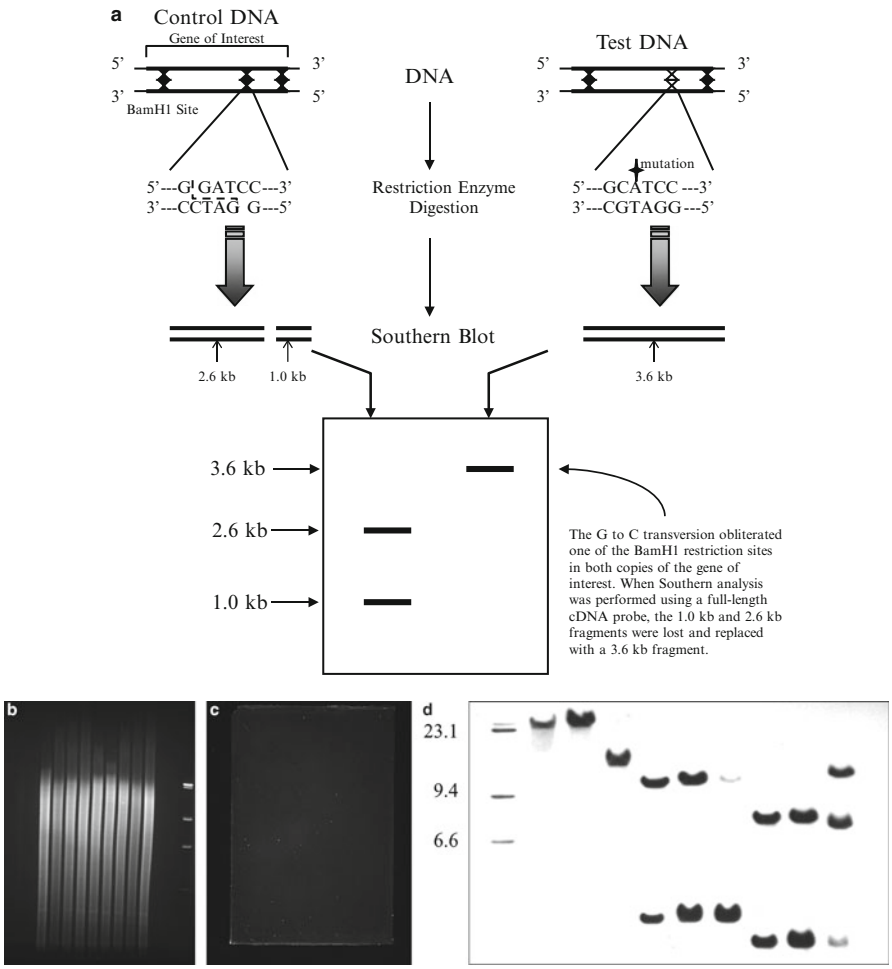

Fig. 2.4 Southern blotting. Variations in DNA sequences that alter restriction endonuclease recognition sites can be detected by Southern blotting (**a**). After digesting genomic DNA with restriction endonucleases, the DNA is subjected to agarose gel electrophoresis and then transferred to a membrane. The agarose gel can be imaged before (**b**) and after (**c**) the transfer has taken place to confirm adequate amounts of digested DNA and proper transfer of the DNA from the gel to the membrane. The membrane is then incubated with radiolabeled or chemiluminescent DNA probes which hybridize to specific DNA fragments. Exposing the membrane to film allows for visualization and sizing of these fragments (**d**).

2.2.6.1 Principles of PCR

Every PCR reaction must contain several key components: a small amount of target DNA to be used as a template; a thermostable polymerase, such as *Taq* polymerase that is not denatured at high temperatures; a pair of single-stranded DNA oligonucleotide primers; and deoxynucleotides (dNTPs), the building blocks for the DNA to be amplified. The DNA may be genomic DNA isolated directly from experimental or patient material, or it may be cDNA that has been synthesized from an RNA template by reverse transcriptase. The target for any PCR reaction is dictated by the specific oligonucleotide primers used. Two primers are designed to anneal to sites at either end of the region of interest, on opposite template strands (Fig. 2.5). The primers are extended in the 5′–3′ direction by DNA polymerase to yield overlapping copies of the original template. PCR is a cyclic process, consisting of three steps: denaturation of template (94 °C), annealing of primers (temperature is sequence dependent; often between 50 and 60 °C), and extension of primers (72 °C). The three steps are repeated, with each cycle resulting in amplification of the target sequence. By the end of the third cycle, a new double-stranded molecule is formed in which the 5′- and 3′-ends coincide exactly with the primers [51, 52]. The copies that are produced of this targeted DNA sequence are referred to as the amplicon. These double-stranded molecules accumulate exponentially during subsequent cycles of PCR, so that the majority of products are of a defined size and are seen clearly as a sharp band upon electrophoretic separation. Due to the incredible sensitivity of PCR, even a miniscule amount of DNA can be amplified, which makes it a powerful tool but also mandates that precautions are taken to avoid introduction of contaminating DNA which could result in misinterpretation.

2.2.6.2 Design of Primers for PCR

When constructing primers for PCR, it is important to keep in mind a few basic concepts. Primer length can influence target specificity and efficiency of hybridization. As a general guideline, primers should be 20–30 nucleotides in length. Whenever possible, both primers should be the same length because primer length is considered when calculating an appropriate annealing temperature. The base composition of the primers is also important, since annealing temperature is governed in part by the percent G+C content of the primers. Ideally, G+C content is between 40–60 %, and the percent G+C should be the same in any primer pair. A simple formula can be used to

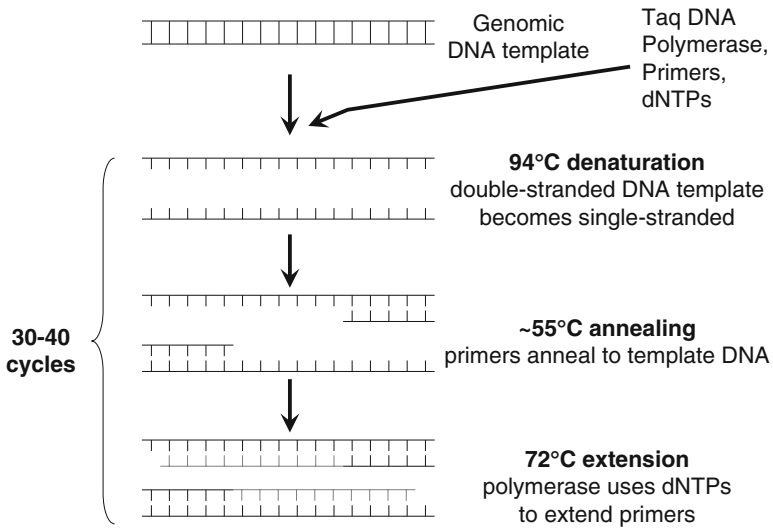

Fig. 2.5 The polymerase chain reaction (PCR). Specific sequences of DNA are amplified by PCR using pairs of oligonucleotide primers. Genomic DNA, primers, *Taq* DNA polymerase, and deoxynucleotides (dNTPs) are combined in a suitable buffer and subjected to repeated cycles of alternating temperatures which denature the template DNA, allow for primer annealing to the template and finally extend the primer to create a new strand of DNA.

calculate an appropriate annealing temperature for any given primer: $T_m = 69.3 + 0.41(\%G + C) - (650/L)$, where L = primer length in bases [53]. Repetitive or palindromic sequences should be avoided in a primer to avoid self-hybridization, and primer pairs should not contain sequences complementary to each other to avoid primer dimers.

2.2.6.3 The Role of Polymerase in PCR

A DNA polymerase enzyme is essential for the primer extension step of PCR. Early PCR experiments employed the Klenow fragment of *E. coli* DNA polymerase I, but this enzyme is heat labile and must be replenished with each amplification cycle. The developments of thermostable DNA polymerase and commercially available thermal cyclers have greatly improved the efficacy of PCR methodology. *Taq* DNA polymerase was isolated from *Thermus aquaticus*, and is characterized by its 5′–3′ exonuclease activity, thermostability, and optimum performance at 70–80 °C [54, 55]. Temperature, pH, and concentration of Mg^{++} influence the activity of *Taq* polymerase. Lower divalent cation (Mg^{++}) concentrations decrease the rate of dissociation of enzyme from template by stabilizing the enzyme-nucleic acid interaction [56]. The optimum pH for a given PCR reaction will be between 8.0 and 10.0 (usually ~8.3), but must be determined empirically. While *Taq* DNA polymerase is ideal for routine PCR, there are many other DNA polymerases with unique qualities which make them useful for special PCR applications such as amplification of long stretches of DNA or high-fidelity amplification [56].

2.2.6.4 Detection of PCR Products

Once the PCR is complete, the products must be analyzed and interpreted. Amplification products of routine PCR reactions can be separated by standard agarose gel electrophoresis and visualized by staining with ethidium bromide or other DNA dye. When finer resolution is needed, such as in the analysis of very small (<100 bp) products, polyacrylamide gel electrophoresis is standard. In addition, newer technologies such as bead arrays, microarrays, and capillary electrophoresis can be used to detect PCR products (Fig. 2.6).

2.2.6.5 Contamination Issues

Due to the extreme sensitivity of PCR, care must be taken to avoid exposing PCR reagents, set-up areas, and equipment to DNA that is not intended to be a part of the PCR reaction, especially amplicons from previous PCR runs. Unwanted false-positive results can occur if issues of contamination are not addressed. One laboratory practice that is often used to avoid this type of contamination issue is designating separate pre- and post-PCR work areas. After a PCR run is complete, all handling of the amplicon, such as for gel electrophoresis, is performed in an isolated work area with equipment that is designated for post-PCR use only. Pipettes, pipette tips, and buffers, for example, used in post-PCR handling should not be outside of the area designated for post-PCR work. Gloves used in this area should also be discarded before returning to other work areas in the lab. Additionally, the use of filtered pipette tips, especially in the pre-PCR work area, can help in eliminating PCR contamination issues.

2.2.7 Modifications and Improvements of PCR

Many variations to the original PCR procedure have been developed to improve its utility, ease, sensitivity, and specificity. Many companies now offer PCR master mixes which contain a DNA polymerase and dNTPs in buffers optimized to amplify most target sequences. This often eliminates the need for exten-

sive optimization of PCR components and cycling conditions and simplifies PCR set-up by only requiring the addition of a DNA template and primers to the master mix. In order to eliminate some types of PCR contamination, some master mixes are available that contain the enzyme uracil N-glycosylase (UNG) and the nucleotide dUTP along with the normal dNTPs needed for PCR. If a PCR is contaminated by an amplicon from a previous PCR made with dUTP, a pre-amplification incubation will degrade the contaminating amplicon, preventing it from being used as a template in the current PCR.

2.2.7.1 Hot Start PCR

Hot start PCR was developed to reduce background from nonspecific amplification by preventing polymerization of new DNA during the set-up and the initial phase of the reaction when nonspecific binding may occur between primers and other DNAs in the mixture [57, 58]. Hot start may be achieved by limiting the initial Mg^{++}, dNTP, or enzyme concentration, or by separating the components with a barrier, such as wax beads that melt as the mixture is heated. Alternatively, hot start polymerases bound by antibodies or

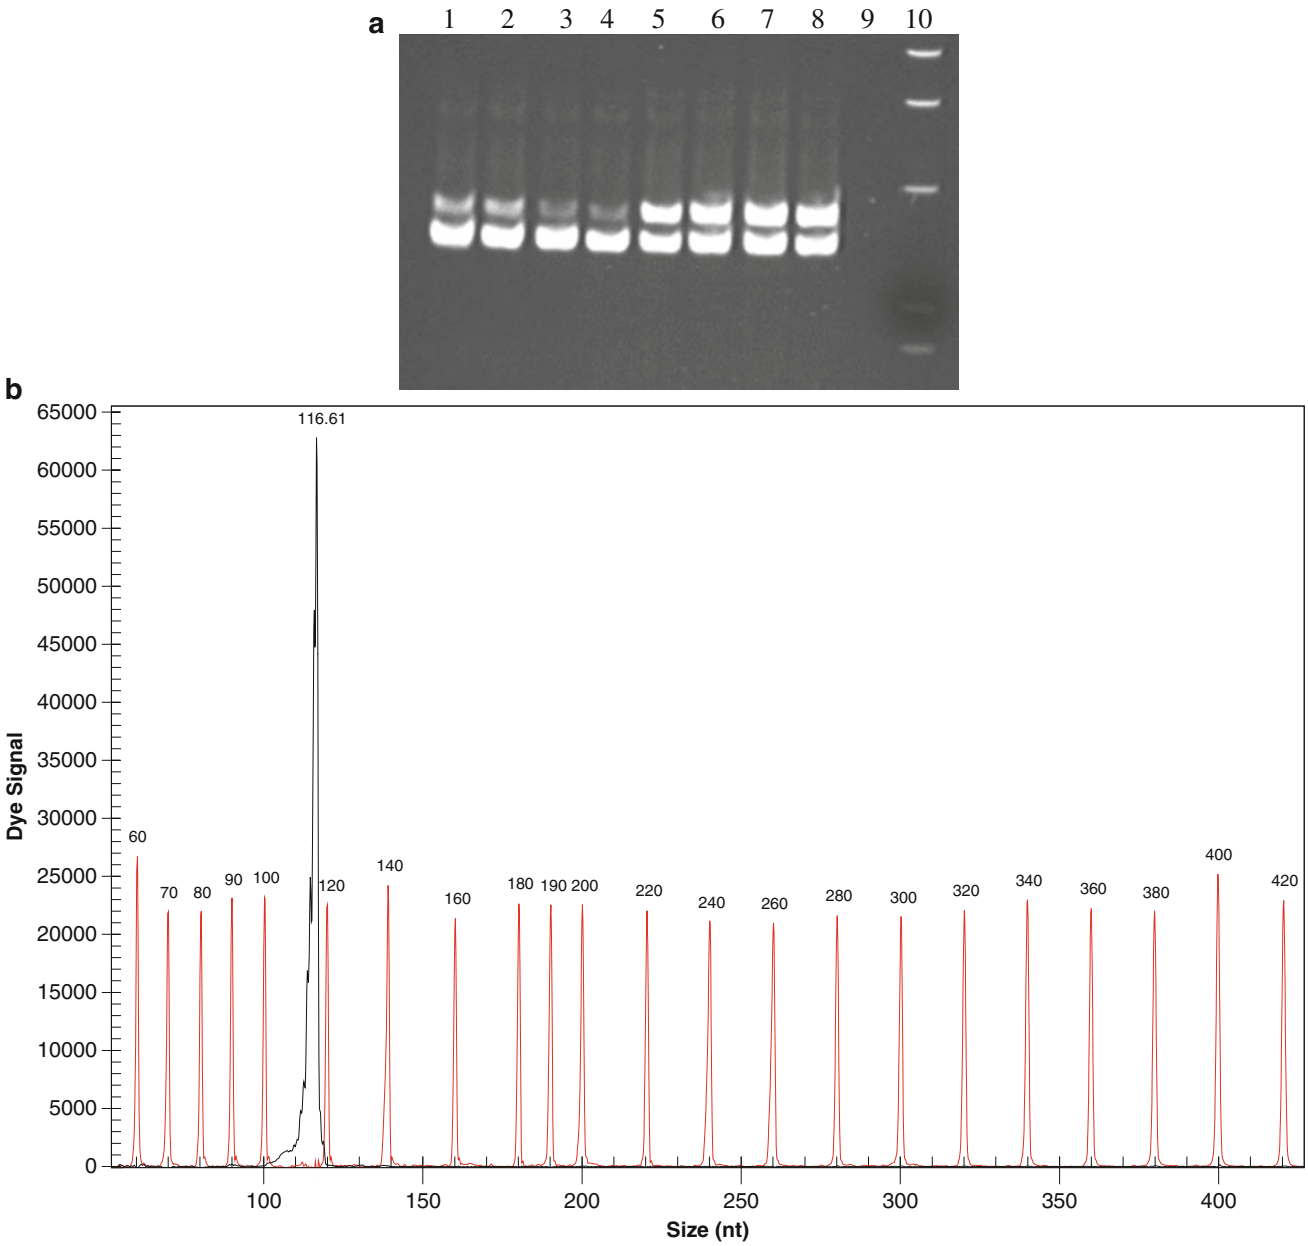

Fig. 2.6 Methods for analysis of DNA amplified by PCR. Gel electrophoresis separates DNA fragments based on size since smaller DNA fragments migrate at a faster rate through the gel (**a**). When DNA of an unknown size is run alongside a "ladder" containing DNA fragments of known sizes, the length of the unknown DNA can be estimated. More precise sizing of DNA can be made when using capillary electrohoresis (**b**), in which fluorescently labeled DNA (*black peak*) is moved through thin capillary tubing along with a DNA sizing standard (*red peaks*) to obtain higher resolution than possible with standard gel electrophoresis. Alternatively PCR-amplified DNA can be analyzed based on sequence due to its ability to hybridize with probes in microarrays and bead arrays (**c**).

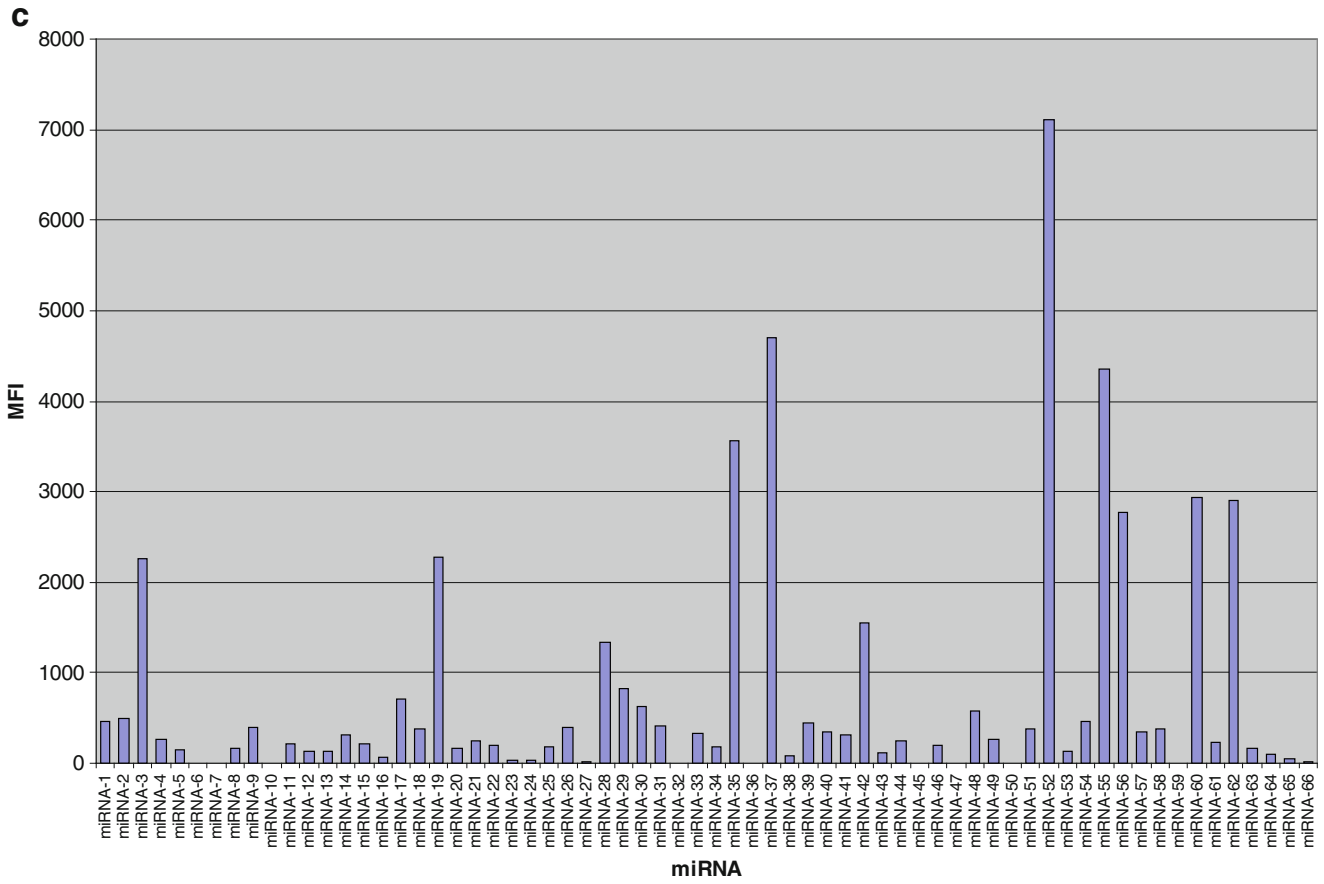

Fig. 2.6 (continued)

other molecules are enzymatically inactive until a high temperature incubation (immediately preceding normal PCR cycling) activates the polymerase, thereby preventing premature or nonspecific DNA amplification in the time between mixing the components of the reaction and the PCR cycling.

2.2.7.2 Touch-Down PCR

Touch-down PCR was developed to enhance amplification of the desired target sequences while reducing amplification of artifacts [59, 60]. The initial cycle begins with an annealing temperature that is greater than the expected T_m of the primer and the annealing temperature is lowered progressively with each cycle. As a result, the desired amplicon will accumulate preferentially while the amplification of undesired products is minimal.

2.2.7.3 Nested PCR

Performing nested PCR can increase both the sensitivity and specificity of amplification [52]. The amplification product(s) generated in the first PCR reaction are used as the template for a second PCR reaction, in which primers are used that are internal, or nested, within the first primer pair. Nonspecific products that are produced within the first round of PCR are not likely to contain sequences complementary to the nested primers, so that spurious products are eliminated during the second round of PCR. Extremely rare target sequences can be detected using nested PCR, since the first round of PCR effectively amplifies the specific template for the second round of PCR. Due to the sensitive nature of nested PCR, special care must be taken to avoid contamination.

2.2.7.4 Long-Distance PCR

It is possible to amplify sequences as large as 50 kb using long-distance PCR (LD-PCR) [61]. One step toward successful LD-PCR is the use of thermostable, long-life polymerases that are capable of generating long strands of cDNA. The first LD-PCR was accomplished by using a 5′-endonuclease-deficient, N-terminal deleted variant of *Taq* DNA polymerase in combination with Pfu DNA polymerase in a 180:1 ratio [62]. Many special DNA polymerases capable of performing well in LD-PCR are now available commercially. Other prerequisites for successful LD-PCR are high quality DNA for use as template, and carefully constructed primers with matching melting temperatures.

2.2.7.5 Reverse Transcriptase PCR (RT-PCR)

Specific RNA sequences can also be detected using PCR. An enzymatic reaction using reverse transcriptase creates a complementary DNA (cDNA) copy of the RNA, which can then be amplified using standard PCR conditions. RT-PCR is

a useful tool for detecting the presence or absence of mRNAs for specific genes and can be performed quantitatively or semiquantitatively to detect variations in gene expression between samples.

2.2.7.6 Multiplex PCR

Often it is desirable to amplify more than one target sequence at a time. The use of more than one pair of PCR primers in a single reaction is often possible, although these multiplexed reactions become increasingly difficult to optimize with increasing numbers of amplicons. Designing primers with similar melting temperatures helps ensure successful multiplexed PCRs and using Mg^{++} concentrations that are higher than normal PCRs is usually necessary.

2.2.7.7 Quantitative PCR

Quantitative PCR provides a quick and simple alternative to Southern blot analysis for the evaluation of gene copy number or gene expression levels [63]. The underlying premise for quantitative PCR is that the accumulation of amplified products occurs exponentially and follows a predictable curve. The overall profile of product accumulation throughout the course of a reaction may be reproducible enough to extrapolate the amount of starting material. Accurate quantification requires that the analysis be done during the exponential (sloped) part of the amplification curve, and not during the plateau phase when the DNA amplification rate has leveled off. Accurate quantitative PCR experiments using traditional (endpoint) PCR methods must include control template fragments, which may be synthesized or may be isolated from other sources. The control fragments should have priming sites and secondary structure that is identical to the test DNA, but should be sufficiently different in size that they can be discriminated upon electrophoretic separation. In a typical quantitative PCR reaction, replicate tubes are prepared with a fixed concentration of test DNA; then known quantities of control DNA are added in a range of concentrations, PCR is conducted, and the samples are subjected to gel electrophoresis. When one template is in excess, it will yield a greater abundance of PCR product; but when the concentration of both the control and test templates are equal, amplification will occur at equal rates, ultimately producing two bands of equal intensity on the gel. Quantitative approaches to PCR are useful when careful attention is paid to experimental reproducibility [63, 64]. Although this method can achieve quantitative results, it is rather tedious and has been replaced in most situations by one of the most useful modifications of the basic PCR method: real-time PCR.

2.2.8 Real-Time PCR

Previously, DNA amplified by PCR was analyzed in a post-PCR process. Newer technologies allow users to observe the amplification of DNA as each cycle occurs, in real-time. Real-time PCR eliminates the need for post-amplification analysis, often saving hours of analytical time and minimizing the risk of contamination. Real-time PCR also increases the ease with which quantitative results can be obtained and thus be applied to gene dosage and expression analysis. For this reason the term "quantitative PCR" (qPCR) has become synonymous with real-time PCR.

Real-time PCR is made possible by the use of fluorescent signals which increase as the target sequence is amplified. This can be accomplished in several ways, but the two main methods include the addition of SYBR Green (or similar dyes that emit fluorescence in the presence of double-stranded DNA) to a standard PCR and using fluorescent probes specific for sequences between PCR primers.

SYBR Green is a dye that fluoresces only in the presence of double-stranded DNA. As the amount of amplicon increases during each PCR cycle, the amount of fluorescence also increases. Measuring the amount of fluorescence at each PCR cycle makes it possible to graph the amplification that occurs during the PCR (PCR cycle number on the *X*-axis and fluorescence on the *Y*-axis) showing the extent of amplification over time (Fig. 2.7) [65]. Since any double-stranded DNA will be detected by SYBR Green, precautions must be taken to ensure any increase in fluorescence represents the desired amplicon from the target sequence. In standard PCR this is accomplished using gel electrophoresis to make sure the length of the amplicon matches the expected size and that no nonspecific PCR products appear on the gel.

A second and slightly more complex method for detecting amplification in real-time PCR uses oligonucleotide probes that are fluorescently labeled. The exact design of these fluorescently labeled probes can vary but they all contain a sequence complementary to a region of the target sequence between the forward and reverse primers. In one example of a fluorescent probe-based real-time PCR chemistry, 5′ hydrolysis probes or TaqMan® probes an oligonucleotide probe is designed with a fluorescent molecule such as FAM bound on one end and a quencher molecule on the other end. The fluorescent signal is usually not detected due the close proximity of the quencher. During the annealing step of each PCR cycle this probe anneals to the target sequence along with the primers (Fig. 2.8). During the extension stage of each PCR cycle, the 5′–3′ exonuclease activity of *Taq* polymerase digests the probe, separating the quencher dye from the fluorescent dye, which results in a detectable increase in fluorescence [66, 67]. This fluorescence can be used to create an amplification curve similar to the one produced when SYBR Green is used.

2.3 Microarray Technology

DNA and RNA microarrays have greatly expanded the amount of data that can be obtained in a single experiment, often using the same basic principles of hybridization as Southern blotting.

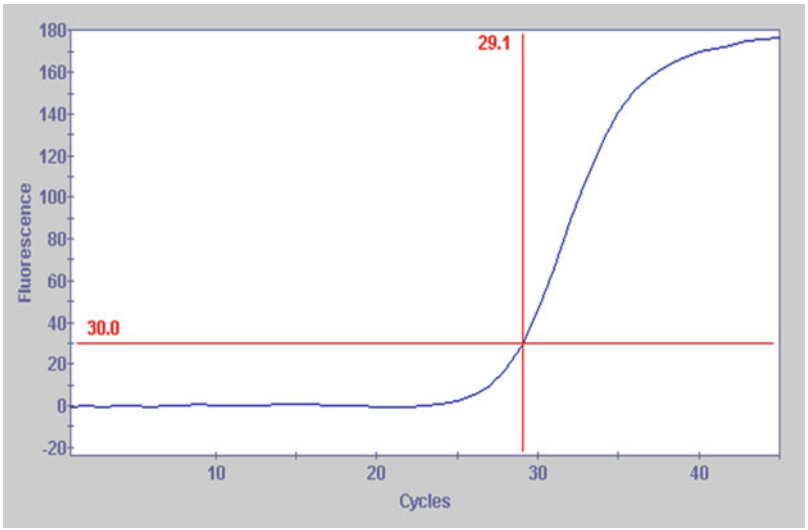

Fig. 2.7 Real-time PCR. Fluorescent detection of DNA being amplified by PCR can be in "real-time" by measuring the fluorescence emitted at each cycle. This fluorescence can be produced by adding a dye such as SYBR Green to the PCR buffer which fluoresces when bound to double-stranded DNA. Alternatively, fluorescence can be produced by adding sequence-specific probes that can be fluorescently labeled in various ways to produce fluorescence at specific points during each PCR cycle. The exact or relative amount of starting template can be inferred by determining when the amplification curve (*blue*) crosses over a certain threshold (30.0) of fluorescence. The cycle when this occurs is designated as the cycle threshold value or Ct (29.1).

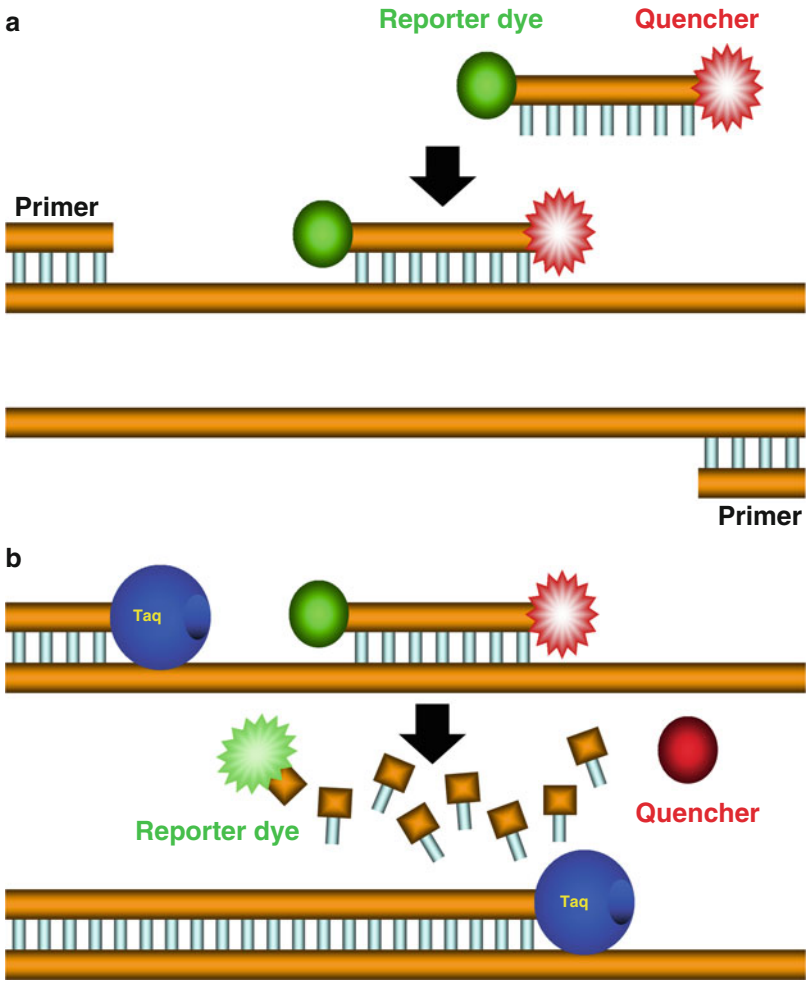

Fig. 2.8 Real-time PCR using hydrolysis (TaqMan) probes. PCR primers are used to amplify target DNA as in standard PCR. During the annealing step of each PCR cycle a fluorescently labeled oligonucleotide probe, complementary to one strand of the template DNA, anneals along with the primers (**a**). The TaqMan probe contains one detection dye (shown in *red*) whose fluorescence is absorbed by another quencher dye (shown in *green*) when the probe is intact. During the extension step of each PCR cycle (**b**) the TaqMan probes are digested. This physical separation of the dye from the quencher allows for increased fluorescence during the extension step of each PCR cycle.

Microarray designs vary greatly among manufacturers but in the more traditional arrays contain many thousands or millions of unique DNA probe sequences that appear as separate dots or features on a fixed surface. Each of these features contains a unique nucleotide sequence that represents a specific gene, chromosomal location or other nucleic acid sequence being interrogated. Labeled nucleic acids, prepared from the samples being analyzed, are incubated on the surface of the microarray to allow hybridization between the microarray probes and the sample-derived nucleic acid. A washing step is then used to remove any labeled sample that is not hybridized to reduce background signaling on the chip when scanned.

Numerous formats and applications for microarrays exist but three main microarray applications predominate in both the research and clinical laboratory setting: gene expression arrays, chromosome arrays (CMA), and genotyping arrays (Fig. 2.9). These three applications differ in the design of the microarrays and in the type of nucleic acid being interrogated [68–77]. In gene expression microarray applications, mRNA or cDNA is applied to a microarray containing features for large groups of genes, often all known genes expressed in a particular organism. The levels of gene expression can be determined by the intensity of the signals at each spot. Microarray results using mRNA isolated from two or more groups of cells or tissue can

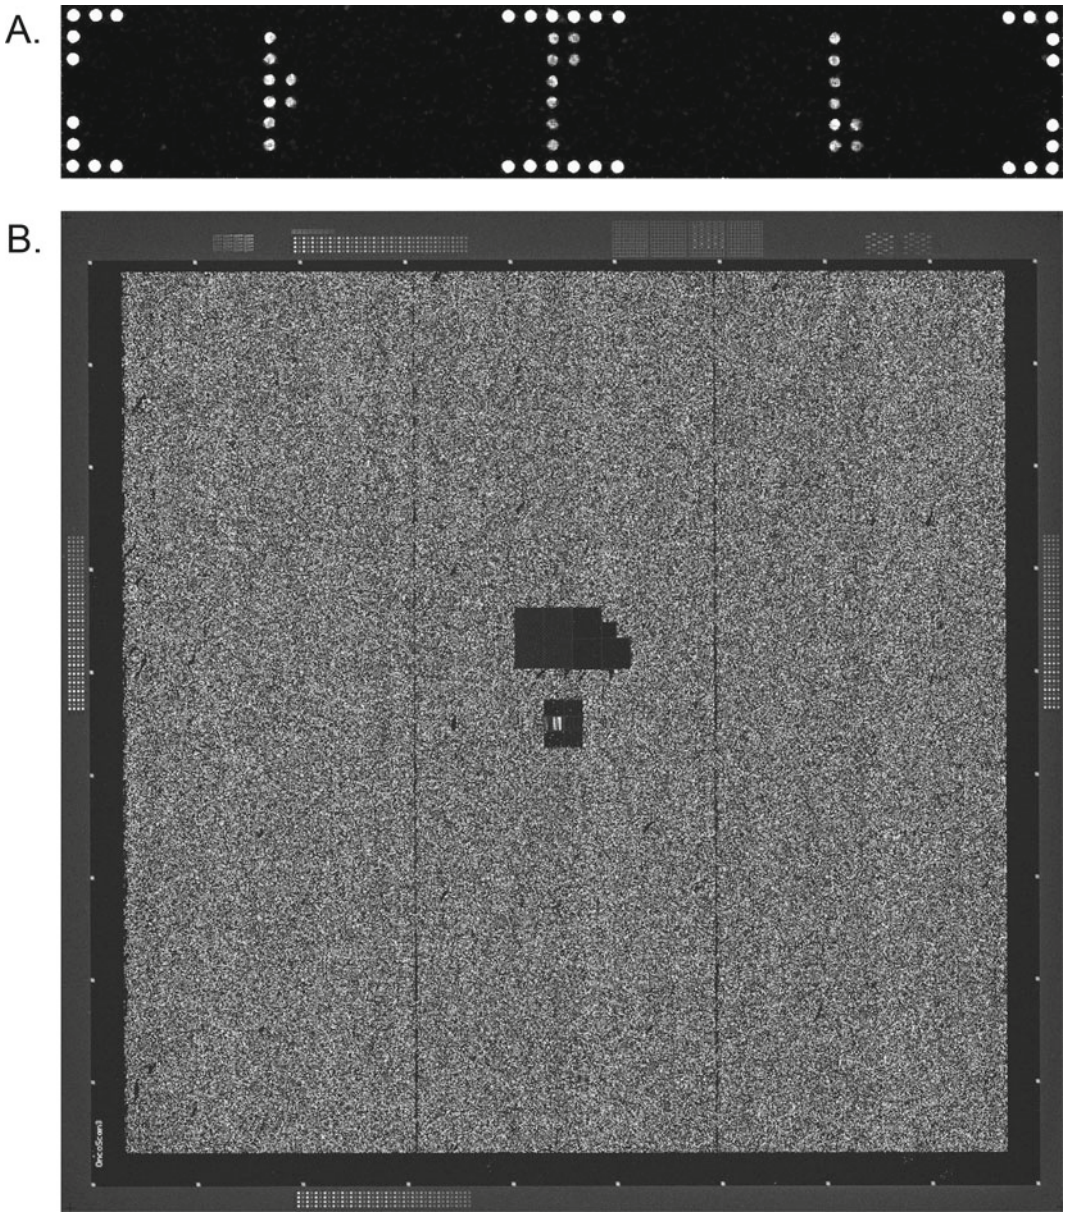

Fig. 2.9 Microarray technology. Genomic DNA or PCR-amplified DNA can be detected by hybridizing with probes that have been attached to specific locations on the surface of a microarray. Interrogation of a few or up to a few million different sequences in a DNA sample can be determined simultaneously. Genotyping of three loci is performed with a low-density array developed by Nanosphere which can use PCR-amplified or non-amplified genomic DNA (**A**). High-density arrays such as the OncoScan microarray (Affymetrix, Inc.) can detect changes in copy number and loss of heterozygosity by targeting hundreds of thousands of single nucleotide polymorphism (SNPs) across the genome (**B**).

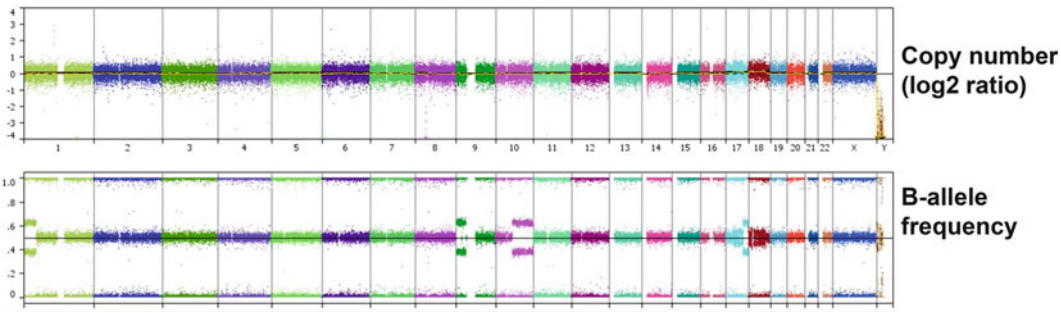

Fig. 2.10 SNP-based microarrays. Genomic DNA derived from formalin-fixed, paraffin-embedded tumor tissue can be used to detect changes in copy number and loss of heterozygosity. In this example, changes in copy number are not detected but regions of copy neutral LOH can be observed within chromosomes 1, 9, 10 and 17. This example shows microarray data from OncoScan FFPE Assay kit (Affymetrix, Inc) analyzed with using Nexus software.

be compared to look for up- or down-regulation of each gene represented on the microarray [68, 69]. This is often used to compare normal and diseased tissue, varying grades of tumors, or samples treated and untreated with a drug or other agent in the research setting. In the clinical setting, gene expression microarrays are used with metastatic tumor in which the site of the primary tumor is unknown despite the available imaging and pathological findings. The expression profile of a tumor with an unknown primary is compared to known expression profile signatures of tumors in which the site of the primary tumor is known. Clinical expression profile tests may be helpful in this setting for predicting the site of origin and choosing the most appropriate form of therapy [70, 71]. In addition to mRNA from protein-coding genes, expression microarrays can also measure the expression of a large number of regulatory noncoding microRNAs or miRNAs.

While some microarrays provide information about the presence, absence and abundance of a particular target, genotyping microarrays are able to differentiate between two alleles at a given locus. This type of technology allows for the genotyping of many thousands or millions of single nucleotide variants (SNVs), also called single nucleotide polymorphisms (SNPs), in a given sample for a relatively small cost. The methodology varies between platforms but in some cases can be as simple as having two nearly identical oligonucleotide probes for each locus being genotyped. The sequence of each probe will differ near the middle of the probe at the position of the SNV with the probe at one feature annealing to one allele and the probe at another feature annealing to the other allele. Signal at one or both of these features indicates that a sample is homozygous or heterozygous for an allele with respect to each loci represented on the microarray. High-density genotyping arrays have been used frequently in genome-wide association studies (GWAS) but lower density genotyping arrays are more common in the clinical setting to evaluate a smaller number of clinically relevant loci [72, 73].

Genotyping microarrays can be designed to examine genomic DNA or select PCR-amplified targets for any number of single nucleotide polymorphisms, variants or mutations [72]. In the clinical laboratory, these SNP microarrays have been used as a tool to create low to high density multiplexed genotyping assays [73, 74].

Chromosome microarrays (CMA) detect copy number variations (CNVs), such as deletions, duplications and gene amplifications in genomic DNA samples. These changes in copy number include trisomies or monosomies of entire chromosomes or smaller CNVs affecting only one arm of a chromosome or smaller regions of chromosomes. The dense coverage across each chromosome offered in many chromosome microarrays allows for detection of CNVs down to the range of 10–100 kb, which would be too small for detection by traditional cytogenetic techniques [75–77]. Depending on the design of the microarray used, CMAs can fall into one of two main categories. Copy number microarrays, commonly called array comparative genomic hybridization (aCGH), previously used BAC probes and now shorter oligonucleotide sequences to compare signal intensities across the genome of an unknown or patient same to that of a normal control genomic DNA sample. Alternatively, CMAs based on high-density SNP arrays similar to the high-density genotyping microarrays described above detect both copy number variations and long contiguous stretches of homozygosity. These stretches of homozygosity may suggest consanguinity, uniparental disomy (UPD) or in cancer, copy neutral loss of heterozygosity (cnLOH) (Fig. 2.10).

2.4 Sequencing Technologies

2.4.1 Sanger Sequencing

For many years DNA sequencing has been an essential tool in both the research and clinical laboratory. Until recently, DNA sequencing has been performed almost exclusively by Sanger sequencing technology in which target DNA, amplified by PCR or cloning into a bacterial vector, is sequenced by the extension of a single oligonucleotide primer by a DNA polymerase in the presence of both dNTPs and labeled dideoxynucleotide triphosphates (ddNTPs). The addition of

a ddNTP blocks the addition of any other dNTPs or ddNTPs, creating a somewhat random assortment of single-stranded DNA molecules of various lengths, each labeled with a fluorescent molecule corresponding to the ddNTP added on the 3′ end (A, T, C, or G). These DNA fragments are separated, most commonly by capillary electrophoresis, to create an electropherogram from which the DNA sequence following the sequencing primer can be determined [78].

The sequencing of individual human genes and later, the entire human genome, led to the identification of countless sequence variants with pathological significance in the fields of genetics, hematology, and oncology. Likewise, sequencing portions of or entire genomes of bacterial and viral pathogens provided valuable biological information regarding infectious disease processes and also lead to the advent of molecular infectious disease testing. Clinical sequencing of bacterial 16S rRNA genes aids in identification of unknown organisms and sequencing of HIV genes from patient specimens can identify the presence of mutations causing resistance to antiviral therapies [79, 80]. Information obtained from sequencing also makes it possible to design clinical molecular tests to monitor viral loads in patients infected with HIV, HCV, BKV, and others and to quickly detect organisms that are difficult to grow and identify in culture.

Although traditional DNA sequencing is an invaluable tool in molecular diagnostics, it does have its limitations. A single sequencing reaction can produce a read length of approximately 600 nucleotides and often requires another sequencing reaction of the opposite DNA strand (bidirectional sequencing) for confirmation. When the sequencing of large stretches of DNA is required, the costs and time involved can be limiting. The analytic sensitivity of traditional sequencing methods can also be problematic in some situations. Sanger sequencing can easily detect two alleles when they are present at nearly equal frequencies as in genomic DNA samples that is heterozygous at a given locus. In some situations, however, an allele or sequence may be present at levels below 10–20 % of the total targeted DNA sequence which may not be detectable by Sanger sequence [81]. For example, tumor specimens submitted for somatic mutation testing often contain a significant amount of non-tumor cells. Germline DNA from these cells can dilute the signal from a low-level somatic mutation to the point of where the signal from the mutation is indistinguishable from background noise.

2.4.2 Next-Generation Sequencing

Newer DNA sequencing technologies, normally referred to as next-generation sequencing, have been developed by several companies that can produce massively parallel sequencing data to overcome some of these limitations of more traditional DNA sequencing [82]. Instead of the individual reads of amplified DNA segments obtained by Sanger sequencing, next-generation sequencing can produce large numbers of shorter reads across an entire gene, group of genes, or an entire genome with each segment of DNA being sequenced tens, hundreds, or thousands of times. These features provide an increased ability to detect low-level variations and also make sequencing across large stretches of DNA more feasible. The cost of sequencing an entire genome is currently too high to make the regular use of whole genome sequencing a reality in the clinical setting but more targeted approaches to these next-generation sequencing technologies are becoming more feasible. Assays capable of sequencing an entire gene or group of genes related to a specific genetic syndrome or cancer have quickly infiltrated clinical laboratories in recent years. In coming years this approach to large-scale sequencing may replace current multiplexed genotyping methods used to screen patients for large numbers of mutations such as those in the *CFTR* gene responsible for cystic fibrosis and the often tedious, large-scale approaches to whole gene sequencing to detect mutations that can predispose carriers to cancers [83]. The coverage or read-depth can also be used to detect low-level somatic mutations found in various tumor types. Although the expenses involved in next-generation sequencing are still quite high the technology is becoming more and more affordable everyday and the typical cost per nucleotide sequenced for laboratories using these technologies on a regular basis is much lower than traditional Sanger sequencing [84].

Although the chemistry and workflow can vary greatly between next-generation sequencing platforms and even between different applications on the same platform, there are a number basic steps that are common to most next-generation sequencing. After isolating DNA from a specimen, the sample must be processed in such a way to enrich for the desired target sequences and to modify the DNA to make it suitable for sequencing. For example, in clinical testing of cancer specimens, this target enrichment may be performed using PCR to specifically amplify exons of cancer genes known to be hotspots for clinically relevant mutations. After PCR amplification various adapter oligonucleotide sequences can be attached to the ends of the amplified DNA. These adapters often include molecular barcodes to uniquely identify sequences obtained from a specific sample. This barcoding allows for pooling of multiple samples in a single sequencing reaction. If PCR-based enrichment is not used, the addition of adapters can be used along with various capture methods to enrich for the desired sequences. Capture-based enrichment is typically preferred when sequencing larger numbers of target sequencing, as is needed in whole exome sequencing [85, 86]. Regardless of the method used, these prepared libraries DNA to be sequenced can be pulled together and processed on next-generation sequencing platform [87]. After the sequencing is complete, the raw sequence data must be submitted to a bioinformatics pipeline to align the sequence reads to a reference sequence, make variant calls and then filter out benign variants and rank the remaining variants based on clinical significance. This pipeline may vary greatly based on platform, application,

types of variants expected and the preference of a particular lab. Much of this pipeline may be automated but manual review and interpretation is always needed to make the final calls and interpretations. Various software programs and algorithms can be used for this alignment and variant calling and care must be taken to select a suitable component of an analysis pipeline. Compared to more focused sequencing, one of the biggest challenges to successfully implementing clinical next-generation sequencing is the interpretation of variants and dealing with a larger number of variants of unknown significance. This becomes more of an issue as one moves from gene panels to whole exome to whole genome sequencing. In some situations where sequencing a larger number of exons or genes may be technically and financially viable, restricting the targeted sequences of an assay may be desired to reduce the possibility of uncertain findings [88-91].

Cancer Genomics

3

Jonathan R. Pollack

3.1 Cancer Genomics

3.1.1 Genetics Versus Genomics

Cancer is at heart a genetic disease, resulting from the accumulation of somatic mutations (and epigenetic alterations) in key genes controlling processes like cell proliferation and cell death, that together drive cancer development and progression. Over the past three decades, cancer researchers have made enormous progress identifying and characterizing important cancer genes, like the oncogenes *MYC*, *KRAS*, and *ERBB2*, and the tumor suppressor genes *RB1* and *TP53*. For most of that time, cancer geneticists have studied one or a small number of genes at a time.

If cancer genetics is the genetic study of cancer genes, cancer genomics is the study of whole cancer genomes. Increasingly, newer technologies like DNA microarrays have enabled researchers to study thousands of genes simultaneously, essentially characterizing genetic or gene expression variation across whole cancer genomes. As shall be seen, genomic-scale or global analyses are much more than the sum of their parts. In addition, several overarching considerations emerge: (1) Discussions of cancer genomics often emphasize emerging technologies. However, the real novelty and power of genomic approaches is that they provide an entirely new looking glass onto cancer through the exploration of high-dimensional (i.e., many genes, many samples) datasets, revealing patterns of genes with biological meaning and clinical relevance. (2) Genomics studies are exploratory investigations, and as such have been disparaged as descriptive, non-hypothesis-driven, or perhaps at worst fishing expeditions. However, a steady stream of paradigm-shifting discoveries has silenced most critics, and such hypothesis generating research is now increasingly recognized as an important complement to traditional hypothesis-driven research. (3) Analyzing and critically evaluating genomics data requires knowledge and facility in basic statistical and biocomputational methods. Cancer research, like other fields in biological sciences, is becoming increasingly quantitative, and the cancer researcher at any level of training benefits from a solid biostatistical foundation. (4) Cancer researchers have long benefited from sharing reagents like cell lines, antibodies, recombinant DNA clones, and even DNA sequences submitted and curated in public databases like Genbank (http://www.ncbi.nlm.nih.gov/genbank/). Cancer researchers now benefit as well from the public availability of well-annotated genomics datasets. Depositing genomics data in public repositories is increasingly a requirement for journal publication, and regardless should be viewed as a community responsibility, especially for publicly funded research.

3.1.2 Spectrum of Genomic Aberrations

The immediate objective of cancer genomics is to catalog the genetic and epigenetic aberrations of cancer genomes. Different methods are used to assay different types of aberrations, and it is therefore useful to enumerate the major classes. DNA sequence changes can result in mutant or truncated proteins which can activate oncogenes or inactivate tumor suppressors. Chromosome translocations can result in aberrantly expressed oncogenes, or create gene fusions and chimeric oncoproteins. DNA copy number alterations (CNAs) include unbalanced chromosome number (i.e., aneuploidy), unbalanced chromosome rearrangements, and focal DNA amplifications and deletions, all of which alter the dosage and potentially expression of affected cancer genes. Loss of heterozygosity (LOH) refers to the absence of one parent's alleles along a chromosome segment, caused by deletion or from a copy-number neutral event like mitotic recombination, and can result in loss of the wild type allele of a tumor suppressor. In addition to these genetic aberrations,

W.B. Coleman, G.J. Tsongalis (eds.), *The Molecular Basis of Human Cancer*, DOI 10.1007/978-1-59745-458-2_3

cancer cells amass epigenetic changes—DNA modifications that are heritable through cell divisions, but do not involve mutations in the DNA itself. Such epigenetic changes include principally DNA methylation and chromatin modifications such as histone acetylation and methylation. Finally, all the above mentioned genetic and epigenetic aberrations result in the altered expression of genes and proteins. Measuring gene expression can therefore provide an integrative readout of the genetic and epigenetic changes in tumor cells.

3.1.3 Goals of Cancer Genomics

While the catalog of aberrations is the currency of cancer genomics research, the broader goals are multifold. Some studies aim to improve our basic understanding of cancer, for example by discovering new cancer genes, or defining genes and pathways underlying processes like cancer metastasis. Other studies are more clinically oriented. For example, gene-expression patterns (also called signatures) are sought to refine cancer diagnosis and classification, which guide selection of therapy. Likewise, gene-expression signatures are sought to improve prognostication, to predict response to specific therapies, and to monitor therapeutic efficacy. Genomics approaches can also speed cancer drug development, for example identifying new drug targets and mechanisms of action, and anticipating off-target effects, facilitating the ultimate goal of personalized medicine and tumor-tailored therapies.

3.2 DNA Microarrays for Expression Profiling

3.2.1 DNA Microarray Platforms

The workhorse for cancer genomics research over the past 10–12 years has been the DNA microarray. DNA microarray technology arose in the 1990s, building on two concurrent advances. First, large-scale sequencing efforts, preceding the Human Genome Project and targeting cDNAs (the expressed complement of genes), provided DNA sequences and physical clone sets for thousands of human genes. Second, new microfabrication methods permitted the manufacture of microarrays, comprising thousands of DNA sequence features (functioning as hybridization probes) ordered on the surface of a slide or chip as a high density array of rows and columns.

Two different DNA microarray platforms emerged. Patrick Brown and colleagues at Stanford University developed cDNA microarrays, in which PCR-amplified cDNA clones (0.5–2 kb in length and each representing a different gene) are robotically spotted onto a glass microscope slide [1]. This relatively low cost spotting technology was adopted at many academic centers. Meanwhile, Stephen Fodor and colleagues at Affymetrix (Santa Clara, CA) adapted photolithography methods from the semiconductor microchip industry to manufacture GeneChips [2, 3]. In this process, a series of light masks is used to direct the highly parallel in situ synthesis of DNA oligonucleotide probes on a silicon wafer. The oligonucleotide probes are 20–25 nucleotides in length, and typically multiple different probes are used to report on each gene.

While there were many potential uses for DNA microarrays, profiling gene expression became the predominant application in the early years. The power of the technology derives from the ability to measure, in the case of gene expression, mRNA levels across thousands of genes simultaneously. Microarray technology continues to evolve, and there are now many different in-house and commercial options. One general trend has been the increased use of oligonucleotide probes, eliminating the need to track recombinant DNA clone sets. Another trend has been the increased number of probe features (along with feature density), permitting the assay of additional genes, transcript variants or genetic loci.

3.2.2 Labeling and Hybridization

Protocols for profiling gene expression differ among microarray platforms. Experiments using spotted cDNA (or oligonucleotide) microarrays are typically carried out as two-color hybridizations (Fig. 3.1). Two different RNA samples are labeled with two different fluorescent dyes (e.g., Cy5 and Cy3), typically using reverse transcriptase to incorporate fluorophore-conjugated nucleotides in a first-strand cDNA synthesis reaction. The labeled nucleic acid target molecules are then combined and hybridized to the microarray, where they bind their cognate DNA sequence probes by Watson–Crick base pairing. Following washing to remove unbound nucleic acid, the microarray is imaged using a fluorescence scanner. For each gene represented on the microarray, the ratio of fluorescence represents the relative level of that gene's expression (i.e., transcript abundance, a dynamic balance between synthesis and degradation) between the two samples. Two-color hybridizations permit robust target quantification in spite of potential variation in hybridization conditions, since any effect on the ratio numerator will be canceled by a similar effect on the denominator.

Experiments using Affymetrix GeneChip arrays, in contrast, are carried out as one-color hybridizations (Fig. 3.1). A single RNA sample is labeled by cDNA synthesis, using an oligo(dT) primer with a T7 RNA polymerase promoter site,

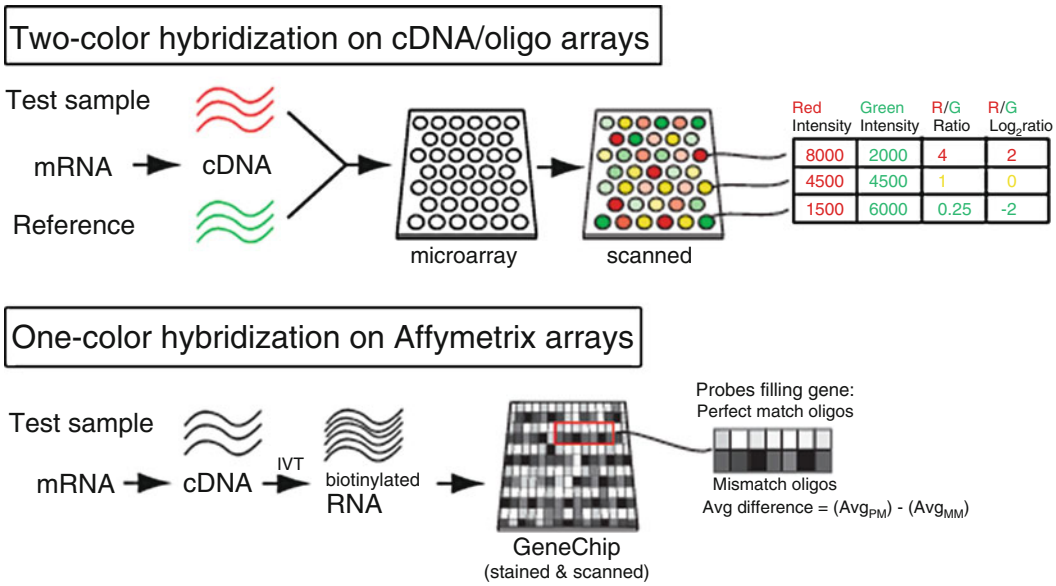

Fig. 3.1 Expression profiling schema. A*bove*, schematic depiction of two-color hybridization on cDNA or oligonucleotide microarrays. RNA isolated from test and reference samples is labeled with two different fluors (here *pseudocolored red* and *green*), then co-hybridized to the array. For each gene on the array, the ratio of red/green fluorescence (typically reported in $\log_2$ scale) reflects its relative transcript abundance in the test compared to reference sample. *Below*, schematic depiction of one-color hybridization on Affymetrix GeneChip oligonucleotide arrays. RNA is biotin-labeled by in vitro transcription (IVT), then hybridized to the array. Multiple different probes report on each gene, where expression levels can be represented by the difference in average staining intensity between perfect match (PM) and control mismatch (MM) probes.

followed by in vitro transcription in the presence of biotinylated nucleotides. The resultant biotinylated antisense RNA targets are then fragmented and hybridized to the microarray, where they bind to their cognate sense oligonucleotide probes. Following washing, a streptavidin–phycoerythrin fluorophore conjugate is used to stain bound target which is then visualized by fluorescence scanning. For each gene represented on the array, the fluorescence intensity reflects that gene's level of expression in the labeled sample.

3.2.3 Experimental Design Considerations

For experiments comparing test and reference samples, a two-color microarray platform provides a more direct comparison. Examples of such studies include treatment (e.g., drug or siRNA) versus control, tumor versus matched normal, or time course experiments where the zero time point is a natural reference. For studies profiling collections of tumors there is no such natural reference, but a universal reference RNA, e.g., comprising pooled RNA from a set of tumor-derived cell lines, can be used [4]. Since all tumor samples are hybridized against the same reference RNA, tumor gene-expression ratios share the same denominator and can be compared amongst one another [5]. For tumor profiling studies, a single-color microarray platform obviates the need for a reference RNA.

Like any other assay, microarray results need to be reproducible. Technical replicates, where the same sample is labeled and hybridized again, can be used to verify measurements. Dye-swap experiments, where for two-color hybridizations the fluorophores used to label the test and reference sample are interchanged, serve as a control for possible dye-labeling bias. Biological replicates, in which the experimental samples are themselves recreated, and then labeled and hybridized, provide the greatest measure of reproducibility, controlling for biological as well as technical variation [6]. However, for exploratory profiling studies, assaying additional cancer samples may generate greater depth of information than assaying fewer samples, but in replicate. Microarray results, at least for key genes, are often verified using independent assays. Such technical validation might include Northern blot or quantitative reverse-transcription PCR (qPCR). Using a second, different microarray platform can serve to verify measurements for many genes at once.

A goal of expression profiling studies is often to identify genes differentially expressed between two groups. Because such studies are exploratory, it is difficult to estimate the number of samples needed. Analysis of existing datasets indicates that at least five samples from each group are needed [7]. However, reason would dictate that the more similar the sample groups are to one another, the larger the number of samples would need to be profiled to identify significant expression differences.

3.2.4 Specimen Considerations

Common epithelial cancer types are heterogeneous at the tissue level, composed of varying fractions of neoplastic cells, normal epithelial cells, and tumor stroma, including fibroblasts, endothelial cells, and various immune cells. Even different parts of the same cancer may vary in these cell fractions. Studies using undissected cancer tissues should be interpreted with this cellular heterogeneity in mind. Microdissection techniques, including laser capture microdissection [8], can be used to obtain and profile specific tissue compartments like cancer epithelium. Alternatively, computational methods can be used for in silico dissection of whole cancers, where for example specific gene-expression patterns are attributed to cell types by comparison to expression patterns of cognate cultured cells [9], or by correlating patterns with cell fractions observed histologically [10].

Conventional RNA labeling methods require microgram quantities of input RNA. However, microdissected specimens typically yield only nanogram amounts. Protocols are available to amplify the input RNA. A common method of linear amplification, better preserving relative transcript abundances, makes use of in vitro transcription [11]. Alternatively, signal amplification can be used to augment the hybridization signal from low amounts of input RNA [12]. While fresh or freshly frozen specimens provide the highest quality RNA for microarray analysis, some success has been reported in extracting usable RNA from formalin-fixed paraffin-embedded (FFPE) specimens [13, 14], which are more readily available from pathology archives.

3.3 Analysis of Expression Profiling Data

3.3.1 Data Processing

After imaging the hybridized microarray, feature extraction (spot finding) software is used to locate DNA features on the microarray, and to associate annotated probe features with fluorescence intensity measurements. For two-color hybridizations on spotted DNA microarrays, background fluorescence intensity surrounding spot features is typically subtracted out to better estimate specific hybridization signal. For each gene spot, fluorescence intensities for the two colors are next converted to a single fluorescence ratio, which describes the relative expression of the corresponding gene between the two samples. By converting fluorescence intensities to ratios, information on the absolute level of expression is lost, but might be inaccurate anyway due to variation in the amount of spotted DNA probe. Fluorescence ratios are then converted to log ratios, most often using $\log_2$ values. In log space, increased and decreased expression is mathematically symmetric with opposite signs (while in linear space decreased expression is compressed within ratios between 0 and 1).

For Affymetrix GeneChip arrays, where a set of DNA oligonucleotide probes is used to report on each gene, fluorescence intensities are calculated as the mean intensity for the probe set. Nonspecific hybridization, calculated from the mean intensity of a matched set of oligonucleotide probes containing a single central nucleotide mismatch, can be subtracted out to yield an average difference. While fluorescence intensities bear some relation to absolute expression levels, target amplification is inherent in the labeling protocol and can bias transcript representation. Therefore, log intensities are typically converted to ratios as described further below.

Once fluorescence signals are extracted, the data need to be normalized to compensate for any differences in the amount of input RNA, or in the labeling or detection efficiency occurring either between two samples on the same array, or between samples on different arrays [15]. For two-color microarray hybridizations, global normalization entails scaling intensities such that the sum of all gene intensities for the two fluorescence channels is set equal (which is equivalent to scaling the average log ratio to zero). Lowess normalization can also correct for signal intensity-dependent dye biases [15]. Another approach is to use the so-called housekeeping genes, those whose expression is most invariant across samples, to normalize ratios between different samples. Likewise for Affymetrix arrays, normalization between different arrays can be accomplished by scaling intensities globally or by using housekeeping genes.

In addition to array normalization, another common data transformation is mean centering genes across a set of array hybridizations. This transformation is often applied to two-color microarray datasets such as tumor profiling studies where a universal reference RNA is used. For each gene in each sample, the log fluorescence ratio is mean centered by subtracting that gene's average log fluorescence ratio for the sample set. The result is that fluorescence ratios reflect gene expression levels in relation to the sample set average, rather than to the arbitrary universal reference. For Affymetrix datasets, log intensities for each gene are often converted to log pseudo-ratios by subtracting the average log intensity for that gene in the sample set, which in effect centers genes.

The quality of a microarray hybridization can be assessed using external spike-in controls (e.g., bacterial transcripts, with cognate probes on the array), where observed and expected fluorescence ratios can be compared. In addition, replicate features on the microarray can provide a measure of intra-array reproducibility indicative of performance. Ultimately, raw and processed microarray data files, along with annotations compliant with minimal information about a microarray experiment (MIAME) standards [16], can be deposited into a public repository like GEO [17] or ArrayExpress [18].

3.3.2 Visualizing Data

Whichever microarray platform is used, the end result of a set of array hybridizations can be summarized in a table (or matrix) of gene expression values (typically ratios) (Fig. 3.2). Each row of the table corresponds to a different gene probe on the array, each column corresponds to a different arrayed sample, and each entry in the table represents the expression level of a particular gene for a particular sample. To more readily discern patterns in the data, these numeric tables are typically visualized as colorimetric tables, or heatmaps, where expression levels are represented with a color scale (Fig. 3.2). Common colorimetric representations include red/green (or red/blue) for increased and decreased expression, respectively. Several software tools are available to process, visualize and/or perform basic analyses of microarray data, from academic (Stanford Microarray Database [19]), government (BRB-ArrayTools [20]), and commercial sources (GeneSpring, SpotFire, and Oncomine [21, 22]).

3.3.3 Analyzing Data

Microarray data are often filtered prior to analysis. For example, genes whose expression varies little across the sample set can be excluded from subsequent analysis, using ratio-fold or standard deviation cutoffs. Such data filtering can increase the subsequent yield of significant genes (by reducing the total number of genes tested), though also represents a source of variable findings among different microarray studies.

Analysis of microarray data can be broadly divided into two approaches, supervised and unsupervised [23, 24]. Supervised methods make up-front use of specimen

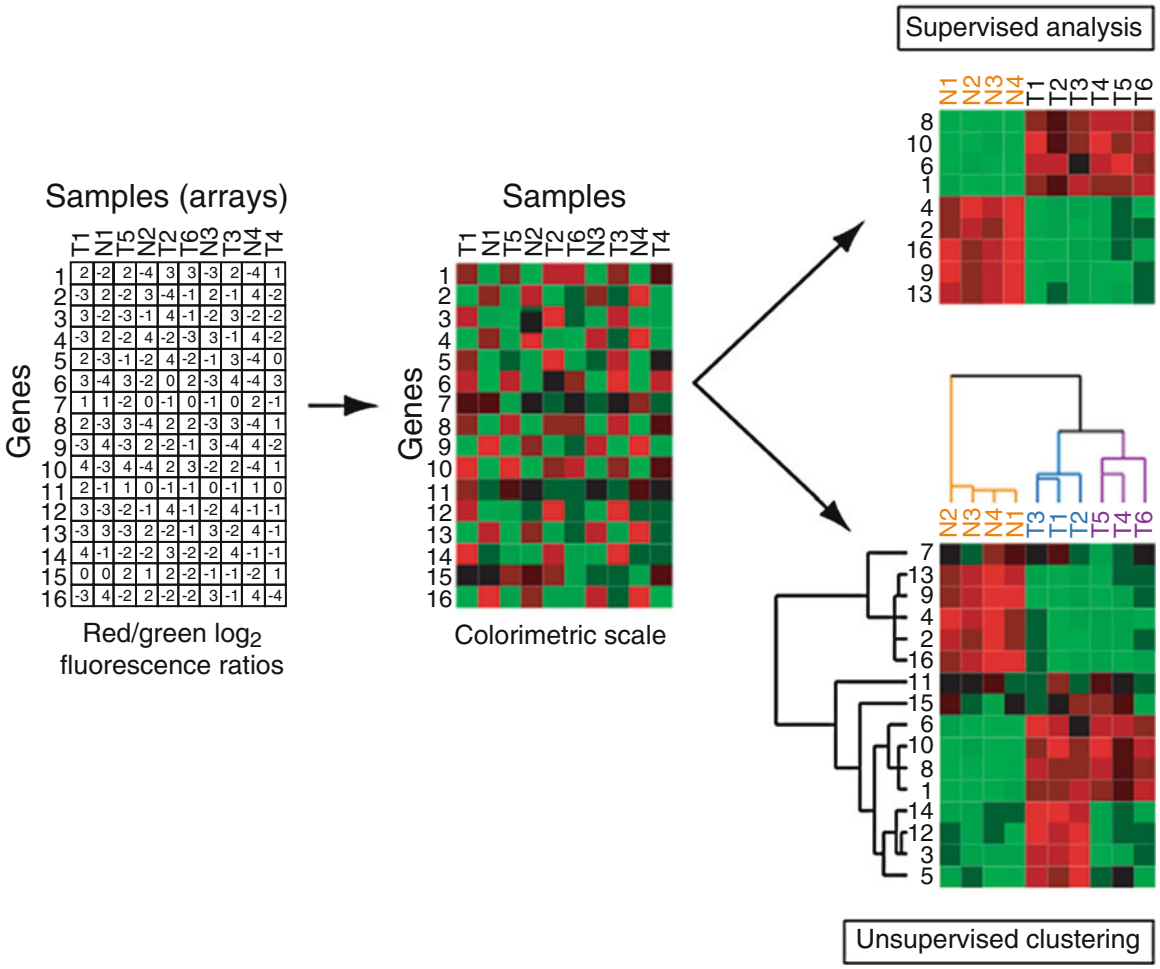

Fig. 3.2 Microarray data analysis. *Left*, the starting point of microarray analysis is a matrix of gene expression ratios, where each row is a different gene and each column is a different sample (array). *Center*, viewing ratios in colorimetric scale facilitates recognition of expression patterns. *Above right*, analysis supervised on the tumor (T) versus normal (N) distinction identifies the subset of genes with significant differences in expression, here ranked by *t*-statistic. *Below right*, hierarchical clustering analysis of the same input data matrix reveals the tumor-normal distinction, but also suggests the presence of two tumor subclasses (highlighted by *blue* and *purple dendrogram branches*).

information, for example to identify genes differentially expressed between two different specimen classes such as cancer and normal (Fig. 3.2). Various metrics can be used, like ratio-fold difference, or the Student's *t*-statistic which highlights genes with a large between-class difference in average expression compared to within-class expression variance. While metrics like the *t*-statistic provide an associated *P*-value, it is important to correct for multiple hypothesis (gene) testing (discussed more below). The number of truly (and falsely) significant genes can be estimated by comparing the number of genes observed (at any given threshold) in the real data to the median number observed in many samplings of randomly permuted data, generated for example by shuffling the sample class (e.g., cancer versus normal) labels. Significance Analysis of Microarrays (SAM) is a commonly used analysis software tool that provides such false discovery rate estimates [25].

Genes differentially expressed between sample classes can provide a basis to classify new samples. There are different methods for classifying samples, including weighted voting [26] and Prediction Analysis of Microarrays (PAM), based on nearest shrunken centroids [27]. Though the specifics differ, the principle is to determine whether the expression of classifier genes in a new sample better matches that of one or the other known sample classes used to develop (or train) the classifier. The new sample is assigned to the class with the better match, and the confidence of that assignment can be summarized as the strength of the prediction for one class over the other. The overall performance of a classifier can be estimated in the training set (where classes are known) by leave-one-out cross-validation (LOOCV), wherein one sample is omitted and a classifier is trained on the remaining samples and tested by predicting the class of the omitted sample. The process is repeated leaving a different sample out each time, and performance is then summarized by the overall classification accuracy on all samples. Classifier performance should also be validated by analyzing a separate test sample set that is independent of the training set.

In contrast to supervised approaches, unsupervised methods organize data agnostic to information about the samples, and are therefore useful for discovering previously unknown relationships in the data. Hierarchical clustering analysis is one such widely used unsupervised method [28] (Fig. 3.2). In hierarchical clustering, an iterative agglomerative algorithm is used to reorder the rows (genes) and columns (arrayed samples) of the expression matrix such that genes with similar vectors of expression across the samples (e.g., by Pearson correlation) are clustered (or grouped) together, and, independently, samples with similar vectors of expression across the genes are clustered together. Analogous to phylogenetic analysis, dendrograms (or trees) display the hierarchical relationships among genes and among samples, and the reordered heatmap highlights prominent patterns of gene expression. Information about the samples and genes can then be overlaid on the dendrograms to assist in interpreting patterns of expression. Such clustered heatmaps have been likened to molecular portraits [9], and provide a powerful new approach to observe, describe, and understand the molecular variation within cancer specimens, and in particular to discover previously unrecognized cancer subtypes.

Another useful way to organize and view microarray data, and to interpret expression patterns identified from supervised or unsupervised analysis, is pathway (or network) analysis. Gene ontology (GO) terms categorize genes by cellular component, biological process and molecular function [29]. Likewise, database resources like BioCarta and the Kyoto Encyclopedia of Genes and Genomes (KEGG) [30] place genes in biological pathways (e.g., metabolic and signal transduction pathways) [31]. Finding statistical enrichment of specific GO terms or cellular pathways can suggest biological meaning for a group of genes of interest. Another related approach is gene set enrichment analysis (GSEA), which evaluates enrichment for each of several hundred curated gene sets by determining their overrepresentation at the top of a list of genes rank ordered by their expression distinction between two sample classes [32]. The gene sets include groupings from biological pathway databases, as well as groups with shared expression (from published microarray studies), promoter regulatory motifs, or cytogenetic location. Related methods can be used to assess enrichment of interactive networks of genes [Ingenuity Pathways Analysis—http://www.ingenuity.com/] or molecular concepts [33].

3.3.4 Common Pitfalls in Data Analysis

In profiling across many genes and specimens, the resultant high-dimensional microarray datasets have brought new statistical challenges [6, 34]. A common pitfall is reporting significant differentially expressed genes without having corrected for multiple gene testing. In large datasets, almost any particular expression pattern sought can be found, but may not be statistically meaningful. For example, in identifying genes differentially expressed between cancer and normal tissue from a dataset of 10,000 genes, about 500 genes would be expected to have individual *P*-values of less than 0.05 (the standard threshold of statistical significance) just by chance! True statistical significance is best assessed by comparison of observed findings to those from randomly permuted data.

Another common pitfall is over-fitting the data, where data models (like classifiers or outcome predictors) are developed and then tested on the exact same samples, rather than on an independent sample set. The result is an inflated estimate of test performance. An additional common shortcoming is the use of insufficiently large sample sets in both training and

validation phases of analysis. Early microarray studies using inappropriate statistical methods likely contributed to overly inflated expectations of the technology.

3.4 Expression Profiling—Applications

3.4.1 Cancer Classification

A major goal of many DNA microarray studies is cancer classification. Cancers are classified principally based on their tissue of origin and histology, and sometimes with the aid of ancillary tests like immunohistochemistry, flow cytometry, and cytogenetics. Classification schemes provide important information for prognostication and for the selection of optimal therapies. Much as the pathologist uses histologic patterns to classify cancers, DNA microarrays describe patterns of molecular variation, hitherto unrecognized, having the potential to improve cancer classification.

In an early landmark study, Golub et al. [26] described the computational framework for applying DNA microarrays to the problem of cancer classification. Using supervised methods, the investigators identified genes differentially expressed between two classes of leukemia, acute myelogenous leukemia (AML) and acute lymphoblastic leukemia (ALL). Statistically significant differences could be defined as those occurring above what was expected by chance, estimated by comparison to randomly permuted data. Using the top-most significant genes, a classifier could be developed that accurately predicted the diagnosis of new cases. While AML and ALL are in reality readily distinguishable by existing cytochemical staining and flow cytometry techniques, the concepts developed, and many variations on the original computational methods, are applicable to more challenging classification problems.

One such classification problem currently receiving attention is that of metastatic cancers of unknown primary (CUP), which account for up to 5 % of newly diagnosed cancers [35]. Despite subsequent immunohistochemical staining and imaging studies (like computed tomography), the anatomic site and tissue of origin remains undetermined in many cases, where knowing that information is important for selecting the optimal treatment regimen [36]. DNA microarrays have been used to define cancer type-specific patterns of gene expression, which have been shown to classify new cancer cases (where clinical truth is known) with ~80–90 % accuracy [37–40].

3.4.2 Cancer Class Discovery

Another important application of DNA microarrays is the discovery of new, previously unrecognized tumor classes, as first reported by Alizadeh et al. [41]. By unsupervised cluster analysis of variably expressed genes, these investigators identified two subtypes of diffuse large B-cell lymphoma (DLBCL) with distinct expression patterns. One pattern shared similarities with normal germinal center B cells, while the other with activated B cells. The latter DLBCL subtype was also associated with constitutive NFκB activity and less favorable prognosis [41, 42]. Therefore, while indistinguishable by histology, expression profiling nonetheless suggested a refined classification of DLBCL that might improve outcome prediction and possibly selection of therapies. Indeed, *BCL6* gene expression, a surrogate indicator of the germinal center B cell-like subtype, has since been shown to predict survival independently of the currently used International Prognostic Index score [43].

Microarray analysis of breast cancer has also identified multiple tumor subclasses, refining the existing classification [9, 44]. Estrogen receptor (ER)-positive breast tumors could be subdivided into two luminal subtypes (called so because of shared expression markers with the luminal layer of normal breast epithelium), luminal A and B, with the latter associated with higher proliferation rates and less favorable outcome. ER-negative tumors included those with *ERBB2* (Her2/neu) amplification as well as a previously underappreciated basal-like subtype (with shared expression markers of the basal/myoepithelial layer of normal breast epithelial) with poor prognosis. Similar microarray studies have identified tumor subclasses within other tumor types as well [45].

3.4.3 Outcome Prediction

Microarray analysis has also been applied to directly define gene signatures for prognostication and for prediction of response to therapies. In a seminal study, van't Veer et al. [46] compared gene-expression profiles of breast cancers from women who either did or did not develop distant metastases within 5 years of follow-up. Supervised analysis defined a 70-gene signature that could predict disease-free and overall survival in an independent cohort of breast cancer patients [47], outperforming current prognostic indices based on clinical and histological parameters such as the St. Galen and NIH consensus criteria [48]. The poor-prognosis signature might therefore improve the selection of patients who would benefit from adjuvant therapy. Prognostic and predictive signatures have been proposed for other cancer types as well, including a 133-gene prognostic signature in AML [49], independently validated [50] and with potential utility in risk-stratification for cases with normal cytogenetics.

3.4.4 Biological Insight

Expression profiling has made many other significant contributions to our understanding of cancer biology. For example, Ramaswamy et al. [51] explored gene expression differences

between unmatched primary and metastatic adenocarcinomas of diverse tumor types. The investigators defined a 17-gene signature of metastasis which, unexpectedly, was also expressed in a subset of primary tumors where its presence predicted metastasis and poor clinical outcome. Importantly, this study challenged the existing paradigm that metastases arise from rare cells in the primary tumor that have acquired additional genetic alterations, suggesting rather that the propensity to metastasize characterizes the bulk population of tumor cells, and therefore by inference is determined early in tumor development.

Another seminal contribution of microarray analysis was the relatively recent discovery of recurrent gene fusions in prostate cancer. By analyzing outlier values of gene expression in microarray datasets, Tomlins et al. [52] identified elevated expression of *ERG* and *ETV1* (oncogenic ETS family transcriptional factors) in subsets of prostate cancer. Further characterization revealed chromosome rearrangement and gene fusion, resulting in the promoter of the androgen-regulated gene *TMPRSS2* driving overexpression of *ERG* or *ETV1*. This finding provides novel insight into androgen-dependent prostate tumorigenesis, and challenges the longstanding assumption that recurrent chromosomal rearrangements, frequent in hematologic and mesenchymal malignancies, are rare in common epithelial tumor types. Indeed, this discovery has reinvigorated the search for recurrent rearrangements in epithelial tumors.

It is worth noting that in both the above examples, the key discoveries emerged from exploratory rather than hypothesis-driven investigations, underscoring the importance of exploratory research. In addition, both studies benefited enormously from the public availability of clinically annotated microarray datasets.

3.4.5 Therapeutic Targets

Microarray studies have also aimed to identify new targets for cancer therapy. For example, in a study of acute leukemias Armstrong et al. [53] found that ALL cases with rearrangements of the *MLL* (mixed lineage leukemia) gene exhibited patterns of gene expression distinct from other ALL (and AML) cases, and in particular noted high-level expression of the *FLT3* receptor tyrosine kinase. Further studies validated FLT3 as a therapeutic target in MLL, where a small molecule inhibitor of FLT3 was shown active in a mouse model of the disease [54].

Looking beyond individual genes, a promising strategy to discover new treatments has been to connect gene-expression signatures of specific disease states to gene-expression signatures of cultured human cells perturbed with various bioactive small molecules, a compilation called the Connectivity Map [55]. For example, Wei et al. [56] identified that among 164 different drug-associated expression profiles, the profile of the mTOR inhibitor rapamycin significantly (by GSEA) overlapped with the expression profile of glucocorticoid-sensitive (as compared to resistant) ALL. This finding suggested that rapamycin might revert glucocorticoid resistance, which was subsequently verified in cultured ALL cells, and is now being evaluated in clinical trials (facilitated because rapamycin is already an FDA-approved drug).

3.5 Genomic Profiling

3.5.1 Array-Based Comparative Genomic Hybridization

In addition to profiling RNA transcripts, profiling DNA aberrations in cancer genomes has emerged as a major application of DNA microarray technology. One such method is array-based comparative genomic hybridization (aCGH), derived from the cytogenetic method CGH [57] and used to delineate genomic DNA copy number alterations (CNAs). In aCGH, test (tumor) and reference (normal) genomic DNAs are labeled with two different fluors, then compared by hybridization onto microarrays comprising DNA probes of defined human (or mouse, etc.) genome map position, such as large genomic clones (e.g., bacterial artificial chromosomes; BACs) [58, 59], genes (cDNAs) [60], or oligonucleotides [61–63] (Fig. 3.3). For each probe present on the microarray, the ratio of fluorescence represents the relative copy number of that locus in the tumor compared to normal sample.

In contrast to expression profiling, analysis of aCGH data emphasizes genome position information. Tumor/normal log fluorescence ratios are first normalized for each array so that the average log ratio is set to zero. As such, CNAs are defined relative to the average copy number for the sample (which may well vary from diploid). Normalized tumor/normal ratios are then mapped onto an ordered representation of the normal genome sequence, where DNA gains and losses are identified as ratio peaks and valleys (Fig. 3.3). Note, this method does not reveal the actual location of CNAs in the cancer genome, where it is known for example that DNA amplification can occur in situ on the chromosome (homogeneously staining regions) or elsewhere in the genome, even extra-chromosomally (double minutes).

Because genomic DNA comprises a more complex mixture of DNA sequences compared to the subset of expressed genes (transcripts), aCGH presents additional technical challenges compared to expression profiling. Further, accurate quantification of very small ratio-fold changes, like single-copy tumor DNA gains and losses in

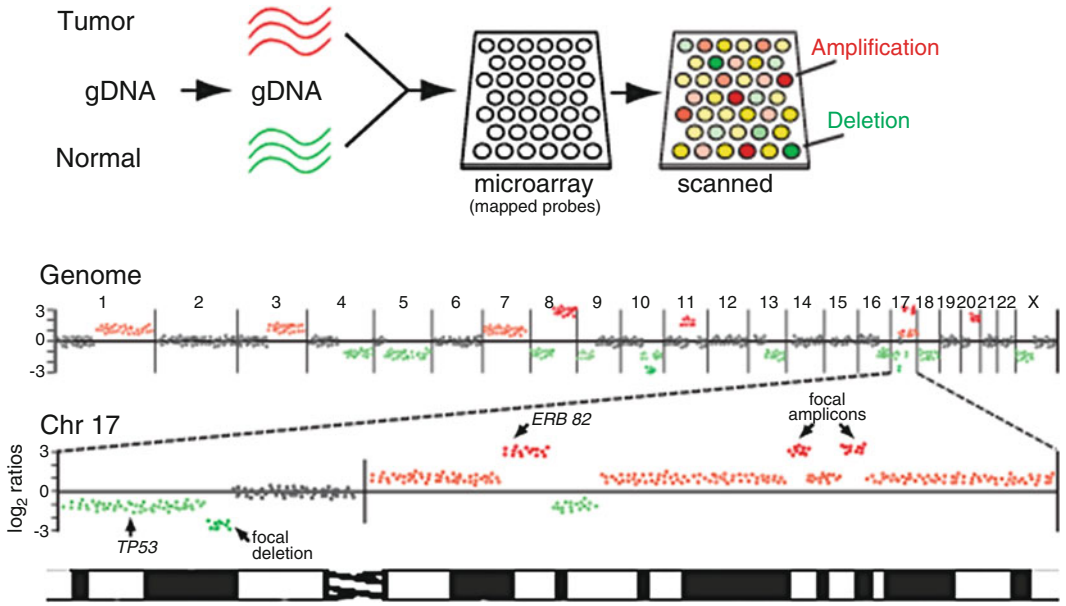

Fig. 3.3 Genomic profiling by array CGH. *Above*, schematic depiction of array-based comparative genomic hybridization (aCGH). Genomic DNA isolated from tumor and normal reference is labeled with two different fluors (here *pseudocolored red* and *green*), then co-hybridized to the array. For each gene on the array, the ratio of red/green fluorescence reflects its relative DNA copy number in the tumor compared to normal reference. *Below*, tumor/normal $\log_2$ ratios (here, for a hypothetical breast cancer sample) are plotted according to reference genome position, shown for the whole genome and for an enlarged view of chromosome 17. *Red* and *green ratios* indicate DNA gain and loss, respectively, some corresponding to known cancer genes (e.g., *ERBB2*, *TP53*), while other focal amplicons and deletions pinpoint novel cancer genes.

admixtures of normal DNA stromal contamination, is key to localizing and discovering new cancer genes. The sensitivity of detecting low amplitude and focal aberrations is dependent on many factors, including the performance characteristics of the array platform and the density of probe coverage across the genome, with the trend moving towards arrays with 100,000 or more oligonucleotide probes. Measurement accuracy can be improved by averaging ratios across neighboring probes, though at the expense of spatial resolution. Statistical algorithms (and corresponding software tools) are available to call gains and losses in aCGH data [64, 65] and to identify loci recurrently gained or lost across tumor samples [66, 67]. Such recurrently aberrant loci are more likely to harbor cancer genes whose altered copy number and expression provides selective growth advantage, rather than represent secondary inconsequential alterations resulting from genomic instability.

While the above discussion centered on somatic CNAs, germ line DNA copy number variants (CNVs) are increasingly recognized as a source of hereditable variation [68]. CGH arrays can be used to identify CNVs, some of which might be associated with increased cancer risk, or represent preferred sites of tumor genome rearrangement. In defining somatic CNAs, the use of normal reference DNA matched from the same individual can assist in discriminating between somatic CNAs and germ line CNVs.

3.5.2 Single Nucleotide Polymorphism (SNP) Arrays

DNA sequence changes are a major source of heritable variation, and measuring DNA sequence variation was a major motivation for developing DNA microarray technology. Single nucleotide polymorphisms (SNPs) are present on average every 300 bp in the human genome [69], and several million SNPs have been characterized [70]. Affymetrix SNP arrays [71] comprise oligonucleotide probes spanning tens of thousands of SNPs, with separate probes matching the major (i.e., more frequent) and minor SNP alleles (A and B), and can be used to type alleles by DNA hybridization. In brief, target genomic DNA is digested with a restriction endonuclease, and then PCR amplified (using ligated universal adapters) and biotin-labeled for hybridization. Array probes are designed to detect SNPs predicted to reside on restriction fragments within the preferred PCR size range (~0.25–2 kb), and the PCR step serves to reduce target complexity, thereby improving assay performance. SNP genotypes (AA, AB, or BB) are called based on relative hybridization intensities for allele-specific probes. Illumina BeadChip arrays provide a distinct approach with comparable performance for SNP genotyping [72].

SNP arrays can be used to genotype SNPs for whole-genome scan genetic linkage and association studies [73],

for example to discover loci conferring cancer risk [74]. SNP arrays can also be used to identify somatic DNA aberrations in tumors, including both CNAs, by scoring hybridization intensity, and LOH, by scoring allelic loss (at informative heterozygous loci) along chromosome segments [75, 76]. Because LOH can result in loss of genetic information in the absence of deletion, SNP arrays can provide additional information useful for mapping tumor suppressors.

3.5.3 Genomic Profiling—Applications

The major application of genomic profiling by CGH (or SNP) arrays has been the discovery of new cancer genes. CGH on microarrays affords orders of magnitude higher mapping resolution compared to prior cytogenetic methods, and has revealed hitherto unappreciated complexities of CNAs in cancer genomes [60, 77]. In various tumor types, recurrent CNAs have been identified that do not contain known cancer genes, and therefore presumably pinpoint new cancer genes. Functionally validated cancer genes discovered by genomic profiling include *PPM1D* (at 17q23.2), a negative regulator of TP53 amplified in breast cancer [78], and *MITF* (3p14.1), a master transcriptional regulator of melanocytes amplified in melanomas [79]. Indeed, the discovery of *MITF* amplification suggested the concept of lineage-dependency oncogenes, where the aberrant expression of genes with key roles in normal cell lineage proliferation or survival is required for tumor cell survival in certain genetic contexts [80]. Another such example is *NKX2-1* (*TITF1*), a transcriptional regulator of normal lung development recently found amplified by genomic profiling of lung cancers [81–83].

With the commercial availability of high-density CGH and SNP array platforms, genomic profiling is increasingly utilized, and has been a featured technology of NCI's The Cancer Genome Atlas (TCGA) project [84] to systematically characterize cancer genomes. Beyond single genes, patterns of CNA, analogous to signatures of gene expression, have been proposed for cancer classification and outcome prediction [85–88].

3.5.4 Data Integration

While expression and genomic profiling each provides important information, integrating data from both these methods can reveal additional insight. For example, while many genes exhibit elevated expression in cancer, the subset that is also highly amplified is enriched for key genes driving tumorigenesis (Fig. 3.4); such an integrative analysis is therefore valuable for cancer gene discovery. Integrative

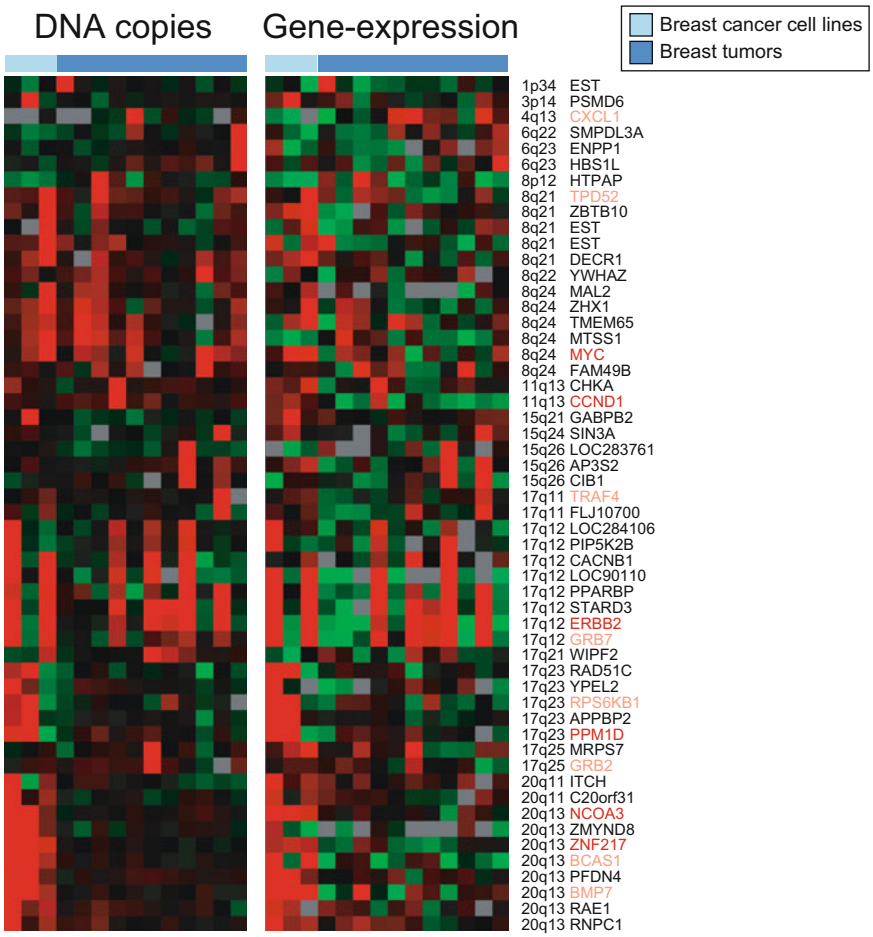

Fig. 3.4 Data integration. Shown is an integrative analysis of aCGH and expression profiling data. Gene copy number (heatmap, *left*) and expression (*right*) are depicted for the subset of genes identified by microarray to be both highly amplified and overexpressed (a characteristic of oncogenes) in breast cancer cell lines or tumors. Samples are ordered identically in both panels; genes are ordered by chromosome location. *Red* indicates amplification (*left*) or overexpression (*right*). This subset of amplified overexpressed genes is a rich source for breast cancer gene discovery; known putative (*pink text*) and bona fide oncogenes (*red text*) are highlighted, the latter including *MYC*, *CCND1*, and *ERBB2*. Data abstracted from Pollack et al. [89].

analysis of DNA copy number and expression has also uncovered a significant impact of aneuploidy (chromosome copy number imbalances) on gene expression patterns [89, 90]. This finding, observed in many tumor types, suggests that aneuploidy might contribute to cancer progression through the altered expression of many (possibly even hundreds of) genes. Integrative analysis has also revealed that breast cancer subtypes are associated with distinct patterns of CNA, with luminal-B tumors characterized by high-level DNA amplifications and basal-like tumors by low-amplitude segmental gains and losses [88, 91]. This finding suggests that breast cancers arise not only via different oncogenic pathways but also by distinct underlying mechanisms of genomic instability.

There is an increasing interest in integrating data across diverse platforms, not just gene expression and copy number, but additional layers of genomic-scale data (like epigenetic regulation), protein expression (and modification and activity), protein interactions, and phenotypes, some generated from model organisms [92–94]. Such analyses have been dubbed integromics [95] or systems approaches. Finally, integrating data may reveal interplay between the germ line and tumor genomes, for example in predisposition to specific cancer subtypes (e.g., *BRCA1* mutation carriers develop basal-like breast cancers [96]) or in determining response to specific anticancer therapy (i.e., pharmacogenomics) [97].

3.6 Other Microarray Platforms

3.6.1 DNA Methylation Arrays

The DNA microarray platform has been adapted to other applications as well (Fig. 3.5), including defining patterns of 5-methylcytosine DNA methylation. Cancer genomes exhibit global hypomethylation, but focal hypermethylation upstream of tumor suppressors (often within CpG islands) associated with transcriptional silencing [98]. Several microarray-based approaches have been developed to assay DNA methylation, useful for locating new tumor suppressor genes. Transcriptional profiling following treatment of cells with the DNA methyltransferase inhibitor 5-aza-deoxycytosine can reveal methylation-silenced genes, but the method is limited to cultured cells and does not distinguish methylated genes from secondary transcriptional changes. One approach to directly assay DNA methylation, by Differential Methylation Hybridization (DMH) [99], takes advantage of methylation-sensitive restriction endonucleases. Genomic DNA from tumor and matched normal are separately restriction endonuclease digested, ligated to universal PCR linkers, and then further digested with a methylation-sensitive restriction endonuclease. DNA fragments methylated in tumor (but not normal) are protected from methylation-sensitive digestion, and therefore produce PCR products that can be detected by two-color hybridization (cancer versus normal) to a microarray containing probe sequences from the upstream regions (CpG islands) of genes.

In a second approach, Methylated DNA Immunoprecipitation (MeDIP) [100], cancer-derived DNA is fragmented and then immunoprecipitated using an antibody specific for 5-methylcytosine. Immunoprecipitated and reference input DNA are differentially labeled and co-hybridized to a microarray containing upstream sequence probes, where increased ratios indicate methylated DNA. A third approach makes use of bisulfite modification, whereby unmethylated but not methylated cytosines are converted to thymine by chemical treatment followed by PCR. DNA methylation is then detected by differential hybridization to methylation-specific oligonucleotide (MSO) microarrays, with probes designed to discriminate between the unmethylated (converted) and methylated (unconverted) DNA sequences [101].

3.6.2 Protein–DNA Interactions by ChIP on Chip

Another application of DNA microarrays is determining genome-wide the physical positioning of DNA-associated proteins, including chromatin proteins and transcription factors (to identify transcription targets), by chromatin-immunoprecipitation followed by microarray (chip) hybridization, or ChIP on Chip [102, 103]. First, cultured cells are treated with formaldehyde to reversibly crosslink proteins to DNA. Next, cell lysate DNA is fragmented, and the protein of interest (along with bound DNA) is immunoprecipitated using an antibody specific to the native protein, or to an epitope tag (where the corresponding protein has been tagged). The DNA is then separated, PCR-amplified, labeled and hybridized to a microarray containing upstream or tiling DNA sequence probes. Protein–DNA interactions are identified by increased hybridization signal compared to an appropriate reference, for example input DNA or control mock-immunoprecipitated input DNA.

3.6.3 Gene Function by Transfected Cell Microarrays

DNA microarrays have also been applied to assess gene function. In one approach, cultured cells are overlaid onto a spotted DNA microarray comprising full length genes (cDNAs) cloned into mammalian expression vectors [104]. Cells overlaying DNA spots take up the DNA by reverse transfection, such that each cell cluster expresses a different transfected gene. Gene functions are then inferred by resultant

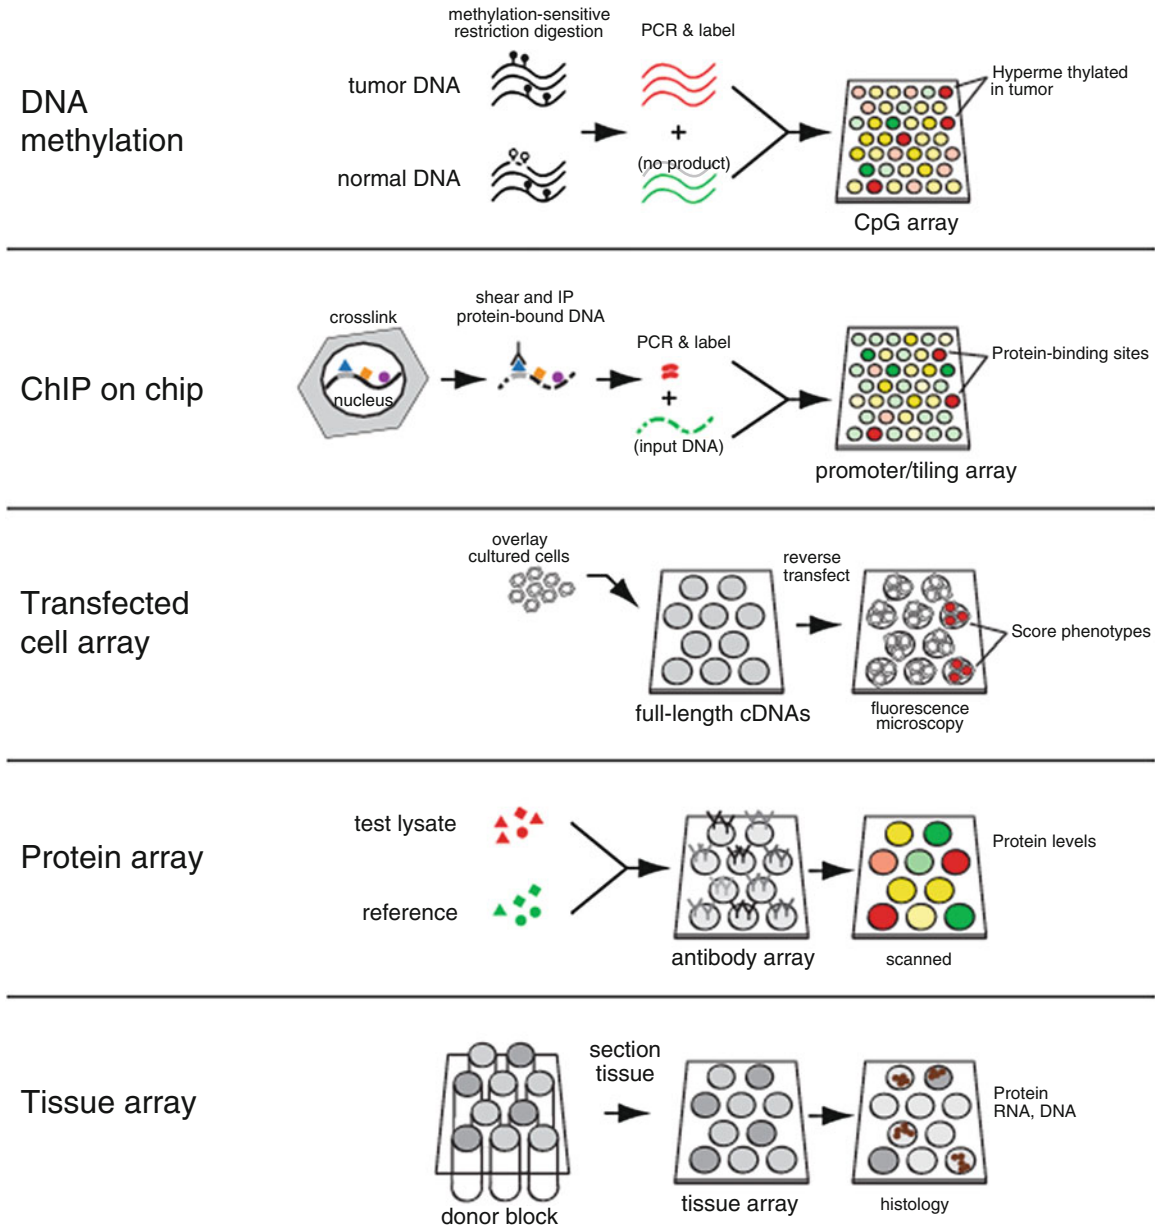

Fig. 3.5 Other array platforms and applications. Shown schematically are representative microarray-format applications for profiling DNA methylation by Differential Methylation Hybridization (*filled circles* indicate methylated CpG sites); protein–DNA interactions by ChIP on chip; gene function by transfected cell array; protein levels by antibody array; and high-throughput histology by tissue array. See main text for additional detail.

molecular and cellular phenotypes, scored for example by fluorescence microscopy. An analogous approach uses microarrays of small interfering RNAs (siRNAs) or short hairpin RNAs (shRNAs) effecting gene knock down to screen for loss of function phenotypes [105, 106].

3.6.4 Proteomic Arrays

The previously described applications utilize microarrays containing DNA probes. Other applications make use of arrays containing other classes of molecules. For example, arrays of spotted antibodies can be used for the highly parallel measurement of protein levels (or phosphorylated-state) in body fluids or cell lysates [107, 108]. Conversely, spotted proteins can be used to identify protein interactions [109] or, as antigens, to define the antitumor humoral immune response [110]. While for DNA arrays binding by Watson–Crick base pairing is relatively uniform across an array, a challenge for protein arrays is the considerable variation in binding kinetics and affinities for different protein-protein interactions.

3.6.5 Tissue Microarrays

With a DNA microarray, a single sample is profiled across many genes. The converse approach is implemented with tissue microarrays (TMAs) [111], where a single gene is profiled across many samples. TMAs comprise up to several hundred different tissue pieces (each 0.6–2 μM in diameter), not individually spotted but rather sectioned from a donor block (assembled as an array of cylindrical tissue core biopsies) onto a glass microscope slide. TMAs permit the highly parallel histologic analysis of gene expression by RNA in situ hybridization (RISH) or immunohistochemistry (IHC), or copy number determination by fluorescence in situ hybridization (FISH). TMAs, which also provide information on cellular localization of expression, markedly speed the evaluation and validation of initial DNA microarray discoveries across larger patient cohorts. Because they are typically built from formalin-fixed paraffin-embedded (FFPE) specimens often linked to long-term clinical follow-up, TMAs are particularly useful for retrospective evaluation of prognostic markers.

3.7 Clinical Applications

3.7.1 Biomarkers and Signatures

Current diagnostic applications resulting from microarray discoveries rely mainly on methods already in common use in histopathology and molecular pathology laboratories, such as IHC or RT-PCR. For example, *AMACR* (alpha-methylacyl-CoA racemase) was identified by microarray analysis to be more highly expressed in prostate cancer compared to normal prostate [112–114]. IHC analysis of AMACR expression is now in routine use in some pathology centers to evaluate difficult biopsy cases for the presence of prostate cancer.

Multigene tests derived from microarray data are also being evaluated for clinical use. A 70-gene breast cancer prognostic signature, described above and assayed by DNA microarray analysis of freshly frozen specimens (Agendia's MammaPrint), has been FDA-cleared for the prediction of breast cancer recurrence for node-negative tumors [115]. Similarly, a 21-gene signature (16 cancer-related and five reference genes), derived in part from microarray studies and assayed by Q-RT-PCR using FFPE specimens (Genomic Health's Onco*type* DX), predicts risk of tumor recurrence in ER-positive, node-negative breast cancers [116]. Such tests, in conjunction with other clinical and laboratory information, might be used to select patients who are likely to benefit from adjuvant chemotherapy. Another interesting group of multigene signatures with potential prognostic utility reports on key biological features of tumors, like metastasis [51], wound response [117], stemness [118], stroma [119], oncogenic pathways [120], hypoxia [121], chromosomal instability [122], and invasiveness [123].

3.7.2 Microarray Platform for Clinical Diagnosis

Many challenges remain in adopting DNA microarrays as a commonplace platform for diagnostic testing [124]. Early concerns with expression profiling centered on discordances of microarray findings among different research laboratories. Gene-expression signatures ostensibly reporting on the same biological or clinical parameter often shared few genes in common. Such discrepancies are likely attributable in large part to differences in specimen cohorts, array platforms (and probes), protocols, and analysis methods. More recently, investigators have shown high reproducibility of findings when standard operating procedures are followed, and improved inter-platform concordance with careful matching of probe annotations between platforms [125, 126]. In addition, further scrutiny has revealed that the disparate gene-signatures might nonetheless reflect the same underlying biology [32], or provide comparable clinical utility [127]. Microarray-based clinical tests are likely to emerge where (1) microarrays provide additional clinical information or outperform standard histopathologic markers, (2) many genes provide more information than one or a few, (3) adequate performance characteristics are demonstrated, (4) testing impacts a patient management decision, (5) there has been appropriate validation of clinical utility, and (6) testing is cost worthy.

3.8 DNA Sequencing Technologies

3.8.1 Conventional Dideoxy Sequencing

DNA sequence point mutations represent a major class of cancer genome aberrations only recently surveyable by genomic-scale approaches. For the past three decades, Sanger dideoxy DNA sequencing has been the preferred methodology, and advances in sequencing chemistry and automation have led to increased read lengths, accuracy and throughput, culminating in the completion of the draft human genome sequence in 2001 [128]. Subsequent directed resequencing efforts focusing on oncogene candidates in cancer genomes have led to the discovery of novel mutations, including activating mutations of *BRAF* (in the MAP kinase pathway) in two-thirds of melanomas [129], and of *PIK3CA* in approximately 30–40 % of colorectal [130] and breast cancers [131, 132]. Larger scale sequencing efforts have identified other candidate cancer genes [133, 134], though a

Fig. 3.6 Serial Analysis of Gene Expression (SAGE). Shown is a schematic depiction of the SAGE method. Captured cDNAs are digested with an anchoring endonuclease followed by a tagging endonuclease, releasing DNA sequence tags that uniquely identify transcripts. Counting of tags by sequencing tag concatamers provides quantitative information on transcript abundances.

remaining challenge in the field is distinguishing pathogenic driver mutations from noncontributory passenger mutations consequent to genomic instability.

3.8.2 Serial Analysis of Gene Expression

Sanger sequencing has also been used for census applications, where counting DNA sequence tags permits a quantitative characterization of complex nucleic acids populations. Serial Analysis of Gene Expression (SAGE) is one such application developed to quantify transcripts (Fig. 3.6) [135]. In SAGE, mRNA transcripts from a specimen are converted to cDNA using a biotinylated oligo(dT) primer, then digested with a frequent cutting (anchoring) restriction endonuclease where the 3'-most cDNA portion is captured on streptavidin beads. Bound cDNAs are then digested with a tagging type IIS restriction endonuclease which recognizes a site in a linker ligated to the 5′ end but cleaves 14 bp downstream. Resultant released short sequence tags are then dimerized, PCR amplified, serially concatenated (to increase throughput), cloned and dideoxy sequenced. The resultant 9–10 bp sequence tags (or up to 22 bp using a type III restriction endonuclease [136]), located at a defined position within the transcripts (between the anchoring and tagging sites) uniquely identify transcripts, and therefore counting tags provides a quantitative cataloging of expressed genes. Potential advantages of SAGE (over DNA microarray-based expression profiling methods) are that it provides absolute quantification as well as information on previously uncharacterized transcripts. A major disadvantage has been the substantial effort of SAGE library construction and the resultant low sample throughput.

3.8.3 Next-Generation DNA Sequencing Methods

In the past 3–4 years, the so-called next-generation (next-gen) DNA sequencing technologies have been introduced that provide orders of magnitude increased sequencing throughput capability, and have revolutionized cancer genomics (much as DNA microarrays had a decade earlier). Most of these technologies rely on cyclic array sequencing methods, where DNAs to be sequenced are immobilized as clonal features on an ordered or random array (Fig. 3.7) [137]. Each cycle, the identity of a single base position is interrogated at each feature on the array using an enzymatic sequencing chemistry and read out by imaging luminescence or fluorescence. By carrying out multiple cycles, contiguous DNA sequences are simultaneous decoded for each of the up to tens of millions of arrayed DNA features. This massively parallel sequencing combined with low reagent volumes (shared across the array) translates to enormously increased throughput and concomitant per base pair (bp) cost reduction.

While the technology is still evolving, several commercial platforms are in use, differing mainly in the method for generating DNA features, the sequencing chemistry, and the resultant sequence read lengths, throughput, and error types [138, 139]. Both the 454/Roche [140] and Applied Biosystems (ABI/SOLiD) [141] platforms use compartmentalized water-in-oil emulsion PCR to generate clonal polymerase colonies (polonies), where multiple copies of each DNA sequencing template are captured on micron-scale beads (Fig. 3.7). Thousands to millions of beads, each with a different DNA template, are then either orderly self-assembled on an etched fiber optic bundle (454/Roche) or immobilized on a glass surface as a disordered array (ABI/SOLiD). The 454/Roche platform uses a DNA polymerase-based sequencing-by-synthesis pyrosequencing method (with real-time luminescence detection) to interrogate bases, and achieves long sequencing read lengths (~400 bp), though errors can occur at long homopolymer stretches. The ABI/SOLiD system uses a sequencing-by-ligation chemistry with fluorescence detection to query bases, and achieves significantly higher sequencing capacity (by increased feature density) though with shorter read lengths (35–75 bp).

The Solexa/Illumina platform generates DNA features by bridge PCR, where universal PCR primers are immobilized on a glass slide such that resultant PCR-amplified sequencing templates form locally tethered clonal features (Fig. 3.7) [138]. Bases are interrogated using a polymerase-based single nucleotide extension method with reversible fluorescent terminators, yielding high sequencing capacity (comparable to ABI/SOLiD) with modest read length (36–150 nts). For all these platforms, throughput can be doubled by sequencing both ends of DNA templates. Such paired-end sequencing can also facilitate sequence alignment (and in particular de novo assembly), which is more challenging for short reads.

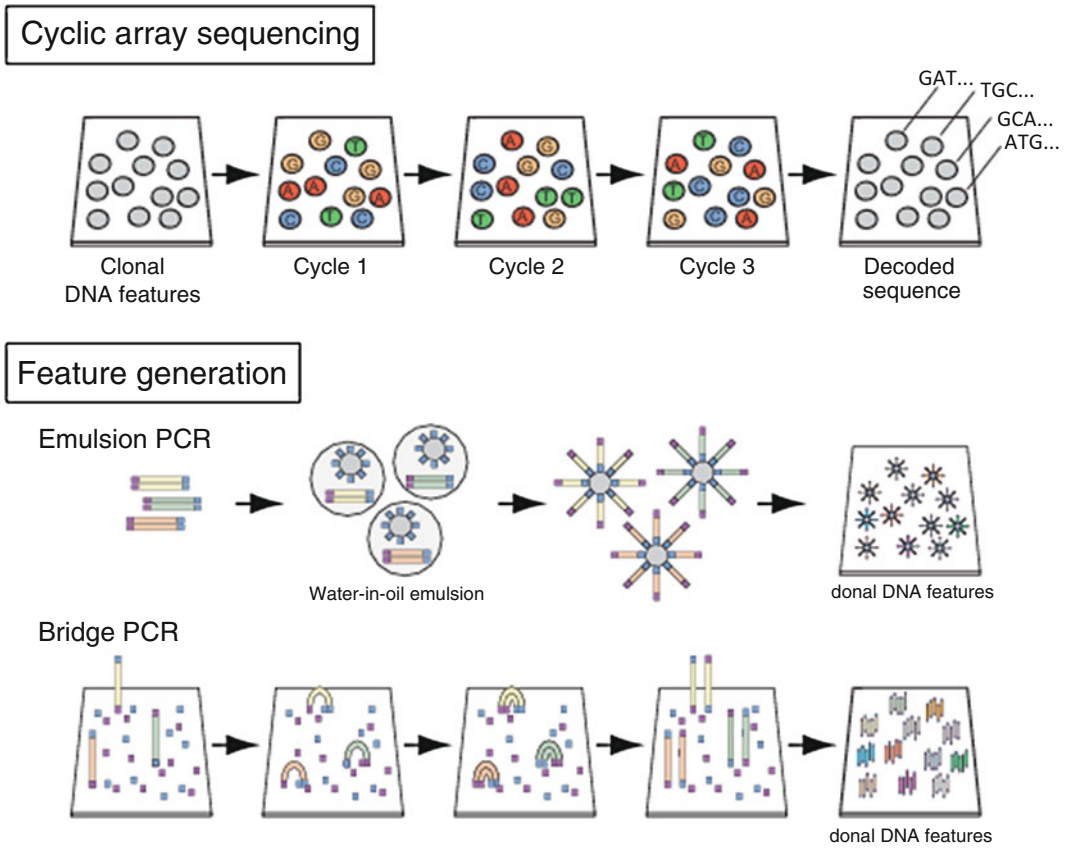

Fig. 3.7 Next-generation DNA sequencing. *Above*, schematic depiction of next-gen cyclic array sequencing. Arrayed DNAs are clonal features each comprising multiple PCR-generated copies of a different DNA sequencing template. Each cycle (only three cycles shown), enzymatic sequencing chemistry interrogates a subsequent base pair position, and multiple cycles permit the decoding of DNA sequence stretches. DNA sequences are decoded across millions of features in parallel, providing ultra-high throughput capability. *Below*, schematic depiction of two different methods of generating clonal DNA features for next-gen sequencing. In emulsion PCR, individual DNA sequencing templates (along with primer-coated capture beads) are sequestered within micelles formed by water-in-oil emulsion. Resultant clonally amplified beads are subsequently arrayed on a solid surface for sequencing. In bridge PCR, individual sequencing templates are captured on a primer-coated surface, such that resultant PCR-amplified products remain locally tethered as clonal features.

Recent and emerging technologic advances include single molecule DNA sequencing (rather than sequencing PCR-amplified features), for example as developed by Helicos BioSystems [142] and Pacific Biosciences [143]. With the continued rapid pace of technologic advances, a stated goal [144] to sequence a human genome (or cancer genome) at a cost of less than $1000 is within sight.

3.9 Next-Gen Sequencing Applications

3.9.1 Census Applications

For practical concerns of throughput and cost, next-gen sequencing technologies were first widely adopted in census applications of lower-complexity (compared to whole cancer genomes) nucleic acid mixtures [145, 146]. For example, in RNA-seq, analogous to SAGE, transcripts (or small RNAs) are profiled by next-gen sequencing of cDNAs (typically prepared by first fragmenting and then reverse transcribing RNA) [147, 148]. Resultant sequence reads are mapped to the reference genome or transcriptome using alignment software (e.g., ELAND, MAQ, Bowtie) (Fig. 3.8) [139, 149]. Transcript counts are then normalized with respect to the kilobase size of the transcript (to compensate for larger transcripts having more sequence reads), as well as the total number (of million) of mapped reads (which can vary among samples), often expressed as reads per kilobase per million (RPKM) [149]. The resultant dataset can then be analyzed and visualized as described for DNA microarrays.

Compared to DNA microarrays, RNA-seq is more quantitative (providing a digital count rather than an analog read-out by hybridization), covers a larger dynamic range, provides greater coverage (not limited to what is printed on a microarray), and yields single base-pair resolution. These latter advantages make it particularly suited to the discovery of novel transcripts, and the delineation of transcript variants (from reads spanning splice junctions). RNA-seq has similarly found

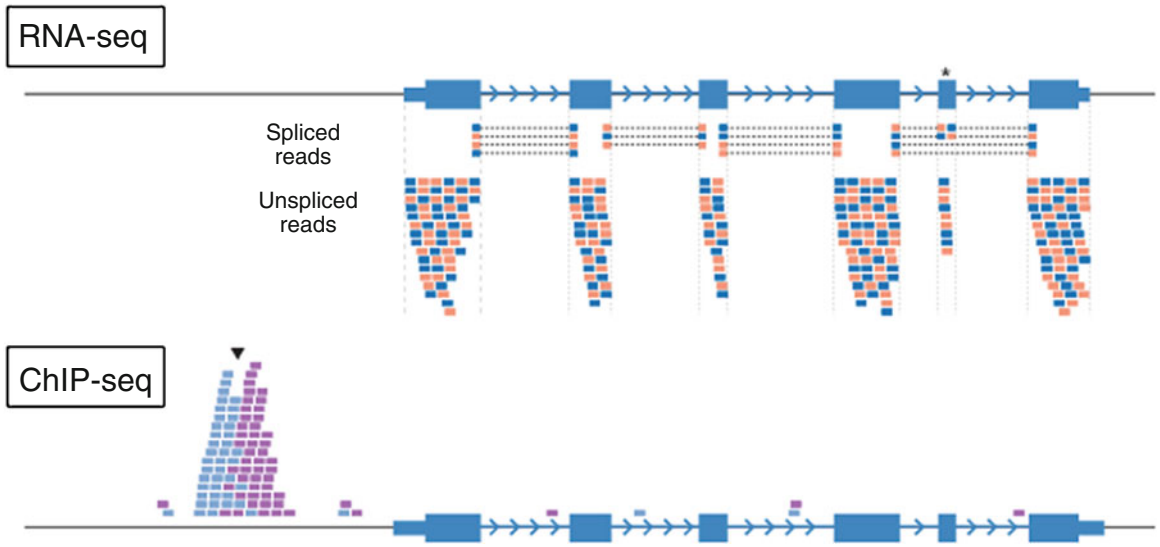

Fig. 3.8 Next-gen sequencing census applications. *Above*, schematic depiction of RNA-seq reads aligned to a gene-coding segment of the genome (exon structure shown). Sequence reads are denoted by *small blue* (aligned to + strand) and orange (aligned to − strand) rectangles. Most reads align to single exons, while some span exon splice junctions, defining transcript variants (including here, an alternatively spliced exon denoted by asterisk). *Below*, schematic depiction of ChIP-seq reads aligned to the same gene-coding region. Sequence reads are denoted by small blue (aligned to + strand) and purple (aligned to − strand) rectangles. A region of increased read density upstream of the gene defines a protein-binding peak. Note, single-end reads of ChIP-enriched fragments result in shifted peaks for + and − strand reads, where an inferred central summit (*arrowhead*) identities the protein binding site.

utility in the search for oncogenic fusion transcripts, as chimeric sequence reads [150] or paired-end reads mapping to two different genes [151]. Short-read RNAseq is also well suited for analysis of the fragmented RNA typical of formalin-fixed paraffin-embedded specimens [152]. Potential obstacles to sequence-based approaches include the availability of sequencing instruments, the infrastructure for data management and analysis, and the still generally higher reagent costs. However, with improving infrastructure and analysis tools, and ever-declining costs, next-gen sequencing is poised to replace DNA microarrays for transcript profiling as well as other applications. Nonetheless, the shared fundamentals of experimental design and dataset analysis remain valid.

Another census-based application now in wide use is ChIP-seq, the enumeration of protein interactions on DNA by next-gen sequencing of chromatin-IP enriched DNAs [153, 154]. Resultant sequence reads are aligned to the reference genome, and then binding peaks (regions of increased read density) called in relation to background (often determined by sequencing non-IP'd input DNA) (Fig. 3.8) [149]. Noted advantages, compared to microarray-based ChIP on chip, include the higher (single bp) mapping resolution and whole genome coverage [155]. DNA methylation can also be surveyed by next-gen sequencing, for example in Methyl-seq by comparing reads for the small DNA fragments generated by paired methylation sensitive and insensitive restriction endonucleases [156, 157].

Similar to aCGH, DNA copy number alterations can be enumerated by next-gen technology, by sequencing tumor genomic DNA, and then aligning and simply counting reads (e.g., per 10 kb window) across the reference genome. Further, by sequencing the paired ends of genomic DNA fragments, structural rearrangements can be identified, including balanced rearrangements otherwise invisible to aCGH (Fig. 3.9). For example, paired end reads mapping (on the reference genome) to greater or less than the expected distances apart (i.e., as compared to the known size of the fragments sequenced) are indicative of DNA deletions or insertions, respectively. Paired ends in reverse of the expected orientation identify inversions, and paired ends mapping to different chromosomes reveal chromosomal translocations. Proof-of-principle for this approach was first shown by conventional Sanger sequencing of paired ends from cloned BAC libraries derived from cancer cell lines [158]. More recently, next-gen sequencing of small (e.g., 0.5–3 kb) genomic DNA fragments has revealed the detailed landscape of structural alterations in lung and breast cancer genomes [159, 160].

3.9.2 Surveying DNA Mutations

In a remarkable feat, Parsons et al. [161] Sanger-sequenced essentially all protein-coding genes from 22 glioblastoma multiforme samples, where they discovered somatic mutations of *IDH1* (isocitrate dehydrogenase) in 12 % of cases. The mutations have since been shown to alter enzymatic activity [162], suggesting IDH1 as a tractable target for cancer therapy. This finding portended the value of screening

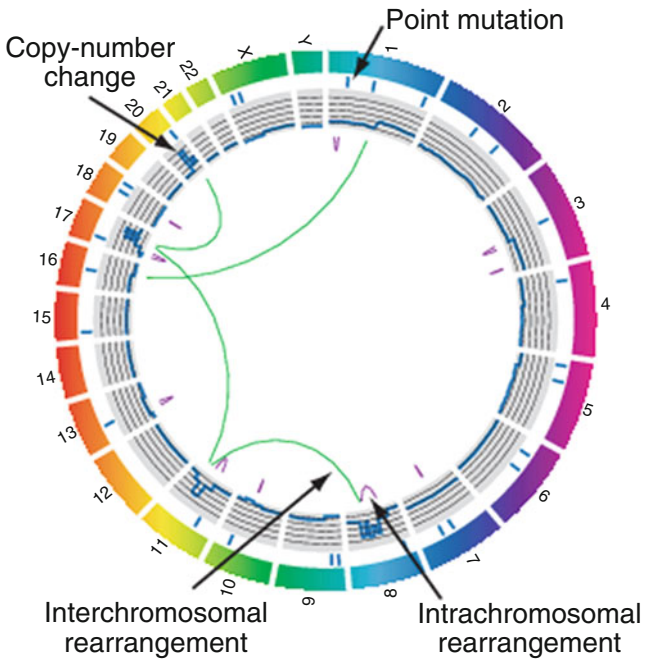

Fig. 3.9 Landscape of the cancer genome. Schematic Circos plot illustrating somatic alterations in a single cancer genome. Concentric tracks (from outside to in) depict reference genome (chromosome) position, point mutations, DNA copy number alterations (from counting sequence reads), and intrachromosomal (*purple*) and interchromosomal (*green*) rearrangements (from discordant paired-end reads).

cancer genomes for DNA mutations, an undertaking that is now facilitated enormously by next-gen technology.

Many early efforts (motivated in part by costs) have focused on sequencing transcriptomes or targeted exomes [163] (the 1.5 % of the genome that codes for proteins). The first whole cancer genome sequence (an AML case) was described in 2008 [164], and with decreasing costs many more cancer genomes are being reported. Challenges of short-read sequencing are in large part bioinformatic, and include accurate assessment of error rate, alignment and de novo assembly, and calling of polymorphisms and somatic mutations [139]. Oversampling (e.g., 30-fold redundant sequence coverage) can mitigate sequencing errors, and facilitate assembly (as does paired-end sequencing). Sequencing matched normal DNA can assist in distinguishing somatic mutations from personal germ line variants (that might not be represented in SNP databases). Distinguishing oncogenic driver mutations from nonsynonymous passenger mutations remains problematic, though a gene recurrently mutated at a significant frequency implies a driving role. Ultimately, functional studies are required to verify oncogenic activity. Despite the many challenges, early successes of next-gen mutation discovery include *ARID1A*, identified by transcriptome sequencing and mutated in ~50 % of clear cell ovarian cancers [165], and *DNMT3A*, found by whole-genome sequencing and mutated in ~20 % of AML cases [166].

Beyond discovery of cancer genes, surveying somatic mutations can also reveal the carcinogenic exposures and forces shaping the landscape of cancer genomes [167]. For example, next-gen sequencing of a small cell lung cancer genome uncovered mutation signatures reflective of tobacco exposure [168]. Likewise, analysis of a melanoma genome revealed a mutational signature of ultraviolet light exposure, a known risk factor for melanoma [169].

Concerted efforts to fully sequence the genomes of diverse cancer types are now underway, organized by the International Cancer Genome Consortium (ICGC) [170], an umbrella organization that includes the Wellcome Trust Sanger Institute's Cancer Genome Project, and coordinates with the NCI's TCGA research network. An up-to-date *c*atalog *o*f *s*omatic *m*utations *i*n *c*ancer is accessible at Sanger Institute's COSMIC database [171]. Finally, a growing number of actionable mutations/aberrations (i.e., that impact clinical decisions including choice of therapy) in cancer genomes [172], coupled with decreasing sequencing costs, suggests the possible utility of next-gen sequencing for clinical diagnosis in the not so distant future.

3.10 Conclusions

The past decade has witnessed an explosion of genomics technologies, ushered in by DNA microarrays, and providing for the first time global views of cancer genomes and the altered complement of transcripts and proteins. Genomics approaches have yielded new insights into cancer pathogenesis, and suggest strategies for improved cancer diagnosis, prognostication and patient management. Genomics technologies continue to advance, most recently in the arena of next-gen DNA sequencing. As cancer genomics data accumulate in the public domain, bioinformatics approaches are becoming increasingly important in integrating data from different platforms and disparate sources to derive biological meaning and clinical insight. Cancer researchers knowledgeable in both wet bench and computational analysis are best prepared to leverage the potential of cancer genomics.

Cancer Cytogenetics

4

Thomas Ried, Kerstin Heselmeyer-Haddad, Jordi Camps, and Timo Gaiser

4.1 The Development of Cancer Cytogenetics as a Scientific Discipline

The term *chromosome* was coined by the German pathologist Wilhelm Waldeyer in 1888. At that time, chromosomes just appeared as *stained bodies*, and their biological relevance had not been recognized. It was probably David von Hansemann who first speculated about the fact that the number of chromatin segments and their irregular distribution to daughter cells could have something to do with cancer. He summarized this concept in a study published in 1890 with the title "*Über asymmetrische Zellteilung in Epithelkrebsen und deren biologische Bedeutung*" (Translated: *On asymmetrical cell division in epithelial cancers and its biological relevance*) [1]. In this report he wrote that "*Chromatin plays a crucial role for the inheritance of specific cellular features, and it is in particular the number of segments that carries important biological significance which is proven through the constant number in different tissues and species*." He continues to state that "*The asymmetric divisions do not follow a specific rule regarding the numbers of chromatin segments. i.e., in one and the same tumor we can observe cells with a different numbers of segments*." This phenomenon is "*…in many cases consistent with an anaplasia, because the results of tumorigenesis are cells with increased growth potential…*". These cells "*…frequently can be found far away from the initial tumor and can become the origin of identical tumors*." Clearly, von Hansemann was on the right track [2]. However, it was the zoologist Theodor Boveri of the University of Würzburg (Fig. 4.1a), who injected his chromosome theory of heredity into the cancer problem and with that generated the theoretical scaffold for cancer cytogenetics to develop as a scientific discipline [3–5] (Fig. 4.1b and c). Boveri did not work with cancer tissues or cancer cells. He instead studied ascaris larvae or sea urchin eggs, which, when fertilized with two sperms begun to show centrosome aberrations and abnormal mitoses. Boveri hypothesized that chromosomes should have continuity throughout the cell cycle, and in fact, individuality. This implies that chromosomes are unique. He then postulated that chromosome segregation errors would ensue as a consequence of centrosome abnormalities, leading to daughter cells that in terms of the genetic make up would be different from each other. This imbalance could cause cancer. He wrote: "*To assume the presence of definitive chromosomes which inhibit division, would harmonize best with my fundamental idea. If their inhibitory action were temporarily overcome by external stimuli, then cell division would follow. Cells of tumors with unlimited growth would arise if those "inhibiting chromosomes" were eliminated.*" And he continues: "*On the other hand, the assumption of the existence of chromosomes which promote division, might satisfy this postulate. On this assumption, cell-division would take place when the action of these chromatin parts, which are as a rule too weak, should be strengthened by a stimulus; and the unlimited tendency to rapid proliferation in malignant tumors cells would be deduced from a permanent predominance of the chromosomes that promote division*." Arguably, what he proposed is consistent with the interpretation that chromosomal aberrations would activate specific oncogenes when gained, or impair the function of tumor suppressors when lost, as a consequence of genomic copy number changes. We now know that this is correct [6–8].

Progress in the years to follow was slow. This was probably not attributable to a lack of interest or due to an a priori rejection of Boveri's hypotheses, but due to insurmountable challenges in the analysis of chromosomes. The analysis of tissue sections per se was exceedingly difficult, fixation and

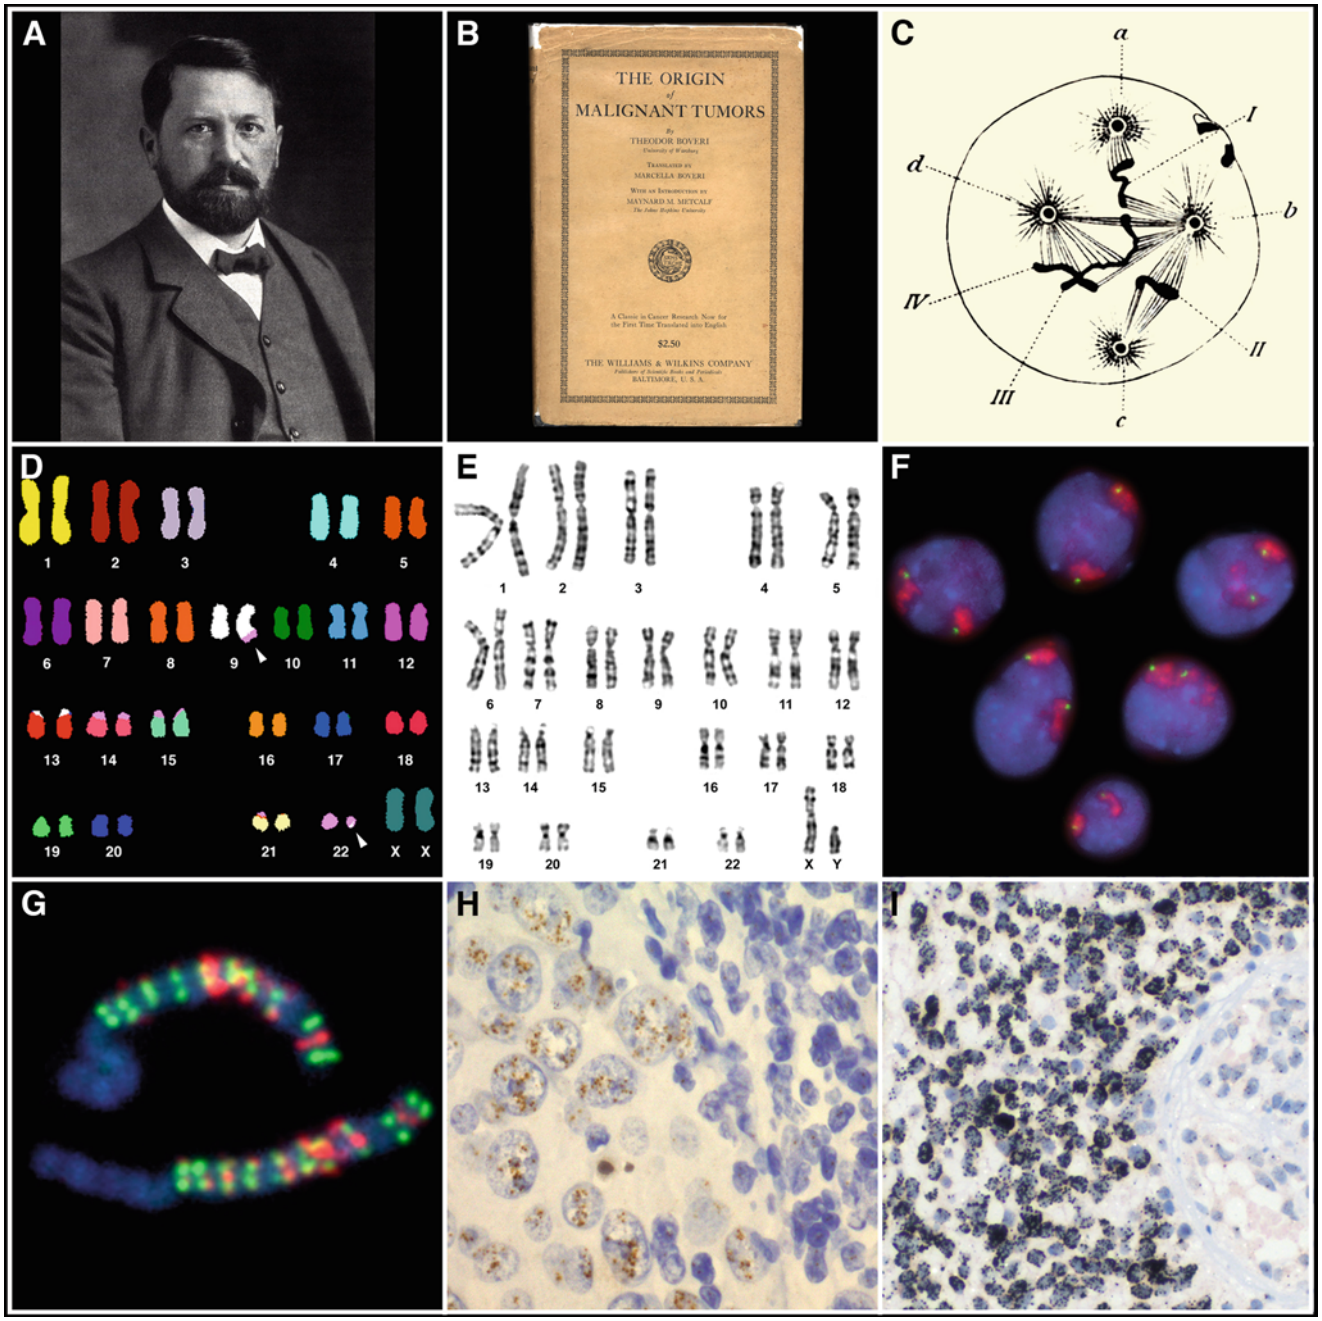

Fig. 4.1 Early chromosome analysis and molecular cytogenetics. (**a**) Photograph of Theodor Boveri (1862–1915). Boveri was a professor of zoology in Würzburg, Germany. Combining his theory that chromosomes carry genetic information with observations he made when studying cell division in ascaris larvae and double fertilized sea urchin eggs, Boveri postulated that cancer is a disease of the chromosomes. These studies were published in 1914 with the title "*Zur Frage der Entstehung maligner Tumoren.*" (**b**) Cover of the English edition of Boveri's book, which appeared in 1929. His wife and former student Marcella Boveri translated the text. (**c**) Additional centrosomes and aberrant mitoses in ascaris. These observations led Boveri to conclude that tumorigenesis ensues as a consequence of the loss of *inhibiting* and the gain of *promoting* chromosomes. (**d**) SKY analysis of chromosomes from a patient with chronic myelogenous leukemia. The balanced translocation between chromosomes 9 and 22, t(9;22), the so-called Philadelphia chromosome, is readily visible (*arrowheads*). The consequence of this translocation is the generation of a fusion protein with increased tyrosine kinase activity, generated by the juxtaposition of the genes *BCR* and *ABL*. Note that all other chromosomes are normal. (**e**) G-banded, normal male human karyotype. Chromosome banding revolutionized the discipline of cancer cytogenetics by providing the possibility to identify nonrandom, cancer specific chromosomal aberrations. (**f**) Dual color hybridization targeting chromosome 8 (*red*) and the *MYC* oncogene (*green*), which resides on chromosome band 8q24. Note that chromosomes occupy specific territories in the interphase nucleus. The *MYC* oncogene, expressed in the colon cancer cell line DLD1, is contained in the territory. Note that most of the territories are in the periphery of the nucleus, consistent with the fact that chromosome 8 is gene poor. (**g**) Dual color high-resolution mapping of multiple BAC clones on the long arm of chromosome 6. These clones are part of the CCAP collection, which was established to systematically integrate the cytogenetic and sequence maps of the human genome by FISH mapping sequenced BAC clones (http://cgap.nci.nih.gov/Chromosomes/CCAP). (**h**) Chromogenic in situ hybridization (CISH) of a breast cancer sample with probes detecting the *ERBB2* oncogene. The brown precipitates indicate high-level amplification in cancer cells. The adjacent lymphocytes are negative. The slide was stained with hematoxylin (*blue*). (**i**) Silver-enhanced in situ hybridization (SISH) of a malignant brain tumor (glioblastoma multiforme) showing amplification of the gene encoding the epithelial growth factor receptor, *EGFR*. The pronounced black stain can be analyzed automatically. Cells of vascular proliferation (right side of the slide) are negative for this gene amplification. The slide was stained with hematoxylin (*blue*).

preparation techniques were insufficient, and the preparation of metaphases slides was impossible, to name just a few hurdles for a systematic cytogenetic approach to the analysis of chromosomal abnormalities. The inability to identify consistent cancer-specific cytogenetic changes did not help to promote the field, and it is very conceivable that the subsequent frustration, which was mainly attributable to shortcomings in analytical technologies, supported the prevalent interpretation that cytogenetic abnormalities were present in cancer, but were merely disease-correlated, but not the cause of this disease [9, 10]. The fact that the correct number of human chromosomes was only established 4 years after the structure of the double helix was deciphered attests to the problems that cytogeneticists faced [11, 12] (the reader may consult the enlightening publication by Kottler, who discussed some additional shortcomings in cytogenetics at that time [13]).

After establishment of the normal human chromosome count, the field of human cytogenetics exploded. In particular, numerical chromosomal aberrations associated with congenital abnormalities were reported in short order [14–18]. However, the identification of recurrent aberrations in cancer cells came later. In 1960, Nowell and Hungerford described a consistent marker chromosome (termed the Philadelphia chromosome) in patients with chronic myelogenous leukemia (CML) [19]. This description was undeniably facilitated by the discovery that lymphocyte cultures can be stimulated with phytohemagglutinin (PHA) by the same authors [20]. For the first time, cancer was associated with a specific genetic abnormality that is visible through a microscope. The importance of this discovery cannot be overestimated. The consistency with which the Philadelphia chromosome was observed in CML all but proved that its presence reflected the molecular lesion accounting for the development of this hematological malignancy. Yet technical hurdles again prevented a thorough characterization of this marker chromosome because the structural integrity of chromosomes could not be analyzed in detail due to the lack of discernible features along individual chromosomes. This changed with the introduction of chromosome banding techniques [21, 22] (Fig. 4.1d). This revolution also facilitated the identification of intrachromosomal changes, and most importantly, the description of the reciprocal character of the Philadelphia chromosome—a balanced translocation involving chromosomes 9 and 22 [23] (Fig. 4.1e). Many more specific reciprocal translocation were subsequently identified, the translocation t(8;14) in Burkitt's lymphoma among them [24, 25]. Similar consistent aberrations were found in mouse models of human cancer, such as those characterized in murine plasma cell tumors [26, 27]. Together, these findings prompted the development of the hypothesis that the sites of the consistently observed breakpoints pointed to the location of cancer-promoting genes, which would be activated as a consequence of such translocations [28]. In fact, this was the case. The human *MYC* oncogene is juxtaposed to the immunoglobulin heavy chain gene via the translocation t(8;14) in Burkitt's lymphoma [29, 30], and an equivalent situation occurs in mouse plasma cell tumors on the respective orthologous chromosomes [26, 31]. The functional consequence is the deregulation of MYC expression by an active promoter of *IGH* in hematological cells, which is sufficient for malignant transformation. The Philadelphia chromosome represents a second mechanism for the translocation-induced activation of an oncogene—the generation of a fusion transcript with constitutively active tyrosine kinase—again sufficient and the cause for the emergence of leukemic cells.

The paradigm of translocation-induced oncogene activation and tumorigenesis was discovered based on cytogenetic analyses [32]. The importance of these discoveries cannot be overstated—not only does the detection of such aberrations serve as a diagnostic and prognostic tool and can be used for monitoring the efficacy of treatments, but it also identifies specific molecular targets for therapeutic intervention. For instance, BCR-ABL is the target for Gleevec in the case of CML [33]. The comprehensive analysis of chromosomal aberrations in solid cancers remained more complicated and had to await the development of molecular cytogenetic techniques that we review in the following sections.

4.2 The Emergence of Molecular Cytogenetics

The development of chromosome banding techniques is likely the single most important technical development in cytogenetics. Chromosome banding was first developed by Torbjörn Caspersson and Lore Zech in Stockholm using quinacrine mustard fluorescence and was immediately applied to establish karyotypes of hamster, human, and mouse chromosomes. As described above, the application for the detection of chromosomal abnormalities followed in short sequence. A conference held in Paris in 1971 published an official version of the human karyogram and established a map of human chromosomes. With the introduction of Giemsa banding by Seabright in 1971 [34], which omitted the requirement for fluorescence microscopy and generated permanent banding patterns, the method quickly entered laboratories around the world, and for decades to come was the most frequently performed genetic test (Fig. 4.1d). Besides its application in cancer, chromosome banding has become the method of choice for the detection of constitutional chromosomal abnormalities, both in the postnatal and prenatal settings. While the knowledge gained through the systematic application of chromosome banding techniques is vast, the technique has limitations. First, the resolution is low. Second, chromosome banding can only be applied to fresh tissues from which the cells can be cultured and arrested

in metaphase (or prometaphase when higher resolution was desired). Third, the interpretation of banded karyotypes requires a skill set that not everyone can muster. These limitations combine to account for the fact that considerably more karyotypes from hematological malignancies have been published than from solid cancers [35, 36]. Most solid cancers are difficult to culture, and the morphology of metaphase chromosomes is often poor. In addition, the sometimes enormous number of cytogenetic abnormalities in solid cancers prevented a comprehensive analysis of all aberrations, and cytogenetic correlates of oncogene amplification, such as double minute chromosomes (dmin) and homogeneously staining regions (hsr), could be described, yet their chromosome of origin remained elusive. Most of these shortcomings were overcome by the marriage of classical cytogenetic chromosome analysis with independently developed molecular techniques (DNA cloning and hybridization).

4.2.1 In Situ Hybridization

The first relevant achievement was the successful in situ hybridization with radioactively labeled nucleic acids by Joe Gall and Mary Pardue in 1969 [37–39]. This was followed by the first in situ hybridization with fluorescently tagged probes by Rudkin and Stollar in 1977 [40]. Clearly, omitting radioactivity had intrinsic advantages, such as increased resolution, shorter detection times, and the possibility to increase the number of simultaneously detectable targets. Rudkin and Stollar used indirect immunofluorescence for the visualization of RNA/DNA hybrids. Another very important development for the success of molecular cytogenetics was the development of covalent labeling of nucleotides with haptens, the first of which, and still one of the most widely used, was biotin [41]. These hapten-conjugated nucleotide analogs can be incorporated enzymatically into DNA molecules, hybridized, and visualized with suitable detection systems, such as avidin conjugated fluorochromes or antibodies against other haptens, such as digoxygenin or dinitrophenol. Their advantage lies in the fact that their use increases the multiplicity and sensitivity of in situ hybridization experiments, increasing experimental versatility. More recently, nucleotide analogs directly coupled with fluorochromes have become available as well. The authors of this chapter purposely abstain from providing details of protocols for in situ hybridization experiments. Such protocols can be found in great detail and abundance for instance in the following references [42–45] and websites (http://www.riedlab.nci.nih.gov/).

Using a hybridization format for cytogenetic analyses obviously brought with it the possibility of designing DNA probes that were suitable to answer the specific experimental question asked. Among the first probes used for fluorescence in situ hybridization (FISH) were probes that targeted the centromeric or paracentromeric heterochromatin of specific chromosomes. Such probes readily allowed chromosome enumeration in metaphase preparations, but even more importantly enabled the concept of interphase cytogenetics. This meant that numerical chromosomal aberrations could be detected in nondividing cells, throughout all stages of the cell cycle, opening the door for pathologists to use cytogenetics to augment the morphology-based diagnosis of samples in the clinical laboratory. The concept and the term *interphase cytogenetics* were first conceived and published in a paper by Cremer and colleagues, who used a radioactively and nonradioactively labeled probe to detect the number of chromosome 18 in fibroblasts [46]. The concept of interphase cytogenetics proved to be very useful for the detection of aneuploidies in prenatal diagnostics, where numerical chromosomal abnormalities of chromosomes 13, 18, and 21 play a major role for constitutional syndromes, which previously could be diagnosed only after in vitro culture of amniotic fluid cells [47]. Interphase FISH is now widely used in the screening for chromosomal disorders in prenatal diagnostics.

4.2.1.1 Chromosome Painting

A second set of probes that became immensely useful in the diagnosis of chromosomal disorders were probes that allowed delineation of entire chromosomes. Chromosome painting probes were first reported for the human Y chromosome by Christoph Cremer, Joe Gray, and colleagues at the University of Freiburg and the Los Alamos National Laboratory [48]. Two groups, one with Thomas Cremer and David Ward at Yale University, and the other with Dan Pinkel and Joe Gray at the University of California in San Francisco, developed methods for painting specific chromosomes based on suppression hybridization [49–51]. Initially, such painting probes were cloned in phage or plasmid vectors [52], which resulted in acceptable signal to noise ratios. However, chromosome painting probes were soon prepared by either flow-sorting or by microdissection of individual chromosomes [53, 54]. Both techniques require amplification of the isolated nucleic acids using universal DNA amplification [55], but the signal to noise ratio is superior to that of the cloned chromosome libraries. Suppression of repetitive sequences is necessary to assure chromosome specific hybridization, which is achieved by including unlabeled DNA (either whole genomic DNA or repetitive sequence enriched Cot1-DNA) in the hybridization mixture. Chromosome painting probes are now routinely used to verify suspected aberrations in the clinical cytogenetic or in the cancer cytogenetic laboratory. Probes already labeled with different fluorescent dyes are commercially available from a variety of commercial suppliers. Chromosome painting probes have proven to be valuable experimental tools above and beyond their applications in diagnostics, for instance in

the study of the three dimensional (3D) architecture of the interphase nucleus [56]. FISH with painting probes to interphase nuclei has unambiguously confirmed classical studies using UV-microbeam experiments [57] showing that chromosomes maintain their integrity throughout all stages of the cell cycle and are arranged as domains, or territories. Now we also know that chromosomes are not randomly distributed in the 3D nuclear space. Several groups have generated solid evidence that gene-rich chromosomes tend to be found more towards the interior compartment, whereas gene-poor chromosomes are positioned more towards the nuclear periphery [58, 59]. This organization appears to also be maintained to a certain degree in cancer cells, and in cells which contain artificially introduced chromosomes [60–62]. Chromosome painting has therefore become instrumental in attempts to decipher how the architecture of the nucleus affects transcriptional regulation in physiological states as well as in cancer, and how the dedifferentiation of cancer cells affects or is affected by the organization of chromosome territories. In combination with probes for specific genes, chromosome painting probes can be used to investigate whether the transcriptional state of a specific gene is reflected by the relative position in its territory [63, 64] (Fig. 4.1f).

4.2.1.2 Gene-Specific Probes

With the improvements in microscopic techniques and the availability of more and better probe labeling methods and fluorochromes, the versatility of FISH experiments also greatly increased [65]. These developments were paralleled by progress of the Genome Project and the availability of bacterial artificial chromosome (BAC) clones for essentially every gene. Historically, some of the first gene specific probes were cloned into lambda phage vectors and used for the visualization of specific chromosomal breakpoints associated with different malignancies, including CML and Burkitt's lymphoma. For instance, the groups of Pinkel and Gray first succeeded in visualizing the *BCR-ABL* fusion in malignant cells from a patient with CML in interphase cells using a two-color hybridization format which resulted in a co-localization event on metaphase chromosomes and in interphase nuclei in which the Philadelphia chromosome was present [66]. Ried and colleagues developed a three-color approach that included a chromosome 8 painting probe together with probes specific for the *MYC* oncogene and probes for the *IGH* locus to achieve specific metaphase and interphase detection of the translocation t(8;14) in cell lines derived from a patient with Burkitt's lymphoma [67]. The usefulness of this probe set was also explored for the detection of minimal residual disease [68]. The obvious advantage of being able to visualize specific chromosomal translocations directly in nondividing cells led the community of hematological oncologists to embrace the use of FISH very quickly. Today, specific FISH probes for a plethora of chromosomal translocations, inversions, deletions, and amplifications are available from a variety of suppliers. An appealing feature of FISH is that it can be combined with immunohistochemistry or specific pertinent stains. This allows identification of cancer-causing chromosomal aberrations in tissues that maintain the phenotypical appearance that a diagnostic pathologists is used to [69–71].

FISH probes are not restricted to specific genes known to be the target of chromosomal aberrations. The National Cancer Institute has established a resource that systematically integrates the cytogenetic and sequence maps of the human genome. This was achieved by mapping a set of more than 1300 sequence-verified BAC clones to high-resolution banded chromosomes. Any suspected cytogenetic abnormality can now be confirmed and characterized with these tools, and the molecular events at sites of chromosomal aberrations pursued to the very sequence [72–75] (Fig. 4.1g).

4.2.1.3 Molecular Cytogenetics for the Pathologist

While many molecular techniques never became part of routine pathology, FISH was implemented relatively soon after its development. This was due to the fact that the protocol was fairly simple, that tissue morphology was conserved, the method was affordable, and it was able to detect aneuploidy and structural chromosomal rearrangements, both highly relevant for carcinogenesis. Applying in situ hybridization with appropriate probes augments the morphological assessment and can contribute to diagnosis, differential diagnosis, and to prognostication. Using sequence-specific probes, virtually all known translocations can be identified. Next, we review two of the main nonfluorescent in situ hybridization formats used in routine pathology laboratories. In subsequent sections we summarize some of the major applications of in situ hybridization in pathology, with an emphasis on solid cancers.

4.2.1.4 Chromogenic In Situ Hybridization

Evaluation of FISH slides has some drawbacks since it requires an epifluorescence microscope, the analysis needs to be performed in a dark environment, and the signals eventually fade. To overcome these disadvantages, an alternative has been developed—chromogenic in situ hybridization (CISH). CISH is based on the same molecular principles as FISH but uses chromogens instead of fluorescent dyes to visualize the hybridized probes. A comparison of features between FISH and CISH can be found in Table 4.1. The best staining results are obtained with indirect labelling protocols using either biotin or digoxigenin as haptens. The digoxigenin-labeled DNA probe is detected by using anti-digoxigenin antibodies, while the biotin labeled probe is visualized with avidin conjugated with enzymes such as alkaline phosphatase (AP) or horseradish peroxidase (HRP). These enzymes produce, in a secondary reaction, a stable precipitate of chromogens that are generated by the enzymatic conversion

Table 4.1 Overview of commonly used in situ hybridization systems in the pathology laboratory

	FISH	CISH	SISH
Automation	Semi	Semi	Full
Specific equipment	Yes (epifluorescence microscope)	No (standard bright field microscopy)	No (standard bright field microscopy)
Assay time	Overnight	Overnight	6 h
Scoring time	Time consuming, needs trained personnel and expertise	Fast interpretation of the results	Fast interpretation of the results
Morphology conservation	Reduced due to fluorescence	Normal "IHC" morphology	Normal "IHC" morphology
Signal quality	Good	Sometimes faint	good
Multiple probes simultaneously	Yes, direct	Yes, indirect	Not yet
Concordance with FISH	–	Good	Good
Image Analysis	Yes, but not routinely	Yes, but not routinely	Yes, with fast results
Processing time	1 day	0.5 days	1 h
Archivability	No	Long term	Long term

from soluble states. The sections are subsequently counterstained with hematoxylin and can be evaluated with bright field microscopy. Most of the current CISH applications are based on a single-color detection method, which does not allow simultaneous illustration of a reference probe on the same slide [76–78]. This limitation was overcome by the development of dual-color and triple-color in situ hybridization protocols [79–81]. Recent publications attest to the robustness and reproducibility of such protocols. The concordance with FISH based experiments is excellent [82, 83] (Fig. 4.1h).

4.2.1.5 Silver-Enhanced In Situ Hybridization

CISH overcomes some of the limitations of FISH, but has not yet found broad acceptance in pathology laboratories. The reasons for this might be the requirement for manual processing, overnight hybridization, and the need for two separate detection steps (one for the gene of interest and one for the reference probe). Furthermore, some CISH samples are difficult to evaluate because the signal can be weak. This led to the development of a fully automated in situ hybridization protocol, producing a stable and discrete chromogenic reaction product—silver in situ hybridization (SISH) [83]. SISH is fast and the experiment is analyzed by standard light microscopy. The technology applies an enzyme-linked probe, which in turn accumulates silver particles, forming a dense, punctuated, high-resolution black signal, which is easily recognizable. It provides a permanent record, with no fading or photobleaching, and its sensitivity allows visualization of single genes. The SISH technique is performed as an automated protocol and completed within one working day (about 6 h). Several studies have verified a very high concordance rate between SISH and FISH, proving clinical applicability [84–88] (Fig. 4.1i). A comparison of features between FISH and SISH can be found in Table 4.1.

4.2.1.6 Hybridization With Genomes

Chromosome banding, albeit with limited resolution, allows the survey of an entire genome. This feature is critical if the investigator has no a priori knowledge of the aberrations to be identified or characterized. The previously described molecular cytogenetic methods lack this characteristic and were therefore most useful to confirm, specifically and in nondividing cells or tissue sections, the presence of suspected aberrations. The research community therefore attempted to combine the advantages of both and developed genome-screening tools based on fluorescence in situ hybridization.

4.2.1.7 Comparative Genomic Hybridization (CGH)

The first such concept was realized with the introduction of comparative genomic hybridization (CGH) by Kallioniemi and colleagues at the University of San Francisco in California and by the group of Thomas Cremer in Heidelberg. Using a CCD camera (or other digital imaging device) fluorescent intensities can be measured quantitatively, that is the measured intensity is proportional to the amount of hybridized fluorescently labeled probe. If sequences in a test genome labeled with a green fluorochrome are more abundant than in a red-labeled reference genome, this difference should become visible upon hybridization to normal metaphase chromosomes as reflected by increased fluorescent signal. Conversely, losses of genetic material in the test genome would result in reduced green intensity. In papers published in 1992 and 1993 both groups presented convincing proof-of-principle experiments [89–91] by mapping genes amplified in cell lines and primary cancer, and by showing that by hybridizing DNA from individuals with constitutional chromosomal abnormalities such numerical imbalances can be identified. CGH has become one of the most important techniques in the study of cancer genomes,

and essentially all major cancers and cell lines derived from them have been studied in great detail. Several databases now contain comprehensive catalogues of chromosomal imbalances, and several reviews summarize the many primary publications [92–94].

As apparent from the experimental concept, screening the genome for imbalances using CGH does not require the preparation of metaphase chromosomes from cancer samples for banding analysis. This feature was particularly useful for the analysis of solid cancers of epithelial origin (carcinomas), because cell culture of such samples is often difficult, and only for some carcinomas could cell lines be established in sufficient quantities. Karyotyping was further impeded because the morphology of metaphase chromosomes was poor, and in general the karyotypes revealed more aberrations compared to spreads prepared from hematological malignancies [36]. The fact that only cancer DNA was required for genome screening had another significant advantage—it opened the door to apply cytogenetic analysis to formalin fixed and paraffin embedded samples [95–97]. This feature allowed accessing the richly stocked pathology archives to perform retrospective analyses and to compare genomic aberration profiles with clinically relevant parameters, such as outcome and response to therapy. Moreover, it greatly facilitated the analyses of premalignant lesions. It is eminently difficult to establish cell lines for cytogenetic analysis from bona fide precursor lesions of carcinomas, and the earlier the lesions are situated in the sequential progression events to malignant, invasive disease the more normal cells are present. This problem could be overcome by dissecting morphologically identified premalignant lesions from surrounding normal tissue and extracting DNA exclusively from morphologically suspicious lesions [98, 99]. Of course, the earlier such lesions are detected the smaller they usually are, and not always is the quantity of DNA recovered sufficient for standard CGH experiments (which is in the range of a few micrograms). This limitation was overcome by the development of protocols for the sequence independent universal amplification of DNA using degenerate primers followed by cycles of PCR [100]. In essence, these combinations of methodologies enabled characterization of the sequential genomic imbalances in the progression of solid cancers. When combined with micro-dissection or macro-dissection of morphologically characterized lesions one could then establish a phenotype/genotype correlation and provide insights into the dynamics of genomic aberrations during tumorigenesis [99, 101]. Through improvements in protocols for microdissection, genome amplification, and CGH,)genomic aberrations profiles could be established from only a few, and possibly from single cells, with considerable implications for the study of cancer heterogeneity, clonal composition, tumor dormancy, identification of disseminated cancer cells, and for the identification of the cell of origin of metastatic lesions [102–105].

CGH does not require the analysis of aberrant chromosomes, yet even the correct identification of DAPI banded normal chromosomes requires a certain cytogenetic skill set and prevented automation and high-throughput. Furthermore, the resolution with which chromosomal gains and losses could be detected is limited by the resolution of the target metaphase chromosomes (in the megabase range), and was dependent on the copy number change. High-level copy number amplifications could be more readily detected than subtle deletions (but the mapping resolution along the axis of chromosomes of course remained the same). Accordingly, the molecular cytogenetic community quickly realized that these drawbacks could be overcome if metaphase chromosomes are replaced by specific nucleic acids arrayed on a suitable medium as the hybridization target [106, 107]. The analysis of CGH experiments on such a format does not require identification of banded chromosomes, increases the resolution essentially to the length of the blotted nucleic acid sequences, allows automation, and with the genome sequence available enables investigators to seamlessly identify the nature of the genes affected by copy number imbalances. Initially the concept of array-based CGH was realized using BAC clones immobilized on glass slides. While suitable for detecting gene-specific copy number variations, improvements in this technology now utilize defined oligonucleotide sequences, either synthesized or printed onto slides, or attached to beads, to provide remarkably robust and reproducible tools for the high-resolution mapping of genomic imbalances in test genomes. Many of these arrays not only allow detection of copy number changes, but also identification of sequence polymorphisms, to provide information on allelic imbalances (loss of heterozygosity). The application of aCGH to cancer samples of the same entities as analyzed by CGH)confirmed the predominance of recurrent, cancer-specific chromosomal gains and losses (Fig. 4.2a). However, aCGH is particularly useful for the high-resolution mapping of amplified regions, and for the detection of subtle deletions (Fig. 4.2b). Furthermore, aCGH shows that chromosomal breakpoints in carcinomas (here specifically colorectal carcinomas) map to the site of copy number variants (CNVs) in the human genome [108] (Fig. 4.2c). Only high-resolution platforms enabled the detection of such unrecognized plasticity of the human genome in cancer cells.

4.2.1.8 Spectral Karyotyping (SKY) and M-FISH

An alternative avenue to pursue hybridization-based analysis of entire genomes was taken by increasing the multiplicity (the number of simultaneously discernible targets of chromosome painting experiments) with the ultimate goal of visualizing all human chromosomes in different colors. Serious attempts to increase multiplicity were pioneered in Leiden, The Netherlands, by realizing the concept of differentially labeling chromosome painting probes and dissecting

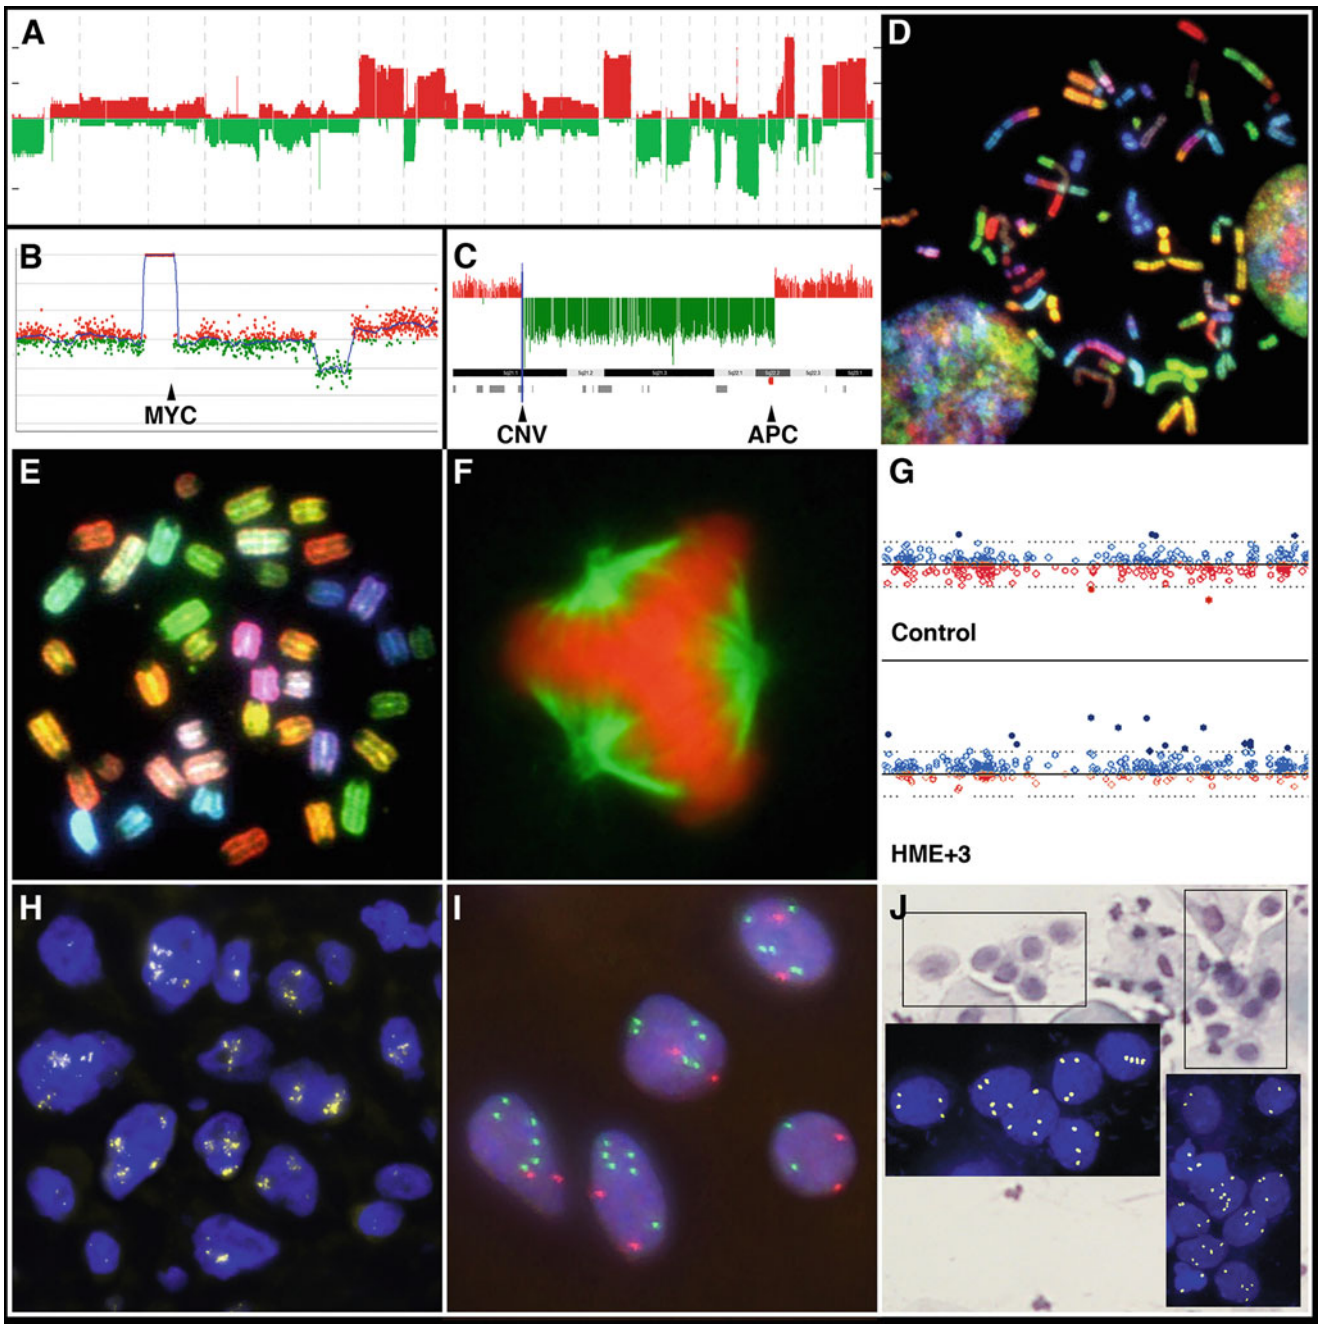

Fig. 4.2 Methods and applications of molecular cytogenetics. (**a**) aCGH analysis of colorectal carcinomas. Shown is a map of chromosomal gains and losses over the entire genome. The *vertical dotted lines* demarcate individual chromosomes. The distribution of genomic imbalances is strictly conserved and specific for this cancer entity. For instance, gain of chromosome 13 occurs only in CRC, but not in other cancers of epithelial origin. CRC is defined by gains of chromosomes 7, 8q, 13, and 20q, and losses that map to chromosomes 8p, 14, 15, 17p, and 18q. This CRC-specific distribution of whole and partial chromosomal gains and losses is maintained in local and distant metastases, and in cell lines derived from primary cancers. (**b**) High-resolution mapping of an amplicon in CRC. In this case, the *MYC* oncogene is part of a localized high level amplification on 8q24, as indicated. aCGH also identified a small deletion (*green dots*) and a copy number gain (*red dots*) towards the telomere of the chromosome. (**c**) Structural variants in the human genome are prone to cause cancer initiating chromosomal aberrations. In this case, the deletion of the *APC* tumor suppressor gene, which is frequently inactivated in CRC, was likely triggered by recombination events at the site of a copy number variant (CNV). Possibly, replicative stress at these sites can induce double strand breaks which can result in chromosomal aberrations. (**d**) SKY analysis of the most malignant brain tumor, glioblastoma multiforme. The poor prognosis of this tumor is paralleled by the enormous amount of genomic instability, accentuated by the fact that most chromosomes are involved in rearrangements. Yet chromosome territories are clearly demarcated in the interphase nuclei (incomplete in the lower left and middle right section of the image). (**e**) SKY analysis of mouse chromosomes. The image shows normal murine chromosomes. SKY was particularly helpful in validating mouse models of human cancer, because it allowed a rapid assessment of chromosomal instability in cells prepared from a great

the fluorescence with specific optical filters and digital imaging devices [109–111]. The approach increased the number of simultaneously visible targets beyond the numbers of utilized fluorochromes. This approach was extended to the detection of up to seven targets, including centromere-specific probes, chromosome painting probes, and cosmid clones along chromosome 5 [112] and was applied to the simultaneous detection of aneuploidies of human chromosomes 13, 18, 21, X, and Y directly in uncultured cells from amniotic fluid [47]. These efforts culminated in the development of spectral karyotyping (SKY) and M-FISH (Fig. 4.2d).

Both techniques) allow simultaneous discernment of all human chromosomes with chromosome specific hues. M-FISH was based on continuous improvements in optical filter technologies, chromosome painting probes and more sensitive imaging equipment. Sequential capture of combinatorially labeled painting probes with narrow band pass optical filters was used to generate composite images that displayed all chromosomes separately. In contrast, SKY used an imaging approach that had not been previously used in cytogenetics—after labeling and hybridization of combinatorially labeled flow-sorted chromosomes, images were acquired in a single exposure using an epifluorescence microscope to which an interferometer and a CCD camera were attached. This combination allowed reconstruction of the spectrum of individual pixels over the entire CCD chip, and hence assignment of spectral information to all points of the image. Specifically developed software then allowed for seamless assignment of pseudo-colors to each pixel, and with that for automated karyotyping based on whole genome hybridization. The first publications reporting the respective approaches were published in 1996 [113, 114]. From then to now, numerous publications followed that attest to the usefulness of SKY and M-FISH with respect to cancer cytogenetics. SKY proved useful for the identification of hidden chromosomal aberrations in hematological malignancies [115], including the characterization of the widely used leukemia cell line HL60 [116]. Other examples pertain to the detection of translocations in multiple myeloma [117, 118], the identification of novel translocations in patients with acute myelogenous leukemia [119], and the identification of mechanisms of drug resistance in acute leukocytic leukemia [120]. Regarding cytogenetic analysis of solid cancers, SKY was instrumental in identifying jumping translocations as a frequent mechanism for the generation of specific genomic imbalances [121], for elucidating the role of centrosome aberrations related to chromosomal instability in colorectal cancers [122], and for a comprehensive and definitive characterization of the karyotype of the HeLa cervical cancer cell line [123].

SKY was quickly adapted to the analysis of murine karyotypes [124] and proved eminently useful for the characterization and eventual validation of mouse models of human cancer (Fig. 4.2e). Two examples demonstrate this here. A knockout mouse model that was designed to study the consequences of deletions of the gene that causes ataxia telangiectasia in patients showed that homozygous deletion of the mouse homologue results in the development of a hematological malignancy (among other features that recapitulate the human disease phenotype). In fact, SKY analysis of the T-cell lymphomas that developed at early age in *Atm*-deficient mice revealed chromosomal aberrations involving mouse chromosome 14, which carries the T-cell receptor genes. Subsequent high-resolution analysis with BAC clones)for these genes confirmed their involvement, validating this mouse model not only as a model for ataxia telangiectasia, but also for human T-cell derived hematological malignancies [125]. A second example pertains to the development of pro-B-cell lymphomas in mice deficient for the DNA repair genes *Ku70/80*. Invariably, these mice succumbed to tumors and the SKY-based cytogenetic analysis disclosed consistent aberrations involving mouse chromosomes 12 and 15—

Fig. 4.2 (continued) number of mouse models. Mouse chromosome analysis based on banding alone is challenging because all mouse chromosomes are acrocentric and less different in length compared to human chromosomes. (**f**) A tripolar mitosis in cancer cells (note the similarity with Fig. 4.1c). Alpha tubulin (stained in *green*) labels microtubules required for proper chromosome segregation upon attachment to the centromeres of metaphase chromosomes. DNA is stained in *red*. In this case the deletion of the tumor suppressor gene *BRCA1* led to an amplification of centrosomes that caused abnormal mitoses. The DNA content of the daughter cells will not be normal (one of Boveri's hypotheses). (**g**) Consequences of chromosomal aneuploidies on the transcriptome. This figure visualizes the result of a chromosomal trisomy on transcriptional activity of genes on that chromosome. The trisomy was induced using microcell-mediated chromosome transfer. Gene expression profiling demonstrated that the expression levels of most genes are dependent on genomic copy number (*lower profile*). This is consistent with observations in primary cancers or cell lines. (**h**) FISH on tissue sections. Shown is the amplification of the cell cycle regulating gene *CCND1* in a tissue section of a head and neck cancer (this malignant neoplasm was located in the tongue) in highly aneuploid nuclei. Diploid copy numbers of this gene are present in lymphocytes in the lower left corner of the image. (**i**) Extra copy numbers of chromosome 3q are always present in cervical cancer. This figure shows cervical epithelial cells collected at a routinely performed Pap smear. The *arrow* denotes a normal diploid cervical cell, with two copies of the long arm of chromosome 3q probed using the human telomerase gene *TERC* (*green*) and a control probe for the centromere of chromosome 7 (*red*). The cells with an aberrant hybridization pattern all show six copies of *TERC,* which clearly suggests a clonal expansion once the cervical cancer specific aneuploidy was acquired. (**j**) Phenotype/genotype correlation of a high-grade cervical dysplasia (high-grade squamous intraepithelial lesion, or HSIL). This Pap smear was repeatedly assessed as being normal, yet was followed by the diagnosis of an invasive cervical carcinoma. Retrospective analysis of this case clearly demonstrates the potential of molecular cytogenetics in augmenting the morphology-based evaluation of cytological specimens. The presence of four copies of *TERC* is obvious. Again, the emergence of cervical cancer is consistent with a clonal expansion of cells that acquired the gain of 3q.

chromosomes that carry the *Myc* oncogene and the *IgH* locus, respectively. This triggered a targeted analysis and showed that indeed the *Myc* oncogene was juxtaposed to the *Igh* locus, creating a genetic error identical to the one observed in human Burkitt's lymphoma [126]. In subsequent analyses, this particular mouse model has become exceedingly useful for the elucidation of mechanisms of double-strand break repair and the emergence of chromosomal translocations [127].

The above-described examples do not provide a complete review of the cytogenetic literature. This was neither intended nor can it be accomplished within the scope of such a book chapter. Rather, the authors wished to exemplify how cytogenetic based screening for chromosomal aberrations can be successfully used to home in on disease initiating, causal molecular mechanisms of cancer development.

4.3 Chromosomes in Cancer Cells

All cancers have chromosomal aberrations. Despite the fact that such apodictic statements are problematic in general, and even more so when related to biology, it is indeed the case that the vast majority of human cancer shows at least one abnormality in their karyotypes. There are a few exceptions to this rule—in some instances of hematological malignancies chromosome banding analyses revealed no aberrations, and familial colorectal cancers that arise due to deficiencies in the DNA mismatch repair machinery can have a stable and normal karyotype. Regarding the hematological malignancies, the failure to detect chromosomal aberrations might be due to the fact that culture conditions favored cells other than those derived from the cancer, and we know that in mismatch-deficient colorectal cancers the enormous number of point mutations might make the acquisition of cytogenetic abnormalities superfluous. Despite these specific exceptions, cancer is a disease of the chromosomes [5]. The cytogenetic analysis of hematological malignancies (leukemias and lymphomas) reveals recurrent chromosomal aberrations, often manifest as translocations, that strongly suggest that they denote disease-causing and not just correlated, genetic changes. We know today that recurrent chromosomal translocations invariably point to the location of genes whose deregulation causes malignant transformation in tissues of hematological origin. In most cases the mechanism of deregulation adheres to one of the following concepts. In one instance, the chromosomal translocation results in the generation of a fusion gene that encodes an aberrant protein with transforming activity. The Philadelphia chromosome translocation t(9;22) and its consequence, the *BCR-ABL* fusion and resulting increased tyrosine kinase signaling, serve as the paradigm [128]. The second mechanism juxtaposes an oncogene into the vicinity of a gene constitutively active in a certain tissue, hence taking over the transcriptional regulation of that oncogene. This mechanism was first identified in Burkitt's lymphoma and in mouse plasma cell tumors [26, 29, 30]. Here, the chromosomal translocation t(8;14), in human, or the T(12:15), in the mouse, result in transcriptional deregulation of *MYC* due to its regulation by the *IGH* regulatory elements (variant translocations of *MYC* to other immunoglobulin loci are observed as well, albeit with lower frequency). Another prominent example is the deregulation of the apoptopic pathways through upregulation of *BCL2* via the t(8;14) translocation in follicular lymphoma [129], or the inversion of chromosome 14 in T-cell leukemia which results in the deregulation of *TCL1* expression because of fusion with the T-cell receptor locus [130, 131], as well as the translocation t(8;21) of *ETO* and *AML1*, which causes acute myelocytic leukemia [132]. A comprehensive summary of cytogenetic abnormalities can be found in the book ***Cancer Cytogenetics*** by Heim and Mitelman and in the compendium by Avery Sandberg [35, 36], or online at the Cancer Genome Anatomy Project website (http://cgap.nci.nih.gov/Chromosomes/).

4.3.1 Patterns of Chromosomal Aberrations and Genomic Imbalances

The comprehensive cytogenetic analysis of cancers of epithelial origin was more difficult to generate for technical reasons, but also due to the sheer number of chromosomal aberrations found in the carcinomas [36]. This feature, together with the observation of centrosome amplification, irregular mitotic spindles, apolar mitoses, anaphase bridges as a consequence of telomere dysfunction, and chromosome segregation errors led to the perception of a cytogenetic chaos that governs the karyotype of carcinomas (Fig. 4.2f). Compared to the hematological malignancies, it was more difficult to identify a recurrent pattern of chromosomal changes, which, as a result of its consistency, would suggest a disease-causing, and not only a disease-associated, event. While in some solid cancer entities chromosome banding analyses showed nonrandom aberrations, such as the loss of chromosome 3p in lung cancer [133] or gain of chromosome 7 in colorectal cancer (CRC) [134], the dominance of specific genomic imbalances was only established with the introduction of molecular cytogenetic techniques, and in particular CGH. It is now common knowledge that distinct carcinoma entities are defined by a strictly conserved and nonrandom distribution of gains and losses of chromosome arms or entire chromosomes with ensuing specific genomic imbalances. The distribution of these imbalances is cancer-specific and can be specific for discrete cancer stages. For instance, cervical carcinomas invariably carry extra copies of the long arm of chromosome 3. This specific lesion occurs before the transition to invasive disease and can be found as

probably the earliest genome mutation. In contrast, in colorectal cancer chromosome 3 does not appear to be important. However, the landscape of genomic imbalances in CRC is defined by the acquisition of extra copies of chromosomes 7, 8q, 13, and 20 which are accompanied by losses on 8p, 17p, and 18q. Chromosome 7 gains are observed in early adenomas. In general, this distribution of genomic imbalances is maintained in metastases of this disease, and is also conserved in cell lines established from these cancers, even after long periods of in vitro culture [135]. These interpretations would be consistent with a constant selection of clones that contain such imbalances [136]. It should be obvious from these features that these specific patterns of chromosomal imbalances are perfectly suited to distinguish one cancer type from another [8]. This was confirmed in a large dataset by Beroukhim and colleagues [137]. Here, the authors compiled results from aCGH analyses of more than 3000 cases of divergent cancer entities and identified somatic copy number alterations that extended over entire chromosomes or chromosome arms, or were localized. Not surprisingly, cancers could be classified into the lineage of origin, and for those belonging to the same lineage (for instance lung versus CRC) into specific cancer entities, based on the distribution of whole chromosome or chromosome arm specific gains and losses. Interestingly, this classification deteriorated when only those events that presumably are the target of genomic imbalances were used, such as amplification of *MYC* on chromosome 8q. This again attests to the functional relevance of chromosomal aneuploidies in tumorigenesis and suggests that genes other than the most obvious targets are required for malignant transformation, or for the maintenance of the transformed phenotype.

The question then arises as to the consequences of chromosomal aneuploidies on the transcriptome of cancer cells. One could envision several scenarios: (1) chromosomal aneuploidy targets the expression of only one or a few genes on the affected chromosomes, (2) the expression of most if not all genes is affected, and (3) chromosomal aneuploidies are neutral regarding gene expression. This basic question in cancer biology has been unambiguously answered. For instance, Upender and colleagues used microcell-mediated chromosome transfer to generate artificial trisomies in otherwise karyotypically normal cells. Gene expression profiling was then used to query the consequences on the transcriptome, and showed that transcript levels followed genomic copy numbers for the majority of genes [138] (Fig. 4.2g). The same situation has been observed in primary cancers and in cancer cell lines in a variety of different cancer entities [139–146]. This justifies the general conclusion that transcript levels in cancer cells are affected by genomic copy numbers. Therefore, aneuploidy results in a massive deregulation of the cancer transcriptome by changing the expression of hundreds to thousands of genes. One of the basic questions in cancer biology that has not been satisfactorily answered is to what extent the aneuploidy-dependent transcriptional deregulation is necessary for carcinogenesis [147]. One could favor the explanation that aneuploidies are just convenient mechanisms for the transcriptional deregulation of a few target genes, and that their frequency is more a reflection of the ease with which they can be acquired and maintained. In this interpretation, aneuploidy is a passenger rather than a driver. Alternatively, one could postulate that tissue-specific metabolic changes (induced via aneuploidy-dependent transcriptional changes) operate in concert with the activation or inactivation of specific oncogenes and tumor suppressor genes, respectively. However, the answer to this important question remains unknown.

4.3.2 Diagnostic and Prognostic Applications

FISH has become a versatile tool for the detection of chromosomal translocations in hematological malignancies. Increased probe multiplicity, improved protocols and more sensitive imaging equipment, and a large set of sophisticated probe designs have made interphase FISH the method of choice in many diagnostic laboratories. The possibility to combine the visualization of disease causing genetic aberrations with the phenotype of cells further enhances its value. The practical application of these methods has been made easier through the commercial availability of probe sets with a high signal to noise ratio.

The role of FISH for the diagnosis of carcinomas is far less developed, which actually cannot be attributed to the lack of disease-specific aberrations. The gain of chromosome arm 3q in cervical carcinomas is as common as is the Philadelphia chromosome in patients with CML [99]. The reason for the delay in adapting FISH to augment the diagnosis of carcinomas and its precursor lesions might be manifold. However, two reasons appear rather obvious: (1) FISH signals are difficult to enumerate on tissue sections from the surgical pathology laboratory, and (2) the target gene (or more likely, target genes) for the recurrent acquisition of genomic copy number changes in solid cancers are not well understood (whereas the disease-initiating role of chromosomal translocations in hematological malignancies is clear). Despite these hurdles, interphase cytogenetics will become more widely applied in solid cancer diagnostics, certainly in such cases in which the diagnosis or screening does not primarily rely on tissue sections but on cytological preparations. We now discuss several applications pertaining to different carcinomas, some of which can be diagnosed on routinely collected cytological specimens, collected by either aspiration or exfoliative sampling, or on histological sections. One general advantage of interphase cytogenetics is the fact that the detection of genetic alterations is performed

on a single cell basis. This makes the test insensitive to dilution with normal cells, which tends to be a problem (in particular when analyzing precancerous lesions). The single cell nature of interphase cytogenetic analysis also compensates for sampling errors to a certain degree. In the following sections we summarize the most pertinent examples of molecular cytogenetic applications for the detection of chromosomal aneuploidies and gene amplifications in a variety of carcinomas.

4.3.2.1 Bladder Cancer

Like most other carcinomas, bladder cancers carry a distribution of chromosomal aneuploidies that are specific to the disease [148, 149]. Accordingly, a test that targets the centromeres of chromosomes 3, 7, and 17, and a locus specific probe for chromosome band 9p21, termed UroVysion (Abbott Molecular), was developed and applied to voided urine samples from patients with bladder cancer and controls [150, 151]. Compared to other standard tests (including cytology), UroVysion exhibits the highest combined sensitivity and specificity for the detection of bladder cancer. There are also successful (and FDA-cleared) imaging solutions that allow for an automated analysis of FISH signals in urine samples.

4.3.2.2 Lung Cancer

Lung cancer is one of the most common causes of cancer death in the world. As with other cancer entities, early detection significantly improves prognosis. The development of radial computed tomography of high-risk patients for lung cancer development has allowed for an earlier diagnosis of lung cancer. However, the challenge in lung cancer diagnosis using this imaging method relates to its relatively low specificity [152]. Hence, imaging requires follow-up analysis and one possibility is the collection of sputum samples or samples collected by fine needle aspiration for cytological characterization [153]. The phenotypic characterization of exfoliated cells (which lacks tissue context) can be difficult. Therefore, the inclusion of genetic markers for lung cancer should be a reasonable approach of improving diagnosis. The feasibility of such an approach was convincingly demonstrated in several studies over the past few years [153–156].

4.3.2.3 Breast Cancer and ERBB2

With the introduction of trastuzumab (Herceptin®), a humanized monoclonal antibody, the first target-specific therapy against the epidermal growth factor receptor 2 (*ERBB2* or *HER-2/neu*) became available [157]. Before a patient becomes eligible for trastuzumab therapy, the FDA requires determination of whether their cancer overexpresses ERBB2 [158]. The *ERBB2* oncogene is located on chromosome 17 (17q12-21.32) and is a member of the human epidermal growth factor receptor family. ERBB2 overexpression occurs primarily through amplification of the wild-type gene and is clinically correlated with poor outcome, positive lymph node status, high histological grade, high proliferation rate, and negative progesterone and estrogen receptor status [157, 159–164]. Twenty-five to 30 % of all breast cancer cases show an amplification of the *ERBB2* gene [165, 166]. In addition to immunohistochemistry to measure ERBB2 protein levels, the FDA approved a test based on in situ hybridization to identify the *ERBB2* gene amplification status. In situ hybridization is a sensitive and specific method that identifies gene copy numbers either with a single detection probe (mono color FISH) or in combination with a reference probe for the centromere of chromosome 17 (dual color FISH) in which the gene and the centromere are visualized using different fluorochromes. The protocol can be applied on formalin-fixed, paraffin-embedded tissues using standard sections. In dual color FISH, 20 cancer cell nuclei are counted for *ERBB2* and centromere 17 signal number. Subsequently, the *ERBB2*/centromere 17 ratio is calculated by dividing the total number of *ERBB2* signals by the total number of centromere 17 signals. A ratio >2.2 serves as the threshold for ERBB2 positivity and eligibility for trastuzumab treatment while a ratio <1.8 defines non-amplified and not eligible for trastuzumab. If the ratio is between 1.8 and 2.2, additional nuclei are counted by a second observer. If the second observer also achieves a ratio of 1.8–2.2, the cut-off is changed to 2.0. A ratio of >2.0 is therefore considered positive, while a ratio of <2.0 indicates a negative case.

4.3.2.4 Non-small Cell Lung Cancer, Colorectal Cancer, and Glioblastoma, and EGFR

With an increasing number of drugs available for targeting EGFR (the epithelial growth factor receptor), tests that evaluate the expression of this receptor and its gene copy numbers have become a clinical necessity [167]. Unfortunately, precise evaluation guidelines for *EGFR* gene status are still missing [168], and are therefore not comparable to current ERBB2 testing. This is partly due to the fact that the patterns of *EGFR* gene alterations detectable by in situ hybridization are complex and dependent on cancer type (Fig. 4.2h). Several scoring systems for EGFR testing have been proposed for selection of patients with non-small-cell lung cancer to treat with tyrosine kinase inhibitors, but these scoring systems lack broad consensus. In colorectal cancer, patients with high *EGFR* gene copy number in general respond better to therapy with cetuximab or panitumumab (human monoclonal antibodies with specific binding to the EGFR), and one group demonstrated that colon cancers with less than 2.92 signals of *EGFR* per nucleus are less likely to respond to cetuximab [169]. Unfortunately, several other studies have suggested different thresholds [170, 171]. In glioblastoma, the most malignant form of brain tumors with less than 12 months median survival [172], *EGFR* gene amplification occurs in 40–50 % of cases and are present almost invariably as high-level amplification which can be determined easily [173].

Clinical trials are ongoing to establish the predictive value of gene amplification for clinical benefit of treatment with tyrosine kinase inhibitors or antibodies [174]. It appears inevitable that cancer type and the nature of anti-EGFR therapy must be taken into account to develop FISH evaluation guidelines.

4.3.2.5 Cervical Cancer

Despite the possibility that an early diagnosis of cervical cancer could be achieved through the implementation of screening cytology based on the Pap (Papanicolaou) test cervical cancer is still one of the most common malignancies in women world-wide [175]. In populations in which Pap testing is offered the incidence of cervical cancer was greatly reduced. However, Pap test-based screening is associated with specific challenges—the test has low sensitivity and is subjective [176]. The introduction of HPV screening overcame some of these shortcomings because the development of cervical cancer in the absence of high-risk HPV genomes is extremely unlikely [177]. However, HPV testing has a very low specificity because most of the cytologically abnormal lesions are positive for HPV, yet only around 15–20 % of them progress to higher-grade disease and to cervical cancer. The diagnostic challenge is to identify a marker that will be both sensitive and specific.

The analysis of cervical cancer and its precursor lesions had been attempted for decades, and some progress has been made. Even before the chromosome-banding era, Ingrid Granberg in Stockholm [178] and Atkin and colleagues in Great Britain [179], among others [180], attempted to identify recurrent chromosomal aberrations in cervical cancer and its precursor lesions. The situation was complicated by the fact that it was exceedingly difficult to establish cell lines from cervical carcinomas. Accordingly, application of CGH, which does not require preparation of metaphase chromosomes for cytogenetic analysis, was exceedingly useful for the identification of genomic imbalances during tumorigenesis. In a paper by Heselmeyer and colleagues such a phenotype/genotype correlation was realized using a combination of tissue microdissection and comparative genomic hybridization [99, 181]. This analysis revealed that (1) invasive cervical carcinomas are invariably associated with a gain of the long arm of chromosome 3q, and (2) that the gain of 3q already occurs in dysplastic lesions (despite the fact that tissue dissection was employed, the percentage of this aberration was probably underestimated because CGH was performed with pooled cells). In many studies that followed this initial description, the prevalence of 3q amplification in cervical carcinomas was confirmed [182, 183]. This led to the development of a FISH test for this disease [184]. The probe cocktail includes a marker for 3q, which is a BAC clone contig centering around the human telomerase gene *TERC*, and pertinent control probes for the ploidy of the cells (Fig. 4.2i and j). Applications in numerous studies have led to the following conclusions: (1) the detection of genomic copy numbers of 3q allows the diagnosis of cervical cancer, independent of morphology, (2) the gain of 3q occurs before the transition to invasive disease, (3) the gain of 3q can occur in diploid cells, or can develop after the genome has become tetraploid, (4) progression from low-grade disease to higher grades or to invasive carcinomas does require the gain of 3q and progression does not occur without the acquisition of extra copies of 3q, and (5) detection of genomic amplification of 3q has the highest combined sensitivity and specificity compared to all other clinically used biomarkers [185–191]. These results, in conjunction with studies in other cancer entities mentioned above, clearly show that the diagnosis of human carcinomas and its precursor lesions can benefit from the introduction of pertinent genetic markers that should be selected based on the profile of genomic imbalances. In our opinion, these markers should be selected based on the pattern of recurrent genomic imbalances in solid cancers. We think that the inclusion of pertinent genetic markers would overcome the limitations of a cytology-based diagnosis of solid cancers, and could reduce the need for histopathological sections in which the tissue context is maintained so that a morphological diagnosis is easier to make [192].

4.4 Conclusion

The comprehensive molecular analysis of carcinomas has unveiled that the theme of what is often lumped together as an ill-defined chromosomal instability phenotype is in fact a remarkable stability on a different plateau of genomic copy number changes. Overcoming the perception that carcinomas are characterized by a cytogenetic chaos, in which ongoing chromosomal instability contributes to a rearranged genome with no recurrent features will help to promote interphase cytogenetics as a valuable tool for the early detection of emerging cancers, will thereby improve diagnosis, and eventually result in a better prognostication of patients with malignant diseases.

Acknowledgements The authors are grateful to Dr. Hesed Padilla-Nash, Dr. Michael J. Difilippantonio, Dr. Darawalee Wangsa, Dr. Madhvi Upender, and Danny Wangsa for providing figures, Turid Knutsen for helpful comments, and Dr. Reinhard Ebner for critically reading the manuscript. We thank all members of our laboratory for their input and most of all for their dedication to cancer research. We greatly appreciate the help of Buddy Chen with creating the figures.

Epigenetic Basis of Human Cancer

5

Thomas Mikeska and Alexander Dobrovic

5.1 Introduction to Epigenetics

5.1.1 Epigenetics

Although events that we now understand as epigenetic in nature had already been described in model organisms, the origin of the concept of epigenetics may be considered to date back to 1942 when, in the context of development, Waddington wrote "*between genotype and phenotype lies a whole complex of development processes*" and termed the phenotypic result of these processes, the "*epigenotype*" [1]. The most important role of epigenetics is the normal process of the establishment and maintenance of the cell-to-cell heritable gene expression patterns that occur during development. Alterations of the primary DNA sequence do not underlie these changes and yet characteristic patterns of gene expression can be inherited. Over time, the definition of the term epigenetic has varied [2–5]. A current definition that is used in this chapter is: "*an epigenetic trait is a stably heritable phenotype resulting from changes in a chromosome without alterations in the DNA sequence*" [6].

So far, several distinct layers of epigenetic regulation are known including DNA methylation, histone modifications, and organization of the chromatin within the nucleus, although the direct heritability of some of these remain unclear. DNA methylation and histone modifications are probably the best understood epigenetic mechanisms to date. In this chapter, we first give a general introduction to DNA methylation and histone modifications, followed by a review of how they are altered in cancer, and concluding with the implications of these changes for cancer diagnostics and therapy.

5.1.2 DNA Methylation

In mammals, DNA methylation occurs almost exclusively at cytosine residues within CpG dinucleotides (CpGs). The covalent attachment of a methyl group to the fifth carbon of a cytosine residue results in the formation of 5-methylcytosine. The origins of DNA methylation in multicellular organisms remain unclear. DNA methylation probably maintains genomic stability by silencing repetitive elements, such as transposons [7, 8]. Furthermore, DNA methylation is involved in maintenance of chromosomal structure as can be seen in the aberrant pericentromeric regions in individuals lacking methylation at certain satellite DNA sequences as a consequence of ICF syndrome [9–11].

CpGs are unevenly distributed throughout the entire human genome and the majority of them are methylated [12]. However, some CpGs are also found in regions of high CpG density spanning hundreds to thousands of base pairs in length, referred to as CpG islands [13]. About 70 % of human gene promoters are associated with the presence of a canonical CpG island [14–16] and the CpGs in these islands are generally unmethylated. By contrast, CpG islands within actively transcribed genes are generally methylated [16].

The proportion of CpGs outside CpG islands is markedly decreased relative to that expected from the base composition. The depletion is a direct consequence of methylation as 5-methylcytosine can undergo spontaneous deamination to thymine [17]. Although the vast majority of ^{5me}CpG:TpG mismatched lesions are repaired by MBD4, a thymine DNA glycosylase that binds to the mismatches when the cytosine is methylated and can initiate the repair of these lesions [18], a proportion is not repaired [19]. Therefore, methylated CpG

positions are mutational hot spots and this has led to a depletion of CpGs throughout most of the genome during evolution. Many inherited disease-causing mutations arise at CpG dinucleotides because of this increased mutation rate [20]. Methylated CpGs are also mutational hot spots in cancer [21, 22]. Studies on the TP53 gene have shown that some somatic mutations occur at normally methylated CpGs and thus result from the unrepaired spontaneous deamination of 5-methylcytosine [23].

A small but important subgroup of CpG islands are methylated in normal tissues; genes on the inactive X-chromosome, alleles of imprinted genes, and certain tissue-specific genes. X-chromosome inactivation in females is mediated by the expression of the XIST noncoding RNA and is locked into place by DNA hypermethylation of the promoter region CpG islands [24]. DNA methylation regulates the allele-specific expression of imprinted genes by maintaining DNA methylation marks on only one parental allele [25]. It was initially proposed that DNA methylation might underlie tissue-specific gene expression [26], but this seems to be the exception rather than the rule. Epigenomic analysis will soon clarify how frequent DNA methylation actually is in tissue-specific gene expression.

Although the definition of a CpG island is arbitrary, two algorithms have been widely used to identify CpG islands in genomic DNA sequences [13, 27]. The identification is based on three sequence related criteria: sequence length, C+G content, and ratio of the observed CpGs over the expected CpGs. More sophisticated algorithms and approaches have since been developed [28, 29]. Depending on the methods applied and the stringency of the criteria for defining a CpG island, it is estimated that the human genome contains about 28,000–110,000 CpG islands [15, 30, 31].

It is widely recognized that the presence of DNA methylation in the promoter region of a particular gene or transcript generally causes silencing or transcriptional repression [32]. The presence of DNA methylation may prevent the direct binding of transcription factors [33] or facilitate the binding of methyl-CpG-binding proteins, which bind to methylated DNA through their methyl-CpG-binding domain [34, 35]. Methyl-CpG-binding proteins recruit specific histone deacetylases and histone methyltransferases, which then establish a chromatin structure that is not accessible to the transcriptional machinery. However, there is also considerable evidence that the establishment of a repressive chromatin state can be the initial event leading downstream to DNA methylation which then reinforces the original transcriptional silencing [36, 37].

DNA methylation patterns are established by several DNA (cytosine-5) methyltransferases (DNMTs) [38–40] which utilize *S*-adenosyl-L-methionine (SAM) as the methyl group donor. In humans, four DNMTs are known, DNMT1, DNMT3a, DNMT3b, and DNMT3L. In general, DNMT1 acts as the maintenance DNMT, whereas DNMT3a and DNMT3b are de novo DNMTs [41, 42]. DNMT1 exhibits a strong affinity for hemi-methylated DNA [43] and is responsible for reestablishing preexisting, parental DNA methylation patterns during cell divisions [44] and participates in DNA repair, probably by restoring DNA methylation [45]. The two active de novo DNMTs, DNMT3a and DNMT3b, methylate previously unmethylated CpGs and are responsible for reprogramming the DNA methylation pattern during gametogenesis and early developmental stages [40, 44]. DNMT3L belongs to the DNMT3 family, but does not exhibit DNMT activity. It acts as a regulatory factor [46], which enhances the catalytic activity of DNMT3a and DNMT3b [47]. The human methyltransferase DNMT2 (TRDMT1) has a high sequence and structural homology to DNMTs, but has been identified as a methyltransferase [48], which methylates a cytosine moiety on the aspartic acid tRNA using the same catalytic mechanism as DNMTs [49].

DNA methylation marks can also be removed. This process is called DNA demethylation and can be divided into passive and active DNA demethylation. Passive DNA demethylation takes place in the absence of maintenance DNA methylation by reducing the amount of DNA methylation progressively via DNA replication [50]. Active DNA demethylation (replication independent demethylation) requires the presence of enzymes capable of erasing DNA methylation [50–52]. One suggested mechanism is direct enzymatic removal of the 5-methyl group from 5-methylcytosine (bona fide demethylation), thereby restoring cytosine. The formation of 5-hydroxymethylcytosine by hydrolyzing 5-methylcytosine via the TET family of enzymes plays an important intermediary role [53, 54]. Other presumed mechanisms involve the DNA repair machinery for the entire removal of the 5-methylcytosine base, the nucleoside or the nucleotide (indirect demethylation).

5.1.3 Histone Modifications

Another important component of epigenetics is mediated by the nucleosome. The nucleosome comprises an octamer of two each of the four core histones H2A, H2B, H3, and H4 which is then associated with histone H1. A complex, multidimensional, and interrelated regulation mainly arises from posttranslational, covalent modifications of specific conserved residues of core histone tails [55–57]. Multiple posttranslational histone modifications have been characterized. Acetylation of lysine residues [58] and methylation of lysine (or arginine residues) [58–60] are the best characterized modifications. Other modifications include phosphorylation [61, 62], ubiquitinylation [63, 64], poly-ADP-ribosylation [65], sumoylation [66], biotinylation [67], propionylation, and butyrylation [68].

The different and substrate specific enzymes involved in the addition or removal of certain histone marks are responsible for the composition and combination of the different modifications, which defines the chromatin status. The different histone marks are referred to as the "*histone code*" [69–71]. While most of these modifications are reversible, their type and degree allows the dynamic and subtle regulation of the transcription level of the affected region, and more globally their impact on and regulation of cellular processes [72, 73].

5.1.3.1 Histone Acetylation

Acetylation of histone tails, especially H3 and H4, is associated with transcriptionally active genes [74]. The addition of acetyl groups counteracts the positive charges of the lysine residues of the histone tails and therefore diminishes their electrostatic interaction with the negatively charged DNA backbone. The removal of acetyl groups on the other hand unmasks the positive charges of the histone tails and enables them to interact with the negatively charged phosphate groups of the DNA. This leads to a more condensed chromatin structure.

The addition or the removal of an acetyl group at lysine residues of histone tails is dynamic in nature. These processes are mediated by several families of histone acetyltransferases (HATs) [75] and by several families of histone deacetylases (HDACs) [76–78]. The different HATs can be classified as whether they belong to the GNAT, MYST, or p300/CBP families, and the HDACs are divided into four classes based on their homology to yeast histone deacetylases [79].

5.1.3.2 Histone Methylation

Methylation of the lysine residues of the histone tails is more complex. Different methylation marks code for an active or an inactive chromatin state, depending on the histone, the position of the amino acid on the histone tail and the number of methyl groups at each position [73]. The amino groups of the lysine residues can be methylated with one, two, or three methyl groups. The methylation code is probably not as dynamic as the acetylation process. Histone methylation marks are established by histone methyltransferases (HMTs) [80]. Some of the HMTs belong to the trithorax (e.g., MLL) and polycomb (e.g., EZH2) protein groups which were first identified in *Drosophila melanogaster* [81]. They are responsible either for maintaining (trithorax group of proteins) or repressing (polycomb group of proteins) lineage specific transcriptional activity respectively. Proteins capable of removing methyl groups from the lysine residues include lysine (K)-specific demethylase 1A (KDM1A, LSD1) [82], which specifically demethylates monomethylated or dimethylated H3-K4, and the Jumonji family of proteins, with a range of specific substrate specificities [83–85].

5.1.3.3 Active and Inactive Chromatin

Despite the myriad of possible combinations, a useful generalization is that chromatin regions showing a high level of acetylated histones and trimethylation of H3-K4 [86] as well as methylated H3-K36 [87] and H3-K79 [88] are transcriptionally active [56]. On the other hand, deacetylated histones and dimethylation or trimethylation of H3-K9 [89] and trimethylation of H3-K27 [90] and H4-K20 [91] are associated with a more condensed chromatin structure and an accordingly repressed transcription level [56]. Both DNA methylation and histone modifications define a chromatin environment, which regulates gene transcription. The mechanisms and their role in regulating cellular processes may be different, but an intimate relationship is obvious [15, 92].

5.2 Epigenetic Changes in Cancer

Cancer can be considered as a disease of disordered development manifesting as a disease characterized by altered gene expression patterns. Thus, epigenetic mechanisms are likely to be as important in cancer-specific gene expression as they are in developmental gene expression.

5.2.1 Aberrant DNA Methylation in Cancer

During cancer development, the distribution of DNA methylation becomes markedly altered. Two general phenomena are frequently observed in cancer cells: (1) the overall DNA methylation level is decreased, and (2) de novo DNA methylation of promoter-associated CpG islands occurs. We still need to understand what drives and is responsible for global DNA hypomethylation or the establishment of multiple hypermethylation events. Furthermore, we need to determine whether these events are dependent or independent. The rapid development of new technologies, especially those that allow analysis of DNA methylation changes on a global scale will enable us to reevaluate this.

5.2.1.1 Global DNA Hypomethylation

One of the earliest indications of altered DNA methylation in human cancer was the observation that the overall 5-methylcytosine content of cancer cells was decreased [93, 94]. The genome-wide depletion of 5-methylcytosine in cancer is particularly pronounced in repetitive sequences [95, 96]. Multiple copies of repeats are found throughout the human genome and encompass repeats in constitutive heterochromatin (classical satellites), interspersed repeats (LINEs and SINEs), and long terminal repeats (LTRs) (a good overview is given in ref. [97]). The contribution and consequences of hypomethylated repetitive DNA sequences to carcinogenesis

and cancer progression is far from understood. One may expect that these massive changes have a profound impact and could result in inappropriate recombination or replication events. They may even be responsible for the large scale changes in nuclear organization that can be seen under the light microscope and are a hallmark of cancer.

DNA hypomethylation may move the genome into an unstable state, promoting further cancer evolution, involving both genetic and epigenetic changes [96, 98, 99]. Interestingly, depending on the cancer type and cancer stage, the onset, development, and progression of DNA hypomethylation is different. For example, DNA hypomethylation is associated with early stages of gastric cancer [100] and advanced stages of prostate cancer [101]. DNA hypomethylation can lead to chromosomal instability [102]. Genome-wide studies on gastric and colorectal cancer samples showed a direct link between global DNA hypomethylation and genomic instability [103, 104]. Global DNA hypomethylation destabilized all the chromosomes and was not correlated to a particular kind of chromosomal alteration [104]. On the other hand, a significant correlation between DNA hypomethylation and aberrations on chromosome 8 was reported for prostate cancer [105].

The elevated frequency of some chromosomal abnormalities observed for some cancers might be directly related to DNA methylation changes. Wilms' tumor, a malignant pediatric tumor of the kidney, is frequently less methylated in centromeric alpha satellite sequences on chromosome 1 compared to normal kidney tissue. In addition, the satellite 2 sequences of chromosome 1 and 16 are also hypomethylated. Furthermore, Wilms' tumors show an association between hypomethylation of satellite 2 sequences on chromosome 16 and loss of chromosome 16q [106]. It was also shown that hypomethylation of satellite 2 sequences was often associated with an increased chromosome 1q copy number for hepatocellular carcinoma [107].

5.2.1.2 Locus-Specific DNA Hypomethylation

DNA hypomethylation has also been observed for the normally methylated promoters of individual genes. The list of genes aberrantly regulated by DNA hypomethylation is relatively small, compared to the list of genes reported to be affected by DNA hypermethylation [108].

The cancer/testis antigens are a particularly important example of genes that are methylated in nearly all somatic tissues and that become reactivated in cancer [109, 110]. They can be divided in two subgroups: cancer/testis antigen genes located on the X-chromosome (e.g., *MAGEA1*), and those which are located on autosomes. Cancer/testis antigens are normally expressed in germ cells of the testis and placenta but are not expressed in the vast majority of normal somatic tissues. The cancer/testis antigens encoded on the X-chromosome are associated with CpG islands, which are methylated in normal somatic tissues. However, these cancer/testis antigens are frequently reexpressed in several tumor types and reexpression is associated with the global loss of DNA methylation [111, 112]. Cancer/testis antigens are potential targets in cancer therapy and vaccines are currently being tested in clinical trials [113, 114].

Synuclein-γ (*SNCG*) encodes a member of the neuronal protein family whose expression is normally limited to the peripheral nervous system and the brain [115]. *SNCG* is silenced in normal tissues by DNA methylation. Ectopic SNCG protein expression has been observed for several human cancers [116–121]. The level of *SNCG* expression is determined by the extent of decrease of DNA methylation [122]. *SNCG* hypomethylation is observed in multiple cancers [117, 119–124] and is generally associated with a more advanced and invasive tumor phenotype. Interestingly, loss of methylation of *SNCG* is induced in the hepatoma cell line HepG2 by exposure to aflatoxin B1, a carcinogenic mycotoxin often found on certain crops [120]. This finding establishes a link between environmental factors and their influence on aberrant DNA methylation. It is likely that many more such links will be identified.

Cancer-related loss of DNA methylation can also occur at alleles of imprinted genes. The insulin-like growth factor 2 gene (*IGF2*), in which the maternal allele is usually methylated and silenced, is one of the most frequently deregulated genes in human cancer. DNA hypomethylation results in the aberrant expression of *IGF2* from the maternal allele (loss of imprinting). It has been suggested that loss of imprinting of *IGF2* could be a useful DNA methylation-based biomarker for the early detection of colorectal cancers [125]. Furthermore, loss of imprinting of *IGF2* has been detected in normal colon tissue and peripheral blood and might serve as a biomarker for the identification of individuals with cancer predisposition [126].

DNA hypomethylation not only affects protein-coding genes but also affects non-protein-coding genes. A good example is the X (inactive)-specific transcript (*XIST*) locus, which encodes an untranslated RNA transcript that effects X-chromosome inactivation in females. It is inactive in males in whom the promoter is methylated. The 5′-region of the *XIST* locus can become hypomethylated in testicular germ cell cancers [127] and in prostate cancer [128].

Aberrant expression of normally methylated microRNAs can also arise as a consequence of DNA hypomethylation. As examples, cancer-associated hypomethylation and overexpression has been observed for *let-7a-3* in lung cancer [129], *miR-200a/200b* in pancreatic cancer [130], and *miR-196b* in gastric cancer [131].

5.2.1.3 Promoter-Associated DNA Hypermethylation

The gain of DNA methylation at specific CpG islands is a hallmark of cancer development [32, 102, 132, 133]. There are many targets, especially those genes that are kept in a bivalent chromatin state in embryonic stem cells [134, 135]. Although unmethylated in the stem cell, they are frequently methylated in cancer cells.

The first report of a recurrently methylated promoter region in cancer was for the calcitonin gene (*CALCA*) [136]. However, the turning point that implicated DNA methylation as a driver in carcinogenesis was the report that methylation of the retinoblastoma 1 (*RB1*) tumor suppressor gene was observed in a subset of non-inherited retinoblastomas [137, 138]. Initial studies focused on other tumor suppressor genes including *VHL* [139], *CDKN2A* (*p16*) [140], and *CDKN2B* (*p15*) [141].

Promoter-associated DNA hypermethylation is an alternative mechanism for inactivation of a tumor suppressor gene in Knudson's two hit model [32]. Most of the mutations in these genes are recessive, so both alleles need to be inactivated before the function of the gene is lost. Gene silencing as a consequence of DNA methylation has a similar impact to a genomic deletion or an inactivating mutation. Whereas a genomic deletion or an inactivating mutation is a defined alteration of the primary genomic sequence, inactivation by DNA methylation generally occurs in the absence of sequence change and is in principle reversible.

Many of the driver genes (genes which underlie cause of cancer initiation or progression) of carcinogenesis have been discovered by studies of familial cancer syndromes (Table 5.1). Further demonstration of the critical role of DNA methylation in carcinogenesis is made by the observation that many of these genes, in addition to the *RB1* gene, are methylated in sporadic cancers that often phenocopy the type and subtype of the hereditary cancers in which they were first discovered [142]. Thus, the *MLH1* mismatch repair gene not only underlies much of hereditary non-polyposis colorectal cancer (Lynch syndrome) but is also methylated in many sporadic colorectal cancers [143]. Similarly, the *BRCA1* gene underlies both much of hereditary breast and ovarian cancer and is methylated in sporadic breast and ovarian cancers which often share pathological features with their hereditary counterparts [144]. Furthermore, DNA methylation of these genes is rare or absent in tumor types that are not characteristic of the hereditary cancer [145–147].

A recent interesting discovery is that some of these driver genes may show constitutional DNA methylation—methylation of a given gene may occur in multiple somatic tissues (often in a mosaic pattern)—in normal individuals. The individual is then predisposed to develop characteristic cancers similar to the spectrum seen when this driver gene is mutated in familial cancer syndromes [142].

Besides the hereditary cancer genes, a large variety of genes that affect every facet of the cancer phenotype are subject to DNA methylation (a large list is given in ref. [148]). In addition to protein-coding genes, hypermethylation can occur at CpG islands associated with non-protein-coding genes, such as microRNAs, which are frequently dysregulated in cancer [149]. It has been estimated in genome-wide studies, that each cancer can harbor several hundreds of aberrantly methylated CpG islands [95, 150].

It is remarkable how many of the DNA methylation changes in cancer occur in genes that are plausibly involved in cancer, although this probably reflects the preponderance of candidate genes that have been studied. It is however certain that many of the genes that are reported to be methylated in cancer are not directly involved in the initiation or progression of the cancer as they are tissue-specific genes such as *CALCA* and *MYOD1* that are not expressed in the normal cells from which the cancer arose.

Many of the genes that become methylated in cancer are restricted to certain types of tumors. In some cases, such as GSTP1 in prostate cancer, DNA methylation of the gene is virtually a hallmark of the cancer. However, for most cancer types

Table 5.1 Known hereditary cancer genes that are methylated in cancer

Gene symbol	Pathway	Tumors in which DNA methylation occurs	Familial involvement
BRCA1	DNA repair	Breast, ovarian	Breast, ovarian
CDH1	Cell adhesion	Diffuse gastric, lobular breast	Diffuse gastric, lobular breast
CDKN2A (*p16*)	Cell-cycle	Widespread includes non-Hodgkin's lymphoma, gastric, melanoma	Melanoma
DAPK1	Apoptosis	Chronic lymphocytic leukemia, colon, lung, gastric	Chronic lymphocytic leukemia
LKB1	Signal transduction	Colon, lung	Peutz–Jeghers syndrome
MLH1	DNA repair, apoptosis	Colon, endometrium, ovarian	Lynch syndrome (colon, endometrium, ovarian)
RB1	Cell cycle	Retinoblastoma, breast	Retinoblastoma
VHL	Angiogenesis	Renal, chronic lymphocytic leukemia	von Hippel–Lindau syndrome (renal)

DNA methylation of no one single gene is predominant. However, profiling DNA methylation over a large panel of genes reveals patterns that are characteristic of certain types of cancer [151]. Thus, different cancer types can be discriminated by their distinct DNA methylation pattern (epigenetic fingerprint) [150, 152]. Many research groups are trying to identify panels of genes that best characterize subgroups of each major cancer as biomarkers for that cancer [153].

Other methylated genes may be passenger genes (also known as bystander genes). Passenger genes may become aberrantly methylated because they are part of an epigenetically silenced domain. Also, genes that are methylated in cancer may be methylated in the cell of origin of the tumor and escape demethylation. Other genes may become methylated because of aging related incursions of DNA methylation into normally unmethylated regions which then become further methylated in the altered DNA methylation milieu of the cancer [154].

The extent to which a gene promoter region has to be methylated to result in silencing or decreased gene expression is still unknown. DNA methylation patterns are often heterogeneous and show variable degrees of methylation throughout the region analyzed [155–157]. In addition, the amount of DNA methylation of a given promoter tends to increase with cancer evolution [158, 159]. It has been reported that the *CDKN2B* (*p15*) promoter CpG island needs to be methylated at 30–40 % of the CpG sites for silencing to occur [160]. It is expected that the minimal DNA methylation level is dependent on the gene and its genomic context.

Two mechanisms have been suggested to explain local promoter associated CpG island hypermethylation in cancer [15, 161]. One mechanism is based on random seeding of DNA methylation marks by an aberrant DNA methylation machinery. The second mechanism proposes that certain regions are prone to aberrant DNA methylation, either intrinsically or by a misrouted DNA methylation machinery. This may also explain DNA hypomethylation in these cases. However, neither concept can entirely explain aberrant DNA methylation levels and patterns.

5.2.2 Factors Influencing Methylation Changes in the Epigenome

The accumulation of alterations to the normal epigenome (epimutations) can be a step in cancer development analogous to the accumulation of DNA sequence changes (mutations). The underlying causes of and contributions to alterations to the epigenome remain largely elusive. Nevertheless, there is strong evidence, that the aging process and nutritional history have an impact on DNA methylation as well as changes in histones and chromatin structure [162–164]. These parameters are not easily investigated separately and are usually interwoven with other parameters, such as environmental exposures, which may also influence the epigenome alterations to a certain extent [163, 165, 166]. For example, heavy metals (e.g., nickel and arsenic) [167] as well as toxins (e.g., aflatoxin B1) [120] are well recognized substances capable of altering the epigenome.

Aging is associated with a global loss of DNA methylation as well as a local increase in DNA methylation of usually unmethylated CpG islands in normal tissues [168]. Initially, it was reported that the CpG island-associated with the estrogen receptor (*ER*) gene showed increasing level of DNA methylation in colorectal mucosa samples in an age dependent manner [169]. Subsequently, multiple other genes were shown to display age-related DNA methylation in normal colorectal mucosa [154, 170, 171]. Aberrant expression of DNMT1, DNMT3a, and DNMT3b may be responsible for deregulated DNA methylation patterns in aging cells [172–174]. In cultured human fibroblasts, DNMT1 expression decreases during the aging process and this is probably associated with global DNA hypomethylation [175]. Furthermore, the increased expression of the *DNMT3b* gene may lead to aberrant DNA methylation at single-locus genes [175].

The genetic background can also determine susceptibility to alterations cellular DNA methylation. The one-carbon pathway is involved in the synthesis of the methyl group donor, S-adenosyl-L-methionine (SAM), which is utilized by DNMTs to establish DNA methylation. In particular, variants in two members of this pathway, MTHFR (5,10 methylenetetrahydrofolate reductase) and MS (methionine synthase), influence the 5-methylcytosine content of the cell.

TT homozygous and CT heterozygous individuals of the *MTHFR* variant C677T were shown to cause a genome-wide reduction of DNA methylation level in normal tissue [176–178]. The C to T substitution leads to thermolabile MTHFR protein, with reduced catalytic activity [179]. The AA homozygotes of a second *MTHFR* variant, A1298C, were also associated with a lower content of DNA methylation [176, 180]. This MTHFR protein variant shows also a decreased enzymatic activity [181]. GG homozygotes at the A2756G variant of the *MTR* gene (coding for 5-methyl tetrahydrofolate-homocysteine methyltransferase) had less methylation at tumor suppressor genes in their cancers than the other genotypes [178].

Genetic variation in promoter regions may also alter their propensity to become methylated with time. The T allele of the common germ-line polymorphism c.-56C>T (rs16906252) in the promoter region of the *MGMT* gene is associated with aberrant DNA methylation at this locus in colorectal cancer [182] and malignant mesothelioma [183]. Furthermore, gain of DNA methylation in normal tissues such as colonic mucosa [184] and peripheral blood [185] is

also correlated with the presence of the T allele. So far, the underlying mechanism for this predisposition is unknown. As not every individual with the T allele has detectable methylation, and the amount of methylation is highly variable, *trans*-acting factors must also be involved. Susceptibility for aberrant DNA methylation associated with single nucleotide polymorphisms seems to be widespread and the importance of this in cancer predisposition remains to be fully understood [186, 187].

5.2.3 CpG Island Methylator Phenotype (CIMP)

The CpG island methylator phenotype (CIMP) has been widely used to describe cancers with extensive CpG island methylation. This phenotype was first proposed in 1999 for colorectal cancers [188]. Cancers are scored as CIMP-positive if the majority of a small panel of CpG promoter regions are methylated in a manner analogous to the scoring for microsatellite instability. Analysis of a large panel of CpG islands has subsequently confirmed that CIMP is a distinct phenotype in colorectal cancer [189].

Classifying cancers as CIMP-positive is not always straightforward. Alongside the original gene panel of *CDKN2A*, *MINT1*, *MINT2*, *MINT31*, and *MLH1* [188], several other gene panels have been proposed. Weisenberger et al. [189] chose a panel of *CACNA1G*, *IGF2* (a non-imprinted CpG island at this locus), *NEUROG1*, *RUNX3,* and *SOCS1*, while Ogino et al. recommended a minimal panel of *RUNX3*, *CACNA1G*, *IGF2*, and *MLH1* [190]. In addition to the different gene panels, different methods have been used to detect DNA methylation. Quantitative approaches are superior to qualitative approaches (methylation-specific PCR) as they allow for the identification and subsequent exclusion of genes with low-level DNA methylation, which are probably biologically not significant [191]. Further difficulties in defining CIMP-positive cancers arise by using different CIMP cut off values [192, 193] and different CIMP grading systems [189, 192, 194].

Despite the nonstandardized use of different marker panels and methodologies, CIMP-high colorectal cancers share multiple clinicopathological and molecular characteristics. CIMP-high colorectal cancers are usually proximally located [188, 195–197] and are associated with an older patient age [193, 196]. They often exhibit microsatellite instability as the DNA mismatch repair gene *MLH1* is frequently methylated [193, 195–198]. CIMP cancers that are methylated for *MLH1* have a different profile of genetic changes to those that are not methylated for *MLH1* [195]. They are mainly *TP53* wild-type [193, 195, 197].

CIMP cancers show a very high mutation frequency in the *BRAF* gene (V600E) [189, 191, 194–196, 199, 200]. The occurrence of CIMP and the oncogenic *BRAF* mutation has been linked to the serrated pathway of colorectal carcinogenesis. The *BRAF* mutation and CIMP are observed in over 75 % of sessile serrated adenomas which are precursor lesions associated with the serrated neoplasia pathway [194]. Hereditary non-polyposis colorectal cancers caused by germline mutations in the DNA mismatch repair genes *MLH1*, *MSH2*, *MSH6*, or *PMS2* [201] do not belong to the serrated neoplasia pathway and do not show either CIMP or *BRAF* mutations.

A significant problem in understanding CIMP is that the mechanism underlying the phenotype in colorectal cancer has not been identified. Existing theories encompass a genetic and/or environmental cause [202, 203]. An interesting hypothesis raises the possibility that chemotherapy with DNA damaging agents might drive or select for cancers associated with CIMP [204]. It is also important to note that in melanoma, the *BRAF* V600E mutation does not appear to be associated with high levels of aberrant promoter methylation [205].

Since the first report of CIMP in colorectal cancers, other solid tumors and leukemias have been suggested to be CIMP-positive [205, 206]. It is unclear whether the drivers of CIMP in these cancers are related to the drivers of CIMP in colorectal cancer. In glioma, it has been shown that mutation of a single gene, isocitrate dehydrogenase 1 (*IDH1*), establishes the CIMP phenotype but this is unlikely to drive more than a subset of CIMP-positive colorectal cancers [207].

5.2.4 Histone and Chromatin Changes in Cancer

Repressive histone marks and DNA methylation are often found together [208]. However, the contribution of DNA methylation and histone modifications to transcriptional regulation varies from gene to gene. Whereas for certain genes, DNA methylation plays the predominant role, the expression for other gene loci may depend more on the presence of histone modifications.

Cancer cells also exhibit mechanisms of silencing, which are independent of promoter-associated DNA methylation. The establishment of trimethylated H3-K27 histone marks by the polycomb group protein EZH2, was shown to be the major cause for silencing certain genes, such as *ESR1* and *PGR*, as observed for the PC3 prostate cancer cell line. Most of the genes bearing this histone mark were found not to be associated with the presence of DNA methylation, whereas genes harboring DNA methylation did not show the trimethylated H3-K27 histone modification [209].

Two examples of genes that are silenced without DNA methylation are *CDKN1A* (*p21CIP1/WAF1*) and gelsolin (*GSN*). Expression of the cell cycle kinase inhibitor *CDKN1A* is frequently induced after treatment of various cell lines with

HDAC inhibitors [210]. The treatment renders the *CDKN1A* gene open to transcription, at least in part, by increasing the amount of acetylation of histones H3 and H4 at this locus [211]. Gelsolin, an actin binding protein, is also often upregulated after treatment with HDAC inhibitors in cell lines [212–214]. Altered DNA methylation seems to play only a minor role in *GSN* gene expression [213].

Many of the different enzymes involved in histone-modifying and chromatin-modifying activities have been shown to be deregulated in cancer. Aberrant expression, mutations and translocations are frequently the cause for their malfunction in cancer. Good overviews and the presentation of some examples in greater detail are provided in the literature [215–217].

Chromatin remodeling complexes such the SWI/SNF complex can modulate transcriptional activity and alterations in these complexes are associated with cancer development [218, 219]. *SMARCB1* (*SNF5*/*INI1*) codes for a key component of the SWI/SNF chromatin remodeling complex. This gene is frequently deleted or mutated and its malfunction is thought to be the underlying cause for rhabdoid tumors, a rare pediatric cancer [220]. Interestingly, these cancers do not show genomic instability and it seems that the disruption of the epigenetic machinery can substitute for genetic alterations [221].

5.2.5 Long-Range Epigenetic Silencing (LRES)

The concept of aberrant long-range epigenetic silencing (LRES) originated from genetic studies in model organisms of events such as position effect variegation where de novo silencing occurs along a length of chromatin after it is translocated next to heterochromatin [222]. Studies of gene expression in cell culture systems also revealed cases where adjacent genes underwent coordinate changes in gene expression [223, 224]. An important example of LRES in normal development is the inactive X-chromosome in females which is silenced virtually across its entire length. It shows all the hallmarks of silencing, methylation of promoter region associated CpG islands, heterochromatic appearance and late replication of its DNA. It is considered that the DNA methylation appears after the initial silencing to lock the silent phenotype into place [225].

De novo LRES in cancer was first described in colon cancer [226]. The first chromosomal region found to be silenced by LRES spans 4 Mb and comprises three distinct segments of contiguous CpG islands on chromosome 2q14 associated with cancer-specific DNA hypermethylation of *EN1*, *SCTR*, and *INHBB*. These segments were flanked by CpG islands, which were unmethylated in cancer cells as well as normal cells. Importantly, regardless of the CpG island methylation status, the whole region was associated with the repressive histone mark dimethylated H3-K9, leading to transcriptional suppression of the entire region [226]. Since then, several studies showed LRES in other cancer types. LRES affects large chromosomal regions of approximately 100 kb up to 5 Mb and results in silencing of several contiguous genes. LRES functionally resembles large genetic deletions resulting in silencing of long stretches DNA with the important exception that LRES may be reversible [161].

Another LRES region was found in bladder cancer on chromosome 3p22 and comprises 130 kb [227]. This region encompasses four contiguous genes (*VILL*, *PLCD1*, *DLEC1*, and *ACAA1*) that are coordinately downregulated in cancer cells. Again, the cancer-specific inactivation is characterized by the occurrence of trimethylated H3-K9 in the absence of DNA methylation. This same region is a part of a 1.1 Mb LRES region in the majority of microsatellite-unstable colorectal cancers associated with aberrant *MLH1* DNA methylation [228]. This segment comprises the genes *AB002340*, *EPM2AIP*, *MLH1*, *LRRFIP2*, *GOLGA4*, *ITGA9*, *CTDSPL*, *PLCD1*, and *DLEC1*, most of which show methylated promoter-associated CpG islands and the H3-K9 dimethylation repressive histone mark). Interestingly, *LRRFIP2*, *GOLGA4*, and *CTDSPL* escape aberrant DNA methylation but despite being associated with an active chromatin structure are also transcriptionally repressed in cancer samples.

LRES is not restricted to a particular cancer type and many different regions throughout the genome are subject to LRES [229–231]. Indeed, LRES is now recognized as a common event in cancer, affecting multiple regions throughout the compromised cancer cell genome. Genome-wide studies in prostate cancer [232] and neuroblastoma [233] revealed the presence of 47 and 63 cancer-related LRES clusters, respectively. Interestingly, the neuroblastoma study suggested that LRES regions are more often located at chromosome ends [233].

5.2.6 Is Cancer a Genetic Disease or an Epigenetic Disease?

That cancer is a genetic disease is an often repeated truism. However, our current knowledge of epigenetics must make us raise the question of whether cancer is as much or more of an epigenetic than a genetic disease [234–236]. The most compelling evidence for the latter argument is that at least some cancer cells can be reprogrammed into taking part in normal differentiation despite the presence of activated oncogenes [237]. The number of epigenetic changes in a cancer genome also greatly outnumbers the number of genetic changes in a cancer genome [235, 238] although deciphering which of these changes are critical in cancer development remains a challenge. Sequencing of the entire

genome of one case of acute myeloid leukemia (AML) with a normal karyotype revealed that only very few mutations were present and suggested that the changes driving the carcinogenic process in this case were principally epigenetic [239]. Intriguingly, it was subsequently discovered that one of these mutations was a premature stop codon in the *DNMT3a* gene [240]. Indeed, some of the strongest evidence for an epigenetic basis to cancer comes from the leukemias where one of the fusion partners in a leukemogenic translocation often codes for an epigenetic modifier. In many cases, the translocation serves to maintain the leukemic cells in a stem-like or progenitor-like state. Chief among these fusion partners is the *MLL* gene which is involved in numerous translocations [241]. *MLL* has diverse functions including the establishment of trimethylated H3-K4 histone marks [242].

It is ultimately futile to put genetic and epigenetic mechanisms in opposition to each other as alternate hypotheses for cancer development as they both play pivotal roles and are often interrelated [133, 243]. Silencing of DNA repair genes will establish a mutator phenotype which will accelerate the rate of mutational change and provide tumor evolution with additional raw material [244]. For example, silencing of the promoter of the DNA repair gene *MLH1* results in microsatellite instability which further results in mutations at a variety of genes which have an effect on the cancer cell phenotype [240, 245].

On the other hand, the underlying causes of epigenetic instability or methylator phenotypes such as CIMP may arise from mutations in an as yet unidentified gene. Mutations in oncogenes such as *RAS* have been reported to destabilize the epigenetic machinery and initiate DNA methylation changes in the cell [246, 247]. In FOS-transformed cells, it was noted that DNMT1 protein expression was elevated resulting in a 20 % increase of cellular levels of 5-methylcytosine. DNMT1 seemed moreover to play a fundamental role in FOS transformation as blocking of *DNMT1* gene expression resulted in reversion of transformation [248]. This is consistent with other reports that blocking *DNMT1* gene expression can suppress tumorigenesis [249, 250].

A deregulated histone code and altered chromatin remodeling can also lead to increased mutation rates by altering the accessibility of the DNA repair machinery to the genomic DNA. Proper acetylation of H3-K56 in mammals is important to prevent spontaneous DNA damage probably during DNA replication [251]. Therefore, this histone modification participates in maintaining genomic stability and in an appropriate DNA damage response. In yeast, disrupted H3-K56 acetylation sensitizes the cells to compounds that cause DNA strand breaks during replication [252]. Impaired access to certain damage sites or an impaired DNA damage response will further contribute to the genomic instability of the cell, which further promotes its dysregulation.

Aberrant DNA methylation can also target components of the epigenetic machinery. The *RIZ1* (*PRDM2*) promoter is frequently silenced by DNA methylation in several cancer types [253–257]. RIZ1 is one of the two different proteins encoded by the *RIZ* (Retinoblastoma protein interacting zinc finger gene) gene. RIZ1, which contains a SET related PR domain, acts as a histone methyltransferase, which methylates H3-K9 [258]. RIZ is a common target in cancer as loss of heterozygosity, frameshift mutations and missense mutations also contribute to genetic alterations of the *RIZ* gene [258, 259].

5.3 Epigenetic Changes as Tools for Diagnostics and Targets for Therapy

5.3.1 DNA Methylation-Based Biomarkers

DNA methylation has aroused considerable interest because it generates large numbers of potential biomarkers [260]. Biomarkers fall into several classes. Some are useful because they are present in nearly all cancers of a given type and therefore can be used for disease detection and monitoring. These do not necessarily play a key role in cancer pathogenesis. Others are prognostic biomarkers that predict patient outcome. One of the key advantages of DNA methylation-based biomarkers is that methylation is stable after biopsies are removed. This stability gives it a major advantage over RNA-based expression biomarkers [260].

Methodology is a critical issue when locus-specific DNA methylation is used as a biomarker. DNA methylation assays should be used, which provide a quantitative or at least a semiquantitative result. In many cases, they need to be highly sensitive as well. Although, methylation-specific PCR (MSP) is a widely applied method to detect DNA methylation [261], the results obtained by this method are not quantitative. Methods for quantitative DNA methylation measurement have been based on bisulfite pyrosequencing [262–264], MethyLight [265], or SMART-MSP [266]. A useful semiquantitative approach is given by the methylation-sensitive high-resolution melting (MS-HRM) methodology [267]. It must also be considered that quantitative interpretation can be compromised by the presence of heterogeneous DNA methylation [268].

5.3.2 Early Detection and Monitoring of Cancers After Therapy

The early detection and treatment of most cancer types is considered the best prerequisite for a good outcome. Various body fluids or excretions, such as blood, sputum, saliva,

urine, and stool are relatively noninvasive samples, which can potentially be used for the early detection of cancer. In other cases, ductal lavages or bronchial washes can be used. Because of the relatively low frequency of cancers in the groups being screened, even assays with high specificity are likely to produce more false-positives than cancer cases. Thus, it is important to target such screening to individuals already at high risk of developing a certain type of cancer.

Detection of aberrant promoter DNA methylation of the *SEPT9* gene in plasma samples was shown to be correlated to the presence of colorectal cancer [269, 270] and precancerous colorectal lesions [271]. This epigenetic biomarker is relatively specific for colon cancer which shows *SEPT9* methylation level differences dependent on disease staging.

DNA methylation of the *PITX2* promoter, which regulates the expression of transcript variants A and B was shown to be a predictive epigenetic biomarker in breast cancer. DNA hypermethylation of *PITX2* was associated with an increased risk of recurrence in node-negative, steroid hormone-receptor positive breast cancer patients treated by adjuvant tamoxifen monotherapy after surgery [272, 273]. The presence of *PITX2* methylation was also associated with poor patient outcome for node-negative, steroid hormone-receptor positive breast cancer without any systemic adjuvant therapy and node-positive, estrogen receptor-positive, HER-2/*neu*-negative breast cancer treated by adjuvant anthracycline-based chemotherapy, respectively [274, 275]. Furthermore, methylation of *PITX2* is also a prognostic biomarker in prostate cancer. Increased methylation levels were associated with a higher risk of clinical relapse in patients with prostate cancer after radical prostatectomy [276, 277].

The *GSTP1* gene encodes for the pi class glutathione S-transferase enzyme, which is involved in cellular detoxification processes. The presence of DNA methylation at the *GSTP1* associated CpG island was detected in more than 90% of prostate cancer and about 70% of high-grade prostatic intraepithelial neoplasia [278, 279]. On the other hand, DNA methylation of *GSTP1* is rare in benign biopsies and normal prostate tissue. *GSTP1* methylation appears to be an early event in cancer progression and could be used as a diagnostic biomarker [280, 281]. Furthermore, methylation of *GSTP1* in serum of prostate cancer patients was associated with an elevated risk of clinical relapse after surgery [282].

5.3.3 Targeting Individual Epigenetic Changes—Epigenetics and Personalized Medicine

Biomarkers that predict patient responses to particular therapies are critical to personalized therapy. While considerable attention has been focused on gain and loss of function mutations in oncogenes, epimutations because of their greater frequency are likely to determine or influence therapeutic response.

Currently, cancer is usually treated according to the presumed tissue of origin of the cancer. This approach probably works because similar cancer subsets share similar profiles of genetic and epigenetic changes. Nevertheless, there are intrinsic subtypes within each cancer grouping as has been shown by large-scale gene expression studies [283, 284]. Among cancers that are similar in both clinicopathological features and molecular profiles, there is still heterogeneity when individual genes are examined; each cancer is thus a unique entity. As alterations in the expression or function of many of the individual genes can predict the responses to particular therapies, there will be considerable scope for using this molecular information to guide the treatment of the patient. When epigenetic changes in cancers lead to the silencing of genes and where the gene products are involved in sensitivity or resistance to therapeutics, the DNA methylation status of key genes can act as a predictive biomarker. Thus, the information we can extract from the altered epigenome of a cancer will enable us to understand how to treat the cancer. This has been termed pharmacoepigenomics by analogy to pharmacogenetics.

The DNA repair machinery is repeatedly the target of epigenetic change in cancer [244] as it often also is in cancer predisposition syndromes. This machinery is responsible to repair the multiple forms of damage, which is constantly inflicted upon the genome by endogenous (e.g., replication errors, reactive oxygen species) and exogenous sources (e.g., radiation). Many enzymes and proteins participate directly or indirectly in the important processes to repair and maintain a stable genome. Altering or silencing the gene expression of a given DNA repair gene will result in unrepaired damage setting up a mutator phenotype. The mutator phenotype generates multiple sequence variants. Natural selection then acts on the variants that arise, enabling cancer evolution. However, the repair deficiency is also a therapeutic target in the cancer. This underlies the susceptibility of many cancers to one or other form of chemotherapy. Currently, the best example of a gene whose DNA methylation has predictive value is the *MGMT* gene [285]. Its protein product, *O6*-methylguanine DNA methyltransferase, directly removes alkyl groups from the *O6*-position of guanine residues. If the alkylation damage is left unrepaired, it increases the probability of a G to A transition mutation during replication [286]. Thus, a failure in repairing this damage will lead to an accumulation of mutations over time and constant development of new cell clones in the cancer.

The presence of methylation at the *MGMT* promoter was shown to function as a DNA methylation-based biomarker for the susceptibility of cancers treated therapeutically with alkylating agents [287]. The therapeutic benefit of alkylating agents for cancer patients with a methylated *MGMT*

promoter was clearly demonstrated in the treatment of glioblastoma with temozolomide [288]. The presence of DNA methylation at the *MGMT* promoter was also associated with increased survival in diffuse large B-cell lymphoma (B-DLCL) patients being treated with the alkylating drug cyclophosphamide as part of multidrug regimens [289]. Methylation of the *MGMT* gene is increasingly being used to guide the choice of whether to use alkylating agents in the treatment of glioblastoma patients. This has led to *MGMT* promoter methylation being the first DNA methylation-based biomarker assay that is being adopted in cancer molecular pathology for glioblastoma. However, *MGMT* promoter methylation is not currently used to guide treatment decisions for other tumors such as melanoma and colorectal cancer that also can show methylation at the *MGMT* promoter.

Many assays have been developed to detect DNA methylation at the *MGMT* promoter utilizing different approaches [267, 290, 291]. In addition, several commercial products are available based on quantitative methylation-specific PCR (qMSP), bisulfite pyrosequencing and methylation-sensitive high-resolution melting (MS-HRM). It is critical that quantitative approaches are used as, as previously mentioned, certain individuals have the single nucleotide polymorphism that predisposes to a definite background level of DNA methylation but not one that definitely leads to a methylated cancer [185].

Other DNA repair genes, such as *MLH1* [143, 292], *WRN* [293], as well as members of the BRCA-Fanconi anemia pathway, *BRCA1* [146, 294], *FANCC* [295], *FANCF* [296], and *FANCL* [295], also have been reported to show aberrant DNA methylation in several cancer types. These different alterations render cancer cells susceptible to certain chemotherapeutic drugs either directly [297, 298] or through a synthetic lethal approach [299]. Thus knowledge of which of these genes are methylated may help clinicians to choose the appropriate treatment for an individual cancer patient [300].

5.3.4 Clinical Implications of Chromatin Changes in Cancer

The prognostic value of various histone acetylation and methylation alterations was shown in studies of prostate cancer [301–303] lung cancer [304–306], ovarian cancer [307], pancreatic cancer [307, 308], gastric cancer [309], breast cancer [307, 310], and renal cancer [311]. Interestingly, for some cancer types certain histone modifications were found to act as independent prognostic factors, providing additional nonredundant information to the clinicopathological markers currently in use. This was reported for example for acetylated H3-K18 in breast cancer [310] and renal cancer [311] and for trimethylated H3-K27 in breast, ovarian, and pancreatic cancers [307].

One of the most remarkable examples of the clinical implications of epigenetics in cancer is its role in plasticity of the cancer cell phenotype. A cancer is considered to comprise two populations: a pluripotent stem-cell-like population and a more differentiated population. Sharma et al. showed the existence of a highly drug resistant stem-cell-like population in the PC9 lung cancer cell line [312]. The transition between the stem-cell-like population and the more differentiated population seemed to be mediated by the levels of the lysine-specific demethylase 5A (KDM5A, JARID1A). Such epigenetically determined plasticity has major implications for cancer therapy as no single treatment approach is likely to target both populations of cancer cells.

5.3.5 Targeting Epigenetic Changes Globally

DNA methylation and histone modifications are potentially reversible as was shown by the large scale remodeling of a melanoma nucleus after nuclear transfer into oocytes. An embryonic stem cell line could then be derived from the blastocysts that could give rise to multiple tissues in a chimeric mouse [237]. This raises the possibility, that the epigenetic changes in a cancer cell can be pharmacologically reversed. In an ideal scenario, this should result in the restoration of the epigenetic pattern associated with a certain cell type before the malignant transformation. Two different drug types that have shown some therapeutic benefit are currently in clinical use: demethylating agents and HDAC inhibitors.

Dependent on their chemical structure, demethylating agents can be grouped as nucleoside analogues or non-nucleoside based drugs [313]. The drugs based on nucleoside analogues are cytidine or deoxycytidine analogues and exert their impact in an indirect manner; they need to be incorporated into the genomic DNA and substitute for genomic cytosine. Preceding incorporation, these drugs need to be activated to resemble natural occurring dNTPs and to be capable to participate in strand synthesis. Once they have been incorporated into newly synthesized genomic DNA, they either inhibit the DNMTs irreversibly [314, 315] or form a reversible but stable complex between DNMTs and DNA [316, 317]. As a consequence, the newly synthesized DNA strands show less DNA methylation.

So far, 5-azacytidine (azacitidine, Vidaza) [318] and 5-aza-2′-deoxycytidine (decitabine, Dacogen) [319] have been approved for treatment of myelodysplastic syndromes (MDS) and leukemia by the American Food and Drug Administration (FDA). Another demethylating drug, zebularine, might is also promising in cancer therapy [320, 321].

Concerns in using demethylating drugs address their non-specific character—that the epigenetic status of the whole cancer cell is targeted rather than that of individual genes [322]. Despite the fact that the cancer genome is hypomethylated

overall, epigenetic therapy with demethylating agents is presumed to target hypermethylated promoters. A (potentially) unstable genome caused by global DNA hypomethylation may be further destabilized after drug supply and may face (additional) severe chromosomal damage, which further promotes cancer progression or metastasis. In addition, pathogenic DNA methylation patterns tend to be restored after the removal of the drug by mechanisms which remain unclear [323]. Furthermore, chemotherapeutic opportunities to target epigenetic change at particular genes will be lost. For example, a methylated *MGMT* promoter renders patients susceptible to alkylating drugs. By treating this patient group with demethylating agents, they may lose the opportunity to benefit from this kind of treatment [324].

Nevertheless, treatment with demethylating agents has been demonstrably successful in some cancers notably myelodysplasia where the prolonged treatment with low doses of demethylating agents has led to marked increase in survival with minimal side effects [325–327]. The therapeutic benefit of demethylating agents in the treatment of solid cancers is not yet as evident as for the treatment of hematological malignancies [322, 328], although some promising results have been reported in lung cancer [329]. A prerequisite of successfully using demethylating agents is the ability of cancer cells to proliferate. Many solid cancers harbor cell populations which replicate slowly and therefore may escape drug treatment unless specifically targeted [324, 328].

During cancer onset, development, and progression, some regions in the genome, become aberrantly heterochromatic. Inhibiting the enzymatic function of HDACs will result in increased acetylation of histones. Multiple HDAC inhibitors have been developed in the last years [313, 330, 331].

HDAC inhibitors can induce several anticancer effects and the mechanism(s) by which these compounds exert their inhibitory effect is an active area of research. The affected HDACs are dependent on the drug itself and the inhibitory mode has been investigated in greater detail for some of them. Nevertheless, the mechanism(s) how these drugs exert their antitumor activity on the cellular level is not well understood [331, 332]. Like demethylating agents, HDAC inhibitors have genome-wide effects. Their inhibition also leads to acetylation of non-histone proteins, such as p53 [333] which further complicates estimation of the consequences of their use [334].

To date, several HDAC inhibitors including suberoylanilide hydroxamic acid (SAHA, vorinostat, Zolinza) and Romidepsin (depsipeptide, Istodax) have been approved by the FDA for use in cancer therapy. These drugs have been approved for the treatment of cutaneous T-cell lymphomas (CTCL), where their results can be spectacular [335–338]. Another HDAC inhibitor, valproic acid, approved by the FDA for the treatment of epilepsy and bipolar disorder also shows some promising results in the therapy of hematological malignancies [339] and solid cancers [340].

Combination therapies involving both demethylating drugs and HDAC inhibitors are promising avenues of investigation in clinical trials [328, 341]. They promise to have some of the synergistic effects seen in the combinations of these two drug types in in vitro models [327, 342]. Furthermore, HDAC inhibitors could be combined with other anticancer drugs, which could improve the treatment of hematological malignancies as well as the treatment of solid cancers [341].

5.4 Conclusions

Epigenetic changes are clearly key in the initiation and development of cancer. However, we still are a long way from a complete understanding of the interplay of epigenetic and genetic change in the origin and development of cancers. Understanding the contributions of the environment and nutrition to cancer onset via epigenetic mechanisms, especially in an individual context, is increasingly important. This understanding is being accelerated by the currently developing genome-scale methodologies that will reveal the genetic and epigenetic changes in an individual cancer. Determining cancer therapy will also rely on knowledge of both genetic and epigenetic changes in each case of cancer. No characterization of a given cancer can be said to be complete without a characterization of the epigenome. Thus, the analysis of (aberrant) epigenetic patterns will be a key element in future molecular diagnostics and personalized therapies.

6.1 The Need to Study Cancer

A tremendous amount of intellectual and fiscal resources is poured into cancer research every year. Although statistics between the years 2000 and 2006 reveal a decrease in cancer incidence rates in the USA of 1.3 % and 0.5 % per year for men and women, respectively, cancer remains a major health problem within the USA and virtually everywhere in the world [1]. The death rates among men for all races in the USA decreased 21 % between 1990 and 2006 with decreases in lung, prostate, and colorectal cancers accounting for nearly 80 % of this total. During the same period, the death rates among women decreased 12.3 %, with decreases in breast and colorectal cancers accounting for approximately 60 % of this total. While these numbers are very encouraging, the following numbers are still staggering—1,665,540 new cancer cases and 585,720 cancer deaths are projected for 2014 (www.cancer.org). This number of new cancer cases is larger than the population of all but six US cities (according to the 2000 census) and the number of deaths is just under the population of Washington, DC. A list of estimated new cancer cases and deaths for 2010 is listed for various cancers in Table 6.1.

The fifth leading cause of cancer deaths among women is ovarian cancer. The death rate for this cancer illustrates the need for better diagnostic tools. It is estimated that during 2014, 21,980 women will be diagnosed with ovarian cancer during and 14,270 will die from this disease (http://www.ovariancancer.org/about-ovarian-cancer/statistics/) [1]. Funding to support ovarian cancer research in the USA has predominantly come from federal agencies, which committed $112 million in the year 2010 (http://www.ovariancancerresearch.thegcf.org/). Other nonprofit organizations have contributed another $16 million, for a total national commitment of at least $128 million to support ovarian cancer research. Overall this funding level represents greater than $9000 for every woman who will die from ovarian cancer. Unfortunately, even at this fiscal commitment, the prognosis for women diagnosed with ovarian cancer remains poor. This disease does not have a reliable early detection or screening test, resulting in more than 60 % of patients being initially diagnosed with stage III or stage IV cancer. At these stages the cancer has already spread beyond the ovaries. A lack of progress in diagnosing and/or treating ovarian cancer is reflected in Table 6.2 (http://www.ovariancancer.org/about-ovarian-cancer/statistics/). Over the first decade of this century, there was little change in the number of women diagnosed with this disease and no significant change in the number of deaths. Overall the ratio of new cases report and deaths shows no significant change over this 10 year period.

Ovarian cancer is typically diagnosed in patients that already show symptoms. The symptoms may include pressure or pain within the pelvis, abdomen, back, or legs, bloating within the abdomen, chronic tiredness, gas, diarrhea, constipation, indigestion, and nausea (http://www.medicinenet.com/ovarian_cancer/article.htm; http://www.mayoclinic.com/health/ovarian-cancer/DS00293/DSECTION=symptoms). Other less common symptoms include unusual vaginal bleeding and urinary frequency. Unfortunately the symptoms of ovarian cancer are nonspecific and are similar to those other more common conditions such as digestive and bladder disorders. Before being diagnosed with ovarian cancer, a woman may be told she has another condition such as irritable bowel syndrome, stress and depression. If the physician suspects ovarian cancer he/she will order additional tests. A physical exam, in which the doctor presses on the abdomen to check for

1999	19,676	13,627	1.44

tumors or ascites fluid buildup, as well as a fluid examination, may be conducted. A pelvic exam to check the ovaries and nearby organs for lumps or abnormalities in shape or size may be done along with an ultrasound to get a picture of the ovaries and surrounding tissues. The doctor may also order a blood test to measure the levels of mucinous glycoprotein serum cancer antigen 125 (CA125). After all of these tests are conducted, a biopsy may be required to physically remove tissue from the ovary, as well as surrounding fluid, and have them examined by a pathologist. It is easily seen why most women that receive a diagnosis of ovarian cancer are already at an advanced stage. It would be ideal if the circulating CA125 levels could be used to routinely screen women for ovarian cancer at yearly physicals. However, its measurement lacks the necessary sensitivity and specificity (http://www.cancer.gov/cancertopics/factsheet/Detection/tumor-markers). In fact the US Food and Drug Administration (FDA) only approves the use of CA125 for monitoring the response to ovarian cancer treatment and for detecting its post-treatment recurrence. One of the major issues associated with using CA125 measurement to diagnose ovarian cancer is the large number of false positives that it predicts [2]. Obviously CA125, like the other well-known prostate cancer biomarker prostate-specific antigen, lack the sensitivity and specificity required for diagnosing patients.

6.2 Hypothesis Versus Discovery-Driven Studies

One important change in how cancer research is conducted in the *omics*-age is perspective. In previous decades where data collection was often challenging most cancer studies were hypothesis driven. In a hypothesis-driven study, the investigator formulates an educated guess to explain a cause-and-effect relationship. A series of experiments are performed to examine this idea and determine if the hypothesis is correct. In a discovery-driven study, the goal is to collect a specific type of data on as many features as possible and use the data to draw a conclusion or formulate a hypothesis. The success of many discovery-driven studies is how well the data can formulate novel specific hypotheses. The advent of technologies that can gather large amounts of data on thousands of biological molecules in clinical samples has driven cancer research towards discovery-driven studies at an exponential rate. A great example is genome-wide association studies (GWAS) [3]. In GWAS, the genomes of different individuals are sequenced to determine how their genes vary. The most common comparisons made in GWAS studies are between healthy individuals and those with a specific disease condition. The aim is to find regions in the genome that can be associated with specific traits such as diseases.

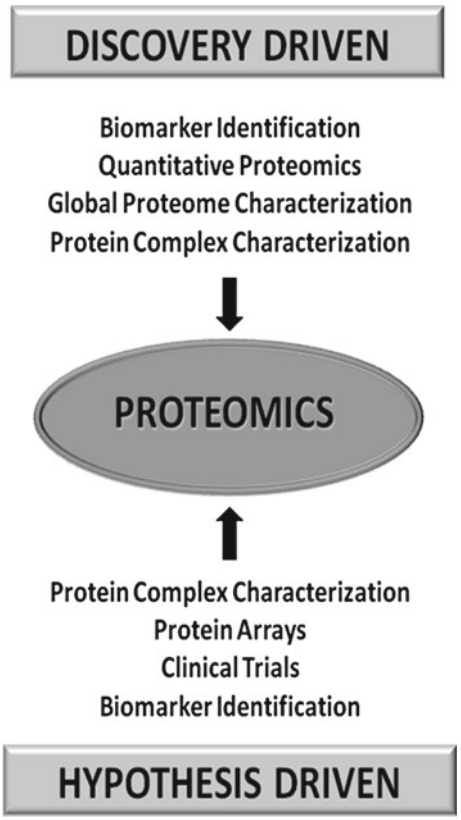

Fig. 6.1 List of discovery-driven and hypothesis-driven studies. In the proteomics era, some studies (such as protein complex characterization and biomarker identification) can be performed using either approach.

In the field of proteomics, the development of high-throughput technologies has enabled discovery-driven studies as never before. As shown in Fig. 6.1, these studies include biomarker discovery, quantitative proteomics, protein complex characterization, and global proteome characterization. Probably the biggest impact to cancer research has been the ability to conduct discovery driven studies to find cancer-specific biomarkers. The greatest challenge in finding biomarkers for specific cancers is having no a priori information as to the identity (or even character) of a protein biomarker for any cancer. It is even impossible to determine which class of protein (e.g., kinase, phosphatase, membrane, or nuclear) a biomarker likely belongs. Therefore, this type of study is often left to a purely unbiased discovery-driven in which samples from healthy and cancer-affected individuals are compared. In addition, the ability to collect large amounts of data has also impacted how hypothesis-driven proteomic experiments are conducted. For example, protein complexes no longer need to be characterized protein by protein, rather the entire complex can be analyzed in a single experiment. The amount of data collected in an experiment does not necessarily indicate if it is hypothesis-driven or discovery-driven. For example, clinical trials that collect a great deal of patient data are primarily hypothesis-driven as specific outcomes are being monitored. This ability to conduct meaningful discovery-driven studies has provided the basis for the large increase in proteomic biomarker discovery, primarily for cancers. Reasonable or not, biomarker discovery projects begin with essentially no information as to the identity of the protein of interest. The only reliable information available is the source of the samples being analyzed. To understand how proteomics is applied to cancer research it is important to gain an understanding of the major technologies used in this field.

6.3 Proteomic Technologies

The previous decade has seen a revolution on how cancer is studied. In times past, cancer research was conducted on a molecule-by-molecule basis, whereas today's experiments aim to simultaneously uncover large numbers of genes, transcripts, proteins, and metabolites that characterize a specific cancer. The primary driver that introduced this new *omics* era was technology development. Massively parallel sequencing methods, such as 454 Sequencing, have made surveying entire genomes for genetic aberrations possible [4]. High-density microarrays allow tens of thousands of transcripts to be characterized in a high-throughput fashion [5]. For proteins and metabolites, advances in chromatography and mass spectrometry (MS) have permitted thousands of these molecules to be characterized in complex clinical samples [6, 7].

In the field of proteomics, gone are the days in which cancer was studied at an individual protein level. While fundamental technologies such as Western blotting, enzyme-linked immunosorbent assays (ELISA), immunoprecipitations (IPs), and other methods will continue to be critical in protein analysis, modern proteomic technologies enable cancer to be studied at pathway, network, and global levels. An excellent example of proteomic technologies changing the way a fundamental experiment is conducted is illustrated by the analysis of protein complexes (Fig. 6.2) [8]. Protein complex isolation has been routinely conducted using IPs. Historically, the extracted material has been separated using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and then transferred to a polyvinylidene fluoride (PVDF) membrane. To identify a protein interaction, the PVDF membrane is blotted using an antibody directed against a protein hypothesized to interact with the protein targeted in the IP. While this hypothesis-driven strategy has proven fruitful over the years, it provides a limited amount of information and lacks the ability to find truly novel interactions that fall outside the investigators hypotheses.

The proteomics era has brought the ability to conduct more discovery-driven approaches. For example, in the characterization of protein-protein interactions no longer requires a hypothesis to identify individual proteins, rather the entire complex can be characterized using mass spectrometry (MS).

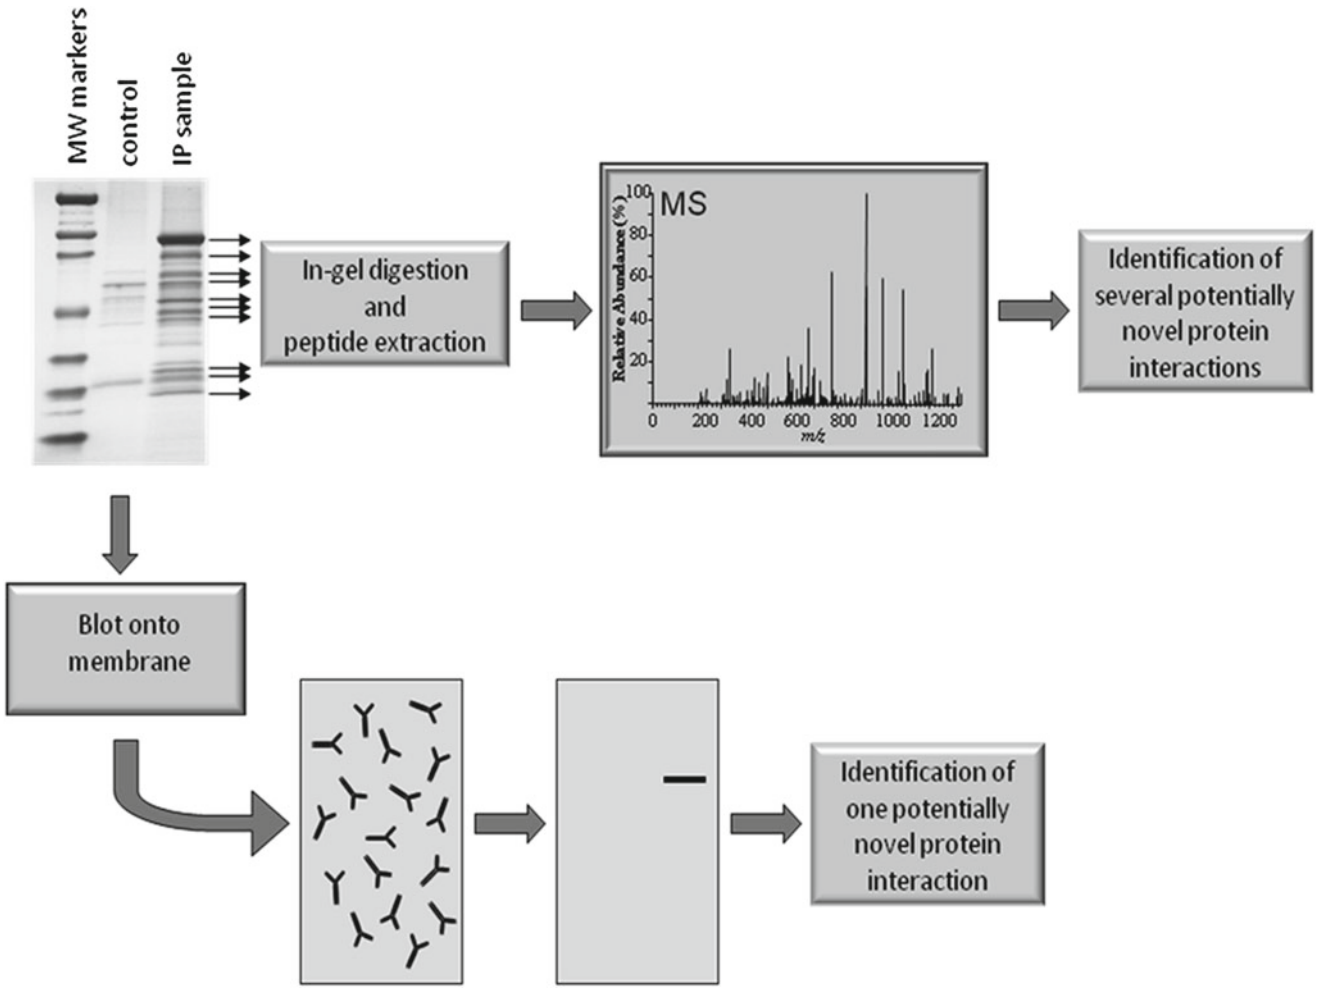

Fig. 6.2 Identifying protein interactions using hypothesis and discovery-driven methods. In a hypothesis-driven approach a protein complex is isolated using a technique such as immunoprecipitation (IP). The complex is separated by gel electrophoresis and the proteins blotted onto a membrane, which is interrogated using an antibody specific for a protein that is hypothesized to interact with the target protein. In the discovery-driven approach the complex is separated using gel electrophoresis, the protein bands are colorimetrically stained, and individually subjected to in-gel digestion. After extracting the peptides from each gel piece, they are individually analyzed using mass spectrometry (MS). While the hypothesis-driven method results in the identification of a single potential protein interaction per experiment, the discovery-driven approach identifies several potentially novel interactions.

The procedure for characterizing protein complexes using MS is straightforward and incorporates many of the steps used in the hypothesis-driven strategy (Fig. 6.2). The isolated protein complex is separated using SDS-PAGE and rather than transferring the proteins to a PVDF membrane, they are stained using a colorimetric reagent such as Coomassie blue or silver stain. The protein bands are excised from the gel and are subjected to in-gel digestion with a proteolytic enzyme (usually trypsin). Peptides are extracted from the individual gel pieces and identified using MS. The identified peptides are then compared to a proteomic or translated genomic database to determine the origin of the peptides. This discovery-driven approach offers a number of key advantages over hypothesis-driven methods. Several interacting proteins can be identified within a single study, no antibodies (save those used to isolate the complex) are required, and truly novel protein interactions can be identified since any testing does not rely on a formulated hypothesis.

6.3.1 Mass Spectrometry

The greatest fundamental advance that proteomics has contributed to cancer research is in the identification of proteins. While having been a mainstay in biochemistry for over a half-century, the technology used for identifying proteins has seen enormous leaps in the past decade. In the 1950s Edman degradation enabled the sequencing of purified proteins [9]. While Edman sequencing is still in use today, it has been largely replaced by MS. The two primary reasons are

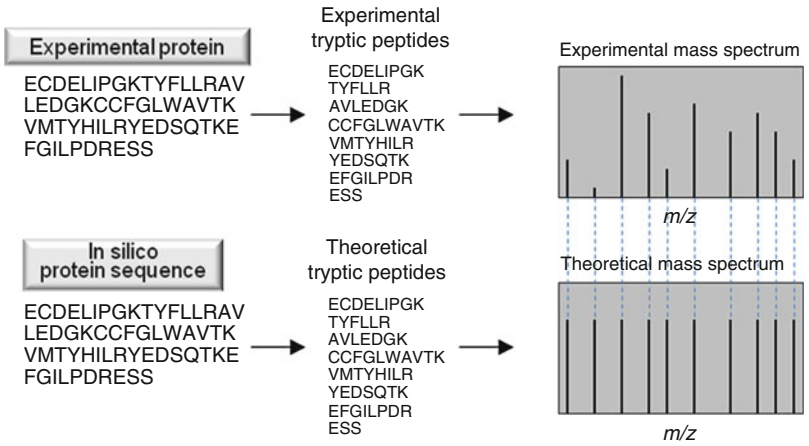

Fig. 6.3 Identification of a protein via peptide mapping. Proteins are digested into peptides (usually tryptic) and their masses are measured using mass spectrometry (MS). The resulting masses are compared to theoretical mass spectra that are generated by an in silico digest of a suitable proteome database. The protein is identified by the correspondence between the list of experimental peptide masses and the in silico digest of each protein within the database.

throughput and the fact that MS does not require a pure sample to confidently identify a protein. Mass spectrometry is able to identify a single highly purified protein or identify thousands of proteins within a complex mixture. The two main methods used to identify proteins by MS are peptide mapping [10] and tandem MS (MS/MS) [11].

To identify a protein using peptide mapping, it is first enzymatically digested into peptide fragments (Fig. 6.3). Trypsin is by far the most commonly used protease for this purpose owing to its specificity and the relative distribution of lysine and arginine residues throughout proteins in the proteome. The masses of the tryptic peptides are measured using MS and this list of experimental masses is compared to theoretical masses of the tryptic peptides that would result from a tryptic in silico digest of proteins present in a protein or genomic database. The protein is identified based on the best match between the experimental peptide masses and the digest of the proteins within the database. The drawback with peptide mapping is that, although it does not require a pure protein, the best identifications come from samples in which the target protein is highly enriched.

When using MS/MS for identification (Fig. 6.4), individual peptides enter the mass spectrometer and are isolated within the instrument and collided with an inert gas (i.e., He, Ar, N_2, etc.). This process, known as collisional induced dissociation (CID) breaks the peptide into fragments that are then sent to detector. Fortunately, the ways in which peptides fragment are fairly well understood with cleavage across the amide bond one of the favored fragmentation pathways. In addition, CID does not cleave every amide bond in every peptide. The fragmentation results in populations of various lengths of residues both from the N-terminus and C-terminus, as well as internally, being recorded for each peptide. Peptides are identified by how well the fragmentation pattern matches the in silico fragmentation patterns calculated from all corresponding peptides within a database. When the sample is primarily comprised of a single protein, the MS/MS spectra of several peptides are used to confidently identify the protein. When very complex mixtures are being analyzed, the MS/MS spectrum of a single peptide can provide evidence for the presence of a specific protein within the sample. However, the rule is that the more peptides identified, the greater the confidence that the protein is present in the sample. The advantage of MS/MS is that it identifies peptides based on sequence information.

When combined with high resolution liquid chromatography (LC), modern mass spectrometers can sequence thousands of peptides per hour. For these types of studies, a complex sample (e.g., biofluid, tissue, or cell lysate) is digested into tryptic peptides. These peptides are fractionated by a selected number of chromatography methods prior to being eluted directly into the mass spectrometer. The most commonly used modes of fractionation involve strong cation exchange followed by reversed phase LC. As they enter the mass spectrometer, the instrument isolates individual peptides based on their intensity and subjects them to CID (Fig. 6.5). The MS/MS spectra are then analyzed against a suitable database turning the raw data into identified peptides. The identified peptides are binned to their specific protein of origin. The seminal example of using MS to identify large numbers of proteins in a biological sample was developed by Dr. John Yates' lab in 2001 [12]. A dual strong cation exchange/reversed-phase LC column was used to separate tryptically digested yeast proteins directly on-line with an ion-trap mass spectrometer. This experiment resulted in the identification of almost 1500 proteins. This multidimensional

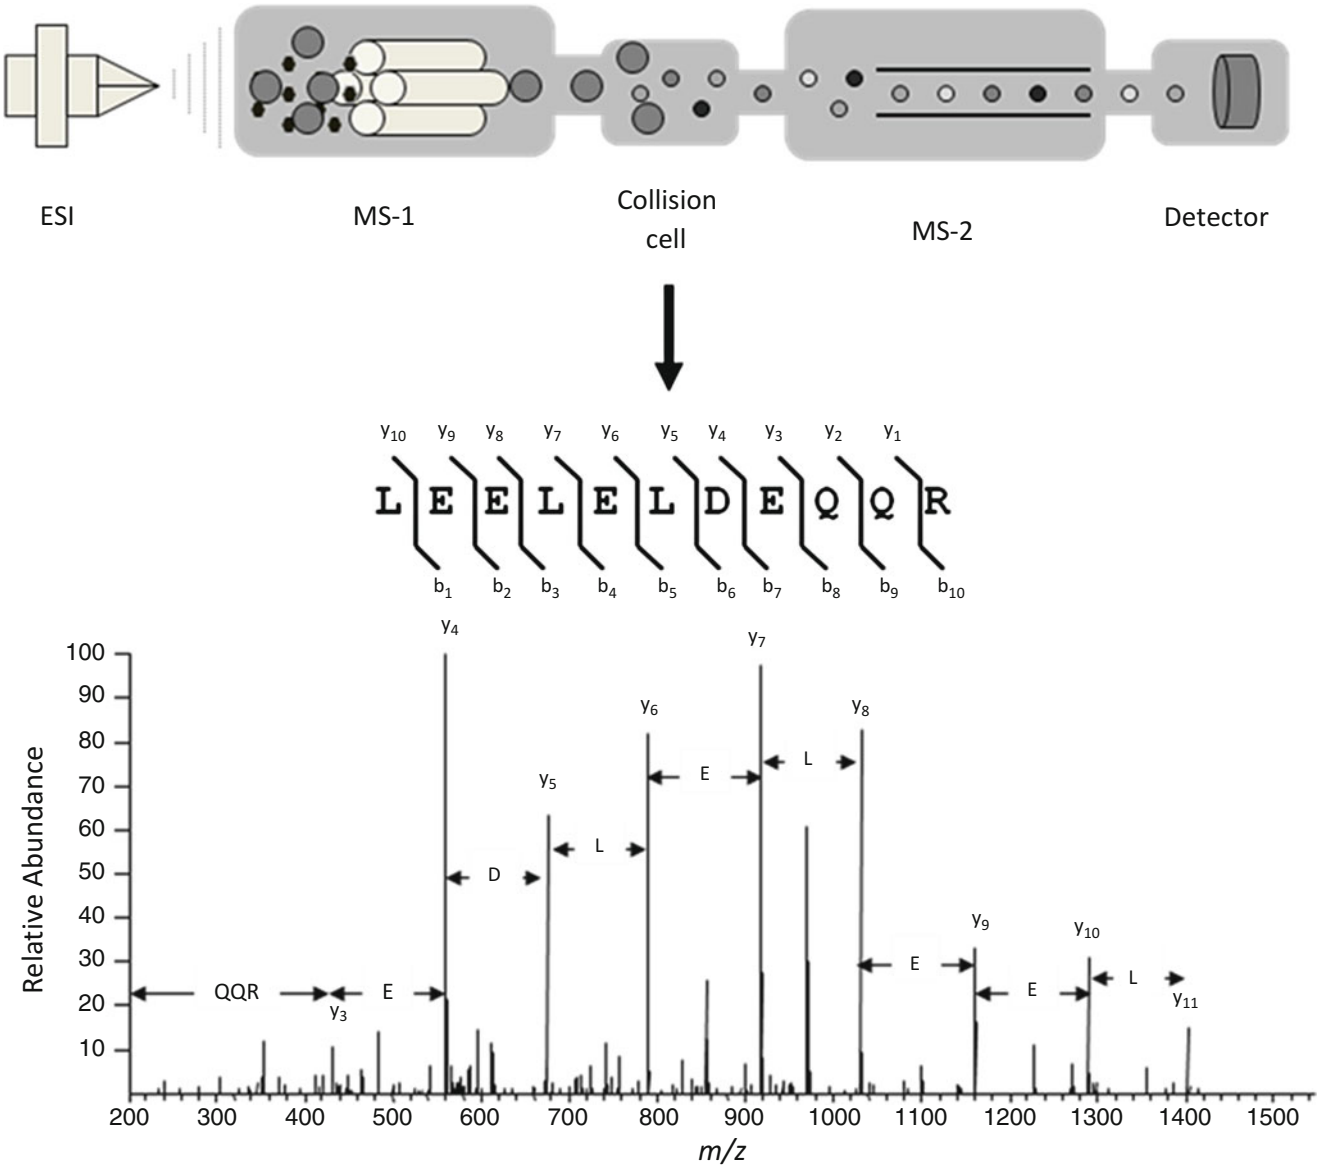

Fig. 6.4 Identification of a protein via tandem mass spectrometry (MS/MS). A specific peptide entering the mass spectrometer (*large grey circle*) is isolated within the instrument and subjected to collisional induced dissociation (CID). The fragments of the peptide produced by CID are then directed onto the detector where the MS/MS spectrum is acquired. The most common fragmentation occurs across the amide bond creating a series of b and y ions. Software programs compare the MS/MS spectra with proteomic databases to determine the sequence of the peptides subjected to CID.

protein identification technology or MudPIT, as it was coined, was subsequently used by different laboratories to interrogate clinical samples with the ultimate goal of discovering biomarkers. This technique, now commonly referred to as *shotgun proteomics*, has been used to tremendously increase our knowledge of the proteome of peripheral body fluids such as serum, plasma, and urine. While today investigators have been able to identify upwards of 4000 proteins within complex samples [13–15], the mass spectrometer is still unable to identify all of the proteins within a complex mixture.

6.3.2 Protein Arrays

While MS has been the primary tool for advancing cancer research into the proteomics era, protein arrays represent a more directed and potentially more powerful tool to perform broad proteome surveys of different cellular systems. Owing to its dominance, this chapter is devoted to the role of MS in cancer proteomics. However, it is worth including a section to make the reader aware of protein array technologies. While MS will continue to play a dominant role in biomarker

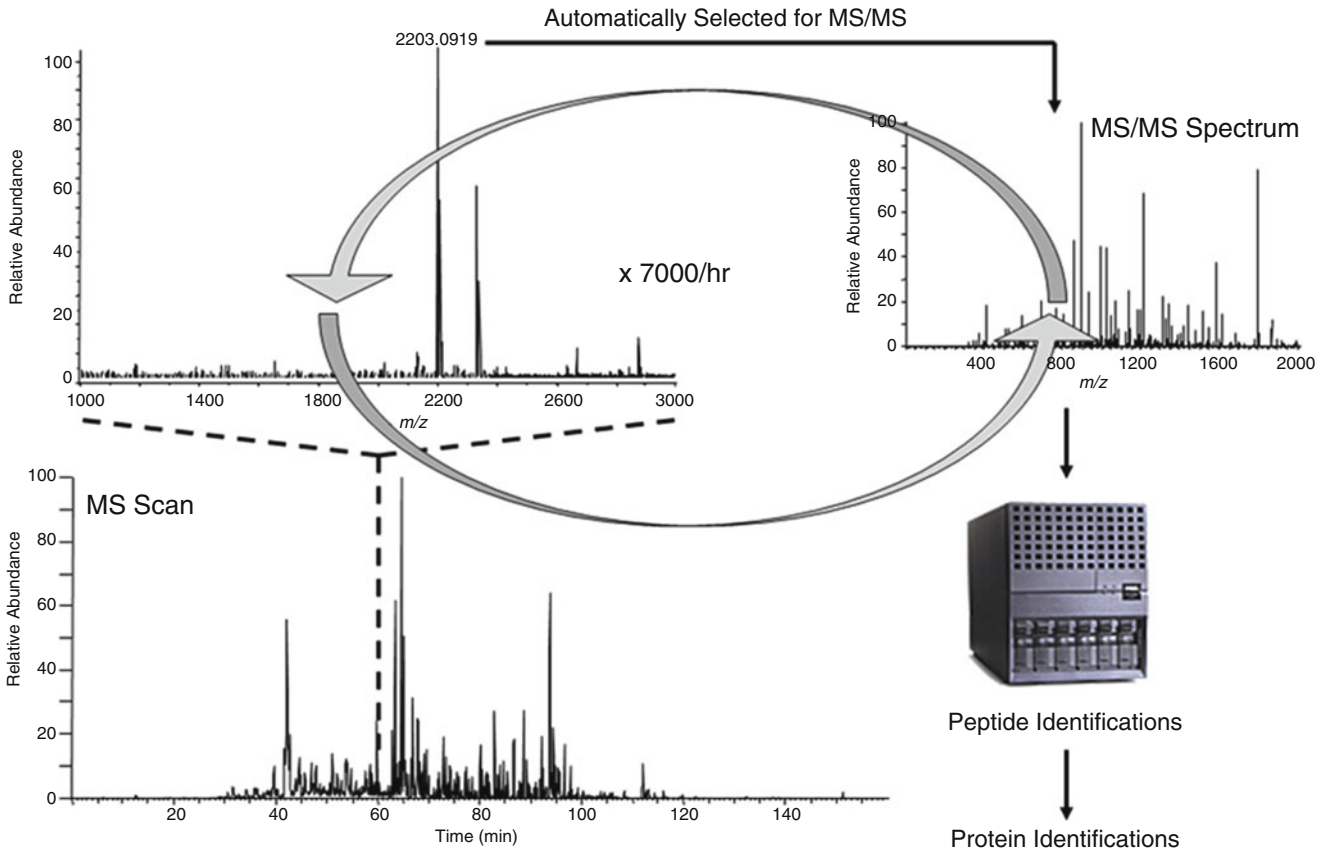

Fig. 6.5 Data-dependent tandem mass spectrometry identification of peptides in complex mixtures. In this method, peptides observed in the MS scan are selected for MS/MS based on their signal intensity. After the MS/MS spectrum of the most intense peptide in the preceding MS scan is acquired, the next most intense peptide signal is selected and so on. After 5–10 peptides are selected the mass spectrometer acquires another MS scan to find new signals from peptides that have eluted into the instrument. This sequence of MS and MS/MS occurs at a rate of approximately 7000 times per hour resulting in the identification of thousands of peptides from complex mixtures.

discovery, protein arrays will be increasingly important in validation studies. Like ELISA's, Western blotting, and immunohistochemistry (IHC), protein arrays make use of affinity reagents (primarily antibodies) to measure changes in proteins present within complex samples. Put simply, protein arrays are essentially an attempt to simultaneously conduct hundreds of microscale IHCs, ELISAs, or Westerns. While protein arrays may seem limited since they target specific proteins (hypothesis-driven), large numbers of different antibodies can be used to provide a comprehensive view of protein changes.

There are currently two types of protein microarrays used in cancer research: (1) forward-phase protein microarrays (FPPAs) [16, 17], and (2) reverse-phase protein microarrays (RPPAs) [18]. The goal of both types of arrays is to map changes in cell pathways and networks in single, high-throughput experiment. The obvious advantage using either type of array is throughput, allowing real-time analysis of multiple patient samples. In FPPAs, antibodies are immobilized onto a solid surface. The antibodies act as bait to capture specific antigens within the sample. As with many immunoaffinity techniques, a secondary antibody is utilized to detect and visualize the antigen. The major disadvantage of FFPAs is the need for two antibodies and the antigen must be in a conformational state capable of binding both unique antibodies.

The second type of protein array is the reverse-phase protein microarray (RPPA). They are called reverse-phase because instead of the antibody, the antigen-containing sample containing the antigens is immobilized to a surface. The types of samples that can be arrayed include cell lysates, laser captured tissues, and tissue cores. The array format allows numerous aliquots of the sample to be arrayed and interrogated with multiple antibodies against unique proteins. The obvious advantage of the RRPA is that a single antibody is required per antigen. The amount of cell lysate obtained from cells acquired using laser capture microdissection (LCM) is plenty for creating an entire RPPA. These arrays typically use on the order of 2 nL of material per spot, allowing hundreds of patient samples to be printed on a single 25 × 75 mm array.

While conventional protein arrays require spotting of cell lysate, investigators have also developed tissue microarrays (TMA) [19–21]. Tissue microarrays are essentially high-throughput devices for conducting multiplexed IHC experiments on tissue sections. Immunohistochemistry is a standard research tool for translational research laboratories as well as being a foundational diagnostic technique in modern clinical pathology. Instead of conducting IHCs on a single tissue, TMAs allow for the concurrent analysis of tens to hundreds of tissue specimen on a single slide. In the construction of a TMA, 0.6–2.0 mm diameter regions are cored from FFPE (formalin-fixed paraffin-embedded) or fresh-frozen tissues and cut into thin sections. The thin slices are then transferred onto a glass slide for automated IHC analysis using specific antibodies. The results can be assessed by an actual pathologist or automatically and then linked to other available clinical data, such as prediction of patient outcome. Beyond the obvious throughput advantage, since several samples are done concurrently TMAs demonstrate a high degree of precision for the analysis of clinically important samples.

6.4 Discovery of Protein Biomarkers

The greatest impact that proteomics could make on cancer research is the discovery of biomarkers. The number of lives that would be saved if more biomarkers could be discovered for cancer would be staggering. The number of deaths due to cancer, in particular, would drop dramatically as biomarkers would open up the possibility of detecting this disease at early stages where modern treatments are more effective. As mentioned earlier, more than 60% of ovarian cancer patients are diagnosed at stage III or IV (http://www.ovariancancer.org/about-ovarian-cancer/statistics/). A biomarker with sufficiently high sensitivity and specificity that could diagnose patients with stage I and II cancer, prior to its spreading beyond the ovaries, would make treatments much more effective. Beyond early detection, biomarkers could have a major impact on treatment and prognosis. Personalized medicine, with the aim of treating patients based on their individual molecular profile, is a major focus in medical science today. To reach the goal of personalized medicine is going to require biomarkers that can be used to evaluate treatment efficacy. These biomarkers would enable the best treatment to be selected quickly eliminating a trial-and-error therapeutic strategy.

The proteomics community has devoted a tremendous amount of time and fiscal resources over the past decade in the search for proteomic biomarkers for cancer. The impetus for this direction stems from the development of high-resolution separation techniques and high-throughput peptide identification ability of modern mass spectrometers. The two primary methods for cancer proteomic biomarker discovery utilize two-dimensional polyacrylamide gel electrophoresis (2D-PAGE) or shotgun proteomics [22–24].

6.4.1 Two-Dimensional Polyacrylamide Gel Electrophoresis

The overall strategy for identifying biomarkers using 2D-PAGE is shown in Fig. 6.6. Proteomes are extracted from samples obtained from cancer and normal patients and they are separated on gels based on their isoelectric point (p*I*) and molecular weight (MW). Each sample is usually separated on their own gel followed by Coomassie blue or silver staining. The intensity of the stained protein spots are then compared to their matching spots on all the other gels and those that show a differential abundance between samples obtained from cancer and control (i.e., normal) patients are cored from the gel and identified using peptide mapping or MS/MS.

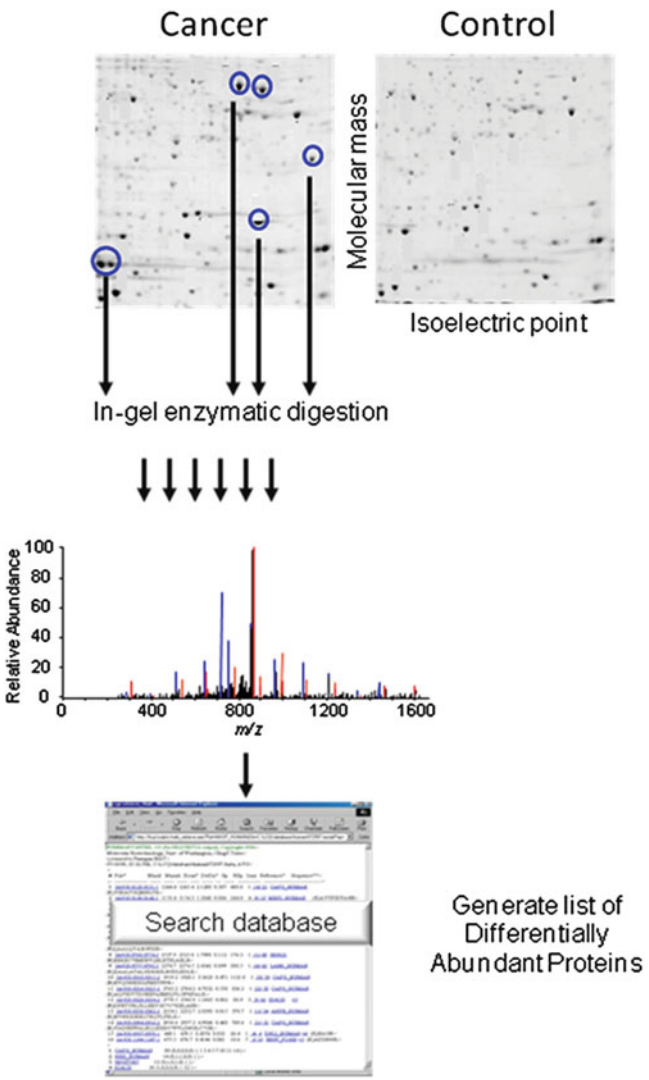

Fig. 6.6 Identification of cancer biomarkers using two dimensional-polyacrylamide gel electrophoresis (2D-PAGE). In this method, proteomes extracted from cancer and control samples are fractionated on individual gels. After staining, protein spots that have a greater intensity compared to their counterpart are cored from the gel, subjected to in-gel digestion and identified using mass spectrometry combined with database searching.

The proteins identified within these spots are then considered putative biomarkers.

The 2D-PAGE strategy has a number of advantages. Only proteins that show a relative abundance difference between the samples being compared require MS identification. The peptides identified for each protein spot can be confidently assigned to that protein as opposed to a potential isoform or another protein that has very high homology. Posttranslationally modified forms of specific proteins, particularly phosphorylation, can be easily recognized via 2D-PAGE as chains of spots across a region of the gel as they will have very similar MWs but different p*I*s.

As with almost every scientific technique, the 2D-PAGE strategy has disadvantages as well. Producing highly reproducible 2D gels can be quite laborious, although automated methods in which several gels are run simultaneously have greatly helped. It also needs to be kept in mind that not every protein on the gel requires MS analysis, saving a lot of labor at the protein identification stage. As far as reproducibility, 2D differential in-gel electrophoresis (2D-DIGE), in which proteomes extracted from different sources are labeled with fluorescent tags, have enabled up to three different samples (as well as an internal control) to be separated on a single gel [25]. This concurrent analysis greatly eliminates irreproducibility. Another disadvantage with 2D-PAGE is the lack of sensitivity. While increasingly sensitive stains can be used to visualize protein spots, ultimately sensitivity is established by the mass spectrometer to identify the spot. Each spot within a gel must be subjected to in-gel digestion and the resultant peptides extracted. The extraction step, in particular, can result in peptide losses and impact overall sensitivity.

6.4.2 Shotgun LC-MS/MS Analysis

While 2D-PAGE has been used, most biomarker discovery studies have been based on shotgun proteomics or slight variations of this method [24]. The basics (and hope) of this strategy are illustrated in Fig. 6.7. A series of samples are collected from disease affected and matched normal patients.

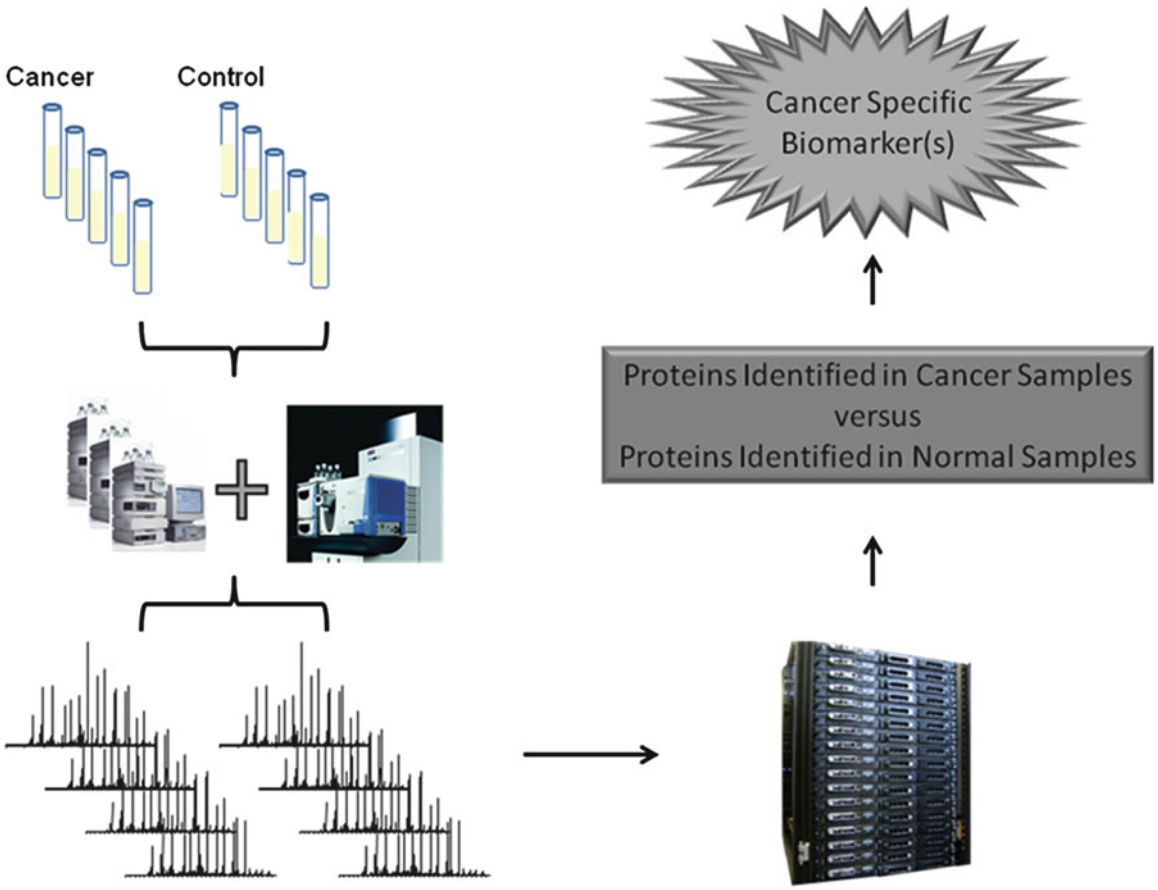

Fig. 6.7 Identification of cancer biomarkers using shotgun proteomic methods. In this method, proteomes extracted from cancer and control patients are digested into peptides. The samples are then separately analyzed using some form of multidimensional fractionation combined with tandem mass spectrometry (MS/MS) to identity as many peptides in each sample as possible. The lists of peptides identified in these samples are then compared to find proteins that have a greater abundance in one of the samples. The hope is that these differences lead to a useful biomarker or a panel of biomarkers.

The proteomes are extracted from each sample and digested into tryptic peptides. If plasma or serum is being analyzed, an immunodepletion step to remove high abundance proteins such as albumin, immunoglobulins, transthyretin, and other abundant proteins must be performed prior to enzymatic digestion or a majority of the peptide identifications observed by MS will originate from these proteins. The tryptic peptides are fractionated prior to being introduced into the mass spectrometer. The aim in fractionation is to elute as few peptides as possible into the mass spectrometer at any time, thereby giving the instrument the opportunity to select as many peptides for identification as possible. While studies have included two, three, and even four dimensions of separation, there is an obvious trade-off between the numbers of fractionation dimensions and throughput. Each LC-MS/MS experiment requires approximately one hour, therefore fractionating a single clinical sample into 20 fractions will require a minimum of 20 h of MS time. If the study contains samples from 20 control and 20 disease-affected patients, the time required will be at least 40 days of constant MS data acquisition. While ultimately the goal is to identify as many proteins as possible from each clinical sample, it is important to balance throughput with number of samples analyzed. For identifying peptides, the mass spectrometer is set up in a data-dependent mode in which the instrument automatically selects peptides to sequence (MS/MS) based on their intensity [26]. The combination of state-of-the-art fractionation and MS allows thousands of peptides within complex samples to be identified. These identified peptides are then correlated to their protein of origin, resulting in a database of proteins observed within each sample and the number of peptides identified for each.

6.4.3 Protein Quantitation

A challenge in conducting shotgun studies for cancer biomarker discovery is how to quantitate differences between peptides within different samples. There are a number of options available with each having their advantages and disadvantages. Isotope-labeling methods [6, 27] such as isotope-coded affinity tags (ICAT), iTRAQ, and O^{16}/O^{18} provide reasonable accuracies. However, these methods only allow at most seven samples (in the case of iTRAQ, the others only permit two) to be directly compared. Biomarker discovery is going to require many more samples than this to be directly compared to gain any sense of confidence in the results even at the discovery phase. To compare large numbers of samples, label-free methods that contrast the number of peptides identified for a specific protein or the actual peak intensities provided by specific peptides in different spectra have been developed.

In one use of label-free quantitation [28], the relative abundances of proteins is determined by the number of peptides identified for each specific protein in different samples. The number of peptides identified for a protein is thought to correlate with its abundance when a sample is analyzed using data-dependent MS/MS. This simple hypothesis is best illustrated by the results obtained in the analysis of undepleted serum. Direct LC-MS/MS analysis of trypsin-digested serum results in the identification of a huge number of albumin peptides, since this protein is present at 40–80 mg/mL. Proteins in the abundance range of ng/mL range (such as a chemokines and cytokines) will probably be identified by one or fewer peptides. To illustrate how relative abundance of a protein is calculated using this method consider an example of two samples—one from a healthy individual and another suffering from ovarian cancer. If nine peptides are identified for CA-125 in serum from the ovarian cancer patient and only two peptides from the other sample, the protein is concluded to be 4.5-fold more abundant in the serum taken from the cancer patient.

This method, known as subtractive proteomics or peptide count, requires minimal sample preparation and allows an unlimited number of samples to be compared. Unfortunately, like most proteomic applications, collecting the data is relatively low-throughput. The method also lacks quantitative precise with the minimum difference that can be reasonably measured being approximately threefold. This lack of accurate quantitation is a major deficiency when attempting to recognize potential biomarkers that are of very low abundance and may be detected by only one or two peptides in the cancer-affected individual. If the protein is not detected in control samples at all, the adage *absence of evidence is not the evidence of absence* applies.

In another label-free method, relative quantitative measurements are based on the ratio of the actual peak area measured for specific peptides in samples being compared [28]. Selected ion chromatograms of the peptides are generated enabling measurement of the peak areas. Proteins of interest are often represented by multiple peptides, therefore the average and standard deviation of the abundance ratio can be calculated for the same protein.

6.5 Sample Types for Biomarker Discovery

A critical decision for designing a proteomic biomarker discovery project is the type of sample to analyze. The choices include tissue (both tumor and stroma), cell scrapings, urine, serum, plasma, cerebrospinal fluid (CSF), saliva, blister fluid, nipple aspirate fluid, breast ductal lavage, and others. The point is there are a lot of different clinical samples to be considered. Unfortunately the guidelines for selection are not well defined and the choice is typically based on what is most available. While the point of this chapter is not to produce

guidelines, a reasonable rule of thumb is to select the sample type that is within closest proximity to the cancer site whenever possible. For example, it may be reasonable to assume that biomarkers for oral cancers will most likely be found within saliva or bladder cancer associated biomarkers found within urine.

6.5.1 Blood

While using the biologic sample that is closest to the cancer site may sound reasonable, in most cases proteomic biomarker discovery studies use serum or plasma [29]. When referring to blood in this chapter, it will be meant to include both serum and plasma. While some studies use plasma and others use serum, there is no definitive study that shows one having an advantage over the other. Approximately 5 L of blood circulates through ~60,000 miles of veins, arteries, and capillaries (http://www.fi.edu/learn/heart/systems/circulation.html) transporting life-sustaining nutrients to cells and carrying waste from cells (http://health.howstuffworks.com/blood.html). Considering the intimacy that blood has with the entire body (no cell is outside of four cell units from the circulatory system) it is not surprising that it contains information concerning the overall pathophysiology of the patient. Essentially everyone has provided a blood sample during a routine physical examination. A variety of different molecules are measured in blood to provide a general assessment of the patient's physical condition. Deviation of these metabolites from a normal concentration range can indicate the presence of a disease.

The question of whether blood is a reasonable source of biomarkers for cancers needs to be addressed. Specific cells within blood contain their own genomes, whereas plasma and serum do not. Many proteins found in blood are believed to arise from those transported out of cells or released by apoptotic or necrotic cells. A comparison of N-linked glycopeptides identified within breast cancer cells, B-lymphocytes and T-lymphocytes, bladder and prostate cancer tissue, and a metastatic liver cancer showed this hypothesis to be accurate. The study demonstrated that extracellular glycoproteins originating from tissues and cells were detected within the blood using current proteomic technology [30]. The study suggests that blood can potentially contain any portion of any protein present within any cell in the body.

Beyond its interaction with cells and tissues, blood is easily acquired from the patient and has a protein concentration on the orders of tens of mg/mL. While on the surface this high protein concentration seems ideal, unfortunately about 99 % of this content is made up of only 22 proteins [31]. The concentration of proteins within blood is estimated to span ten orders of magnitude. This large dynamic range of protein concentration is problematic for MS analysis since the dynamic range of a typical mass spectrometer is only on the order of two orders of magnitude. Therefore, straight LC-MS/MS analysis of serum or plasma will result in the identification of high abundant proteins such as albumin, transferrin, fibrinogen, and immunoglobulins. Low abundance proteins, considered to be the most likely biomarker candidates will rarely be selected for identification.

Two key steps were developed and incorporated to enhance the identification of low abundance proteins in blood. These developments are multidimensional fractionation, such as MudPIT, and immunodepletion of high abundance proteins prior to fractionation [32]. High abundant protein depletion is now a standard technology used in the discovery of biomarkers in blood samples. There are a number of commercially available immunodepletion systems available. One of the earliest, and still quite popular, product is the Agilent multiple affinity removal system (MARS), which immunodepletes albumin, IgG, IgA, transferrin, haptoglobin, and alpha-1-antitrypsin [33]. This column-based product is quite effective in removing these proteins. Subsequently, immunodepletion columns that removed larger numbers of proteins, namely a Top 20 depletion column from Sigma, and the Seppro™ MIXED12 IgY-based affinity LC column, were introduced [34]. Studies have shown that these depletion steps have high reproducibility, an important component when comparing samples from cancer and healthy patients [33].

6.5.2 Urine

The third most popular choice of biofluid, behind plasma and serum, for cancer biomarker discovery is urine. While urine's protein concentration is significantly lower than blood, large amounts of this biofluid can be collected. The completely noninvasive collection procedure allows multiple samples to be easily obtained from a single individual over lengthy time periods. A drawback to its low protein concentration is that urine must be concentrated prior to proteomic analysis. Fortunately, urine does not possess the large dynamic range of protein concentrations that blood does, therefore immunodepletion is not required prior to fractionating and MS analysis. A stark difference between proteomic analysis of urine and blood is in the number of proteins identified. While thousands of proteins can be identified in a typical MS analysis of blood, urine analysis generally only yields a few hundred. Probably owing to its proximity, urine analysis has proven fruitful for the discovery of biomarkers for diseases related to the kidney, bladder, and urinary tract. Indeed, several studies have already found potentially promising biomarkers in urine for conditions such as prostate cancer [35], renal cell carcinoma [36], and bladder cancer [37]. In these studies, a large percentage of proteins originating from lysosomes and

membranes were found showing that urine contains biomarkers for conditions not localized to the kidney, bladder, and urinary tract.

6.5.3 Tissue

Tissue is an obvious choice of sample for the discovery of cancer biomarkers. In a vast majority of cases, the protein(s) that causes a cancer is anticipated to be localized within the cancerous tissue. A useful biomarker does not even have to be the protein(s) responsible for causing cancer formation—the protein could be causally related or simply a bystander whose character (abundance, PTMs, or other) is affected by uncontrolled cell proliferation. Regardless of its role in the cancer, an aberrant protein for a malignant tumor would have the greatest chance of being detected within the cancer tissue itself.

The protein concentration within tissue is in the range of 0.5–1.5 mg/mL of tissue lysate, depending on the source. Unless the tissue is severely infiltrated with blood vessels, immunodepletion of high abundance proteins is not required. These characteristics make tissue a relatively straightforward sample for biomarker discovery. Why then is it not used more to find cancer biomarkers? Simply put the answer is accessibility. It is very difficult to find a cohort of cancerous and matching healthy tissues for conducting a cancer biomarker discovery study and seeking a reasonable number of volunteers for providing such samples is impossible.

Most tissues prepared for cancer research are stored as fresh-frozen or formalin-fixed paraffin-embedded (FFPE) blocks. Thin sections are then cut from these and used for pathological evaluation to determine cancer type and grade. Additional sections may be cut and sent for IHC and fluorescent in situ hybridization (FISH) analysis to measure the levels of specific molecules within the tissue. These tissue blocks have historically only been used sparingly in proteomics biomarker discovery owing to their value. Fortunately, the past 5 years has seen huge breakthroughs in the proteomic analysis of tissue sections. The sensitivity of mass spectrometers made the amount of tissue necessary for analysis quite small. Indeed, studies using as few as d 2–3000 cells have claimed to identify thousands of proteins [13]. While this number is on the low end of the spectrum, reasonable proteome coverage is attainable with 30,000–50,000 cells, a number that can be acquired using techniques such as LCM. Another breakthrough is in the type of tissue samples available for proteomic analysis. Prior to 2005 the only useful source of tissue, either whole or sections, was fresh frozen. Since this time a number of methods have been developed enabling entire proteomes to be extracted from FFPE tissues. These proteomes are extracted in a form making them amenable to MS analysis permitting cancer biomarker discoveries [38]. Previous methods for extracting proteomes from FFPE tissue had proven inadequate owing to the significant covalent cross-linking between biomolecules resulting from formalin treatment [39]. Since FFPE tissues are widely available for almost every cancer imaginable, their availability for cancer biomarker discovery significantly reduces the scarcity of tissue samples intended for these types of studies.

6.5.4 Saliva

Saliva is produced by the parotid, submandibular, sublingual, and other minor salivary glands. Saliva contains proteins, peptides, lipids, minerals, and other small compounds [40]. Salvia is mixed with a variety of components in the oral cavity to form whole saliva. Beyond it role in aiding digestion and speaking, saliva also serves a protective function, through digestion and inhibition of bacterial and viral growth within the oral cavity [41]. Obviously owing to its proximity, saliva is most useful in the detection or oral cancers. There are a number of test procedures for measuring different hormones and drugs in saliva that have been in use since the late 1980s [42]. Saliva collection is obviously quite noninvasive and easy. Since saliva has a protein concentration on the order of a few mg/mL. Saliva, like urine, is not dominated by a few high abundant proteins and does not require immunodepletion prior to downstream MS analysis.

6.5.5 Cerebrospinal Fluid

Cerebrospinal fluid (CSF) is a clear liquid that circulates throughout the central nervous system and is also located between the brain and skull. It is produced from arterial blood by the choroid plexuses of the lateral and fourth ventricles. CSF serves as a mechanical cushion for the brain and transports a variety of molecules including neuroendocrine factors metabolites, toxins, and nutrients to and from cells of the brain and spinal cord. Owing to its direct contact with the extracellular space of the brain, CSF is an ideal biofluid from which to detect biochemical changes in the brain associated with a variety of pathological conditions such as brain tumors, traumatic brain injuries (TBI), inflammatory diseases, infection, neurodegenerative diseases, and hydrocephalus [43]. An adult contains a total volume of about 140 mL of CSF. The protein concentration of CSF of a typical adult is between 150 to 450 mg/L [44]. Studies have shown that the proteome of CSF is significantly different from that of plasma or serum [45]. While the amount of CSF attainable from a patient is sufficient for proteomic biomarker analysis, it is can only be obtained through lumbar puncture, a practice that is not performed as routinely as

blood or urine collection. Therefore, CSF has been used sparingly for biomarker discovery and has been primarily limited to noncancerous conditions such as TBI [46].

6.5.6 Other Biofluids

There are a plethora of other types of fluids that have been analyzed for the purpose of cancer biomarker discovery. These include pancreatic juice [47], tissue interstitial fluid [48], gastric juice [49], nipple aspirate fluid [50], bile [51], and ductal lavage [52]. However, these fluids are not very popular for biomarker discovery studies owing to significant accessibility issues. These fluids could prove useful for the initial discovery phase as long as any useful biomarker was also found to be translated to an accessible biofluid such as serum or urine.

6.6 Moving from Discovery to Validation

With the advent of large-scale shotgun proteomic sequencing, a relatively straightforward strategy was implemented for biomarker discovery. The proteomes extracted from samples obtained from cancer and matched healthy patients are digested into tryptic peptides and then analyzed using multidimensional fractionation combined with MS/MS analysis. The goal is to identify as many peptides within each sample and compare the list of proteins that were observed. The abundance difference between proteins was generally based on the number of peptides identified per protein (the more identified peptides, the more abundant the protein in that sample) or peptide signal intensity. The general belief (or hope) was that potential cancer-specific biomarkers would be obvious when these datasets were compared. Unfortunately, the results were rather surprising (disappointing). Not only were differences found between the datasets, *many* differences were found. Also most of the differences were related to acute-phase response proteins—indicators that the cancer patient is sick but not specific enough to determine the cause.

Why would having too many potential biomarkers be considered a problem? Although it almost sounds paradoxical, having too many potential biomarkers to select from causes a major challenge in deciding how to move forward. The problem is illustrated when considering the steps that a potential biomarker must pass before it can become clinically useful (Fig. 6.8). When potential biomarkers are found in the discovery phase, a more targeted approach is designed to measure these molecules to determine if any pass the qualification stage. Those that pass this stage are specifically measured in a larger number of samples in a verification study. Those that pass this stage are finally measured in a very large number of clinical samples to validate their reliability as diagnostic or prognostic biomarkers.

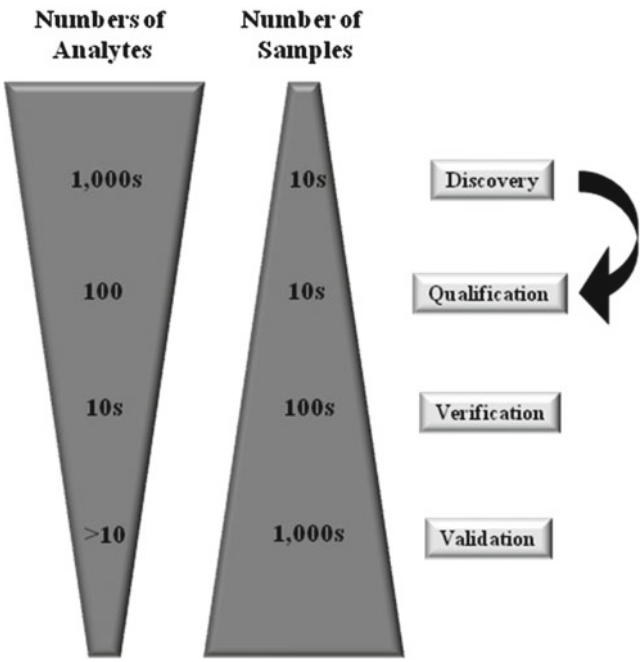

Fig. 6.8 Stages required in the identification of a clinically useful cancer biomarker. As the stages progress through discovery, qualification, verification, and validation the number of analytes measured decreases. However, the number of samples measured increases proportionately. The challenge in finding cancer biomarkers resides in identifying the candidates identified at the discovery phase that have the greatest chance of passing the other three phases.

The problem with the data presented in these shotgun studies is there is little indication which of the numerous potential biomarkers will ultimately pass validation studies. Testing each potential biomarker requires a significant effort and quickly becomes cost prohibitive if too many fail initial qualification. Two recent studies provide a reasonable illustration of the problem. In one study tissue from noncancer diseased kidney, normal kidney, and renal cell carcinoma (RCC) samples were compared [53]. Using a shotgun proteomics approach with isotope labeling for quantitation, 937 proteins were quantitated. A total of 168 under-expressed proteins and 156 over-expressed proteins were identified when the RCC tissue was compared to its normal counterpart. Gene ontology showed that 34 % of the proteins were cytoplasmic, 13 % nuclear, 11 % were localized to the mitochondria, 4 % membranous, and 6 % were extracellular proteins. The authors suggest that the cytoplasmic and membranous proteins are of particular interest since they may have potential for use as cancer markers in biological fluids. In another study, cells from LCM of squamous cell carcinoma of the head and neck and normal oral epithelial FFPE tissue were analyzed using LC-MS/MS and quantitated based on total peptide count [54]. Of the total number of identified proteins, 15 % ($n = 127$) were identified to be unique within cancer cells. This group of potential biomarkers

included those involved in DNA synthesis, metabolism, signaling, and cell structure.

While these studies (amongst countless others) demonstrate that LC-MS/MS is able to discover potential biomarkers, they also illustrate the challenge in determining which of the potential biomarkers should graduate to the qualification phase. Each study had over 100 proteins that showed a significant abundance difference in the proteomes of the cancer and healthy samples. It is impossible to validate all of these potential targets. Beyond having no existing guidelines to determine which potential biomarkers will succeed in passing qualification, it is often impossible to recognize with any certainty those that have the greatest chance of success in being validated. The guidelines should be both data driven (proteins that showed the greatest abundance difference) and biology driven (changes in complement factors are unlikely to be disease specific). As the technology continues to increase in sensitivity and the bioinformatic analysis of raw MS data becomes more sophisticated, this overwhelming problem is only going to get worse.

6.7 Getting Past the Glut of Potential Biomarkers

It is becoming obvious that continuing strategies that simply collect large lists of proteins in a particular sample type are not going to be very efficient. New methods that provide ways to filter potential biomarkers based on empirical data are going to be necessary. An additional, concern is the source of the biomarkers. While biomarkers from any source would be helpful to some degree, finding them within biofluids would be invaluable. Biomarkers that could be assayed from accessible biofluids such as urine or blood would have the greatest impact. To illustrate this point, let's consider the case of an individual with an undiagnosed early stage cancer. The concentration of the biomarker would be highest at the site of the cancer making it easier to measure analytically and nearby healthy tissue can be used as a control. Thirdly, once the biomarker is discovered studies to determine how it functions within the context of the cancer can be readily performed. Unfortunately, even if a tissue-specific biomarker was identified, its use would be severely limited as an early diagnostic, since there is no conceivable way that regular biopsies of various tissues can be taken at regular checkups.

Other studies focus on finding cancer biomarkers in biofluids, primarily serum and plasma. Unfortunately the concentration of any biomarker would be much lower in the blood than in the cancer tissue making it more difficult to detect. It is also impossible to determine with absolute certainty the origin of any circulating biomarker. The primary focus on finding blood-based biomarkers is obviously related to this sample's accessibility. Biofluids can be acquired during routine physical examinations giving biomarkers in this context a wide variety of uses (both prognostic and diagnostic).

In one study, blood and cancer tissue from a single patient was analyzed using a shotgun proteomics approach to determine if the advantages afforded by tissue and blood could be realized for finding potentially validatable biomarkers [55]. For this purpose, cancer and adjacent healthy tissue, and preoperational plasma were obtained from a single patient diagnosed with nonmetastatic RCC. The extracted proteomes were digested using trypsin and the resultant peptides identified using MudPIT. Protein abundance differences were determined using total peptide count. The peptide data was analyzed using a filtering scheme with the relative abundance of proteins based on the number of total peptides found for each protein in the cancer, healthy tissue, and preoperative plasma. The proteins that were identified within each of the three clinical samples are shown in the Venn diagram presented in Fig. 6.9a. Over 200 proteins were uniquely identified within the cancer compared to the control tissue. This number of potential biomarkers is much too large to efficiently validate and are limited in their utility since at this point in the analysis, they are only known to exist in the cancer. The data was subsequently filtered to determine which of these cancer-specific proteins were also found within the plasma obtained from the same patient. Not only did the filtering require that they be found in the plasma, but the number of peptides identified for protein had to be higher in cancer tissue than preoperative plasma. Eight proteins passed this data filtering criteria. There were several encouraging characteristics of this protein on this final list. There were no acute phase response, or other commonly known circulating, proteins within this list. Many of the proteins have been associated with some form of cancers, and three specifically (cadherin 11, VCAM-1, and pyruvate kinase) are associated with RCC. These proteins are also localized to the cell membrane, suggesting they can be easily shed into circulation by apoptotic or necrotic cells.

The data for cadherin 5 shows that four and two unique peptides were found for this protein in the cancer and plasma, respectively (Fig. 6.9b). The MS peak assigned to the cadherin 5 peptide, KPLIGTVLAMDPDAAR had a greater intensity in the sample extracted from the cancer compared to plasma (Fig. 6.9c). The primary structure and topography of this protein show that the peptides identified in all the samples reside within an extracellular domain of this transmembrane protein (Fig. 6.9d). The presence of cadherin 5 in the plasma sample was confirmed using Western blotting, while the protein was not observed in plasma obtained from a matched healthy control. Western-blot analysis also confirmed the presence of cadherin-11, DEAD-box protein-23, and pyruvate kinase in the RCC patient plasma, as well as in the blood of four other patients diagnosed with the same cancer. Fig. 6.9 Combined plasma/tissue shotgun proteomic analysis for the identification of potential biomarkers for renal cell carcinoma (RCC). Cancer tissue, normal tissue, and plasma all obtained from a single RCC patient were analyzed using shotgun proteomics. (**a**) After filtering the data, eight proteins were found to be unique to the cancer and plasma, as well as being more abundant in the cancer tissue than the plasma. Cadherin-5 was found to be more abundant in the tumor than the plasma based on both (**b**) peptide count and (**c**) peak intensity. (**d**) These peptides identified for cadherin-5 all originate from an extracellular domain of the protein.

does not definitely solve the problem of finding cancer biomarkers, it does suggest that a combined tissue/biofluid analysis may increase the efficiency of these studies.

6.8 Conclusion

The ability to routinely discover disease-specific biomarkers is the greatest achievement that will emerge in the proteomics era. The impact biomarkers would have on the public health would be enormous. Physicians could diagnose cancer patients at the earliest possible stages when they can be more readily cured. The correct course of treatment could be readily and reliably determined, rather than having to wait for subtle effects that signal disease remission. Unfortunately the rate at which protein biomarkers have been approved by the US FDA has not kept pace with the increase in technology seen in the recent years. While initially progress appears demoralizing, the overall capabilities for the MS analysis of biological samples have seen enormous improvements. Identifying 400 proteins in a milliliter of serum or plasma was considered monumental less than a decade ago. Now laboratories can identify thousands of proteins starting from a few thousand cells. These developments have made discovering proteomic differences within biofluid samples easy. The next challenge will be finding which of these differences leads to validated biomarkers.

An Overview of Cancer Genes

7

Ashley G. Rivenbark

7.1 Nature of Genetic Mutations

When functioning properly, oncogenes and tumor suppressor genes prevent the development of cancer. The loss of function of both alleles is required for neoplastic transformation. In recent studies, it has been reported that approximately 80 DNA mutations alter the amino acid sequence in a typical cancer and of these mutations less than 15 are likely to result in the initiation, progression, or maintenance of the tumor [1]. Mutations that are causally involved in the tumorigenesis process and are positively selected for are called *driver* mutations. Whereas, mutations that provide no positive or negative selective advantage to the tumor, but are carried during cell division and expansion, are referred to as *passenger* mutations [1, 2]. Several types of mutations can occur and account for neoplastic transformation such as missense and nonsense mutations, insertions, deletions, duplications, frameshift mutations, and repeat expansions (Table 7.1). Interestingly, for example it has been noted that mutations converting 5′-CpG to 5′-TpG were more frequent in colorectal cancer than in breast cancers [1]. Along with genetic mutations, epigenetic dysregulation of genes also occurs in a wide variety of cancers. Epigenetics is defined as changes in genome function that occur without a change in the DNA sequence. Advances in our understanding of cancer oncogenes and tumor suppressor genes, and the mechanisms of their aberrant regulation, will provide insight to develop novel anticancer approaches and therapeutic strategies.

7.2 Proto-oncogenes

The discovery of proto-oncogenes is one of the most fundamentally important findings of this century. Oncogenes are activated (frequently mutated) alleles of normally functioning wild-type genes (proto-oncogenes) that function in cell cycle progression or cellular proliferation. Activated or mutated proto-oncogenes promote unregulated cell cycle progression and cell proliferation, leading to cancer development. Proteins encoded by normal cellular proto-oncogenes function in all subcellular compartments including the nucleus, cytoplasm, and cell surface, and exert their function in most intracellular processes by acting as protein kinases, growth factors, growth factor receptors, or membrane associated signal transducers. Mutations in proto-oncogenes alter the normal structure and/or expression pattern, and the resulting oncogene acts in a dominant manner. That is, a mutation in only a single allele is required for activation of the proto-oncogene and/or loss of regulation of the proto-oncogene product. In genetic terms, this is typically referred to as a gain of function mutation.

7.2.1 Viral Oncogenes

The discovery of proto-oncogenes is rooted in the study of mammalian viruses, and in particular, retroviruses. In the earlier years of the twentieth century, radiation, chemicals, and viruses were shown to induce cancer in experimental animals, and later, transform cells in culture. The study of so called tumor viruses advanced quickly compared to studies of radiation-induced and chemical-induced carcinogenesis, for several reasons. Although both chemical carcinogens and radiation are potent inducers of neoplasia, it was found that tumor viruses could more efficiently and reproducibly transform cells in culture and induce tumors in experimental animals. Tumor viruses caused tumors to develop in a matter of days to weeks allowing rapid analysis following infection. Moreover, both radiation and chemical carcinogens act

W.B. Coleman, G.J. Tsongalis (eds.), *The Molecular Basis of Human Cancer*, DOI 10.1007/978-1-59745-458-2_7

Table 7.1 Gene mutations in human cancer

Mutation	Description
Missense	A change in one DNA base pair that results in the substitution of one amino acid
Nonsense	A change in one DNA base pair that results in the substituting of one amino acid that encodes a stop codon
Insertion	Changes in the number of DNA base pairs in a gene by inserting additional DNA base pairs
Deletion	Changes in the number of DNA base pairs in a gene by removing a piece of DNA
Duplication	A piece of DNA that is aberrantly copied one or more times
Frameshift	The addition or loss of DNA base pairs that changes the reading frame
Repeat expansion	Short DNA sequences that are repeated a number of times in a row

randomly on the cellular genome. Examining the cellular genome to determine the carcinogenic effect of these agents at a level of individual genes or DNA segments was a daunting task. In contrast to the mammalian cellular genome, the small genome of the tumor viruses offered a less complex model for identification of specific sequences responsible for induction and progression of tumors, and a more efficient system for elucidation of molecular mechanisms governing neoplastic transformation.

7.2.1.1 DNA Viruses

Some of DNA viruses and one class of RNA viruses (the retroviruses) have been shown to have oncogenic potential. The Shope papilloma virus was one of the first DNA tumor viruses to be described [3]. It causes benign papillomas that can progress to malignant carcinomas in cottontail rabbits. Papillomaviruses, along with other classes of DNA viruses such as the hepatitis B viruses, have the ability to transform cells in their natural host. Most other DNA viruses, including adenoviruses, simian virus 40 (SV40), and polyomaviruses lack transforming ability. In natural hosts, cells infected with these DNA viruses undergo cell death rather than transformation as a consequence of viral replication. However, these later viruses demonstrate their oncogenic potential in heterologous, nonpermissive species in which viruses cannot replicate. Each class of DNA virus has led to remarkable discoveries in proto-oncogenesis [4].

7.2.1.2 RNA Retroviruses

The RNA retroviruses represent the class of tumor viruses that has contributed the most to our understanding of mammalian carcinogenesis. Retroviruses are the only currently known RNA viruses to have oncogenic potential. A feature common to these viruses is the ability to replicate in infected cells via a provirus intermediate. The proviral intermediate is generated through the action of a retroviral enzyme termed reverse transcriptase, which synthesizes a DNA copy of the retroviral RNA genome. RNA to DNA reverse transcription is obligatory for RNA retroviral replication in infected mammalian cells. The DNA transcript of the retroviral genome incorporates into the cellular genome where it replicates along with cellular DNA. The RNA polymerase enzyme of the host cells transcribes the provirus DNA, generating new RNA virions and retroviral mRNAs needed for synthesis of viral proteins. Importantly, unlike most of the DNA viruses, retroviruses are not cytotoxic or cytocidal to the host cells. This reflects the nature of the retroviral lifecycle, where new retroviral particles are released from the cell by budding rather than by cell lysis. Thus, RNA viruses can transform the same cells in which they replicate. The recombination event that occurs between the retroviral DNA (provirus) and host DNA as part of the replication cycle has significant implications for neoplastic transformation and tumor development [5].

The first oncogenic retrovirus discovered was the Rous sarcoma virus (RSV). Peyton Rous inoculated chickens with a chicken sarcoma cellular extract and was able to demonstrate efficient transmission of an agent that propagated tumor growth [6]. Subsequent studies demonstrated that RSV had transforming properties in cultured cells. This was found to be in contrast to another well-studied retrovirus, the avian leukosis virus (ALV). ALV maintained the ability to induce tumors following inoculation in chickens (albeit after months, and not days to weeks compared to RSV), but did not demonstrate the ability to transform cells in culture [4]. The differences in induction efficiency in animals (in vivo activity) and ability to transform cells in culture (in vitro activity) form the basis for dividing retroviruses into two groups: (1) the acutely transforming oncogenic retroviruses, and (2) the weakly oncogenic or non-transforming retroviruses.

7.2.2 Cellular and Retroviral Oncogene Discovery

The differences between the acutely and weakly or non-transforming retroviruses are extremely important and provided clues towards recognition of the first proto-oncogene. In comparing RSV and ALV genomes, RSV was shown to be 1.5 kb greater in size than ALV. This additional segment was correctly postulated to be responsible for the rapid transforming properties of RSV. In 1971, Peter Vogt isolated RSV mutants that had the weakly oncogenic properties of ALV [7]. These weakly oncogenic RSV mutants were approximately the same size as ALV, did not have the ability to transform cultured cells, and did not efficiently induce sarcomas in animals, but maintained retroviral replication capabilities. The missing 1.5 kb sequence in these mutant RSV genomes was subsequently demonstrated to be required not only for initiation but

also for maintenance of neoplastic transformation. Because different RSV mutants were not complimentary and did not lead to neoplastic transformation in cell culture, it was concluded that a single gene could be responsible for both in vitro transformation and in vivo oncogenesis. The first retroviral oncogene was named v-*src* for its sarcoma inducing action. Since then over 30 viral oncogenes have been discovered in over 40 transforming viruses [4, 8, 9].

Similar to the discovery of the first oncogene, the discovery of the origin of retroviral oncogenes had monumental implications. The extra 1.5 kb of nucleic acid in RSV was not necessary for viral replication/growth. It was not clear where the apparently extraneous nucleic acid segment originated. The answer was obtained through the study of retroviral tumors of the very rare animal that developed tumors after being infected by a non-transforming retrovirus. These previously non-transforming retroviruses were found to have incorporated new genetic material in their RNA genome corresponding to a new oncogene which conferred capability for neoplastic transformation. The portion of the proviral genome corresponding to the newly recognized oncogene was used to probe for similar sequences in host cells. This analysis demonstrated that genes possessing the capability for neoplastic transformation were conserved among several different species. This observation suggested that host cell DNA could be incorporated into the genome of a retrovirus during recombination in the infected cell. Further study of the cellular homologues of retroviral oncogenes showed that they are normal cellular genes that encode proteins involved in various aspects of cellular homeostasis, including cell proliferation and differentiation. The normal cellular counterpart of the retroviral oncogenes is referred to as cellular proto-oncogenes. The current paradigm holds that viral oncogenes originate from cellular proto-oncogenes, and that these genes have been altered in a manner which confers the ability to induce cellular neoplastic transformation in infected cells [4, 8]. In like manner, cellular proto-oncogenes can be activated in various ways (point mutation, deletion, amplification, or rearrangement) that result in the synthesis of an oncogenic protein product [4, 8].

The discovery of the ability of genes to induce tumors in animals and humans linked the study of transforming retroviruses with the field of molecular biology of human cancers. However, it is clear that most human cancers are not caused by infection with transforming viruses. Shortly after it was established that specific virus associated genes could cause cellular transformation, alterations in cellular proto-oncogenes were found to be responsible for human tumors. The first instance linking the possibility of a human proto-oncogene with cancer, when retroviral involvement could be eliminated, was reported in 1981 by two groups, who showed that DNA extracted from a human bladder carcinoma cell line (EJ) could induce transformation in an immortalized but non-transformed mouse cell line NIH 3T3 [9, 10]. In 1982, the first human activated proto-oncogenes were isolated and identified from the EJ bladder carcinoma cell line and a human lung carcinoma. These genes were cellular homologs of the Harvey-*ras* and Kirsten-*ras* retroviral oncogenes, both of which had previously been shown to induce rat sarcomas [11]. The discovery of proto-oncogenes solidified the link between genes and cancer, and ushered in an era of genetic discovery focused on identification of genetic abnormalities that contribute to the development of human neoplasms.

7.2.3 Mechanisms of Activation of Cellular Proto-oncogenes

Cellular proto-oncogenes must become activated in order to express oncogenic potential leading to neoplastic transformation. Activation of cellular proto-oncogenes typically involves chromosomal translocation, amplification, or point mutation. The changes that result can be broadly categorized into (1) changes to the structure of a proto-oncogene which result in an abnormal gene product with aberrant function (examples include the *bcr-abl* translocation and c-*ras* point mutations, described below) and (2) changes to the regulation of gene expression resulting in aberrant expression or inappropriate production of the structurally normal growth-promoting protein (examples include translocations involving c-*myc*, amplification involving N-*myc* in neuroblastomas, and some point mutations in c-*ras*).

7.2.3.1 Proto-oncogene Activation Through Chromosomal Translocation

Translocation leading to structural alteration of bcr-abl. Evolving techniques in cytogenetics over the last century have led to increased resolution of individual chromosomes. Abnormalities in chromosomes were known to occur in neoplastic cells from at least 1914, when Boveri noted somatic alterations in the genetic material of sea urchin eggs fertilized by two sperm. The abnormal cells looked similar to tumors, and he hypothesized that cancer might result from cellular aberrations that produced abnormal mitotic figures [12]. However, it was not clear whether chromosomal abnormalities represented primary oncogenic events, or accumulated errors secondary to neoplastic transformation. Initially, the plethora of chromosomal abnormalities favored the latter scenario, as no consistent chromosomal abnormality was identified upon examination of many tumors and similar tumors from different individuals. That changed in 1960 when Nowell and Hungerford described the first reproducible tumor-specific chromosomal aberration in chronic myelogenous leukemia [13]. They observed the presence of a shortened chromosome 22, subsequently named the Philadelphia chromosome after the city in which it was dis-

covered. It was found in cancer cells from over 90 % of patients with chronic myelogenous leukemia (CML). This observation suggested that (1) the abnormality may have imparted some form of growth advantage over other cells and may be causally related to the development of tumors, and (2) other neoplasms may also harbor their own specific chromosomal or genetic aberrations. Since the first recognition of common chromosomal abnormalities in specific human tumors, numerous translocations involving important genes have been characterized (Table 7.2).

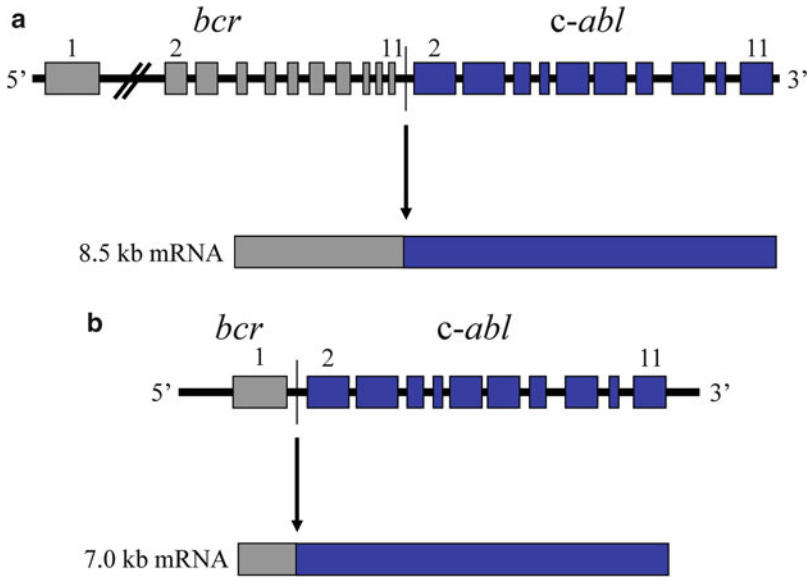

Fig. 7.1 *bcr-abl* translocation in chronic myelogenous leukemia. The c-*abl* proto-oncogene on chromosome 9 is translocated to the breakpoint cluster region (*bcr*) of chromosome 22. The result is a novel tyrosine kinase which functions independently of normal regulatory elements. (**a**) The t(9;22) that is commonly observed in chronic myelogenous leukemia (CML). (**b**) The t(9;22) that is commonly observed in acute lymphocytic leukemia.

Consequent to rapid advances in cytogenetic resolution techniques, Rowley in 1973 [14] found that the Philadelphia chromosome actually resulted from a reciprocal translocation involving the long arms of chromosomes 9 (9q34) and 22 (22q11). Analysis of the affected region on chromosome 9 revealed a proto-oncogene, c-*abl* [15], which when translocated to chromosome 22 generates a fusion gene. The c-*abl* proto-oncogene has 11 exons that encode for a 145 kDa protein with tyrosine kinase activity. The chromosomal breakpoint within the c-*abl* gene consistently involves one of two alternatively spliced exons. Breakpoints along the functional gene on chromosome 22 are clustered near the center in a 6 kb region termed the breakpoint cluster region (*bcr*). Upon translocation, nearly the entire c-*abl* proto-oncogene is placed under *bcr* promoter activity. Transcription and splicing yield a long mRNA transcript encoding a chimeric 210 kDa protein that expresses increased tyrosine kinase activity, likely because it is less responsive to normal regulatory elements (Fig. 7.1). A similar translocation exists in some acute lymphoblastic leukemias, although the breakpoint occurs further upstream in the *bcr* gene which results in a smaller chimeric protein (190 kDa), which has also been shown to have increased tyrosine kinase activity [16–20].

Translocation leading to dysregulation of c-myc. Investigation into the role of the c-*myc* proto-oncogene in neoplastic transformation led to development of a model of proto-oncogene activation based upon insertional mutagenesis. This mechanism of proto-oncogene activation emerged from studies of acutely transforming retroviruses and weakly oncogenic or non-transforming retroviruses. The primary differences between these two classes of retrovirus reflect the amount of time necessary for induction of tumors after infection of cells and the genomic content of their proviral DNA. Acutely transforming retroviruses have oncogenes incorporated into their genome while non-transforming retroviruses do not. Thus, the transformation potential of weakly oncogenic and non-transforming retroviruses depend on insertion adjacent to a cellular proto-oncogene. Although retroviruses insert randomly, in independently derived tumors retroviral sequences were found incorporated into similar chromosomal locations in the host genomic DNA. The site of insertion then became the focus of attention, and

cellular homologs of known retroviral oncogenes and their surrounding sequences were studied intensely. Finally, Hayward and Astrin demonstrated that non-acutely transforming retroviruses insert adjacent to and cause activation of the cellular proto-oncogene c-*myc* [21]. Insertional mutagenesis is based on the ability of proviral DNA to insert into host genomic DNA and cause either activation or inactivation of host genes, independent of expression of retroviral genes (as in the case of acutely transforming viruses). In the case of insertional activation of cellular genes, the proviral DNA may provide a promoter or enhancer for the cellular gene, resulting in an alteration in the normal regulation and expression pattern of the affected gene.

In the early 1980s data on c-*myc* activation by non-acutely transforming retroviruses in chicken lymphomas merged with data accumulating on translocations in Burkitt's lymphoma, a high grade B lymphocyte neoplasm. It was reasoned that if proviral sequences were capable of altering host cellular gene expression to cause tumors, chromosomal alterations that juxtapose promoter or enhancing sequences and cellular proto-oncogenes (through chromosomal translocation) were likely to promote neoplastic transformation. The best studied translocations at the time involved those of Burkitt's lymphoma, in which a portion of the long arm of chromosome 8 is consistently translocated to either chromosome 14, 2, or 22, adjacent to the loci for immunoglobulin heavy chain, k light chain, and λ light chain, respectively. The immunoglobulin loci on chromosomes 14, 2, and 22 were postulated to be good partner candidates to be coupled with and cause activation of a proto-oncogene that was suspected to reside on chromosome 8. Tumor DNA was directly probed for c-*myc* sequences. The gene was detected on chromosome 8, and found to be translocated to chromosomes 14, 2, and 22 in Burkitt's lymphoma and in some plasmacytomas. In plasmacytomas, a form of the c-*myc* proto-oncogene lacking the untranslated exon 1 is involved in the chromosomal translocation (Fig. 7.2). The breakpoints within the c-*myc* gene are more varied in Burkitt's lymphoma. Nonetheless, the translocation results in abnormal (constitutive) expression of a c-*myc* coding sequence identical to its normal allele in both types of tumor. This observation strongly suggested the chromosome translocation-mediated activation of the c-*myc* proto-oncogene as a causal event in human tumorigenesis [4, 22–25].

7.2.3.2 Proto-oncogene Activation Through Gene Amplification

Activation of cellular proto-oncogenes can occur as a consequence of DNA amplification resulting in overexpression of the amplified proto-oncogene, which confers a proliferative advantage to affected cells. Amplified gene segments can be discerned cytogenetically as double minute chromosomes (DMs) and homogeneously staining regions (HSRs). Proto-oncogenes (and other genetic loci) are amplified by repeated DNA replication events that can result in an abnormal homogeneous staining pattern in a karyotypic analysis of affected cells, rather than the familiar chromosomal staining pattern in R-banded or G-banded chromosome spreads. Instead, homogeneously staining regions appear as abnormally extended R-bands or G-bands (Fig. 7.3). The tandem arrays of amplified DNA forming homogeneously staining regions may be excised from the chromosome to form double minutes, which are small chromosomal structures lacking centromeres that do not replicate during cell division. Double minutes may integrate into other chromosomes to create additional stable HSRs able to propagate upon cell division [26, 27].

In the same way that investigation of the c-*myc* proto-oncogene formed the underpinnings of our current understanding of proto-oncogene activation by means of chromosomal translocation, studies of the c-*myc* proto-oncogene led to the unraveling of proto-oncogene activation through gene amplification in human neoplasms [28]. DNA amplification represents

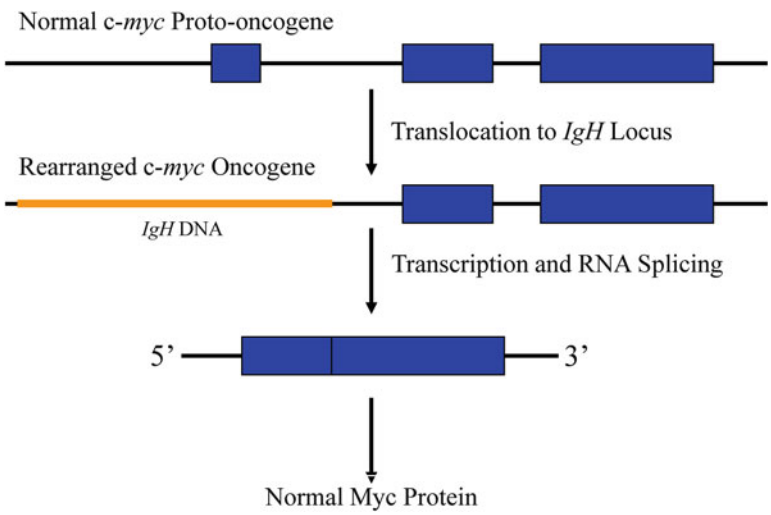

Fig. 7.2 Consequences of the t(8;14) chromosomal translocation. The c-*myc* gene of chromosome 8 is normally not expressed in differentiated B cells. After translocation, it comes under the control of either a cryptic promoter in intron 1 or an enhancer from the immunoglobulin locus of chromosome 14 (*IgH*), leading to constitutive expression of the normal c-myc protein (exon 1 is noncoding). *IgH* gene sequences are depicted in *orange* and c-*myc* gene sequences are depicted in *blue*.

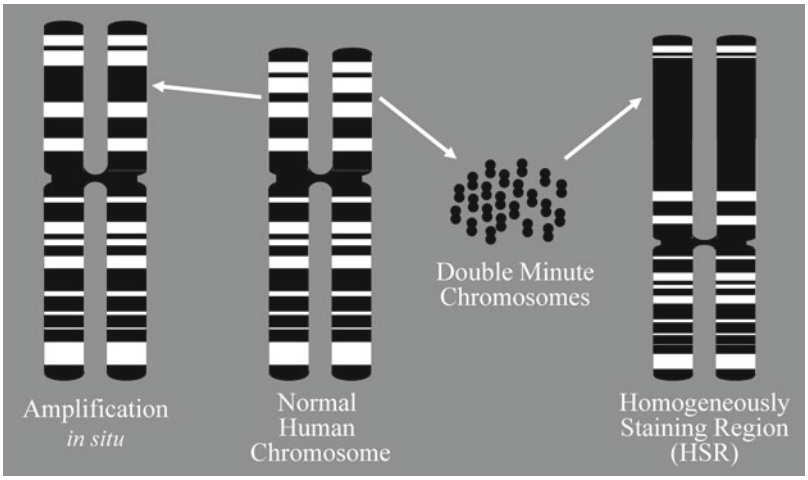

Fig. 7.3 DNA amplification. When DNA is amplified by repeated DNA replication events, the results can sometimes be seen cytogenetically as homogeneously staining regions (HSRs) or double minutes. Double minutes represent the extrachromosomal manifestation of HSRs. Double minutes can insert into any chromosome (the one they are derived form or a different chromosome).

one mechanism leading to drug resistance in mammalian cells [29]. Through direct probing for c-*myc* it was discovered that double minutes and homogeneously staining regions contained amplified copies of the oncogene in human colon carcinoma cells [30]. The c-*myc* gene has been shown to be amplified and overexpressed in a number of human neoplasms supporting the role of DNA amplification as a major mechanism for cellular proto-oncogene activation in neoplastic transformation.

Although the precise mechanism for gene amplification has not been entirely determined, the role amplification plays in cellular transformation in human malignancies is clear, particularly from studies of neuroblastomas and studies involving neoplastic transformation of cells in vitro [31]. Neuroblastoma is one of the most common childhood extracranial solid tumors accounting for approximately 15 % of all childhood cancer deaths [32]. Neuroblastomas exhibit DMs and HSRs that hybridize with probes to the c-*myc* gene. The hybridizing sequences were determined to be related to but distinct from c-*myc* and was designated N-*myc* [33]. The N-*myc* gene is transcribed at higher levels in neuroblastomas that demonstrate gene amplification. N-*myc* amplification is now a major prognostic determinant in neuroblastomas, with high levels of transcription from either a single copy or more commonly from increased gene copy number in the form of DMs or HSRs correlating with poor patient survival [34]. The demonstration of the link between high N-*myc* expression and poor clinical prognosis, and its demonstrated ability to cause neoplastic transformation in cell culture provides strong evidence for the importance of gene amplification in the activation of cellular proto-oncogenes. Table 7.3 lists other cellular proto-oncogenes that have been shown to be amplified in human neoplasms.

11q13 locus	Breast, gastric, esophageal, squamous, ovarian, bladder carcinomas, and melanoma

7.2.3.3 Proto-oncogene Activation Through Point Mutation

Several cellular proto-oncogenes have been shown to be activated through point mutation. However, the c-*ras* family of proto-oncogenes represent the most important subset of proto-oncogenes that are activated through this mechanism. The c-*ras* genes were the first human proto-oncogenes identified using gene transfer assays [9, 10]. This family includes the cellular homologs of the Harvey-*ras* (H-*ras*) and Kirsten-*ras* (K-*ras*) retroviral oncogenes, both of which had previously been shown to induce sarcomas in rats [11]. DNA extracted from various human tumor cell lines have been

shown to induce transformation of mouse fibroblast cell lines in vitro, and the most commonly isolated sequences responsible for neoplastic transformation are members of the c-*ras* family of proto-oncogenes [35, 36]. The activated form of c-*ras* (oncogenic) exhibits markedly different transforming properties from that of the normal c-*ras* proto-oncogene. The activated form consistently and efficiently induces neoplastic transformation in cultured cells, whereas the normal proto-oncogene does not. The critical molecular difference between the two forms of c-*ras* was found in the nucleic acid sequence: the activated form of c-*ras* harbors a point mutation in codon 12 of exon 1, which results in a glycine to valine amino acid substitution [37–39]. Up to 30 % of all human neoplasms are now known to harbor c-*ras* mutations, and mutations in c-H-*ras*, c-K-*ras*, and N-*ras* reflect specific alterations affecting only codon 12 (most mutations), codon 13, or codon 61. An additional mutation in an intron of c-H-*ras* has been shown to upregulate production of the structurally normal gene product, resulting in increased transforming activity [40]. A common theme of c-*ras* mutations is that a single point mutation is capable of drastically altering the biological activity of a normal protein product into one with efficient transforming properties. Mutations of c-*ras* are found in a large number of human tumor types, including thyroid [41–43], gastrointestinal tract [44–48], uterus [49–53], lung [54–58], myelodysplastic syndromes [59], and leukemias [60–63]. The incidence of c-K-*ras* gene mutations is highest for exocrine pancreas and bile duct carcinomas, which has led to the development of ancillary diagnostic techniques for the detection of pancreatic and bile duct carcinomas [64–66].

7.2.4 Protein Products of Oncogenes

Proto-oncogene protein products regulate cell proliferation and differentiation. Oncogene protein products often closely resemble their proto-oncogene protein products, but differ in that they act independently of normal regulatory elements. Events that occur as a part of normal cell growth and differentiation can often be simplified into a series of four steps, all of which involve proto-oncogenes normally, and each of which is subject to disruption during neoplastic transformation: (1) an extracellular growth factor binds to a specific receptor on the plasma membrane, (2) the growth factor receptor is transiently activated, leading to a cascade of signaling cellular events, many of which involve signal-transducing proteins on the plasma membrane, (3) the signal/message is transmitted from the plasma membrane to the nucleus via secondary messenger molecules, and (4) the nuclear regulatory machinery is induced/activated to initiate cell replication and transcription. Within these pathways, there are three major biochemical mechanisms through which these oncoproteins function [67, 68]. The first of these mechanisms involves the phosphorylation of target proteins at serine, tyrosine, and threonine amino acid residues. The second mechanism involves intracellular signal transmission through proteins with GTPase activity. The last of these involves the transcriptional regulation of structural genes in the nucleus.

7.2.4.1 The Fibroblast Growth Factor Family

The discovery of growth factors in the early 1960s led to the isolation of a diverse group of factors affecting all cells. Growth factors are grouped into families that share significant sequence homology and cell surface receptors. One example is the epidermal growth factor (EGF) family which includes among others, EGF and the transforming growth factor TGFα [69, 70]. EGF, one of the earlier growth factors discovered, was shown to be a polypeptide of 53 amino acids that stimulated proliferation of a variety of different cell types. Growth factors were not only capable of promoting growth, but some also concurrently promoted differentiation [71]. In normal cells, growth factors induce cells to exit the resting or G_0 phase and enter the cell cycle, or they may stimulate cells already cycling. It follows that the biochemical and physiologic effect of aberrant expression of growth factors leads to constitutive stimulation of cell growth, potentiating the process of cell transformation.

Platelet derived growth factor (PDGF) is another growth factor shown to have transforming potential, and has an important history in that it provided the first link between two originally disparate tracks of research: (1) biochemical studies of the regulation of cell proliferation (growth factors), and (2) molecular analysis of neoplastic transformation (oncogenes) [72]. In the early 1980s, two groups working independently reported PDGF was the protein product of an oncogene [4, 73, 74]. Each group determined a partial amino acid sequence of PDGF, and with a computer search of a protein sequence database, amino acid sequence homology was demonstrated with the predicted sequence of v-*sis*, the simian sarcoma virus. From this initial work, oncogenes activated by mechanisms described above frequently have been shown to encode growth factors that participate in mitogenic signaling and cell transformation [69].

Further understanding the mechanism of action of transforming growth factors came from a hypothesis forwarded in 1977 by George Todaro [75]. He suggested that because transformed cells are capable of producing growth factors, autocrine stimulation of cell growth could be, at least in part, responsible for transformation [75]. An individual cell abnormally overexpressing a growth factor to which it responds would result in continuous cell proliferation. This hypothesis gained credence with the discovery of the homology between PDGF and the protein product of v-*sis* as well as from work on the EGF family of growth factors (EGF and TGFα, among others). Several human tumors are known to

overexpress TGFα as well as its receptor the epidermal growth factor receptor (EGFR) which substantiated the autocrine mechanism [76, 77]. The transfection of TGFα genes into cultured cells could induce transformation [78, 79]. Finally, the link between mitogenic signaling and cell transformation properties of growth factors and oncogenes was strengthened by data showing TGFα overexpression in transgenic mice results in the development of tumors [4, 80, 81]. Additional growth factors with oncogenic potential are listed in Table 7.4.

7.2.4.2 The EGFR Family of Growth Factor Receptors

The EGFR family is one of many growth factor families capable of promoting neoplastic transformation. The EGFR family includes c-*erb*B1, c-*erb*B2 (also known as *neu*), and c-*erb*B3, and are structurally related to other transmembrane tyrosine kinase proteins with an external ligand binding domain, a transmembrane domain, and an internal tyrosine kinase domain (Fig. 7.4) [82]. These receptors are activated by binding of a ligand which is followed by transduction of a signal into the cell through the kinase activity of the intracellular domain of the receptor protein. Kinase enzymes regulate protein function by phosphorylation of tyrosine, serine, or threonine amino acid residues. Examples of these receptor tyrosine kinase proteins are listed in Table 7.5. The EGFR was implicated as playing a central role as a regulator of normal cellular growth and differentiation primarily because the kinase activity of the EGFR is stimulated by EGF or TGFα binding [83, 84]. Also, the human *EGFR* gene was linked via significant sequence homology to a known avian erythroblastosis virus oncogene, v-*erb*B. Eventually it was determined that the v-*erb*B gene product was a truncated protein derived from the *EGFR* gene. The v-*erb*B gene product lacks the extracellular ligand binding domain (the amino-terminal half

of the normal protein) that is present in the normal EGFR protein. This structural aberration results in a constitutively activated protein with tyrosine kinase activity. The constitutive cell signaling activity of the truncated receptor drives signal transduction and cell proliferation in the absence of growth factor stimulation. Thus, an oncogene was shown to correspond to a known growth factor receptor, which established a direct link between the two [4, 85–89].

Although structural aberrations play an important role in EGFR-mediated neoplastic transformation, a more common mechanism is overexpression of the normal proto-oncogene product, as is seen in breast cancers. Overexpression occurs not only as a result of gene amplification, but also in the absence of gene amplification, suggesting another as yet undetermined mechanism. Overexpression of EGFR has been found to have prognostic significance in several human tumors [77, 90].

7.2.4.3 Proteins Involved in Signal Transduction

c-abl. Once a cell receives a signal via plasma membrane bound receptors, it is transmitted to the cell nucleus by a cascade of messenger molecules. Because abnormal growth factor receptors can function as oncoproteins by stimulating cell proliferation, it follows that protein messengers coupled to receptors, or even proteins involved in signal transduction that are not associated with receptors, can act as equally potent oncoproteins. In fact, many such oncoproteins have been identified, and they have been shown to mimic the normal function of signal transducing proteins. The signal transducing proteins can be widely grouped into two categories (Table 7.6): (1) protein kinases (non-receptor associated tyrosine kinases, such as the c-*abl* protein product, and cytoplasmic serine/threonine kinases) and (2) receptor-associated GTP-binding proteins (which include the c-*ras* proteins). The c-*abl* protein product is present on the inner surface of the plasma membrane. However, its tyrosine kinase activity is not dependent on coupling with a plasma membrane bound receptor. Rather, negative regulatory domains are lost when c-*abl* of chromosome 9 is translocated to the breakpoint cluster region of chromosome 22. The hybrid protein product has increased enzymatic activity responsible for phosphorylating downstream substrates. This constitutive activity drives cells to proliferate, contributing to neoplastic growth. This form of molecular aberration characterizes chronic myelogenous leukemia (CML) and some forms of acute lymphoblastic leukemia (ALL).

c-ras. The larger category of signal transducing proteins is associated with membrane bound receptors, such as the GTP-binding proteins (G proteins), which include the c-*ras* family of proteins. There are many similarities between the latter two sets of proteins. G proteins are located on the inner face of the cell membrane, where they couple signals received

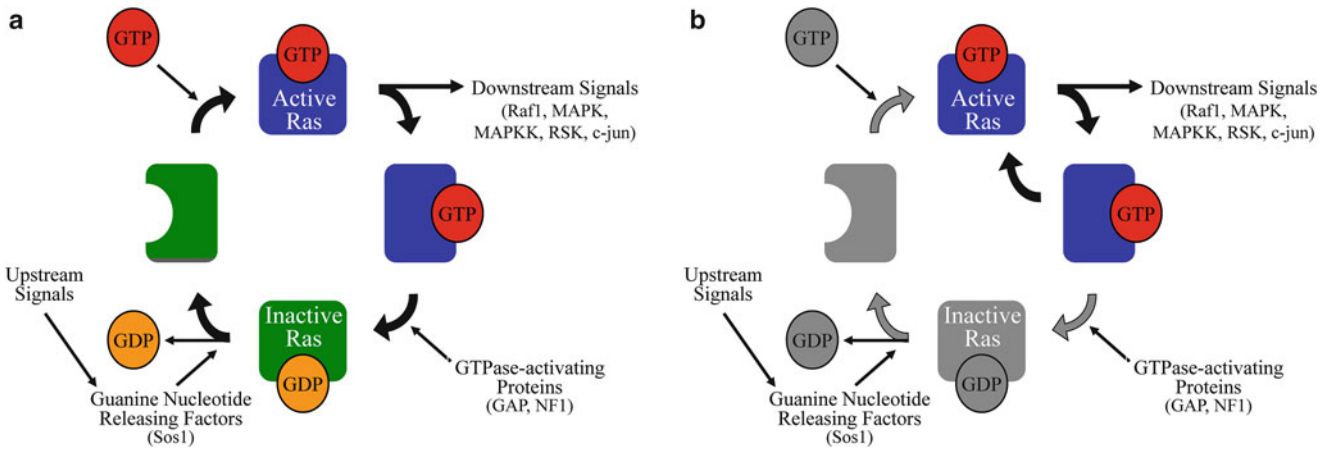

Fig. 7.5 c-ras mechanism of action. The c-ras protein is active when complexed with GTP, and this interaction is facilitated by GEFs in response to growth factor stimulation. Although c-ras has its own GTPase activity, its inactivation by GTP hydrolysis is stimulated by GAPs, such as neurofibromin. Mutated c-ras protein has a decreased ability to hydrolyze GTP, or an increased rate of exchange of bound GDP for free GTP. By either mechanism, the result is increased activated c-ras. (**a**) Depicts normal c-ras regulation (activation and inactivation). (**b**) Depicts aberrant c-ras constitutive activation when mutated.

from activated plasma membrane receptors to other, mainly cytoplasmic, second messengers in a cascade ultimately culminating in the cell nucleus. Cell signaling through G proteins requires GTP binding. Hydrolysis of the bound GTP terminates signaling through a specific G protein molecule.

The c-*ras* proto-oncogenes are activated by point mutations. As would be predicted, the point mutations alter the function of the GTPase activity of its protein product. The mutated protein has a decreased ability to hydrolyze GTP, or has an increased rate of exchange of bound GDP for free GTP (Fig. 7.5). The decreased ability to hydrolyze GTP results from interactions between c-*ras* and GTPase activating proteins (GAPs), an example of which is neurofibromin, the gene product of the tumor suppressor gene neurofibromatosis 1 (NF1). GAPs inactivate normal c-*ras* protein by augmenting the conversion of GTP-*ras* (active form) to GDP-*ras* (inactive form). The activated c-ras oncoproteins bind GAP, but their GTPase activity is stunted, leading to upregulation of active GTP-*ras*. Given the central role of GAPs in c-*ras* regulation, it is not surprising that the loss of activity of the GAP neurofibromin also results in upregulation of *ras*-GTP in affected cells. In response to growth factor stimulation c-*ras* is activated by guanine nucleotide releasing or exchange factors (GEFs). They are responsible for the exchange of GDP for GTP (converting inactive ras-GDP to active ras-GTP). The increased exchange of GDP for GTP produces the same result: constitutively active c-ras protein bound to GTP. Interestingly, a GEF domain is present in the *bcr* protein product as well as in the *bcr-abl* fusion protein product created in the t(9;22) translocation, suggesting a possible role in c-*ras* regulation [4, 35, 91–95].

7.2.4.4 The c-myc Family of Nuclear Regulatory Proteins

The final steps in the mitogenic signaling pathways involve signal entry into and the subsequent events which occur in the nucleus. The protein products of many proto-oncogenes (and tumor suppressor genes) are localized to the nucleus, and function to control the transcription of growth-related genes through interaction with specific regulatory DNA sequences. Regulation of transcription is a key mechanism through which proto-oncogenes (and tumor suppressor genes) exert control over cell proliferation. Nuclear proteins involved in these processes generally bind upstream to a specific gene and function as a transcription factor. Once bound to a specific DNA sequence, they act to increase expression of the target gene by interacting with other proteins involved in transcription. In order to be able to span the interaction between DNA and other proteins, most transcription factors have two functional domains: (1) a DNA binding domain, and (2) a protein binding domain. The DNA binding domain is often either a cysteine rich region, the secondary structure of which binds zinc and forms looped structures (called zinc fingers), or a stretch of basic amino acids proximal to leucine zipper motifs (ZIP) or basic helix-loop-helix (bHLH) domains. The leucine zipper is composed of a stretch of hydrophobic leucine residues and functions in protein dimerization. The bHLH motif is composed of two amphipathic α-helical regions separated by a loop and also functions in protein dimerization [5].

Because the c-*myc* oncogene is commonly involved in human tumorigenesis, there has been tremendous research activity into its mechanism of action. The c-*myc* proto-oncogene is expressed in nearly all eukaryotic cells and its

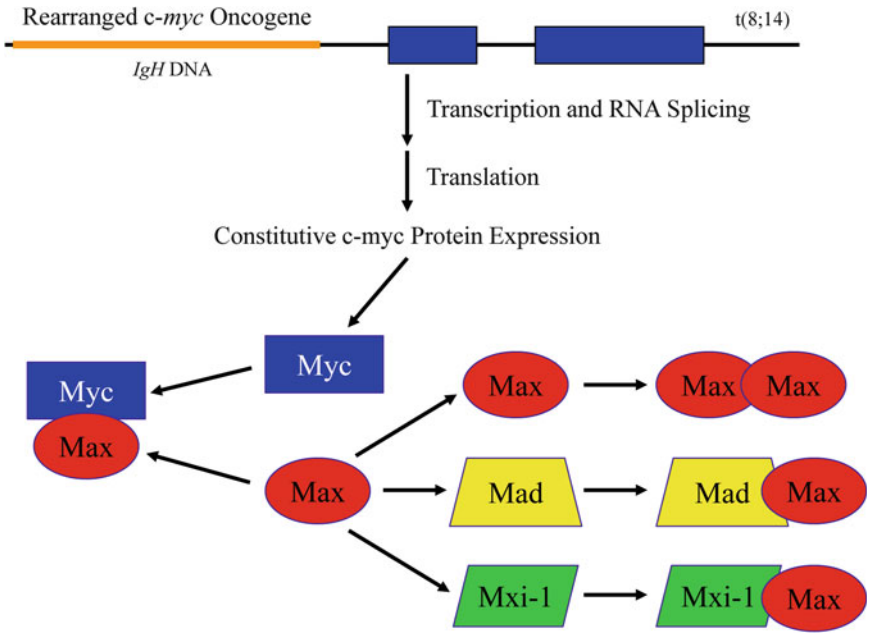

Fig. 7.6 The myc/max/mad/mxi-1 transcription network in Burkitt's lymphoma. The c-myc protein is expressed constitutively as a result of a chromosomal translocation: t(8;14), t(8;22), or t(2;8). The t(8;14) translocation is depicted in the schematic. The Myc protein dimerizes with Max to activate transcription. The Max protein can homodimerize, or form complexes with Mad or Mxi-1. Each of these complexes inhibits transcription. Constitutive expression of c-myc leads to a shift in the equilibrium in favor of transcriptional activation.

mRNA synthesis is rapidly induced when quiescent cells receive a signal to divide. The C-terminal region of c-myc proteins has one basic DNA binding domain followed by bHLH and ZIP domains. The c-myc protein was suggested to function as a transcription factor based upon the pattern of transient expression following cell stimulation by growth factors and sequence similarities with other DNA binding transcription factors. However, it was found that the c-myc protein by itself does not bind DNA well. Rather, c-*myc* binds to DNA with greater affinity when dimerized with another protein possessing c-*myc*-like bHLH and ZIP domains, called max (Fig. 7.6). Max is a small protein that forms homodimers, interacts with all members of the c-myc family, and forms heterodimers with other proteins called mad and mxi1. Although c-*myc*, max, and mad share sequence domains, they differ in that c-*myc* has a transcriptional activation domain at its amino terminus. Thus, the *myc*-max heterodimer represents the functional form of c-*myc*, and upon binding to specific CACGTG DNA sequences, stimulates expression of genes involved in cell proliferation.

Max-max homodimers and heterodimers composed of max-mad and max-mxi1 also binds DNA efficiently. These other max-containing complexes compete with *myc*-max heterodimers for DNA binding. However, the proteins that compose these complexes lack a transcriptional activation domain. Therefore, DNA binding by any of these other complexes results in repression of transcription. The control over cell proliferation is influenced by the balance between transcriptional activation by *myc*-max heterodimers and transcriptional repression by max-max, max-mad, and max-mxi1 complexes. A common theme of c-*myc* activation by chromosome translocation, insertional mutagenesis, or amplification, is overexpression of the c-myc protein. Overexpression of the c-myc protein leads to a shift in equilibrium toward *myc*-max dimers, activating transcription, promoting cell proliferation, and thereby contributing to neoplastic transformation [4, 22, 96–103].

7.3 Tumor Suppressor Genes

While proto-oncogenes are normal cellular genes that act in a positive fashion to promote physiologic cell growth and differentiation, tumor suppressor genes act as the cellular braking mechanism, regulating cell growth in a negative fashion. Normal tumor suppressor proteins exhibit diverse functions and are found in all subcellular compartments. As alterations of tumor suppressor protein function contribute to the development of cancer, their principle normal function is likely the control of cellular proliferation and differentiation. The specific types of mutations in these genes invariably lead to the inability of the encoded protein to perform its normal function. In general, neoplastic transformation requires loss of tumor suppressor protein function, and this requires mutational inactivation or loss (deletion) of both alleles of the tumor suppressor gene. Thus, tumor suppressor genes are termed recessive and alterations of these genes are typically considered loss of function mutations. A list of known or putative tumor suppressor genes is given in Table 7.7.

In the mid and late 1960s theories about the genesis of malignant tumors were enormously influenced by studies of virus and gene transfer experiments. Introduction of a virus

Table 7.7 Putative and cloned tumor suppressor genes

Gene	Chromosomal location	Inherited cancer	Sporadic cancer
Rb1	13q14	Retinoblastoma	Retinoblastoma, sarcomas, bladder, breast, esophageal, and lung carcinomas

VHL	3p25	von Hippel–Lindau syndrome	Renal cell carcinomas
MEN1	11q23	Multiple endocrine neoplasia type 1 (MEN1)	Endocrine tumors such as pancreatic adenomas
nm23	17q21	–	Melanoma, breast, colorectal, prostate, meningioma, others
MTS1	9p21	Melanoma	Melanoma, brain tumors, leukemias, sarcomas, bladder, breast, kidney, lung, and ovarian carcinomas

into cultured cells added new genetic information that led to transformation. Most investigators believed at the time that neoplastic transformation resulted from a simple gain of genetic information, rather than from a loss of some cellular gene. In Mendelian terms, malignancy was thought to be a dominant characteristic. Henry Harris of the University of Oxford in collaboration with George Klein of Stockholm forwarded another approach [104]. Cells from mouse tumor cell lines were fused with non-malignant cells, and the resulting hybrids were evaluated for their tumorigenic potential in appropriate hybrid animals. The hybrid cells produced very few tumors compared with the malignant parent cells. These results were interpreted to mean that normal cells contain one or more genes that act as negative regulators of the neoplastic phenotype. They postulated that malignancy was determined by a loss and not a gain of genetic information. At the time, these results were vigorously challenged [105].

Additional cell hybrid studies strengthened the concept that normal cellular genes can function to suppress the tumorigenic potential of neoplastically transformed cells. A cytogenetic analysis of cell hybrids that reexpressed tumorigenic potential established the chromosomal location of one of the normal genes in mouse that suppressed the malignant phenotype [106, 107]. Similar studies in human hybrid cells derived from the fusion of normal fibroblasts and HeLa cells (cervical carcinoma cell line) showed that reversion to the tumorigenic phenotype followed the loss of chromosome 11. Introduction of the wild-type allele by fusion with a normal cell once again suppressed malignancy, suggesting the presence of a tumor suppressor gene on this chromosome [4, 108, 109].

Some generalizations about tumor suppressor genes can be made (Table 7.8), and are further illustrated with specific examples below. Tumor suppressor gene mutations or deletions are often found as germ-line mutations associated with hereditary syndromes that predispose to the development of specific tumors. Mutations or deletions in the same genes involved in cancers arising in the setting of these hereditary syndromes are also found in sporadic tumors (tumors that arise in individuals known not to have germ-line mutations). Commonly, these somatic mutations can be found in tumors not related to those associated with hereditary syndromes. The latter findings in sporadic tumors suggest a broader role for these genes in tumorigenesis. In many but not all cases, tumor suppressor activity can be demonstrated in gene transfer assays. Tumor suppressor gene products are integral components of cell signaling pathways, in addition to having

Table 7.8 Characteristics of oncogenes and tumor suppressor genes

Characteristic	Oncogenes	Tumor suppressor gene
Number of mutational events required to contribute to cancer development	One	Two
Function of the mutant allele	Dominant (gain of function)	Recessive (loss of function)
Activity demonstrated in gene transfer assays	Yes	Yes
Associated with hereditary syndromes (inheritance of germ line mutations)	Seldom (c-*ret* proto-oncogene)	Often
Somatic mutations contribute to cancer development	Yes	Yes
Tissue specificity of mutational event	Some	In inherited cases, there is often a tissue preference

roles in cell–cell and cell–matrix interactions. Their role in the development of cancers has been demonstrated to be as significant as the role played by proto-oncogenes.

7.3.1 Mechanism of Tumor Suppressor Gene Action

The mechanism of action for the products of tumor suppressor genes is diverse and not fully understood. Conceptually, the products of tumor suppressor genes can be thought of as functioning to receive and process growth inhibitory signals from their surroundings. When a cell loses components of this signaling network, or loses responsiveness to extracellular growth inhibitory signals, the cellular consequences are the same as for unchecked stimulation of cell growth, neoplasia. The tumor suppressor gene products function in parallel with the protein products of proto-oncogenes, but work instead to suppress cell proliferation through the regulation of signal transduction and nuclear transcription. Not all tumor suppressor gene products conform to the growth inhibitory concept. Cell surface and cell matrix molecules are responsible for normal cell morphology, cell–cell interactions, and cell–extracellular matrix interactions. Tumor suppressor genes encode for such proteins, and mutations in these genes lead to altered cellular morphology, loss of normal intracellular signaling pathways, and loss of normal intercellular interactions, all of which are features of neoplastic cells.

7.3.1.1 Tumor Suppressor Gene Products That Regulate Signal Transduction

An example of a tumor suppressor gene whose product regulates signal transduction is the gene product of neurofibromatosis 1 (NF1), which is responsible for the clinical syndrome neurofibromatosis or von Recklinghausen's disease. Neurofibromatosis is one of the more common autosomal dominant disorders in humans and is clinically associated with café-au-lait spots (brown skin macules), benign neurofibromas, and other abnormalities. Patients with neurofibromatosis have a higher incidence of malignant tumors, including neurofibrosarcomas, pheochromocytomas, optic nerve gliomas, and malignant myeloid diseases [110].

The product of the *NF1* gene (neurofibromin) encodes for a GTPase activating protein (GAP). GAP proteins interact with c-ras proteins, which in normal cells are transiently activated upon exchange of bound GDP for bound GTP (Fig. 7.5). The c-ras proteins have intrinsic GTPase activity which is significantly increased upon binding with GAP proteins. Mutations in c-*ras* alter the GTPase activity of its protein product. The ras-GTP oncoprotein is significantly less responsive to GAP augmented hydrolysis [4, 35, 91–95]. It follows that mutations in genes that encode for GAP proteins, such as *NF1*, should be similarly deleterious to affected cells. In fact, *NF1* mutations are associated with and may contribute to the development of not only those tumors found in neurofibromatosis 1, but also adenocarcinomas of the colon, anaplastic astrocytomas, and myeloid malignancies, among others [110].

7.3.1.2 Tumor Suppressor Gene Products That Regulate Transcription

Examples of tumor suppressor genes whose products regulate transcription include *Rb1* and *p53*, the latter representing the gene most frequently involved in human cancers [111–113].

Rb1 gene. The discovery of the retinoblastoma gene (*Rb1*) gene resulted in an intense research effort to understand the mechanism of action of its gene product. In studies of cell cycle regulation, the *Rb1* tumor suppressor gene product was found to be active in a hypophosphorylated state, and inactive in a hyperphosphorylated state. Further, the active hypophosphorylated gene product was present in abundance in the G_0/G_1 stage of the cell cycle as compared to the finding of abundant inactive hyperphosphorylated pRb protein in late G_1, S, G_2, and M, suggesting a role for pRb as a suppressor of cell proliferation between the G_0/G_1 and S phase of the cell cycle. This was found to be true. The pRb protein binds transcription factors, and in particular, the E2F family of transcription factors as well as the product of the c-*myc* oncogene [114, 115]. Cyclin-dependent kinases are responsible for phosphorylating pRb (resulting in inactivation) when cells are stimulated to divide by exogenous growth factors or other mitogenic signals. The pRb protein dissociates from sequestered/bound transcription factors, allowing the cell to progress from G_0/G_1 to the S phase. After mitosis, a phosphatase returns pRb to its active, hypophosphorylated form. Unlike other regulators of transcription, pRb does not directly interact with DNA [116–120].

The inability of pRb to bind and negatively regulate the function of certain transcription factors leads to unregulated cell proliferation, and this can result from deletion or mutation of the *Rb1* gene, or functional inactivation of the pRb protein. In general, mutation of the *Rb1* gene results in truncated and unstable proteins [111]. As might be expected, the significant mutations or deletions in the *Rb1* gene occur in the transcription factor binding domain, also known as the pRb pocket. Functional inactivation of pRb was first recognized in studies of viral oncogenes. DNA viral oncogene products from animals (SV40 large T antigen) and humans (human papilloma virus E7, adenovirus E1A) inhibit pRb function by binding and occupying the pRb pocket. Gene mutations or occupation of the pRb pocket/transcription binding domain have, as a common result, the liberation of activating transcription factors with subsequent uncontrolled cell proliferation. The interplay between the products of these viral oncoproteins and pRb is an illustration of their mutual cooperation, which serves as a paradigm of the multistep

nature of oncogenesis. Inhibition of tumor suppressor genes represents an important way in which oncogenes exert their neoplastic potential [111, 121].

Mechanism of Rb1 Inactivation in Retinoblastoma. Although by the mid-1970s cell hybrid studies clearly established that malignancy is at least in part due to loss of function of critical regulatory genes in malignant cells, the identification of tumor suppressor genes at the molecular level did not occur until more than a decade later. As the prototypic tumor suppressor gene, the mechanism of inactivation and loss of function associated with the *Rb1* are illustrative of the whole class of tumor suppressor genes. The inactivation of both alleles of the *Rb1* gene is required for development of retinoblastoma, an eye malignancy that usually occurs at a very young age. Until the end of the nineteenth century, this tumor was uniformly fatal. During the twentieth century, more of these tumors were recognized and diagnosed at an earlier stage, permitting a surgical cure. It was noted that the offspring of retinoblastoma patients cured by surgery developed the disease at a very high frequency. Pedigree analysis of these families suggested a dominant pattern of Mendelian inheritance [122, 123].

The suggestion that a specific gene was responsible for the disease stemmed not from molecular or cell hybrid analyses, but rather from epidemiological data first reported by Alfred Knudson [123]. He noted that 40 % of the cases of retinoblastoma were bilateral and occurred in young infants (mean age 14 months), who if cured went on to develop secondary tumors (often osteosarcomas). In these patients, there was often a relevant family history of retinoblastoma. In contrast, the remaining 60 % of cases were unilateral and occurred in older children (mean age 30 months), who if cured did not develop secondary malignancies. These patients generally lacked a relevant family history. Knudson proposed that the first group inherited a mutant allele (germline mutation) which conferred a dominant predisposition to cancer to this group of patients. In these patients, a second somatic mutation in retinal cells resulted in retinoblastoma. The second nonfamilial, later onset, form was very rare (occurring in 1 in 30,000 people). Knudson suggested that these patients did not inherit a mutant gene, but rather two independent somatic mutations in retinal cells occurred to give rise to retinoblastoma.

The two-hit model proposed by Knudson did not address the mechanism of action of the gene(s) involved. There were at least two possible explanations. The first is that a dominant mutation of a single proto-oncogene allele is insufficient for the development of neoplasia, or that a second mutation, perhaps in a second proto-oncogene, is required. The second possibility, which proved to be correct, is that two mutations are required for development of retinoblastoma and that these mutations are inactivating mutations. Thus, the loss of both functional copies of the *Rb1* gene is necessary for neoplastic transformation and tumor formation. This conclusion is based upon numerous studies involving cytogenetic, linkage, and restriction fragment length polymorphism (RFLP) analyses of constitutional and tumor DNAs from affected individuals.

Cytogenetic studies demonstrated a loss of the long arm (13q14 region) of chromosome 13 in retinoblastoma tumors, and in the germ line of patients with a hereditary predisposition to retinoblastoma development [124]. Esterase D, a gene present on chromosome 13q14, was used in linkage analysis studies. Assuming that a mutant *Rb1* is closely linked to one of the two esterase D alleles which can be traced back to an affected parent, one can detect offspring who have inherited the mutant *Rb1* allele. Tumors arising in these individuals were shown to be homozygous for one form of esterase D, and by extension, homozygous for the mutant *Rb1* gene [125]. Similar conclusions were drawn from RFLP analysis of retinoblastomas arising in patients with familial predisposition, by comparing tumor DNA with germ-line DNA. Paralleling the findings using esterase D, homozygosity was found in these tumors as well [125–127]. Shortly thereafter, probes from the 13q14 region were used to screen retinoblastomas, and several demonstrated homozygous deletions for at least 25 kb of DNA.

Molecular cloning of the gene was accomplished using probes to human 13q14 to isolate genomic DNA clones corresponding to flanking DNA. The genomic DNA clones from the tumor suppressor gene region were then used as probes against RNA to compare the pattern of mRNA expression between retinoblastoma and normal retinal cells. The retinoblastoma gene was found to have 27 exons extending over approximately 200 kb of DNA and encoding a 928 amino acid protein [127–129]. Once the *Rb1* gene was isolated, mechanisms of inactivation were found and included deletions and inactivating point mutations [130, 131]. Importantly, tumor cell lines into which a cloned normal *Rb1* gene was introduced lost their malignant phenotype, confirming the tumor suppressing action of *Rb1* [132]. These studies definitively established the role of deletion and/or loss of function as a major genetic mechanism involved with neoplastic transformation, and solidified the existence of a new class of genes, the tumor suppressor genes.

The *Rb1* gene has since been found to be associated with many human neoplasms, usually through a genetic mechanism involving mutations or deletions. Most other tumor suppressor genes have similar mechanisms of inactivation as described for *Rb1*. Specifically, any alteration in DNA or functional inactivation of the gene protein product that results in a loss of function of both copies or alleles of the gene is required for the development of tumors. These alterations include inactivating point mutations, deletions, or

insertions. In general, all of these mechanisms have been described for many of the tumor suppressor genes, and it is possible to find in one inactivated gene of a clonal cell population a combination of two mechanisms of inactivation, a different one for each allele.

p53 gene. The *p53* gene is briefly mentioned because of its important and frequent involvement in human neoplasia [82, 112]. Like the *Rb1* gene product, p53 is a nuclear phosphoprotein and functions primarily as a regulator of transcription [113]. Specifically, when the genome sustains mutagenic damage (from radiation or a chemical insult) wild-type p53 protein accumulates in the nucleus where it binds DNA and causes cells to halt in the G_1 phase of the cell cycle, where the genetic damage is repaired. If the damage is not repaired, p53 induces apoptosis [133]. When first discovered, *p53* was thought to be a proto-oncogene because overexpression of cloned *p53* genes was shown to be related to transformation in gene transfer assays. It was later shown that the clones used were actually mutant forms of the *p53* gene. When the wild-type gene was cloned and used in similar transfection studies it did not demonstrate the ability to participate in the neoplastic transformation of normal cells. Rather, overexpression led to inhibition of neoplastic transformation, suggesting it to be a tumor suppressor gene.

Mechanism of p53 inactivation in cancer. The tumor suppressor function of p53 can be inactivated by either mutational events or through negative protein-protein interactions. The *p53* gene is composed of 11 exons spanning 20 kb of genomic DNA, encoding a protein of 393 amino acids. Mutations have been described for each exon, but appear to be most common in exons 5–9. A similar distribution of mutations is found in the Li Fraumeni syndrome, in which patients inherit a germ-line mutation in the *p53* gene. This syndrome is characterized by a familial predisposition to many tumor types, including breast (among other epithelial) carcinomas, soft tissue sarcomas, brain neoplasms, and leukemias [133]. Mutant p53 protein products lose their ability to suppress transformation, and gain the ability to inactivate wild-type p53. A cell with one mutant and one wild type copy of p53 behaves as if it has no wild-type p53 at all. This type of mutation is referred to as dominant negative because the mutant allele acts in a dominant fashion to alter the functioning of the normal allele [134–136]. The half-life of mutant species of the p53 protein tend to be increased compared to the very short half-life of the wild-type protein. This increase in protein half-life enhances the dominant negative effects of the mutant protein. Furthermore, when complexed with oncoprotein products such as from DNA tumor viruses (SV40 large T antigen, adenovirus E1B protein, and the E6 protein of human papilloma virus), the p53 protein is functionally inactivated in a manner analogous to the oncoprotein inactivation of the pRb [136].

7.3.1.3 Tumor Suppressor Gene Products That Function as Cell Surface/Cell Matrix Molecules

Properties of malignant cells include not only uncontrolled proliferation capabilities, but also changes in cell morphology, loss of contact inhibition or cell–cell interactions, and loss of cell–extracellular matrix interactions. This results in an altered phenotype, including morphologic changes which allow recognition by microscopy as malignant, inability to process inhibitory or other signals from adjacent cells, and loss of adhesion properties resulting in metastatic potential. Cell surface and cell matrix molecules thought to play a role in these processes include products from the neurofibromatosis 2 (*NF2*) gene, the adenomatous polyposis coli (*APC*) gene, and the deleted in colon cancer (*DCC*) gene, among others.

APC gene. The *APC* gene was isolated in 1991 and is responsible for the familial adenomatous polyposis (FAP) syndrome, an uncommon autosomal dominant disease affecting approximately 1 in 8000 individuals [137–140]. Patients with FAP typically develop 500–2500 adenomas of the colonic mucosa. The frequency of progression to colon adenocarcinoma approaches 100 % necessitating prophylactic colectomy by the second or third decade of life, and early surveillance of siblings and first degree relatives [140]. The *APC* gene was found to be located on the long arm of chromosome 5 (5q21), a locus known to be deleted frequently in colonic adenocarcinomas. Patients with FAP carry germ-line *APC* mutations leading to the production of truncated APC proteins, the detection of which has provided a diagnostic assay [141]. In addition to its role in the development of hereditary FAP, *APC* mutations have been found in sporadic adenomas, the majority of sporadic colorectal cancers [141, 142], and other human malignancies of the pancreas, esophagus, stomach, and lung [142–146]. Sporadic mutations also lead to the production of truncated proteins. Tumor suppressor activity has not been demonstrated in gene transfer assays using the *APC* gene.

The *APC* gene is large, extending over 8500 nucleotides, and encoding a protein of approximately 2840 amino acids. The protein interacts with catenins, which are cytoplasmic proteins thought to play a role in signal transduction because of their interactions with cadherins, a family of cell surface molecules. Cadherins have been shown to regulate cell–cell interactions and morphogenesis. Based on these observations, it has been postulated that the APC-catenin complex plays a role in cell adherence, and possibly signal transduction such as contact inhibition of cell growth [146]. In FAP, mutations in the 5′-portion of the gene have been shown to correlate with an attenuated form of the disease [147], while mutations at codon 1309 are associated with an early onset of colon cancer in FAP families [148].

DCC gene. The *DCC* gene was discovered using polymorphic DNA markers that showed a loss of heterozygosity (LOH) of the long arm of chromosome 18 in colorectal tumors [46]. The gene was subsequently isolated and shown to be composed of more than 29 exons spanning more than 1×10^6 nucleotides [149, 150]. The *DCC* gene encodes for a transmembrane molecule with unknown function which has homology to cell adhesion molecules (CAMs) involved in cell–cell or cell–extracellular matrix interactions [151]. It may play a role in transmitting negative signals, and inactivation of *DCC* function through deletion or mutation (a rare event) may lead to loss of contact inhibition and subsequent uncontrolled cellular proliferation [151]. LOH at the 18q locus was initially described in colorectal carcinomas as one of several steps involved in the sequence of events from premalignant adenomas to invasive carcinomas. Although no hereditary conditions involving germ-line alterations of the gene have been described (in contrast to most other tumor suppressor genes), *DCC* abnormalities are associated with several tumor types other than colon cancer, including stomach cancer, pancreatic cancer, and leukemias [152–155]. The *DCC* gene has not been formally classified as a tumor suppressor gene because the predicted tumor suppressor activity has not been demonstrated in gene transfer assays [4, 156, 157].

NF2 gene. NF2 is genetically and clinically distinct from NF1 discussed above. It is a rare autosomal dominant disorder in which patients develop bilateral schwannomas affecting the vestibular branch of the eighth nerve (acoustic neuromas), and other tumors of the central nervous system such as meningiomas and ependymomas (hence its designation as central neurofibromatosis). The gene is located on the long arm of chromosome 22 (22q22) and was isolated in 1993 [158, 159]. Mutations of the *NF2* gene have been found in tumors (breast carcinomas and melanomas) other than those associated with the NF2 syndrome [160], as well as in sporadic meningiomas and ependymomas [161, 162], suggesting a role in tumorigenesis extending beyond that played in NF2. Its protein product (schwannomin or merlin) shows sequence homologies to proteins which act as linkers between cytoskeletal scaffolding components and proteins in the cell membrane. On this basis schwannomin is thought to play a role in cell shape, cell–cell interactions, and cell–matrix interactions [159, 160]. Inactivation of the *NF2* gene may lead to changes in cell shape and loss of contact inhibition [110].

Oncogenes and the Initiation and Maintenance of Tumorigenesis

8

Dean W. Felsher, Constadina Arvanitis, Pavan Bendapudi, and Pavan Bachireddy

8.1 Introduction

Cancer is a complex and multistep process whereby an individual cell acquires a series of mutant gene products culminating in a spectrum of pathophysiologic features including relentless proliferation, growth, blocked differentiation, the inappropriate induction of angiogenesis, tissue invasion, and loss of genomic stability. Given the genetic and biologic complexity of tumorigenesis, it is perhaps surprising that there are circumstances when cancer can be reversed through the repair or inactivation of individual mutant genes. However, recent experiments in transgenic mouse models and clinical results using new pharmacological agents demonstrate that cancer can be treated through the targeted repair and/or inactivation of specific oncogenes. Hence, cancers appear to be dependent upon particular oncogenes to maintain their neoplastic properties, thus exhibiting the phenomena *tumor maintenance* or *oncogene addiction*.

We will describe how proto-oncogenes physiologically play a fundamental role in specific critical signaling processes. Hence, when inappropriately activated, as oncogenes, they can initiate tumorigenesis. In addition to summarizing the major signaling pathways that may be most effectively targeted for the treatment of cancer, we will describe how conditional transgenic model systems have been exploited as innovative avenues for discovery and validation of oncogenes as therapeutic targets. Then, we will highlight recent successes and current challenges in the use of targeted therapeutics for the treatment of cancer. Finally, we will discuss current thoughts on why the targeted inactivation of specific oncogenes results in cancer regression.

8.2 Oncogene Signaling Pathways

Oncogenes were first identified as the etiologic agents of retrovirus mediated malignant transformation. Only subsequently was it appreciated that these gene products were mutant versions of normal cellular counterparts [1]. With this epiphany, it rapidly became apparent that cancer was a disease caused by genetic events that resulted in the perturbation of gene products that were intimately involved in the regulation of cellular processes that governed when and how a cell will proliferate and grow. Now, hundreds of oncogenes have been identified. In many cases specific oncogenes have been associated with specific human diseases. In this chapter, the goal is to choose particular examples of oncogenes that are illustrative, rather than attempt the impossible task of cataloging all the different oncogenes that have been implicated in neoplasia.

At least four different classes of oncogene signaling molecules are commonly involved in the pathogenesis of cancer. These include gene products that have several distinct functions: (1) receptors such as ErbB, (2) small GTPases such as Ras, (3) kinases such as BCR-ABL, and (4) transcription factors such as MYC. Correspondingly, the oncoproteins in these interacting signaling pathways have been the most intensely studied as potential targets for the treatment of cancer (Fig. 8.1).

W.B. Coleman, G.J. Tsongalis (eds.), *The Molecular Basis of Human Cancer*, DOI 10.1007/978-1-59745-458-2_8

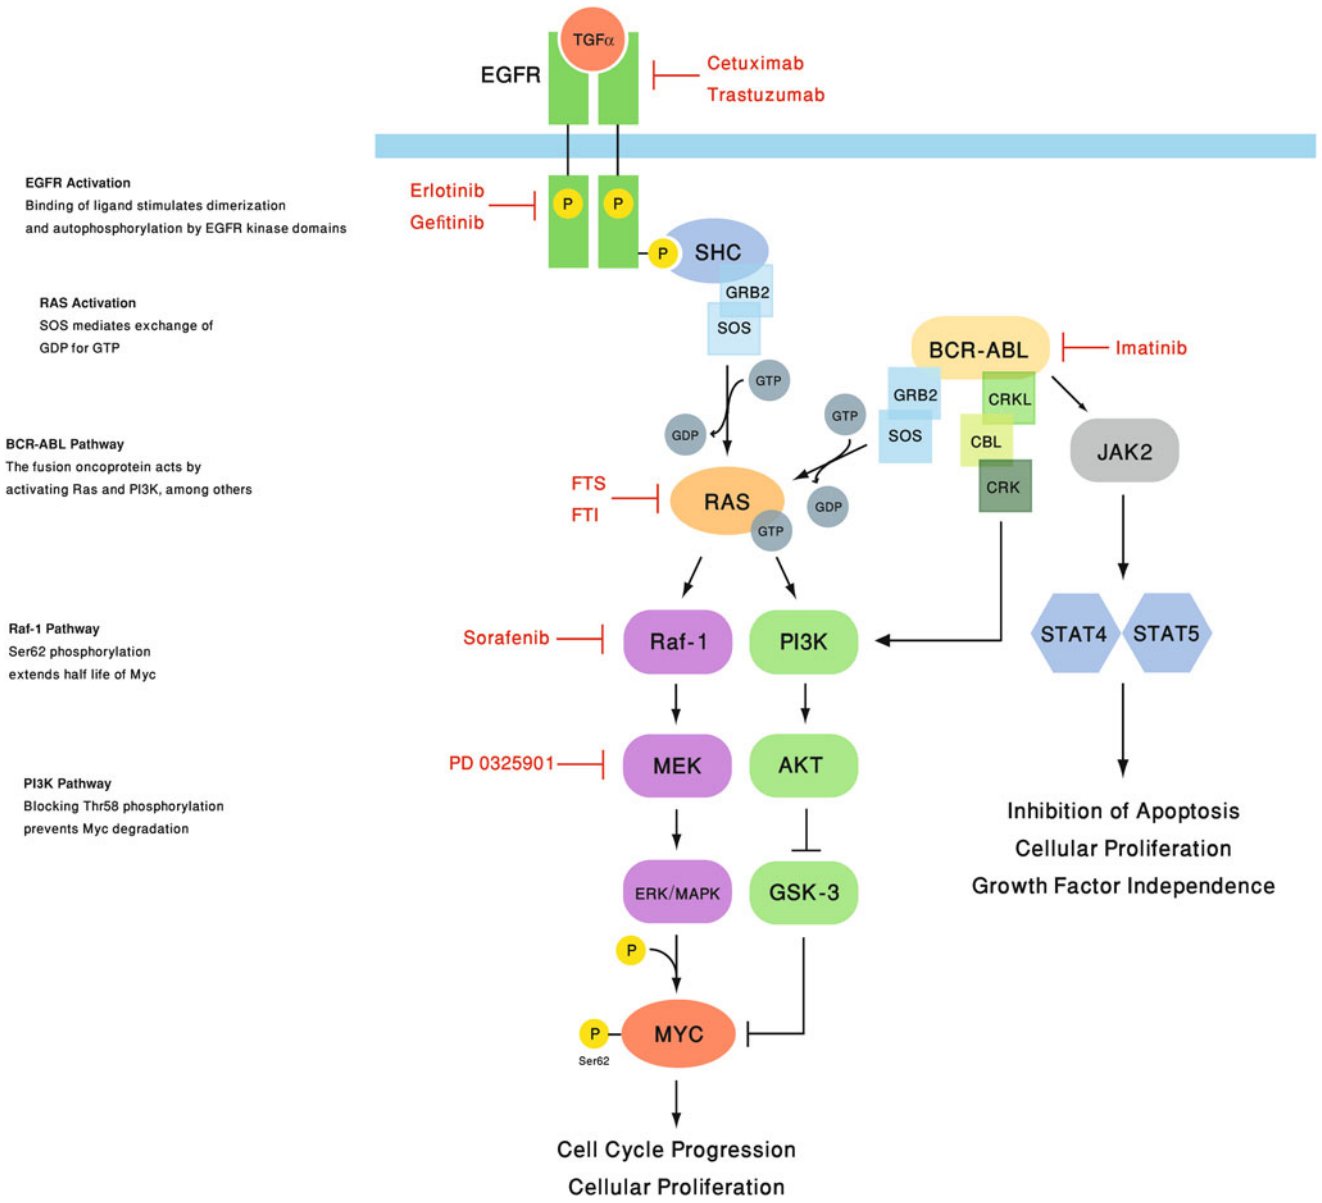

Fig. 8.1 Critical signaling pathways as drug targets for cancer therapy. (**a**) Surface receptors dimerize and activate downstream effectors such as RAS (a GTPase). Many surface receptors are targeted by antibodies, and EGFR has been targeted through cetuximab and trastuzumab. (**b**) RAS activation is caused by SOS-mediated exchange of GDP for GTP on RAS. G protein signaling molecules, such as RAS, have been targeted by farnesyltransferase inhibitors (FTI) and *S*-farnesylthiosalicylic acid (FTS). (**c**) The BCR-ABL fusion protein activates RAS, PI3K, and other oncogenic signaling molecules. Tyrosine kinases are often targeted with small molecules. BCR-ABL has been targeted by Imanitib. (**d**) Transcription factors are often the terminal effectors of a pathway. To date, transcription factors are yet to be successfully targeted. All drugs are in red at their sites of action.

8.2.1 Receptor Signaling

Cell surface receptors are the vehicles of communication amongst cells. They are responsible for initiating the response of cells to their tissue microenvironment and mediate many signaling cascades. Growth factor receptors were some of the first proto-oncogenes discovered [2]. A multitude of cell surface receptors have been implicated in tumorigenesis including the epithelial growth factor receptor (EGFR), platelet-derived growth factor receptor (PDGFR), and insulin-like growth factor receptor (IGFR) [3]. Each of these receptors has been implicated in the pathogenesis of specific types of human neoplasia.

In many regards the ErbB family of transmembrane tyrosine kinase receptors is prototypical of cell surface receptors. This gene family includes four members: (1) EGFR (ErbB1), (2) HER2/NEU (ErbB2 hereafter referred to as HER2), (3) ErbB3, and (4) ErbB4. Ligands have been identified for each

of the ErbB family members with the notable exception of HER2 that likely heterodimerizes with EGFR or HER3. Downstream effectors of these molecules include many other proto-oncogenes including the MAPK/RAF/RAS, PI3K/AKT, and STAT signaling. Activation of these receptor pathways induces cellular proliferation, enhanced survival, and increased cellular motility [4].

Many of these gene products have multiple alleles that appear to exhibit tissue-specific expression. For example, each of the ErbB receptors exhibits unique expression patterns. Correspondingly, mutated receptors have been implicated in particular types of human cancer [5]. For example, EGFR is commonly overexpressed in lung carcinoma [6], while Her2 overexpression is more commonly associated with breast cancer [7]. Thus, the biology and pathophysiology associated with these gene products is associated with specific cellular lineages.

Cell surface receptors are particularly attractive candidates as drug targets. First, receptors are specific to particular tissue types thus allowing for target specificity. Second, pharmacologically blocking a ligand-binding site is an obvious and frequently successful strategy to inactivate a receptor. Finally, drugs that target receptor molecules do not need to be able to transit through cellular membranes.

8.2.2 GTPases

GTPases are a large family of gene products that mediate receptor signaling [8]. A multitude of GTPases have been implicated as oncogenes. A characteristic feature of the biology of GTPases is that they only become activated after post-translational modification that permits their localization to the plasma membrane [9]. Moreover, the enzymes that mediate these modifications are possible targets for the treatment of cancer.

The RAS family represents a prototypical example of GTPases. There are three members: (1) H-RAS, (2) K-RAS, and (3) N-RAS [8]. A mutant RAS was one of the first oncogenes identified to be mutated in a human cancer. Over 25 % of human cancers exhibit activating point mutations of a RAS gene [10]. RAS proteins are known to play a critical role in the regulation of a multitude of cellular programs including cellular growth, proliferation, apoptosis, and angiogenesis [9, 11]. The RAS/RAF/MAPK pathway is a frequent target for pharmacologic treatment of human cancers.

8.2.3 Protein Kinases

Protein Kinases are among the most abundant signaling molecules with approximately 500 members. The phosphorylation of proteins at serine, threonine, or tyrosine represents one of the most common and fundamental mechanisms of cellular signaling. Phosphorylation has been implicated in the regulation of the activity of cellular receptors, signaling molecules, transcription factors, DNA repair molecules, and chromatin structure proteins amongst many different functions. Many of these gene products when mutated exhibit oncogenic function through constitutive activation [12]. The recent ability to pharmacologically target the ATP binding domains of kinases has made these gene products one of the most frequently pharmacologically targeted molecules [13, 14].

An important protein kinase associated with neoplasia is the BCR-ABL fusion protein. BCR-ABL results from a chromosomal translocation between the ABL proto-oncogene and the BCR locus. BCR-ABL overexpression has been implicated in the pathogenesis of both chronic myelogenous leukemia and acute lymphocytic leukemia. Targeted inactivation of BCR-ABL through the drug imatanib mesylate, is the most regarded example of a successful targeted therapeutic (Gleevec, STI-571) [15–18].

8.2.4 Transcription Factors

Transcription factors are some of the most potent oncoproteins in the induction of cancer. By regulating the expression of numerous gene products they can exert broad, concerted, and sustained effects on cellular programming. They include a multitude of gene products including steroid receptors and nuclear transcription factors such as MYC, MYB, and FOS/JUN.

The family of MYC proto-oncogenes (c-MYC, n-MYC, l-MYC) have been implicated in the regulation of many physiologic programs cellular growth, proliferation, differentiation, immortalization/senescence, apoptosis, angiogenesis, adhesion, motility, and DNA repair. MYC is overexpressed in over half of all human cancers suggesting that it plays a role in the pathogenesis of most human cancers [19]. MYC has been shown to regulate the transcription of up to thousands of target genes [20–22], suggesting that these gene products function as grand coordinators of gene expression programs. However, MYC has also been shown to play a role in the regulation of ribosomal biogenesis, RNA processing, DNA replication, and DNA repair.

c-MYC was one of the first proto-oncogenes identified [23]. c-MYC is activated in human cancer through at least three different mechanisms. The chromosomal translocation of the MYC locus to the immunoglobulin or T-cell receptor loci is associated with Burkitt's lymphoma. n-MYC is commonly expressed in neuronal cells and is often overexpressed as a result of genomic amplification in neuroblastoma. l-MYC was first identified in lung tissue and is associated with small cell lung carcinoma [19]. MYC has also shown to be overexpressed as a consequence of the disruption of the

regulation of its transcription regulations, for example, through the disruption of the beta-catenin pathway through mutation of the APC gene. Although MYC and other transcription factors play such a fundamental role in the pathogenesis of cancer, they are yet to be successfully targeted therapeutically.

8.3 Interrogating Oncogenes via Mouse Models

Our understanding of the physiologic function of proto-oncogenes and the contribution of oncogenes to the initiation and maintenance of tumorigenesis has been markedly enhanced by the ability to generate mouse models. Most notably, the development of transgenic mouse models has provided the unprecedented opportunity to model the contribution of specific gene products to the pathogenesis of neoplasia in vivo. The use of conditional transgenic models has made it possible to directly interrogate when and how the inactivation of oncogenes can result in cancer regression.

Several recent reviews have extensively described the application of conventional transgenic mouse models for the development of therapeutics for cancer [24–26]. Here we will focus on the use of conditional transgenic models can be used to define when and how oncoproteins can be used as targets for the treatment of cancer.

8.3.1 Experimental Approaches

Three different strategies have been most commonly utilized to conditionally regulate gene expression in transgenic mouse models: (1) the Tet System, (2) the Tamoxifen System, and (3) the TVA system [24, 27, 28].

8.3.1.1 The Tet System

The Tetracycline Regulatory System (Tet System) was developed as a strategy to regulate the transcription of genes in eukaryotic cells utilizing prokaryotic transcriptional regulatory proteins [29, 30]. There are two variations of this system—one activates transgene expression in the presence of a tetracycline such as doxycycline (Tet-on), while the other system shuts off transgene expression upon doxycycline addition (Tet-off). In both variations, two different transgenes are generated. The first transgene uses a tissue-specific promoter to drive the expression of a tetracycline transactivator (tTA or rtTA). The second transgene contains a tetracycline response element (Tet-O) adjacent to a target gene of interest. The tTA or rtTA protein binds to the Tet-O promoter regulating gene transcription. The presence of doxycycline, prevents binding of the tTA protein to the Tet-O element turning off gene expression (Tet-off) or promotes the binding of the rtTA protein to the Tet-O element turning gene expression on (Tet-on). The Tet system facilitates monitoring of transgene expression at the transcription level in specific tissues within the mouse.

8.3.1.2 The Tamoxifen System

The Tamoxifen System also has been employed to conditionally regulate gene activation posttranscriptionally. MYC fused with the estradiol receptor exhibited conditional oncogene activation [31]. A mutant version of the estradiol receptor, which binds tamoxifen, is utilized to prevent endogenous estradiol from activating gene function [32]. Upon addition of tamoxifen, MYC is active, and withdrawal leads to an inactive product. Subsequently, this strategy was shown to be useful in the generation of conditional transgenic mice [33, 34].

8.3.1.3 The RCAS-TVA-Tet System

The Tet-system can be combined with the RCAS-TVA system [35, 36]. In this approach a tissue-specific promoter is used to drive the expression of the avian retroviral receptor (TVA) in transgenic mice. The cells of these mice also contain a Tet-O regulated transgene, but lack the rtTA protein. Avian retroviral vectors (RCAS) are used to deliver the rtTA transactivator to cells that express the TVA. The successfully infected cells now contain a transgene whose expression can be regulated by doxycycline.

8.3.2 Defining When Cancer Is Reversible

Conditional transgenic models have been used to evaluate the consequences of oncogene inactivation in vivo. From these studies, several general themes emerge regarding the role of oncogenes in the initiation and maintenance of tumorigenesis, as we have described [27, 37–42]. Oncogene inactivation can reverse tumorigenesis by inducing sustained cancer regression through differentiation, proliferative arrest, and/or apoptosis (Table 8.1).

The specific consequences of the inactivation of an oncogene depend upon the type of cancer. In some cases, even briefly inactivating an oncogene may be sufficient to induce sustained cancer regression [43, 44], but in other cases, this has not been observed [45]. Oncogene inactivation may uncover the stem cell properties of cancer cells and induce a state of cancer dormancy [45–49]. Finally, the genetic context can affect whether inactivation of an oncogene will induce sustained regression, or if the cancers can relapse acquiring additional genetic events [45, 50–52]. Conditional transgenic models have been generated for many types of signaling molecules implicated in the pathogenesis of neoplasia.

Table 8.1 Consequences of oncogene inactivation in transgenic mouse models

Oncogene	Model	System	Tumor type	Response to inactivation	Mechanism of tumor regression	References
BCL2	MMTV-tTA Tet-O-BCL-2 Eμ-MYC	Tet-off	Lymphoblastic leukemia	Regression	Apoptosis	[142]

[a]While most of the tumors regressed upon oncogene inactivation, some of the mice relapsed while the oncogene was inactivated

8.3.2.1 Conditional Models of Receptor Induced Tumorigenesis

The Tet system has been used to conditionally overexpress receptors including an oncogenic form of HER2 containing an activating point mutation in its transmembrane domain [52, 53]. Expression was directed to the breast by utilizing the mouse mammary tumor virus (MMTV) promoter to drive the expression of the rtTA protein. Within 4 days of HER2 activation by doxycycline administration, the mice developed hyperplastic abnormalities. Six weeks following oncogene activation, all of the mice developed multiple invasive mammary carcinomas. The tumors were solid invasive carcinomas that often metastasized to the lung. Following 48 h of HER2 inactivation through doxycycline withdrawal, the cancer cells exhibited proliferation arrest and increased apoptosis. The primary carcinomas rapidly and completely regressed in over 90 % of the mice with a mean regression time of 17 days. Within 30 days, the pulmonary metastases

had also completely and rapidly regressed. Thus, tumorigenesis appears to be reversible.

However, a majority of the cancers that had a complete regression upon HER2 repression eventually reoccurred. When the primary cancers and metastases were transplanted into syngeneic hosts, they completely regressed only 55–70 % of the time. The relapse tumors all uniformly lacked both endogeneous and transgene protein expression indicating that the cancers had all become HER2 independent [53]. Subsequently, Snail, a transcriptional repressor was found to be activated in relapsed cancers [52]. Therefore, although oncogene inactivation can cause cancer regression, some transgenic tumors are capable of becoming independent of their initiating oncogenic event.

8.3.2.2 GTPases and Cancer Regression

The Tet-On system has been used to generate a conditional model of mutant H-RAS induced melanomas [54, 55]. The tyrosinase gene promoter (Tyr) was used to conditionally overexpress an H-RAS bearing an activating point mutation (V12G) in an Ink4a-deficient background. Approximately 25 % of the mice developed melanomas within 60 days of H-RAS activation. The melanomas were invasive, highly vascular, and notably amelanotic. The tumors exhibited expression of tyrosinase-related-protein-1 (TRP-1), an early melanocyte-specific maker. Within 48 h of H-RAS inactivation through doxycycline withdrawal, the cancers decreased their proliferation and exhibited robust apoptosis. Within 14 days of H-RAS inactivation, the cancers had completely regressed with only microscopically detectable scattered cancer foci. Notably, melanomas transplanted into SCID hosts also regressed upon inactivation of mutant H-RAS. Approximately 30 % of the melanomas resumed growth, even in the absence of H-RAS, but relapsed tumors failed to express TRP-1, suggesting that these tumors were phenotypically different from the primary cancers [55]. Additionally studies have shown that EGFR signaling is required for maintenance of a tumorigenic phenotype in H-RAS induced melanomas. A dominant-negative EGFR reduced the tumorigencity of melanomas, and sustained expression of EGFR can delay cancer regression [56].

The Tet-System has also been used to generate conditional models of mutant K-RAS induced lung adenocarcinoma [57, 58]. The Clara cell secretory protein (CCSP) promoter was used to regulate gene expression in alveolar epithelial cells. Within 7–14 days post induction of K-RAS overexpression, type II pneumocytes exhibited focal hyperplasia, and after 2 months, multiple solid adenomas or adenocarcinomas were present in the lung. The solid adenomas contained a population of macrophages, but lacked invasive growth and stromal elements. The adenocarcinomas had fewer macrophages and cytoplasmic inclusions, but had local invasion of the pleura. Within 3 days of K-RAS inactivation through doxycycline withdrawal, cancers exhibited decreased cellular density and an increased rate of apoptosis. Within 7 days of K-RAS inactivation, only a few patches of hyperplasia were found, and within a month no residual cancer tissue was found in 5/5 mice. The same mice were generated in either a p53 or an Ink4A/Arf deficient background. Cancers grew rapidly in these mice after K-RAS induction, but regressed with the same kinetics. TUNEL assays revealed that regardless of the genetic context cancers were regressing associated with apoptosis [58]. Similarly, CCSP regulated K-RAS (G12C) induced lung adenomas regressed upon oncogene inactivation [57]. Hence, even aggressive lung cancers in a tumor suppressor-deficient background regress upon the inactivation of a single oncogene.

8.3.2.3 Protein Kinases and Cancer Regression

A conditional transgenic model for BCR-ABL leukemias was generated using either the MMTV or SCL (stem cell leukemia) promoter to drive the expression of tTA [59, 60]. Upon induction of BCR-ABL the mice developed B-cell leukemia associated with lymphadenopathy, splenomegaly, and bone marrow infiltration. A third of mice with BCR-ABL under the control of the SCL promoter developed B-cell lymphoblastic disease resembling blast crisis, closely mimicking what is observed in patients with chronic myelogenous leukemia (CML). Inactivation of BCR-ABL induced rapid cancer regression in all mice. BCR-ABL inactivation was associated with the apoptosis of 80 % of the cancer cells within 20 h and complete tumor regression within 5 days. Sustained regression of cancer was observed in tumors arising from three of the four founder lines, as long as the mice had BCR-ABL continuously inactivated. Upon reactivation of BCR-ABL the cancers rapidly recurred. Interestingly, all the mice derived from the fourth founder relapsed within 4 weeks after complete regression. Relapsed cancers lacked continued expression of BCR-ABL protein and mRNA, suggesting that they had become independent of BCR-ABL expression.

8.3.2.4 Nuclear Transcription Factors

The Tet and Tamoxifen systems have been used to demonstrate that MYC inactivation can induce cancer regression in a multitude of different types of cancer (Table 8.1). The Tet-Off System was used to regulate human c-MYC in lymphoid cells under the regulation of the EμSRα promoter [61–63]. When MYC is constitutively activated, 100 % of the mice developed hematopoietic tumors within 5 months. Upon gross examination, the mice exhibited enlargement of the thymus, liver, spleen, and gastrointestinal lymph nodes. Histological examination revealed that cancer cells had invaded all hematopoietic organs as well as liver, kidney, blood, and the lamina propia of the intestines. In one study, tumors were generally immature CD+4/CD+8 T-cell lymphomas and were rarely acute myeloid leukemias [61]. In another

Table 8.2 Oncogene inactivation in the therapeutic setting

Target	Target type	Drug	Cancer	Clinical efficacy	References
EGFR	Receptor tyrosine kinase	Cetuximab	Colorectal cancer	Synergism with irinotecan in irinotecan-refractory colorectal cancer	[75]
		Erlotinib (Tarceva)	NSCLC	Approved for refractory NSCLC; disappointing results of addition to chemotherapy in initial treatment of NSCLC	[68]

RAF-1	Tyrosine kinase	Sorafenib	Metastatic renal cell carcinoma; advanced melanoma	Improves time to progression in metastatic renal cell carcinoma and produces partial responses in combination therapy against advanced melanoma	[151] and [150]

study, tumors were either B-cell or T-cell lymphomas [63]. In both studies, the resulting hematopoietic tumors exhibited a high degree of genomic instability reflected by chromosomal gains, losses, or translocations [61, 63]. Despite this genomic complexity, the inactivation of MYC resulted in rapid and sustained cancer regression. Upon MYC inactivation, cancer cells arrested, differentiated, and underwent apoptosis. Over 50 % of tumors exhibit sustained regression for over 30 weeks. Thus, MYC inactivation can induce sustained regression of hematopoietic tumors.

Conditional transgenic mice expressing c-MYC under the control of the Eμ-promoter occasionally developed highly metastatic osteosarcomas [44]. Histological examination of the primary cancer reveals the presence of disorganized bone matrix. MYC inactivation induced rapid cancer regression associated with the differentiation of cancer into mature bone. Continuous video time-lapsed microscopy (CVTL) revealed that upon MYC inactivation, cancer cells ceased to proliferate and differentiated, as confirmed by immunocytochemical analysis. Identically, MYC inactivation in cancers in vivo was associated with the differentiation of malignant cells into mature osteoid. Upon MYC reactivation less than 1 % of the cells were able to regain a proliferative phenotype. Surprisingly, MYC reactivation was also associated with the apoptosis of the now differentiated cancer cells. Moreover, even the transient inactivation of MYC was found to increase the survival of mice with these cancers. Hence, at least in some circumstances even brief oncogene inactivation can induce sustained loss of a neoplastic state.

The tamoxifen system also has been used to evaluate the consequences of MYC inactivation in different types of tumors using MycER^{TAM} (Table 8.2). MycER^{TAM} has been expressed in the skin through the involucrin promoter [34, 43]. MYC activation resulted in increased proliferation and blocked differentiation of the suprabasal epidermis. Sustained MYC activation resulted in hyperplasia, dysplasia, angiogenesis, and papillomatosis. MYC inactivation resulted in regression of blood vessels, restoration of cellular differentiation, and the regression of papillomas. A brief inactivation of MYC in keratinocytes caused the cells to differentiate and become unresponsive to MYC reactivation. MYC reactivation could not restore a proliferative phenotype to the differentiated keratinocytes and eventually the cells were sloughed off the skin [43]. Hence, brief inactivation of MYC can induce the sustained loss of neoplastic features in some skin tumors.

MycER^{TAM} was also expressed under the control of the insulin (plns) promoter to induce pancreatic islet cell carcinomas [33]. Within 24 h of MYC activation, virtually all β-islet cells were rapidly proliferating. By 72 h of MYC acti-

vation 4–7 % of β-cells were undergoing apoptosis, and within 6–10 days there were almost no β-cells detectable. MycER^{TAM} was expressed in the presence of BCL-x_L to address the consequences of MYC activation when apoptosis is repressed. Within 7 days of MYC activation β-cells became hyperplastic, ceased insulin production, and decreased expression of the intercellular adhesion molecule E-cadherin. Within 6 weeks pancreatic islet cell carcinomas had formed highly vascularized cancers. Upon MYC inactivation, these cancers regressed completely. The cancers decreased proliferation, differentiated, increased expression of E-cadherin, and exhibited vascular collapse. While these cancers initially regressed upon MYC inactivation, transient MYC inactivation did not result in sustained cancer regression.

The Tet-System has been used to explore the role of MYC in the initiation and maintenance of liver cancer by utilizing the liver activator protein (LAP) promoter to express tTA [46, 64]. The latency of tumorigenesis was inversely correlated with the age at which MYC was activated [64]. When MYC was activated during embryonic development, mice would succumb to neoplasia within 10 days of birth. In contrast, if MYC was activated in adult mice, the mean latency of cancer onset was 35 weeks. The cancers generated in adult mice histologically resembled either hepatocellular carcinomas (HCC) and/or hepatoblastomas. MYC was found to be able to induce proliferation in embryonic or neonatal liver cells, but induce cellular hypertrophy without cellular proliferation in adult liver cells. In part, this was explained by the observation that MYC induced a p53-dependent arrest in cellular division in adult hepatocytes. Thus, it appears that the ability of MYC to induce tumorigenesis depends upon epigenetic parameters dictated by developmental state.

The same Tet system model was used to examine the consequences of MYC inactivation in liver cancer [46]. The liver cancers were locally invasive, occasionally metastasized to the lung, and were readily transplantable into SCID mice. Within 4 days of MYC inactivation, cancer cells stopped proliferating, differentiated into normal liver cells, and subsequently underwent apoptosis [46]. Even after 5 months of continuous MYC inactivation, a residual population of tumor-derived cells remained detectable. However, MYC reactivation immediately resulted in resumption of a tumorigenic phenotype. Thus, these results were in marked contrast to earlier reports that brief inactivation of MYC can result in a permanent loss of a neoplastic phenotype. One possible explanation for these results is that MYC inactivation uncovers the latent stem cell properties of cancer cells that now can differentiate into normal liver, but some of these cancer stem cells retain the capacity to regain their neoplastic features. In support of this hypothesis, upon MYC inactivation, some of the residual cells expressed the liver stem cell marker cytokeratin 19 (CK-19) [46]

MYC also has been conditionally expressed in mammary epithelium using a Tet-on system with the MMTV promoter [45, 50]. MYC activation resulted in mammary adenocarcinomas with a mean latency of 22 weeks in approximately 86 % of mice. Histologically, the cancers exhibited focal hyperplasia, increased proliferation, and dysplasia. Upon MYC inactivation, less than half of the adenocarcinomas completely regressed, and a majority of the cancers that completely regressed spontaneously relapsed. Some relapsed cancers had either sustained expression of transgenic MYC in the absence of doxycycline or had reactivated MYC target genes in the absence of transgenic MYC. The majority of cancers relapsed by becoming independent of MYC. Half of the tumors exhibited an activating mutation in either K-RAS2 (17/23) or H-RAS2 (6/23). Thus, MYC inactivation can induce sustained regression of breast cancers unless they have acquired mutations in K-RAS or H-RAS. These important results underscore the importance of genetic context on the consequences of oncogene inactivation in a cancer.

8.4 Targeted Oncogenes to Treat Cancer

The pharmacologic inactivation of oncogenes has been effective in the treatment of some cancers including acute promyelocytic leukemia, breast cancer, colorectal cancer, and lung adenocarcinoma (Table 8.2). Two general concepts have emerged: (1) small molecules can be used to target mutant signaling proteins, and (2) receptors can be targeted with monoclonal antibodies. However, many gene products are yet to be successfully targeted.

8.4.1 Erlotinib, Gefitinib, and EGFR

EGFR has been successfully targeted by many agents. Gefitinib (ZD1839, Iressa) and erlotinib (OSI-774, Tarceva) were approved by the FDA in 2004 as single agents for the treatment of non-small-cell lung carcinoma (NSCLC) that had proven refractory to standard chemotherapy. Both drugs are members of the anilinoquinazoline class of small molecules and act by competitively inhibiting ATP binding to the intracellular tyrosine kinase domain of EGFR, thereby preventing the autophosphorylation that is necessary for receptor tyrosine kinases to initiate their signaling cascades (Fig. 8.1). Gefitinib was approved based upon results from two studies, the IDEAL-1 and IDEAL-2 trials, that describe an 11–19 % response rate for the drug as a single agent in patients with refractory disease [65–67].

Erlotinib yielded partial responses in 9 % of patients when administered as a single agent to those who had failed one or two regimens of standard chemotherapy [68]. Advanced or metastatic NSCLC entails very poor survival, so gefitinib and erlotinib were at first considered to provide real benefits over existing therapy despite the low response rates associated with their use. Additional studies (the INTACT trials)

illustrated that adding these two drugs to regimens consisting of standard chemotherapy agents yielded no additional benefit [69, 70]. Moreover, almost all patients who showed an initial response eventually relapsed with disease that was resistant to EGFR inhibitors [71]. The prospect of successfully inhibiting EGFR with small molecules was thus cast in doubt, and a concerted effort was made to explain the contradictory findings of the IDEAL and INTACT studies.

One possibility is that a given tumor's response to gefitinib will be dependent on activating mutations in exons 19 and 21 of EGFR [72]. Analysis of the crystal structure of EGFR revealed that these mutations occurred in a crucial ATP binding pocket where the anilinoquinazolines act as competitive inhibitors [73]. Hence, although gefitinib therapy may not be broadly applicable to all lung cancers, genetic subpopulations may be identified that exhibit an increased susceptibility to EGFR inhibitors. Another clue to the possible mechanism of action of these agents is that cells transfected with mutant EGFR uniquely activate anti-apoptotic pathways involving Akt and STAT signaling [74]. Therefore, cells carrying the mutant receptor although resistant to the apoptotic effects of standard chemotherapeutic agents, in combination with EGFR inhibitors may synergize with these traditional chemotherapies for a clinical response.

An important example of a possible synergistic effect between a targeted therapy and conventional chemotherapy is cetuximab (a monoclonal antibody to EGFR) combined with irinotecan (a topoisomerase I inhibitor). Patients with irinotecan-refractory colorectal cancer had higher response rates and modestly prolonged survival when treated with cetuximab in combination with irinotecan than patients treated with cetuximab alone [75] suggesting that cetuximab may reverse resistance to irinotecan. Both preclinical and clinical studies have shown synergy between platinum-based chemotherapy and trastuzumab, a monoclonal antibody against the ErbB family member HER2 [76, 77].

Other possible synergistic effects amongst therapeutics may be anticipated through insight into the mechanisms of action. EGFR acts upstream of the RAS signaling pathway (Fig. 8.1). RAS and EGFR mutations seem to be mutually exclusive, implying that they are interchangeable in tumorigenesis [71]. RAS mutations may allow cancers to circumvent EGFR inhibition [78]. Therefore, it seems logical that targeting the RAS pathway may also be required for inhibitors of EGFR to prevent cancer growth. Whether this proves to be the case in patients with cancer remains to be confirmed.

8.4.2 Targeting RAS

The RAS signaling pathways have been targeted using several strategies. RAS must be localized to the plasma membrane to become activated, so pharmacological strategies that prevent localization have been developed. Farnesyltransferase inhibitors (FTIs) were developed to interfere with the post-translational farnesylation process and thereby abrogate native RAS activity [79]. Initially, these compounds showed promise against tumors driven by activated H-RAS [80]. However, the activity of these drugs was not reproduced in cancer cells with K-RAS and N-RAS, the two isotypes that are much more common in human malignancies.

N-RAS and K-RAS are resistant to FTIs because they can alternatively be geranylgeranylated when farnesylation is not possible and can subsequently carry out their tumorigenic functions [81]. Unfortunately, inhibitors of geranylgeranyltransferase (GGTIs) were found to be exceedingly toxic in mice when used in combination with FTIs [82], and therefore are not a possible treatment option. More recently, *S*-farnesylthiosalicylic acid (FTS) has been identified as a drug that dislodges activated RAS from the plasma membrane. FTS has been shown to inhibit growth of human cancers xenografted into nude mice [83, 84]. Clinical studies of FTS in human trials are pending.

As a final strategy worthy of mentioning, RAS has also been targeted at the transcriptional level through the use of antisense RNA. One antisense oligonucleotide, ISIS 2503, has been administered to patients with very little toxicity. In a Phase II trial ISIS 2503 exhibited some clinical activity in patients with pancreatic cancer [85]. However, more recently interest in this clinical approach has waned, because it is now less clear that these agents can ever be efficacious in vivo.

8.4.3 Imatinib Mesylate and BCR-ABL

One of the most exciting discoveries has been the identification of imatinib mesylate for the inhibition tyrosine kinases for the treatment of chronic myelogenous leukemia and gastrointestinal stromal tumors [15–18]. Importantly, the possible importance of such a drug would perhaps never have been appreciated if it were not well known that BCR-ABL exhibits tyrosine kinase activity that is essential for its ability to mediate malignant transformation [86, 87].

Imatinib mesylate is derived from a 2-phenylaminopyrimidine backbone that exhibits inhibition of multiple kinases including ABL tyrosine kinases, PDGFR, and the c-kit tyrosine kinase [15, 88, 89]. Imatinib mesylate restricts enzyme activity by competitively inhibiting ATP access to the binding pocket of the kinase thereby preventing substrate phosphorylation. Preclinical studies confirmed that imatinib mesylate inhibits BCR-ABL activity [90].

Early phase I trials of imatinib mesylate revealed that the drug was well tolerated, and almost all patients exhibited a positive clinical response [91]. Subsequently, a phase II trial in patients with late chronic-phase CML that failed to respond to interferon-based therapy reported that 41 % experienced a complete cytogenetic response, 60 % showed a major cytogenetic response, and 89.2 % benefited from

progression-free survival at 18 months [92]. Based upon these results, the FDA approved imatinib mesylate for the treatment of CML in advanced phase disease and after failure of interferon therapy. The results of a phase III study (the IRIS trial) proved imatinib mesylate was significantly superior to interferon alpha plus cytarabine in achieving complete hematologic response, major cytogenetic response, complete cytogenetic response, and progression-free survival [93]. Imatinib mesylate was then approved as a first-line treatment for CML in the USA and Europe.

Unfortunately, cancers can become resistant to imatinib mesylate through multiple mechanisms. First, mutations occur in the kinase domain of the BCR-ABL oncoprotein that confer varying degrees of drug insensitivity [15]. Sometimes tumors with mutant BCR-ABL will respond to increased doses of imatinib mesylate [94]. Resistant tumors also appear to respond to new drugs that are not affected by these mutations [95, 96]. Second, tumors can become resistant to imatinib mesylate through BCR-ABL gene amplification and mRNA overexpression [97, 98]. Importantly, resistance to imatinib mesylate is almost always associated with reactivation of BCR-ABL signaling, suggesting that this oncogene is required to sustain tumorigenesis in CML [99].

8.4.4 Future Directions

Ideally, we would understand which oncogenes are best to target and every oncogene could be targeted for the treatment of cancer. However, we do not know for most cancers what to target. Even when there are encouraging experimental and clinical evidence that the targeted inactivation of specific gene products may be useful in cancer treatment, many gene products cannot be targeted using existing pharmacological approaches.

Notably, there are no drugs that clinically target transcription factors. We discuss some of the possible approaches to target MYC that have been employed in experimental models such as: antisense oligonucleotides (ASOs), RNAi, and cationic porphyrin TMPyP4 have been used to target MYC at the transcriptional level; peptides and small molecules have been used to disrupt MYC binding to MAX; and triple helix forming oligonucleotides (TFOs) have been used to target MYC at the posttranslational level [100–102]. Additionally, MYC may be targeted at the posttranslational level by targeting its phosphorylation sites.

ASOs and RNAi both work by hybridizing to MYC mRNA and targeting it for degradation. ASO and RNAi treatments have led to decreased MYC protein levels both in vivo and in vitro. [103–105]. The decrease in MYC results in cellular differentiation, reduced proliferation, and inhibition of G1/S progression in leukemia and lymphoma cells [106–111]. In transgenic mouse models, ASOs have prevented or delayed the onset of Burkitt's lymphoma [112–114]. An ASO type molecule with a morpholino backbone (AVI-4126) has been administered to patients in a Phase I clinical trial and was found to concentrate in the tumor tissues of breast and prostate cancer patients, with little toxicity, thus making it a viable treatment option [115, 116]. Cationic porphyrin TMPyP4 has also been used to target MYC at the transcriptional level. TMPyP4 blocks DNA structures formed during transcription in G-rich regions of DNA (G-quadruplexes) where MYC binds [117, 118]. Additionally, TMPyP4 was able to inhibit in vitro transcription of MYC and decreased growth of Burkitt's lymphoma cells [119].

Peptides and small molecules have been used to disrupt MYC binding to its dimerization partner MAX. Small peptides that mimic the helix–loop–helix (HLH) domain of MYC were found to sequester MYC and prevent MYC–MAX dimerization [120–122]. Interference with this protein–protein interaction leads to decreased proliferation of breast cancer and colon cancer cell lines [123, 124]. Peptide inhibitors are also capable of achieving high concentrations in mouse organs and may therefore be used to treat cancers [123]. Unfortunately, peptides tend to be unstable and must be administered through intravenous injection, leaving a need for the development of small chemical molecules that can effectively prevent MYC–MAX dimerization. Peptidomimetics are an attempt to increase the stability and activity of peptides. Several peptidomimetics have been made that increase stability and activity of proteins that inhibit MYC–MAX dimerization but have not been used in human trails [122, 123]. Additionally, there has been an effort to target MYC–MAX interaction using small chemical molecules [125–127]. One of these approaches uses molecular credit cards, which are planar chemicals designed to physically prevent protein–protein interaction by sliding between the two protein surfaces. In one study, potent inhibitors of MYC–MAX interaction were identified that partially prevented oncogenic transformation of chicken embryonic fibroblasts [126].

MYC has also been targeted at the DNA–protein interaction level. Triple helix forming oligonucleotides (TFOs) can disrupt transcription factor binding to DNA by attaching to purine-rich regions of DNA often found in promoter regions [128, 129]. TFOs against the promoter for MYC have been able to induce apoptosis and cell cycle arrest in several cancer cell lines [130–132]. TFOs may also be conjugated to DNA damaging agents such as daunomycin. This combination agent leads to MYC downregulation in prostate and breast cancer cell lines [133].

MYC may be marked for degradation at the posttranslational level by targeting its phosphorylation sites. MYC has two phosphorylation sites: Thr58 and Ser62. Phosphorylation of Ser62 increases MYC stability and occurs in a RAS-dependent manner. The phosphorylation of Ser62 is followed

by phosphorylation of Thr58 and leads to the degradation of MYC [134, 135]. Thus, it may possible to screen for small molecules that inhibit MYC stabilization, or facilitate MYC degradation.

8.5 The Phenomena of Oncogene Addiction

Observations in experimental transgenic mouse models and in the clinic have a central theme—although cancers are genetically complex and genomically unstable, they appear to be dependent upon the continued activation of specific oncogenes to maintain their neoplastic properties, exhibiting the phenomenon *oncogene addiction*. Thus, specific gene products that mediate critical signaling processes appear to be the most likely best targets for the treatment of cancer. Conditional transgenic mouse models have been particularly useful for validating which signaling molecules are the most useful targets, for gaining insight into the mechanism of cancer regression, and for anticipating mechanisms by which cancers can escape dependence on signaling processes. In several cases, drugs have been identified that target receptors, GTPases, and/or kinases to successfully treat humans with cancer. However, these drugs, although effective in prolonging the survival of some patients, do not cure cancer. The hope is in the future, the correct combination of drugs we will be able to cure cancer. However there are several potential difficulties.

One major difficulty is that many gene products, in particular transcription factors, are yet to be successfully targeted. Thus, we may not be able yet to target the most critical gene products. Many new approaches suggest that even these gene products can be inhibited through small molecules. It may be possible to develop effective pharmacological strategies to target critical signaling molecules for the treatment of cancer. Another problem is that we as of yet do not understand why the repair or inactivation of specific gene products induces cancer regression. Several possible cell-autonomous and cell-dependent mechanisms could account for oncogene addiction. Bernard Weinstein, who was one of the first to articulate the notion of oncogene addiction, proposed that because oncogenes in cancer cells upregulate cellular programs that drive proliferation and block apoptosis, compensatory programs such as proliferative arrest and pro-apoptotic programs are also upregulated. Thus, when a mutant oncogene is inactivated, the balance in the cancer cell shifts to proliferative arrest and/or apoptosis [136].

A final issue to consider is that cancer is not just caused by genetic events and so fixing these events may not be sufficient to reverse the process of tumorigenesis. Thus, it has recently been suggested that cancers consist of cancer stem cells, of generally low abundance, and progenitor cells, that are the majority of the tumor. The cancer stem cells have the capacity for self-renewal, whereas the progenitor cells have a limited capacity of self-renewal. Such a model, provides just one example of a circumstance where the properties that are essential to the neoplastic phenotype are not necessarily dictated by genetic events involving signaling molecules.

Observations in transgenic mouse models have led investigators to reflect on several nonmutually exclusive mechanisms for oncogene addiction. Thus, it has been proposed that oncogenes initiate tumorigenesis by hijacking stem cell features in cells such as proliferation and self-renewal [46, 64], thus driving cell cycle transit despite ongoing genomic instability [137]. Hence, upon oncogene inactivation, cancer cells recover their differentiated physiologic program, undergo proliferative arrest, become aware of their genomic damage, and/or undergo apoptosis.

Many have illustrated that upon oncogene inactivation cell nonautonomous programs such as angiogenesis are shut down, which may also contribute to cancer regression [55, 138, 139]. Hence, cell-autonomous and cell-dependent mechanisms may play a role in oncogene addiction.

One possible unifying mechanism is that oncogene inactivation restores physiologic programs that allow cancer cells to recognize that they are genomically disrupted, hence triggering programs of proliferative arrest, differentiation, cellular senescence, and apoptosis. Indeed, we have recently described that upon MYC inactivation several different cancers variously undergo cellular senescence [140]. However, other mechanisms must also be involved. Thus, oncogene inactivation also shuts down angiogenesis, suggesting that it is not only internal physiological cues that are being restored but also how the cancer interacts with the tissue microenvironment [141]. Other mechanisms are also likely to be involved that are yet to be investigated, such as the potential role of immune or inflammatory mechanisms or the possible that cellular homeostatic regulatory mechanisms are important. Ultimately, insights into the mechanism of oncogene addiction will be essential towards the development of true targeted therapeutics for the treatment and cure of cancer.

Acknowledgements We thank the members of the Felsher laboratory for their many helpful discussions. This work was supported from grants from the NCI and related programs (ICBP, ICMIC, CCNE), Emerald Foundation, Leukemia and Lymphoma Society, Damon Runyon Foundation, Burroughs Wellcome Fund, and Stanford Digestive Disease Center (D.W.F.), as well as the Developmental and Neonatal Biology NIH Training Grant (C.A.).

Positive Mediators of Cell Proliferation in Neoplasia: Growth Factors and Receptors

9

Luca Grumolato and Stuart Aaronson

9.1 Introduction

Complex signaling networks underlie the regulation of fundamental processes such as embryonic development, tissue differentiation, and systemic responses to wounds and infections. Among the major mediators of these events, growth factors are in large part responsible for the control of cell proliferation, differentiation, and survival. The specific interaction of a growth factor with its receptor initiates a cascade of intracellular biochemical reactions that ultimately mediate the biological response in the target cells. The cytoplasmic molecules that participate in these pathways have been termed second messengers—their activation allows the transmission of the signals to the nucleus and eventually the regulation of the expression of genes involved in mitogenic and differentiation responses.

Because of their important role in cell proliferation and survival, the genes involved in growth factor signaling pathways are frequently targeted in tumorigenesis. The pathogenic expression of growth factors can contribute to altered cell growth associated with malignancy, such as in the case of the *v-sis* oncogene of simian sarcoma virus (SSV), which encodes a protein homologous to the B chain of human platelet-derived growth factor (PDGF-B) [1, 2]. Other oncogenes have been shown to encode membrane-spanning growth factor receptors [3, 4] or genes involved in growth factor signal transduction [5, 6]. Present knowledge indicates that the constitutive activation of growth factor signaling pathways through genetic alterations affecting these genes contributes to the development and progression of most, if not all human cancers.

The focus of this chapter is on the normal aspects of growth factor signaling and the alterations that have been implicated in the etiology of human malignancies. Because of the limits of space, the discussion will mainly cover growth factor signaling mediated by receptors with intrinsic protein tyrosine kinase activity. Finally, we will discuss how a better understanding of growth factor signaling may be useful in efforts to design new approaches toward therapeutic intervention with the malignant process.

9.2 Background

The first growth factor was discovered in the 1950s by neurobiologist Rita Levi-Montalcini, who observed that a soluble factor released by mouse sarcoma cells dramatically stimulated the growth of sensory and sympathetic neurons in chicken embryos. This nerve growth factor (NGF), which consists of two chains of 118 amino acids, was subsequently purified by Stanley Cohen from snake venom and mouse salivary glands [7]. During these studies, Cohen discovered another factor present in mouse salivary glands and capable of promoting precocious eyelid opening and tooth eruption in newborn mice. Because of recognition of its effects on epithelial cells, this factor was designated epidermal growth factor (EGF) [8]. The isolation and characterization of NGF and EGF opened the way to the identification, in a number of laboratories, of a series of growth factors, which were often given names based on the tissue or cell of origin, or the target cell initially found to be stimulated.

An important discovery concerning growth factors came from the demonstration of a unique enzymologic activity associated with binding of EGF to its receptor (EGFR) [8]. Studies of the product of the viral oncogene, *v-src*, had led to the demonstration of its ability to act as a protein kinase

[9, 10]. It was well established that phosphorylations and dephosphorylations affected the activities of a variety of proteins, and many protein kinases had been previously identified. However, unlike theses kinases, which have the capacity to phosphorylate serine and/or threonine residues, the *src* product was shown to phosphorylate tyrosine residues [11]. Cohen then demonstrated that addition of EGF led to phosphorylation of its purified receptor on tyrosine residues [8]. Subsequent studies have established that tyrosine kinase activity is central to the functions of a large number of mitogenic signaling molecules.

Several major modes of action for growth factors have been described. Sporn and Todaro [12] defined autocrine and paracrine as major modes of action for growth factors in addition to the classical means by which hormones travel great distances from their sites of production. The autocrine mode refers to the ability of growth factor to act on the same cell releasing it. In the paracrine mode, the released growth factor from one cell acts on a nearby or adjacent cell. Certain growth factors also exist as membrane-anchored forms, which can bind and activate membrane receptors only on adjacent cells. This process, considered a variant of the paracrine mode, has been termed juxtacrine [13] and is capable of delivering spatially localized intercellular stimuli. A number of researchers have observed that factors that are produced in cells, but are not detectably secreted, nevertheless can induce observable phenotypic changes in those cells. The suggestion has been made that this represents an intracrine mode of action, whereby the factor interacts with its receptor directly inside the cell [14]. An example of this mechanism has been shown in acute myeloid leukemia, where the vascular endothelial growth factor (VEGF) internally activates its cognate receptor VEGFR-2/KDR/Flk-1 (kinase insert domain containing receptor/fetal liver kinase-1) to promote cell survival [15]. A sixth mode of action, in which the growth factor is bound to and stored within the extracellular matrix before presentation to the receptor on the cell surface, has also been demonstrated [16].

9.3 Growth Factor Receptors with Tyrosine Kinase Activity

9.3.1 RTK Structure

Many growth factors mediate their biological function through the binding to a family of cell surface receptors with intrinsic tyrosine kinase activity (RTKs). These receptors present a general common structure: a large, glycosylated, extracellular ligand-binding domain, a single transmembrane region, and a cytoplasmic portion with a conserved protein tyrosine kinase domain, which catalyzes the transfer of the γ-phosphate of adenosine triphosphate (ATP) to tyrosine residues within the receptor and to other substrates (Fig. 9.1). In addition to the catalytic domain, a juxtamembrane region and a carboxyl-terminal tail can be identified in the cytoplasmic portion [17]. Because of their structure, RTKs can be visualized as membrane-associated allosteric enzymes with the ligand binding and protein tyrosine kinase domains separated by the plasma membrane [18].

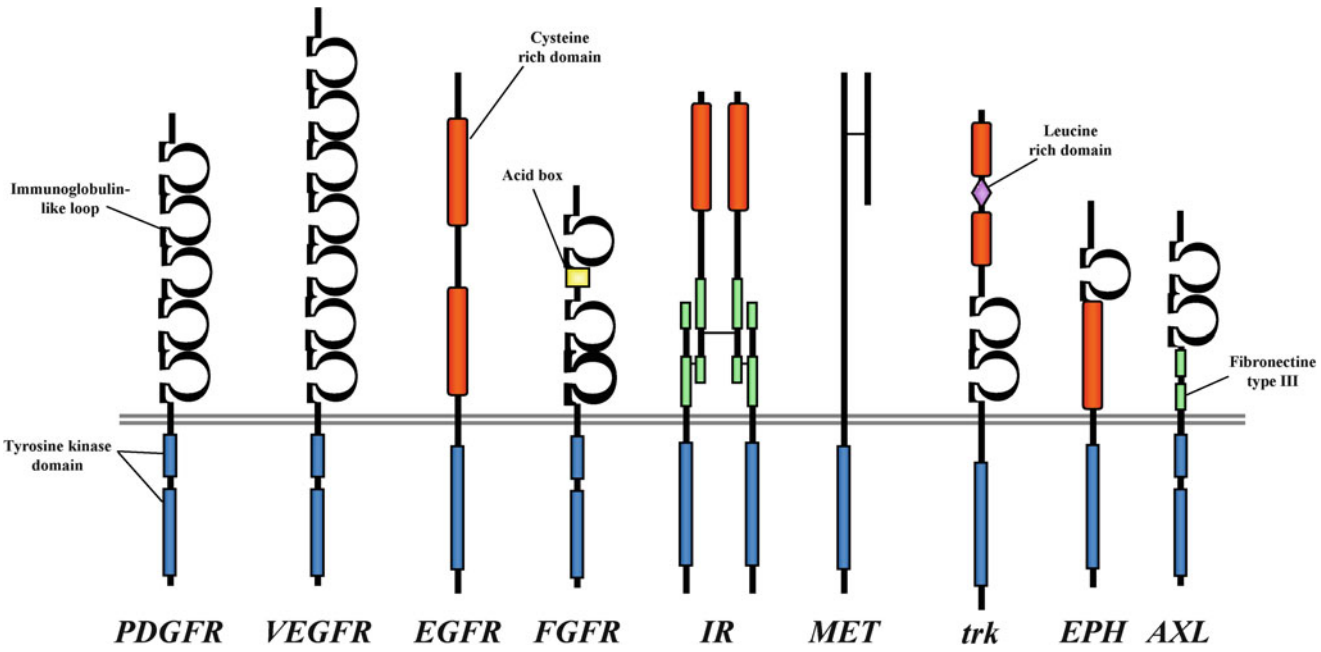

Fig. 9.1 Receptor tyrosine kinase families. Simplified scheme depicts the structural features of the major families of tyrosine kinase receptors.

The extracellular domain of RTKs is poorly conserved among the different subfamilies and displays characteristic structural features that help to determine specificity for ligand binding. These include cysteine-rich motifs, immunoglobulin-like repeats (Ig-like), fibronectin (FN) type III repeats (FNIII), and EGF motifs that can be present singly or in different combinations.

The main function of the transmembrane domain is to anchor the receptor in the plane of the plasma membrane, thereby connecting the extracellular environment with internal compartments of the cell. It was initially thought that this domain represented a passive anchor of the receptor to the membrane [19]. However, point mutations in the transmembrane domain of *neu*/erbB-2 enhance receptor dimerization and consequently its activity and transforming properties [20–22], implying that the transmembrane domain can play an important role to determine the correct conformation of the receptor.

The juxtamembrane sequence that separates the transmembrane and cytoplasmic domains is highly similar within the same receptor family but it is not conserved among different RTK groups. Studies indicate that this domain plays a role in modulation of receptor functions by heterologous stimuli, a process termed receptor transmodulation [19]. For example, addition of PDGF to many types of cells causes a rapid decrease in high affinity binding of EGF to its receptor. This has been shown to be a downstream effect of PDGF receptor (PDGFR) activation in which protein kinase C, itself a serine protein kinase, is activated and in turn phosphorylates a site in the juxtamembrane domain of the EGFR [23]. This region may also play a role in signaling, through the binding to specific substrates in a ligand-dependent manner. For example, it has been shown that *eps8* directly binds to the juxtamembrane domain of EGFR in a phosphotyrosine-independent and SH2-independent manner [24].

The high degree of conservation between the tyrosine domains of receptors belonging to different RTKs families has allowed the identification of several new members by molecular cloning. This domain is absolutely required for receptor signaling: mutation of a single lysine in the ATP binding site, which blocks the ability of the receptor to phosphorylate tyrosine residues, completely inactivates receptor biologic function. Conversely, activating mutation in the tyrosine kinase domain of some RTKs, such as EGFR, have been observed in cancer [25]. These EGFR mutations have a great impact on the choice of the best therapeutic strategy. The kinase domain of some receptor tyrosine kinases, e.g., PDGFR and fibroblast growth factor receptor (FGFR), is split by insertions of up to 100, mostly hydrophilic, amino acid residues. Kinase insertion sequences are highly conserved between species, suggesting an important role of this domain in receptor function. In fact, this region contains important autophosphorylation sites that mediate the coupling with signal transduction [19, 26].

The carboxyl-terminal domains are among the most divergent between known RTKs [23] and they are involved in the regulation of the kinase activity. The tyrosine residues typically present in this region are phosphorylated following ligand stimulation and play an important role in the specific activation of second messengers by RTKs.

9.3.2 Mechanisms of RTK Activation

There is substantial evidence that ligand-induced activation of the kinase domain and its signaling potential are mediated by receptor oligomerization [19]. This event stabilizes interactions between adjacent cytoplasmic domains and controls the activation of kinase activity. Dimerization can take place between two identical receptors (homodimerization), between different members of the same receptor family, or in some cases between a receptor and an accessory protein (heterodimerization) [26]. Heterodimerization of RTKs has been shown to increase the repertoire of ligands that can be recognized by each receptor alone and to expand the diversity of signaling pathways that can be recruited by a given receptor.

How ligands bind to the receptors and induce oligomerization seems specific for each class of RTKs [27]. PDGF, for example, induces receptor dimerization by virtue of its dimeric nature [28]. EGF, instead, binds its receptor as a monomer and dimerization occurs by subsequent association of two EGF-EGFR complexes [29]. FGF is a monomeric ligand like EGF, but it needs the association of heparan sulfate proteoglycans to induce receptor dimerization [30]. Interestingly, the insulin receptor (IR) family exists as disulfide-bonded homodimers or heterodimers of receptor subunits. Thus, ligand binding does not induce receptor dimerization, but presumably causes a conformational change in the preformed dimeric receptor, which leads to receptor activation (Fig. 9.2).

In the unphosphorylated state, RTKs possess a low catalytic activity due to the particular conformation of a specific domain in the kinase region, which interferes with the phosphotransfer event. Although this kinase activity is at a low basal level in the monomeric state, it is sufficient to induce *trans*-autophosphorylation in the cytoplasmic portion of the RTK once the dimer forms. This event stabilizes the tyrosine kinase domain in an active conformation, leading to further phosphorylation in *cis* of other tyrosine residues within the catalytic domain and the carboxyl-terminal tail, creating docking sites for downstream signal transduction molecules.

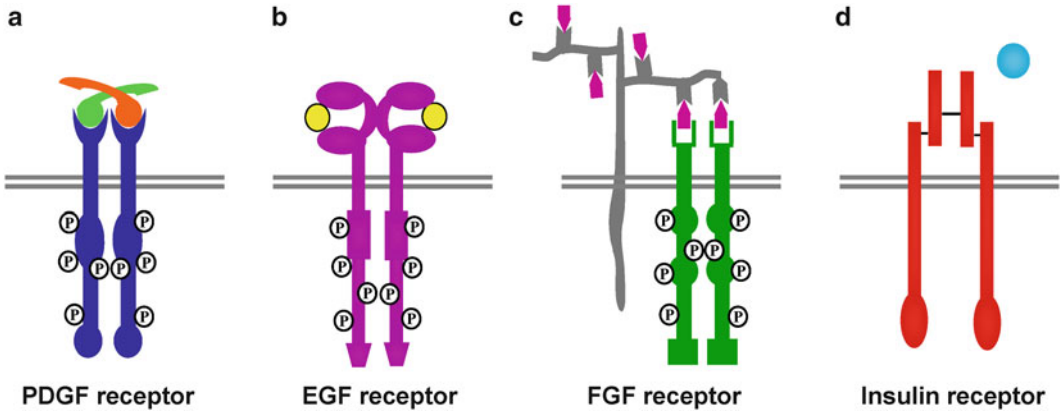

Fig. 9.2 Dimerization and activation of RTKs. Diagram illustrating different mechanisms for dimerization and activation of RTK. (**a**) PDGF ligands are dimers that induce dimerization by their cognate receptors. (**b**) EGF induces a conformational change within its receptor that allows receptor dimerization. (**c**) FGF ligands associate with heparan sulfate proteoglycans that contribute to the dimerization of their cognate receptors. (**d**) The insulin receptors exist as inactive dimmers, and the ligands cause a conformational change that induces receptor activation.

9.4 The Role of Growth Factors and Their Receptors in Malignancy

9.4.1 Platelet-Derived Growth Factor Family

PDGF is the major protein growth factor in human serum and is a markedly heat-stable, cationic protein that consists of four related but nonidentical polypeptide chains. While PDGF-A and PDGF-B have been extensively studied since the 1970s, PDGF-C, and PDGF-D have been only identified in 2000 [31–33] and 2001 [34–36], respectively, using bioinformatics approaches. The PDGF ligands contain a characteristic motif named cystine knot and formed of regularly spaced cysteine residues that allow intramolecular and intermolecular bonds [37]. All PDGF molecules form disulfide-linked homodimers, but PDGF-A and PDGF-B can also exist as heterodimers. Unlike PDGF-A and PDGF-B, which are secreted as active ligands, PDGF-C and PDGF-D become active following cleavage of their N-terminal domain [38]. The two PDGF receptors, PDGFRα and PDGFRβ, exhibit distinctive features, including the five immunoglobulin-like domains in the extracellular portion [39] and the presence of a large kinase insert within the tyrosine kinase domain. There are reports that the kinase insert is required for interaction with certain substrates [40], and deletions in this domain impair receptor mitogenic signaling [41]. As the four PDFG ligands, PDGFRs are encoded by distinct genes [42] and form homo-dimers or hetero-dimers [43]. Ligands have different affinity for the different receptor combinations: AA binds αα, CC and AB bind αα and αβ, BB binds all the three receptor dimers, and DD binds αβ and ββ [38]. Receptor dimerization caused by binding to the ligand induces cross phosphorylation in the cytoplasmic domain on several tyrosine residues, which act as docking sites for protein complexes mediating the activation of second messengers. This is an example of the fine degree of regulation that can evolve in the interactions of ligands with their receptors. Presumably, in the case of PDGF, this relates to quantitative regulation of responses based upon differential availability in tissues of ligands and receptors, since there is evidence that the two PDGF receptors themselves are each capable of mediating the major known PDGF responses including mitogenic signaling and chemotaxis [44].

Gene inactivation of the PDGF receptors and ligands has demonstrated that this signaling is essential during embryonic development. In particular, these studies have shown that PDGF-B and PDGFRβ are crucially involved in vessel formation, while PDGF-A/C and PDGFRα play a broader role in different processes, such as central nervous system, neural crest, and organ development [37, 45]. More specific strategies, including conditional knockout and knockin approaches, have been used to address the primary functions of PDGF signaling during development [45, 46].

The gene for the PDGF-B chain is the human homologue of the *v-sis* oncogene of SSV [1, 2]. The transforming protein expressed by SSV shares close structural similarities with PDGF-B chain homodimers [47]. PDGF-B has been detected in human cancer cells [48, 49] that also possess PDGF receptors. These findings, taken together with the demonstration that the normal PDGF-B gene can act as an oncogene when expressed at high levels [50], suggest that PDGF-B plays a role in the development of certain human cancers (Table 9.1). The PDGF-A chain is frequently expressed by human cancer cells, and AA homodimers are produced by osteosarcoma [51], melanoma [52], and glioblastoma cells [53], which can display autocrine activation of PDGF signaling [54]. Of note, a translocation between chromosomes 17 and 22 in dermatofibrosarcoma protuberans has been shown to bring the PDGF-B gene

Table 9.1 Role of RTKs and their ligands in human cancer

Family	Gene	Mechanism	Tumor
PDGF	*PDGF-A*	Autocrine loop	Glioblastoma, melanoma, osteosarcoma
	PDGF-B	Translocation-autocrine loop	Dermatofibrosarcoma protuberans
	PDGF-C, PDGF-D	Autocrine loop	Glioblastoma, Ewing sarcoma, medulloblastoma, and prostate cancer
	PDGFRα	Activating mutation	GIST
	PDGFRα, PDGFRβ	Translocation	Hematological malignancies
	CSF-1	Paracrine	Breast carcinoma
	c-kit	Activating mutation	GIST
	SCF	Autocrine, paracrine	SCLC, testicular germ cell tumor
	Flt3	Activating mutation	AML
VEGF	*VEGFs*	Paracrine (angiogenesis and lymphangiogenesis)	Several tumors
	PlGF	Autocrine, paracrine	ALL, Ewing's sarcoma
EGF	*TGF-α*	Overexpression	Lung, ovary, colon, prostate, pancreas tumors
	NRG1	Overexpression	Mammary adenocarcinoma
	EGFR	Overexpression	Head and neck tumors
	EGFR	Activating mutations	NSCLC, brain tumors
	ErbB-2	Gene amplification	Breast and ovarian carcinoma
FGF	*FGF-2*	Autocrine	Pituitary adenoma, prostatic and pancreatic cancer
	FGF-3	Autocrine	Mammary and prostate hyperplasia, NSCLC
	FGFR1	Translocation	Hematological malignancies
	FGFR2, FGFR3	Mutations	Gastric cancer, bladder and cervical carcinomas, myelomas, and skin cancer
Insulin	*IGF-I, IGF-II*	Overexpression	Glioblastoma, medulloblastoma, breast, colorectal and pancreatic carcinomas, ovarian cancer
	IGF-IR	Overexpression	Breast and prostate tumors
	IGF-IR	Gene amplification	Breast and pancreatic cancer, melanoma
HGF	*MET*	Mutation (familial)	Hereditary papillary renal carcinoma
	MET	Mutation (sporadic)	Sporadic papillary renal carcinoma, hepatocellular carcinoma, gastric cancer
	MET	Overexpression	Hepatocarcinoma, colorectal, pancreas, stomach, prostate, ovary and breast carcinomas
	RON	Mutations	Gastrointestinal tumors
NGF	*trkA*	Translocation	Papillary thyroid carcinoma
	trkB	Overexpression	Pancreatic and prostatic carcinoma
	trkB, trkC	Mutations	Colon cancer
	trkC	Translocation	Congenital fibrosarcoma, secretory breast carcinoma
Axl	*Axl*	Overexpression	Lung cancer, breast carcinoma, glioma
Ephrin	*EPHB*	Loss of expression	Colorectal tumor
GDNF	*RET*	Mutation (familial)	MEN 2 (medullary thyroid cancer, pheochromocytoma)
	RET	Mutation (sporadic)	Medullary thyroid cancer
		Chromosomal rearrangements	Papillary thyroid cancers
DDR	*DDRs*	Overexpression	Breast cancer
Orphan receptors	*c-ros*	Overexpression, translocation	Brain tumors

under the control of the widely expressed collagen type 1 alpha 1 promoter, leading to an autocrine loop [55]. The more recently discovered PDGF-C and PDGF-D ligands have been reported to possess transforming capacity in some glioblastomas [56] and may be involved in different types of cancers, including Ewing sarcoma, medulloblastoma, and prostate cancer [37]. Aberrant stimulation of PDGF signaling in cancer can also be caused by ligand-independent activation of PDGFRs. For example, mutations in the catalytic and juxtamembrane domains of PDGFRA have been identified in gastrointestinal stromal tumor (GIST), a rare malignancy of mesenchymal origin [57]. Of note, PDGFRA and c-kit mutations in GIST are mutually exclusive, indicating that these RTKs activate common oncogenic downstream pathways in this type of cancer [57, 58]. Another mechanism of ligand-independent activation of PDGFRs has been described in hematological malignancies, where gene translocations can provoke the fusion of PDGFRα or PDGFRβ catalytic domain with different partner proteins [57].

Colony stimulating factor 1 (CSF-1) or macrophage-colony stimulating factor (M-CSF) also belongs to the PDGF family of RTKs [59]. This molecule promotes the growth and maturation of monocytes and macrophage precursors. It also enhances the phagocytic and tumoricidal activity of human macrophage/monocytes and induces them to secrete a variety of different cytokines [60]. Two active forms, one of which is secreted and the other cell associated, arise from differential splicing. The *c-fms* proto-oncogene encodes the CSF-1 receptor [4], another member of this RTK family, which is expressed in cells of the monocyte/macrophage lineage, as well as in the central nervous system (CNS) and placental trophoblasts [61]. Several studies have reported elevated CSF-1 serum concentration in patients affected with different types of cancer [62], and it has been proposed that CSF-1 can stimulate tumor growth and progression to metastasis [63]. For example, one study showed that the invasiveness of breast carcinoma is promoted through a paracrine positive loop between cancer cells secreting CSF-1 and macrophages producing EGF [64].

Stem cell factor (SCF), also designated kit ligand, mast cell growth factor, or steel factor, is a hematopoietic and tissue growth factor consisting of a glycosylated 165 amino acid polypeptide that forms dimers [65]. SCF exists in a secreted or a membrane bound form, resulting from alternative splicing. The SCF/kit ligand is present at relatively high levels in human plasma and it has been shown to augment the in vitro proliferation of both myeloid and lymphoid hematopoietic progenitor cells in the presence of other cytokines [66, 67]. SCF binds to a RTK encoded by the *c-kit* proto-oncogene. The extracellular portion of c-kit contains five immunoglobulin-like domains, which determine the binding specificity and facilitate dimerization. An intracellular juxtamembrane domain separates the transmembrane region and the kinase domain. It has been shown that *c-kit* is frequently mutated in GIST. Activating mutations in *c-kit* gene have been reported on exon 9, 11, and 13, encoding the extracellular dimerization domain, the juxtamembrane domain and the kinase domain, respectively [68]. Other malignancies showing activation of SCF-c-kit signaling through an autocrine or paracrine mechanism include small cell lung cancer (SCLC) and testicular germ cell tumor [68].

The Flt3 ligand is a transmembrane protein that undergoes proteolytic cleavage to generate a soluble factor with a certain similarity in the conserved cysteine residues with the kit ligand [65]. The Flt3 receptor was cloned by low stringency hybridization with a c-fms probe [69] and contains, as the other members of this family of RTKs, an extracellular domain with five immunoglobulin-like domains, a transmembrane region, a cytoplasmic juxtamembrane domain, and two kinase domains liked by a kinase-insert domain [70]. Flt3 is expressed at high levels in CD34+ short-term hematopoietic stem cells, and the Flt3 ligand exerts a proliferative effect on both the myeloid and lymphoid lineages, usually in combination with other cytokines [70]. Activating mutations of Flt3 are the most frequent genetic abnormality in acute myeloid leukemia (AML) and include in-frame tandem duplications in the juxtamembrane domain or missense point mutations in the kinase domain [70].

9.4.2 Vascular Endothelial Growth Factor Family

Efforts to identify factors that control angiogenesis led to the identification of a potent mitogen for vascular endothelial cells of small and large vessels [71, 72]. VEGF was initially isolated from conditioned medium of folliculostellate and bovine pituitary follicular cells [73]. Similar to PDGF, VEGF contains a cystine-knot domain, and the two growth factors are thought to derive from a common ancestor polypeptide [74]. The most abundant and active member of the family, VEGF-A, is a glycosylated, dimeric heparin binding protein capable to stimulate angiogenesis and to increase the permeability of capillary vessels to different macromolecules. Alternative splicing originates several isoforms of VEGF-A. The predominant human isoforms, VEGF-A-121 and VEGF-A-165, are secreted from producing cells, whereas VEGF-A-189 and VEGF-A-206 are not efficiently secreted and seem to bind tightly to cell surface heparin-like molecules [75]. Substantial evidence indicates that the binding of the best-studied form VEGF-A-165 to its receptor is dependent on cell surface associated heparin-like molecules. Four additional endothelial growth factors, which are structurally related to VEGF, have been reported [76–78]. VEGF-B and its alternatively spliced isoform, described as

VEGF-related factor (VRF) [79], are predominantly expressed in embryonal and adult myocardial and skeletal muscle tissues. VEGF-B isoforms can bind VEGFR-1 but not VEGFR-2 or VEGFR-3 [77]. Inactivation of the gene encoding VEGF-B suggested an involvement of this growth factor in heart development and inflammatory angiogenesis [77]. VEGF-C is a ligand for VEGFR-2 and VEGFR-3 receptors, and it is expressed in different organs including the heart, small intestine, placenta, ovary, and the thyroid gland [77]. Mice lacking both VEGF-C alleles die of edema due to incomplete development of lymphatic vessels, while the loss of one VEGF-C allele provokes less severe defects in lymphatic vasculature [78]. VEGF-D binds VEGFR-2 and VEGFR-3 and has both angiogenic and lymphangiogenic properties. VEGF-D is present in most human tissues, with highest expression levels in the lung and skin during development [78]. It has been shown that both VEGF-C and VEGF-D play important roles in promoting tumor-induced lymphangiogenesis [80, 81]. The last member of the VEGF family of growth factors, VEGF-E, was discovered in the genome of the parapoxvirus, which provokes skin lesions with extensive capillary proliferation [82]. VEGF-E is a potent angiogenic factor that binds with high affinity to the VEGFR-2 receptor [78]. More recently, a new VEGF was identified in snake venom and called VEGF-F [78].

Three high-affinity receptors for VEGF have been identified [75, 78]. These receptors, termed VEGFR-1/Flt1 [83], VEGFR-2/KDR/Flk-1 [84] and VEGFR-3/Flt4 [85] are characterized by an extracellular region containing seven (VEGFR-1 and VEGFR-2) or six (VEGFR-3) Ig-like domains and a tyrosine-kinase interrupted by a large kinase insert. VEGFRs are expressed by vascular endothelial cells although expression has also been detected in certain hematopoietic cells, such as monocytes, and in melanoma cell lines. VEGFR-1 was initially considered a decoy receptor reducing the levels of circulating VEGF, but more recent studies have shown that VEGFR-1 can mediate mitotic signals and be involved in the recruitment of endothelial progenitor cells [86]. VEGFR-2 is reported as a major regulator of vasculogenesis and angiogenesis. Its biologic role has been clarified by disruption of this gene in mouse embryos, which failed to develop both endothelial and hematopoietic cells [87]. Heparan sulfate proteoglycan and neurophilin can act as co-receptors by enhancing binding of several VEGF isoforms to VEGFR-2 [75]. VEGFR-3 expression pattern and knockout studies suggest that this receptor is essential during embryogenesis for the development of blood vessels, but it becomes redundant in mature vessels [77]. It has been shown that VEGF-A can promote cell migration and proliferation through direct activation of PDGFR-α and PDGFR-β in human mesenchymal stem cells, providing evidence of cross talk between VEGF and PDGF signaling pathways [88].

Placenta-derived growth factor (PlGF) is another member of this family originally discovered in the placenta [89] and also expressed in the heart and lungs. PlGF forms homodimers or heterodimers with VEGF and binds to VEGFR-1 [78]. PlGF inactivation revealed that this growth factor is not involved in embryonic angiogenesis but it is required in angiogenesis, plasma extravasation, and collateral growth in response to ischemia and inflammation or during wound healing [90]. PlGF has been implicated in colorectal cancer, acute lymphoblastic leukemia (ALL), and Ewing's sarcoma [78].

9.4.3 Epidermal Growth Factor Family

EGF consists of 53 amino acids constrained by three internal disulfide bonds and is generated from a 1200 residue precursor containing 8 units similar to EGF. This precursor is a glycosylated transmembrane protein that undergoes proteolytic cleavage by cell-surface proteases to release the mature form of the ligand [91–93]. Other members of this widely expressed EGF family include transforming growth factor-α (TGF-α) [94], amphiregulin (AR) or schwannoma-derived growth factor (rat homologue of AR), heparin-binding EGF (HB-EGF), betacellulin, the poxvirus mitogens (vaccinia, Shope, and myxoma growth factors), epiregulin, and the neuregulin family. All of these molecules share sequence similarity, at least 28 % sequence identity, and 100 % conservation of the six cysteine residues within the mature sequence of EGF. This EGF-like motif (XnCX7CX2-3GXCX10-13CXCX3YXGXRCX4LXn) is also present in diverse proteins found associated with the cell surface or extracellularly but that are not ligands for the EGF receptor [95]. With the exception of the neuregulins, all of these proteins are able to bind to the EGF receptor and show mitogenic effects on EGF-responsive cells [95, 96]. The membrane-bound form of some of these ligands, including EGF and TGF-α, may interact with receptors on the surface of adjacent cells, thereby potentially contributing to cell–cell adhesion and to cell–cell stimulation [94].

Different ligands of the EGF family bind and activate the same receptor, implying a substantial functional redundancy within the family. Nonetheless, quantitative differences in their biologic activities have been demonstrated. TGF-α was initially identified in culture fluids from various oncogenically transformed cells [97], which gave rise to its designation as a transforming growth factor. TGF-α and EGF display similar ability to bind, activate, and down-modulate the EGF receptor in mammalian cells [97]. EGF is normally expressed in kidney and submaxillary glands and is produced in response to gastrointestinal tract injury [8], while TGF-α appears to be normally expressed by a variety of epithelial cells [94].

AR was initially purified from conditioned medium of a human breast adenocarcinoma, MCF-7, treated with phorbol 12-myristate 13-acetate [98]. Relative to EGF, AR contains a very basic 40 amino acid stretch at its N-terminus, which is also rich in potential N-linked and O-linked glycosylation sites. AR is a heparin-binding growth factor, whose bioactivity can be inhibited by heparin sulfate [99]. It has also been shown that extracellular heparan sulfate proteoglycans are essential for mediation of its mitogenic signal by EGFR [100]. Studies have demonstrated the important role of AR in kidney and postnatal mammary development [101, 102], as well as liver regeneration [103].

HB-EGF was initially purified from conditioned medium of macrophage-like U937 cells, and it is a more potent mitogen for smooth-muscle cells than either EGF or TGF-α [104]. It is also active on fibroblasts, but not endothelial cells. Like TGF-α and AR, HB-EGF is secreted by means of proteolytic cleavage of a transmembrane precursor. In some instances, this processing does not occur with a high degree of fidelity and at least five different forms with amino-terminal heterogeneity have been identified [105]. It has also been demonstrated that the membrane-anchored form of HB-EGF acts as the diphtheria toxin receptor [106]. Betacellulin, initially isolated from an insulinoma-derived cell line, is a potent mitogen for retinal pigment epithelial cells and vascular smooth-muscle cells [107]. Epiregulin was identified as a novel EGFR ligand, isolated from the conditioned medium of a tumorigenic clone of NIH3T3 fibroblasts. It was shown to be capable of inhibiting the growth of several epithelial tumor cells and stimulating the proliferation of fibroblasts, hepatocytes, and smooth-muscle cells [108].

Purification of rat and human stimulatory proteins for the second member of the EGF receptor family led to the isolation of cDNAs encoding novel EGF-related proteins. The 44 kDa rat factor, termed Neu differentiation factor (NDF), stimulates p185neu tyrosine phosphorylation and induces the production of milk components in certain breast carcinoma cell lines [109]. The homologous human factors, termed heregulins (HRGs) or neuregulins (NRGs), were found to be mitogenic for certain mammary tumor cells [110]. These factors are encoded by the same gene, NGR-1, through alternative splicing of at least six recognizable domains: the N-terminal region, an immunoglobulin (Ig) motif, a glycosylation-rich spacer motif, an EGF-like domain, a hydrophobic transmembrane domain, and a cytoplasmic tail [111]. At least 26 different NRG-1 isoforms have been described in different species, including the acetylcholine receptor inducing activity, and glial growth factors (GGF). Based on the N-terminal domain, these isoforms are divided into three types: HRG (type I), GGF (type II), and sensory and motor neuron derived factor (SMDF, type III) [112]. Another characteristic used to classify NRG-1 isoforms is the presence of exon α or β, which encode the last cysteine of the EGF motif. It has been shown that β isoforms have higher receptor affinity and are generally more potent than α isoforms [112]. Like TGF-α, NRGs display a wide distribution in many tissues and organs. Moreover, the expression patterns of some isoforms are tissue specific. For example, the α2 isoform is the predominant form in mesenchymal tissues, whereas the β1 isoform is enriched in brain tissue and spinal cord [111, 112]. Three other genes with a high degree of homology to NRG-1 and displaying different affinities for EGFRs have been identified. NRG-2 and NRG-3 are expressed predominantly in neural tissues both in embryos and adults. NRG-4 was detected in adult pancreas and weakly in muscle [96, 112].

The EGFR was identified and isolated by biochemical techniques and shown to be the cellular homologue of the *v-erbB*, a retroviral oncogene [113]. The other members of the EGF/ErbB receptor family were isolated from genomic DNAs and cDNA libraries by low-stringency hybridization techniques using conserved tyrosine kinase domain probes and include ErbB-2, (also known as HER-2, for homologue of the human EGF receptor, or c-neu for homologue of the rat proto-oncogene neu), ErbB-3, and ErbB-4 [96, 114]. The extracellular domains of each of these molecules contain cysteine-rich motifs in two distinct regions and an uninterrupted tyrosine kinase domain. Whereas the EGFR and ErbB-2 are expressed in a wide variety of cell types, the expression of ErbB-3 is restricted to cells of epithelial or neuroectodermal origin. The four members of this family are normally co-expressed in various combinations in many tissues other than the hematopoietic system [96, 115]. ErbB-2 and ErbB-3 are nonautonomous receptors: ErbB-2 lacks the capacity to interact with a growth factor, whereas ErbB-3 lacks functional kinase domain. However, these two receptors are capable of generating a potent signal through heterodimerization with EGFR, ErbB-4, or each other [93]. EGF family ligands have been classified based on their affinity for EGF/ErbB receptors. The first group of ligands binds to the EGFR and includes EGF, TGF-α, AR, HB-EGF, betacellulin, and epiregulin. The second group, represented by betacellulin, HB-EGF, and epiregulin, binds the EGFR and ErbB4, while all NRGs bind to ErbB3 and ErbB4. ErbB receptor heterodimerization allows the receptors to work synergistically by expanding the array of signaling events that can be activated by a single molecule [116]. Gene inactivation of different components of the EGF signaling showed its crucial role in development, in particular in skin, gastrointestinal tract, kidney, mammary gland, and heart [93, 117]. An aberrant activation of the EGF signaling is a common event in many types of cancer and it can be due to different mechanisms. For example, autocrine production of EGF, TGFα, or NRGs is associated with reduced patient survival in different cancers [93, 118]. Studies have shown that over-expression of EGFR occurs in 80 % of head and neck

cancers, whereas ErbB-2 amplification is frequent in breast and ovarian carcinomas [93, 96]. Large deletions in the dimerization and ligand-binding domain of EGFR are relatively common in brain tumors, while activating mutation in its catalytic domain are present in 10–35 % of non-small-cell lung cancers (NSCLC), according to the population studied [25, 93]. Of note, rare mutations have also been reported for the kinase domain of ErbB-2 in NSCLC with wild-type EGFR and KRAS [119].

9.4.4 Fibroblast Growth Factor Family

FGFs comprise a family of growth factors present throughout evolution from nematodes to human that exert mitogenic activities toward a wide variety of cells of mesenchymal, neuronal, and epithelial origin. While *Caenorhabditis elegans* and *Drosophila* possess only two and three FGF genes, respectively, vertebrate FGF families are larger, ranging from ten genes in Zebrafish to 22 in mouse and human, including acidic FGF (aFGF, FGF-1), basic FGF (bFGF, FGF-2), int-2 (FGF-3), hst/KS3 (FGF-4), FGF-5, FGF-6, keratinocyte growth factor (KGF or FGF-7), androgen-induced growth factor (AIGF or FGF-8), and glia activating factor (GAF or FGF-9) [120–122].

The first to be isolated, bFGF, was recognized in certain hormone preparations by its mitogenicity for fibroblasts and chondrocytes and was later purified as a heparin-binding polypeptide from bovine pituitary. aFGF was purified independently from acidic extracts of bovine brain [123]. Both acidic and basic FGF are pleiotropic factors, capable to induce a strong angiogenic response in vivo, but are also involved in other processes, including neuronal regeneration and bone development [124]. Because of their proliferative effects, aFGF and bFGF have been implicated in different types of cancer [124, 125]. These two growth factors are single-chain polypeptides of about 17 kDa and share 55 % amino acid sequence identity. A striking feature of their structures, in contrast to those of most other family members, is the lack of a consensus secretory signal peptide. This has generated a great deal of speculation regarding their mode of release from cells. It has been shown that under stress conditions, such as hypoxia and low serum, cells secrete aFGF through the formation of a Cu^{2+}-dependent multiprotein complex that includes the S100A13 protein [126]. Conversely, the release of bFGF is constitutive, and it depends on Na^+/K^+ ATPases [124, 126]. Of note, higher molecular weight isoforms of bFGF have been identified that are expressed not only in the cytosol and the extracellular environment, but also in the nucleus, suggesting that products of the FGF-2 gene may act through alternative mechanisms in addition to signaling through their cell surface receptor [124].

Analysis of DNA of mammary tumors induced by mouse mammary tumor virus (MMTV) revealed that the viral genome frequently integrates within a genetic locus termed *int-2* and thereby activates expression of this gene by insertional mutagenesis. The protein encoded by *int-2*, renamed FGF3, is predicted to be 245 amino acids long and highly similar to aFGF and bFGF. The normal expression of FGF3 is apparently limited to embryonic tissues, and there is evidence from in vitro translation studies that it is a weak mitogen for mammary epithelial cells. A recent study revealed that individuals affected with a particular form of deafness presented a missense mutation in the *FGF3* gene, indicating an important role of this growth factor in the development of the inner ear [127]. Transgenic mouse experiments have shown that FGF3 expression leads to mammary gland hyperplasia in female mice and benign epithelial hyperplasia in the prostate of males [128]. A potential role of FGF3 has also been proposed for NSCLC, where it is frequently overexpressed together with EGFR [129].

FGF-4 and FGF-5 were uncovered during searches for oncogenes in human tumor cells [123, 130]. FGF-4 was isolated independently from a human stomach tumor (hst) and a Kaposi's sarcoma (KS3). It is mitogenic for vascular endothelial cells, human melanocytes, and mouse NIH/3T3 fibroblasts [123]. The FGF-5 gene was also isolated by DNA transfection, but by use of a selection system in which cell proliferation was dependent on abrogation of growth factor requirements. FGF-5 was activated by a DNA rearrangement that juxtaposed a retrovirus transcriptional enhancer upstream of its natural promoter. FGF-5 was found to be mitogenic for mouse fibroblasts and bovine heart endothelial cells [123].

An elegant demonstration of the critical importance of different FGF family members at specific phases of normal development derives from gene knockout experiments in mice. Such studies have shown that FGF-4 is required at a very early stage of development involving implantation of the embryo [131]. The absence of FGF-5 is associated with a very different phenotype, in which affected mice develop apparently normally and show only increased hair length following birth [132].

Isolation of additional members of gene families is sometimes possible by low-stringency molecular hybridization employing probes derived from the most highly conserved sequences. FGF-6 was isolated by this approach from a cosmid library prepared from a human lymphoblastoid cell line and was shown to act as a transforming gene for NIH/3T3 cells by transfection analysis [121]. KGF was isolated from medium conditioned by human embryonic lung fibroblasts and was found to be a potent mitogen for epithelial cells but to lack activity on fibroblasts or endothelial cells [133]. Thus, KGF was distinct in its target cell specificity not only from other members of the FGF family, but from other

known polypeptide growth factors as well. Molecular cloning and sequence analysis established KGF as a member of the FGF family, whose predicted amino acid sequence is about 38 % identical to those of aFGF and bFGF. KGF is expressed by stromal, but not epithelial, cells of most major epithelial tissues [134]. There is evidence that KGF plays a role in epithelial renewal during wound repair [135] and as a stromal mediator of epithelial cell proliferation/differentiation in sex hormone-responsive tissues [136], supporting the concept that this factor is important in the normal mesenchymal stimulation of epithelial cell growth. More recently, it has been shown that KGF and the related FGF-10 and FGF-22 share a role in the presynaptic differentiation of the mossy fibers in the cerebellum [137].

AIGF [138] was isolated from media conditioned by a cell line derived from a testosterone-dependent mouse mammary tumor cell line, and it is approximately equidistantly related to the other FGFs. Target cells include epithelial and fibroblast cells, and it appears to act in an autocrine fashion to stimulate the proliferation of mammary carcinoma cells, from which it was isolated. It appears to be restricted to expression in the testes in the adult, and its expression during development is maximal during the period of reproductive tract development [121].

GAF/FGF-9 was purified from supernatants of a cultured human glioma cell line [139]. It lacks a canonical signal sequence but was found to be efficiently secreted from COS cells transfected with the cDNA. Several other FGF family members have been identified by degenerate PCR or by searching genome databases for homology with known FGFs. The role of many of this factors, some of which lack signal peptides and contain nuclear localization sites, are still under investigation.

The prototype FGF receptor closely resembles the PDGF receptor family, but instead contains extracellular domain variants with two or three immunoglobulin-like motifs instead of five. Between the first and the second Ig domain, FGFRs contain a short domain referred to as the acid box domain. In FGFR1, this domain has a core sequence of eight consecutive acidic residues. In the cytoplasmic region, FGFRs contain a shorter (14 amino acids) insert within the tyrosine-kinase domain as compared to the PDGF receptor. Following the TK domain is a carboxyl terminal domain of approximately 55–65 amino acids containing multiple sites of autophosphorylation. The FGF receptor family includes four members (FGFR1, FGFR2, FGFR3, and FGFR4) displaying different affinity for the FGF ligands [121, 140]. Adding to this complexity, alternative splicing generates various isoforms of FGFR1, FGFR2, and FGFR3, including both cell-bound and secreted forms [141]. Of note, it has been shown that alternative splicing of the region encoding the third Ig domain has a profound impact on ligand–receptor binding specificity [122]. Another level of regulation in the signaling is the different spatial and temporal pattern of FGFR expression: FGFR1 is preferentially expressed in developing mesenchyme, FGFR2 predominantly in glial and epithelial cells, FGFR3 mainly in cartilage and blood tissues, and FGFR4 mostly in endoderm-derived tissues, such as the gastrointestinal tract and muscle [141]. Different types of malignancies, including gastric cancer, bladder and cervical carcinomas, myelomas, and skin cancer, contain sporadic mutations in FGFR2 and FGFR3 that cause ligand-independent dimerization or constitutive activation of the tyrosine kinase domain [142–144]. Conversely, fusion between FGFR1 and other genes, including the transcription factor ZNF198 and BCR, have been reported in some hematologic malignancies [144].

9.4.5 The Insulin Family

The diversity of metabolic effects of insulin has been studied intensively for decades [145]. Its primary in vivo functions involve the regulation of rapid anabolic responses, such as glucose uptake, lipogenesis, as well as amino acid and ion transport. In addition to its effects on metabolism, insulin stimulates DNA synthesis and cell growth. The insulin-like growth factors, IGF-I and IGF-II, were first recognized as serum factors, antigenically distinct from insulin. These molecules are induced by growth hormone and serve as its effectors in stimulating growth of skeletal tissues. IGF-I and insulin share 48 % of their amino acid sequences, and their similarity to IGF-II is 50 % [146]. Insulin is synthesized as a 109 amino acid precursor (preproinsulin), which is cleaved to produce an 86 amino acid single chain proinsulin. Proinsulin is further processed in the Golgi complex to insulin, which consists of two chains of 21 and 30 amino acids (A and B), linked by two disulfide bonds. IGF-I and IGF-II are single chain polypeptides with a structure analogous to proinsulin. The IGFs contribute to the insulin-like effects of serum on muscle and adipose tissue, but there are major differences between insulin and the IGFs. For example, whereas insulin levels fluctuate widely according to carbohydrate level, the IGFs are bound to carrier proteins and are maintained at steady concentrations in the blood stream. The carrier proteins belong to a class of proteins that have high affinity and specificity for the IGFs and are designated as insulin-like growth factor binding proteins (IGFBP). Six different IGFBPs have been identified in humans, and they are well conserved among mammals. The IGFBPs are involved in modulation of the proliferative and mitogenic effects of the IGFs at endocrine, paracrine, and autocrine levels [147, 148].

The insulin receptor, IR, is the prototype for a family of RTKs, whose distinctive structural feature is to function as a heterotetrameric aggregation of two α and two β subunits.

The extracellular ligand-binding subunit, containing a single cysteine-rich cluster, is disulfide linked to the transmembrane β subunit, which includes the cytoplasmic tyrosine kinase domain [149]. The IR binds insulin with approximately 100-fold greater affinity than it does IGF-I or IGF-II (100 pM versus 10 nM). The IGF-I receptor is closely related to the IR in sequence and structure, but binds IGF-I with highest affinity (100 pM), followed by IGF-II and insulin [150]. IGF-II is also bound by another receptor, which has been shown to be identical to the cation-independent mannose-6-phosphate receptor. The IGF-II receptor binds IGF-II and with a lower affinity IGF-I, but does not bind insulin, and it is thought to act as a scavenger receptor [151]. A gene encoding another family member, insulin receptor-related receptor (IRR), was identified by low-stringency hybridization of Southern blots of human and guinea pig genomic DNA probed with fragments of IR cDNA. Like the other family members, the IRR is synthesized as a single polypeptide precursor that is proteolytically cleaved into α and β subunits. It has been shown that the IRR does not bind insulin or the other related molecules [152]. However, the intrinsic kinase activity appears to phosphorylate endogenous proteins with a specificity very similar to that of the other two receptors of this family [153]. No ligands for IRR have been identified so far, and it is possible that this receptor forms heterodimers with the IR or IGF-R, in a way analogous to the ligandless ErbB2 in the EGF signaling.

Increased expression of IGF-I, IGF-II, IGF-IR, or combinations thereof have been observed in different types of cancer, including glioblastoma, medulloblastoma, breast, colorectal and pancreas carcinomas, and ovarian cancer [151]. These data, together with studies using cellular and animal models, suggest a role of this signaling in cancer growth and metastasis, and support the idea of the IGF system as a potential target for cancer therapy [151, 154].

9.4.6 Hepatocyte Growth Factor

Hepatocyte growth factor (HGF) was isolated from plasma or platelets as a mitogen for hepatocytes in culture [155–157]. Independent studies led to purification of a fibroblast-derived factor that promotes dissociation and motility of epithelial cells, termed scatter factor (SF) [158], which is identical to HGF. The biochemical and biologic properties of HGF/SF were found to differ from those of other known growth factors. The molecular weight of native HGF is around 90 kDa and consists of two polypeptide chains of about 70 and 34 kDa linked by disulfide bonds. Cloning of HGF/SF cDNA showed that the growth factor is encoded as a single transcript whose 728 amino acid product is processed by proteolytic cleavage into heavy and light chains [157]. The predicted amino acid sequence of HGF/SF was found to be related to plasminogen. In addition to their 38 % sequence identity, both molecules contain serine-protease domains and disulfide bond-linked intrachain structures known as kringles. Neither plasminogen nor plasmin have HGF-like activity, and HGF is not likely to be a protease since the histidine and serine residues in the region corresponding to the catalytic site are replaced by other amino acids [157].

HGF/SCF has been shown to have an expanding array of biologic activities. It is mitogenic for a variety of epithelial cells, as well as endothelial cells and melanocytes. HGF/SCF is also capable of inducing certain cell types to undergo morphogenesis when suspended in a semisolid matrix. For example, it induces tubule formation in canine epithelial cells, which undergo scattering under standard culture conditions. Thus, HGF/scatter factor is a mitogen, a motogen, and a morphogen [159, 160]. The HGF gene knockout is an embryonic lethal, leading to obvious abnormalities in liver and placenta development, as well as in the migration of myoblasts from the somites to the limbs and in motoneuron axon guidance [61, 161]. The increase of HGF/SCF levels following liver, kidney, or heart injury, and the expression of HGF/SCF and its receptor in mesenchymal stem cells strongly suggest the involvement of this growth factor in wound healing and tissue repair [162, 163].

A ligand related to HGF, termed HGF-like or macrophage-stimulating protein (MSP) [164], is a heterodimer of a heavy chain of 53 kDa (α) and a light chain of 25 kDa (β). MSP, which is also referred to as scatter factor 2 (SF-2), shares with HGF the overall four kringle/protease domain-like structure. Liver appears to be the main source of MSP, and its major activity to date is stimulating macrophage migration [165].

c-met was initially identified as a rearranged oncogene in a human osteogenic sarcoma cell line transformed in vitro with a chemical carcinogen [166]. This proto-oncogene encodes a 190 kDa glycoprotein that is processed to form a heterodimer comprised of a 50 kDa α-chain and a 145 kDa β-chain. The extracellular, membrane spanning, and tyrosine kinase domains are located on the β-chain. The juxtamembrane domain contains serine and tyrosine residues that, upon phosphorylation, are involved in the degradation of the receptor, while the C-terminal tail is a unique docking site for the recruitment of several downstream signaling molecules [167]. MET is expressed in a variety of tissues and cell types, but the highest levels are found in epithelial cells. The expression of HGF/SF was first detected in mesenchymal cells of various organs. The MET receptor initiates all of the known responses to HGF/SF mitogenesis, including motility and morphogenesis [159, 160]. Although MET mutations are present in hereditary papillary renal carcinomas and in some sporadic cancers, the most frequent mechanism of HGF/MET activation in human tumors is overexpression of

the receptor, which is associated with increased invasiveness and a poor prognosis [161].

Ron/Stk was identified and isolated as a *c-met*-related gene from cDNA libraries of human keratinocytes and a gastric carcinoma by means of degenerate oligonucleotides [168]. Ron cDNA encodes a glycosylated protein, which shares overall similar topology with the HGF receptor, displays 63 % sequence identity in its catalytic domain and has a similar tissue distribution. The p185 RON product, like MET, is synthesized as a single-chain precursor, which is converted into the mature form by proteolytic cleavage. The ligand for RON is MSP [169]. Truncated variants of RON have been identified in tumors of the gastrointestinal tract, which display constitutive activation and transforming activity [165].

9.4.7 Neurotrophin Family

In addition to NGF [7], the neurotrophin family includes brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4). These factors are crucially involved in central and peripheral nervous system (PNS) development and function, mediating processes such as survival, differentiation, and synaptogenesis [170]. Neurotrophins are 12–13 kDa proteins derived from 30–35 kDa precursors, proneurotrophins, by proteolytic cleavage. Both neurotrophins and proneurotrophins are secreted and can have opposite effects on target cells, such as survival versus apoptosis or synaptic long-term potentiation versus depression [171]. NGF is a basic 118 amino acid protein that acts in sensory and sympathetic neurons in the PNS [7]. NGF is also present in the brain, where it serves a trophic function in the development and maintenance of cholinergic neurons of the basal forebrain [170]. BDNF is necessary for the formation of the vestibular ganglia and have a key role in synaptic plasticity [170, 171]. NT-3 shows a strong sequence similarity to both NGF and BDNF and displays a high degree of regional specificity. Gene inactivation studies have shown that NT-3 participates in the development of the CNS and PNS, in particular for sensory neurons and the enteric nervous system [170, 172]. NT-4 was isolated from *Xenopus* as a molecule with the capacity to stimulate sensory neurons in culture. Another growth factor was almost simultaneously isolated from human and rat and termed NT-5, but was later shown to reflect the same gene. NT-4/5 is the less conserved factor among the family, and the inactivation of its gene provoked a mild phenotype, with reduced visceral afferent fibers in the small intestine and defects in nutrient feedback from the gastrointestinal tract [173, 174].

The neurotrophins interact with two distinct classes of receptors [175, 176]. One is represented by the p75 low-affinity neurotrophin receptor (p75NTR) protein [177]. This receptor is a highly conserved glycoprotein which is broadly expressed in neuronal and non-neuronal tissues. The extracellular region of the p75NTR contains a cysteine-rich domain, also found in the tumor necrosis receptor (TNFR) superfamily [178]. The intracellular domain is not related to any known protein and has no known enzymatic function. p75NTR acts as a co-receptor that allows the other type of receptor, Trks, to respond to low concentration of neurotrophins [178, 179]. p75NTR was recently found to function as a co-receptor for other ligands. Using a furin-resistant form of proNGF, Hempstead and colleagues showed that the NGF precursor binds with high affinity p75NTR and its co-receptor sortilin, but not Trks, and induces apoptosis in neuronal and glial cells [180, 181]. Finally, p75NTR can form a complex with the co-receptors NogoR and LINGO-1 to mediate the effects of the myelin-based growth inhibitors, Nogo, myelin-associated glycoprotein, and oligodendrocyte myelin glycoprotein [178]. The second class of neurotrophin receptors is encoded by the *trk* genes. *Trk* or *trkA* was discovered in efforts to isolate oncogenes from human tumor cells [182]. The other two members of the family, *trkB* [183] and *trkC* [184], were isolated by screening mammalian cDNA libraries with the *trkA* proto-oncogene as probe. In contrast to the p75NTR, the cytoplasmic regions of trks contain tyrosine kinase catalytic domains. Their extracellular regions contain Ig-like and FNIII domains, in addition to cysteine clusters alternated with leucine motif repeats. Structural studies have shown that NGF binds the membrane-proximal Ig-C2-like domain of trkA, which induces receptor dimerization, phosphorylation of cytoplasmic tyrosine and recruitment of adaptor proteins that mediate the signaling cascades [179, 185]

Each member of the trk family can bind at least one member of the neurotrophin family [176, 186]. Although there are obvious preferences for binding of a particular neurotrophin to one of the trk family members, there is some promiscuity. In particular, the presence or absence of short sequences of amino acids in the juxtamembrane region of each trk, determined by alternative splicing, have profound effects on the specificity of the receptors for the different neurotrophins. In summary, trkA binds and becomes activated by NGF and NT-3 in the presence of the insert region. TrkB binds and is activated by BDNF, while the splice variant containing the insert in the juxtamembrane region also binds NT-3 and NT-4. The *trkC* product is activated by NT-3 but not NGF or BDNF [185]. Thus, at least three high-affinity receptors confer different but not absolute specificities for these related ligands.

The expression of neurotrophins and their receptors have been shown to affect the progression of different types of cancers. For example, activation of NT-3/trkC and NGF/trkA

can induce apoptosis in medulloblastoma and neuroblastoma cells, respectively [187]. Conversely, trkB, which is frequently overexpressed in cancer, such as pancreatic and prostatic carcinomas, is a potent inhibitor of anoikis, an apoptotic process resulting from loss of cell–matrix interactions and which is thought to act as a barrier to metastasis [188]. Of note, the kinase activity of trkB was shown to be required and sufficient to suppress anoikis [189], and mutations in the catalytic domain of trkB and trkC have been identified in colon cancer [190]. Another example of the implication of neurotrophin signaling in cancer is the translocation that generates the *ETV6-trkC* gene fusion. This constitutively active chimera, containing the dimerization domain of the ETV6 transcription factor and the catalytic domain of trkC, displays a strong transforming activity and it has been identified in congenital fibrosarcoma and secretory breast carcinoma [191–193]. *TrkA* is also subject to oncogenic rearrangements, and fusions of trkA catalytic domain with other genes, including *tropomyosin 3*, *translocated promoter region gene*, or *trk fused gene*, have been identified in papillary thyroid carcinomas [194].

9.4.8 Axl Family

Protein S, a protease regulator that functions as a potent anticoagulant [195], and Gas6 [196] have been shown to be the ligands for the Axl family of RTKs [197–199]. The critical role of protein S in the coagulation process is illustrated by the massive thrombotic complications suffered by infants homozygous for protein S deficiency. This 70 kDa protein contains several modules, including an N-terminal region containing 11 γ-carboxyglutamic acid residues (Gla), a thrombin-sensitive module, a series of EGF-like repeats that undergo hydroxylation modification, and a module with homology to steroid-binding globulin. The Gla region is posttranslationally modified in the endoplasmic reticulum by γ-glutamyl carboxylase, an enzyme that requires vitamin K as a cofactor [198]. Gas6, first cloned as a growth arrest-specific gene [200], was shown to activate Axl receptor and shares all but the thrombin-sensitive module with protein S [198]. While the majority of the studies on protein S focus on its anticoagulant properties, Gas6 is a more typical growth factor, promoting survival and proliferation. Inactivation of this gene by two independent groups showed that Gas6 promotes glomerular cell proliferation in a model of nephritis [201] and can act as an amplifier of the platelet response during thrombosis [202]. It has been previously shown that other coagulation factors such as thrombin are able to bind and activate intracellular signaling *via* G protein-coupled cell surface receptors. It is possible that proteases and protease regulators, which activate specific cell surface receptors, may serve to integrate coagulation with associated cellular responses required for tissue repair and growth [203].

Axl (from the Greek word *anexelekto* or uncontrolled), was identified and isolated independently as a transforming gene from patients with chronic myelogenous leukemia and myeloproliferative disorders, respectively, by DNA transfection-tumorigenicity analysis [204]. The murine homologue, adhesion-related kinase (*Ark*), was cloned on the basis of relatedness to the tyrosine kinase domain of one of the FGF receptors. The encoded Axl/Ark proteins define a family of RTKs, which feature a new sequence in their cytoplasmic tyrosine kinase domains and an extracellular domain that juxtaposes two Ig-like domains and two FN type III repeats. A similar external domain topology has been observed among several neural cell adhesion molecules and a receptor tyrosine phosphatase [205]. Axl expression has been detected in the majority of cell types examined, with the exception of lymphocytes and granulocytes. Another member of the Axl family was designated Tyro3 (Sky) [206]. The encoded protein showed around 64 % amino acid identity with Axl. Northern blot analysis further revealed that its mRNA is expressed predominantly in the brain, kidney, testis, and ovary [198]. A third family member, *c-mer*, was isolated from a human B-lymphoblastoid cDNA expression library [207]. Sequence comparisons showed that this gene is the human homologue of the chicken retroviral oncogene, *v-nyk* (renamed *v-eyk*), a truncated tyrosine kinase whose expression by retroviral infection produced sarcomas in chickens. The designation *c-mer* was based on its expression pattern in monocytes and tissues of epithelial and reproductive origin. Gas6 is considered the main ligand for this family of RTKs, while protein S can activate Sky and Mer, but only at high, and possibly not physiological, concentrations [198, 208]. The crystal structure of a minimal Gas6-Axl complex has been recently published [208]. The two Ig-like domains of an Axl monomer are linked to the steroid binding globulin domain of a Gas6 molecule. Lateral diffusion of these 1:1 complexes induces the formation of a circular 2:2 assembly [198, 208]. Of note, it has been shown that Axl constitutively interacts with interleukin (IL) 15 receptor α, and that both receptors can be triggered by IL-15 in mouse fibroblasts [209].

Axl signaling has been implicated in the invasiveness of different types of cancer, including lung cancer [210, 211], prostatic carcinoma [212], and gastric cancer [213]. Of note, Axl downregulation by RNAi in a xenograft model of breast carcinoma revealed a role of this RTK in neovascularization [214], while overexpression of a dominant-negative form of Axl inhibited glioma cell proliferation, migration and invasion [215].

9.4.9 The Ephrin Family

The EPH receptors are the largest subfamily of RTKs [216], with at least 16 different members described to date. These genes encode proteins of approximately 130–135 kDa, characterized by an extracellular domain containing two regions with weak similarity to an Ig-like loop and a cysteine-rich region, followed by two FN type-III domains [216]. The TK domains of the EPH receptors do not contain kinase insert sequences and are followed by a carboxy-terminal domain of approximately 90–100 amino acids. Of note, in the TK domains of two of these receptors, EphA10 and EphB6, residues normally essential for the catalytic function are not conserved, suggesting that these receptors might signal through a different mechanism [217]. EPH receptors are classified into two groups (A and B), based on relatedness of their extracellular domain sequences and their affinity for the two groups of ligands. This family of RTKs binds to membrane-bound molecules named ephrins [218]. The ephrins are divided into two groups: ephrin-A subclass, which is anchored to the membrane by a GPI linkage, and ephrin-B, which possesses a transmembrane domain [216]. With few exceptions, ephrin-A binds to EPHA receptors, whereas ephrin-B binds to EPHB receptors [217]. Ephrins are able to function when presented in a membrane-bound form, indicating that they require direct cell to cell contact to activate their receptors. Ephrins bind EPH on juxtaposed cell surfaces with nanomolar affinity, which then leads to the formation of a tetramer comprising two receptors and two ligands. These complexes can aggregate in larger clusters according to the density of Ephrin and EPH on the cell surfaces [217]. Activation by Ephrin induces EPH phosphorylation by the receptors themselves (transphosphorylation) or by other kinases such as those belonging to the SRC-family [217]. It has been shown that the transmembrane ephrin-B molecules can signal bidirectionally following binding and activation of receptors in a neighboring cell [219].

The best characterized role of the ephrin-EPH signaling is the establishment of organized neuronal connections and circuits in several regions of the brain [217]. This RTK family is also involved in the regulation of cell shape in other tissues, such as the vasculature, as well as in cell migration, proliferation and differentiation. In particular, it has been shown that ephrins can modulate the balance between self-renewal and differentiation in different types of precursor and stem cells [217]. Different EPHs have been shown to act as tumor suppressors in cancer, including prostate and colorectal [217, 220]. For example, recent studies indicated that loss of EPHB expression is important for the adenoma–carcinoma transition in colorectal tumors initiated by activation of Wnt signaling, suggesting that the specification of cell positioning can play an important role in inhibiting tumor progression [220, 221].

9.4.10 Agrin Family

Agrin, named from the Greek word *agrein* (to aggregate), was identified as a protein capable of inducing aggregation of acetylcholine receptors (AchRs) in myotubes at the postsynaptic membrane [222]. Agrin is a large heparan sulfate proteoglycan in the extracellular matrix that is capable of inducing aggregation not only of AchRs but also of other synaptic proteins including laminin, heparan sulfate proteoglycan perlecan, rapsyn, vinculin, and dystroglycan [223]. Agrin is synthesized by a large number of tissues and, based on its pattern of expression during fetal development, it has been suggested to play a role in neurogenesis, skeletal muscle development, and mesenchymal–epithelial interaction during organ formation [224]. The effects of agrin on myotubes were abolished by inhibitors of tyrosine phosphorylation. These investigations led to the identification of MuSK (muscle-specific kinase), a novel RTK characterized by an extracellular portion containing four immunoglobulin-like domains [225]. MuSK is expressed at the postsynaptic muscle-fiber membrane, and it is rapidly phosphorylated in the presence of agrin, leading to tyrosine phosphorylation of the AChR β subunit, which probably facilitates AChR clustering [226]. The similar phenotypes of Agrin and MuSK knockout mice confirmed that MuSK is the receptor for agrin at the neuromuscular junctions [227, 228]. It has been shown that the functions of agrin in the central nervous system are probably mediated by another receptor, the α3 subunit of the Na^+/K^+-ATPase [228].

9.4.11 GDNF Family

Glial cell line-derived neurotrophic factor (GDNF), neurturin (NRTN), artemin (ART), and persephin (PSPN) are members of the GDNF family of neurotrophic factors that, based on their cystine knot structure, represent a subgroup of the TGF-β protein superfamily [229]. GDNF was initially identified as a trophic factor for midbrain dopaminergic neurons [230], but it was shown to promote survival of many neurons belonging to the PNS and CNS. GDNF is the most potent survival factor for motor neurons yet identified. It has received attention as a potential therapeutic agent for the treatment of neurodegenerative diseases, in particular for Parkinson's disease, caused by the loss of dopaminergic neurons in the *substantia nigra*, and amyotrophic lateral sclerosis, provoked by the degeneration of motor neurons [231, 232]. NRTN and PSPN promote the survival of basal forebrain neurons [233], while ART supports the survival of sympathetic and sensory neurons [232]. The effects of all four GDNF family members are mediated by the RTK rearranged during transfection (RET). RET contains a typical intracellular tyrosine kinase domain,

but it is characterized by an unusual extracellular domain, comprising four cadherin-like domains and a cysteine rich domain. Unlike other RTKs, RET cannot bind GDNF directly, but it requires co-receptors called GDNF family receptor α (GRFα). The four GRFα receptors provide specificity for the ligand, with GDNF preferentially binding GRFα1, NRTN to GRFα2, ARTN to GRFα3, and PSPN to GRFα4. A dimeric GDNF family member first binds to GFRα and this complex then interacts with RET to induce its dimerization and activation [232, 234]. Germ line activating mutations of RET are found in multiple endocrine neoplasia type 2, causing medullary thyroid cancers (MTC) and pheochromocytomas. Somatic mutations of RET are also present in 50 % of sporadic MTC, and chromosomal rearrangements resulting in constitutively activated RET are frequent in sporadic papillary thyroid cancers [235].

9.4.12 Angiopoietins

The Tie (tyrosine kinase with immunoglobulin and epidermal growth factor homology domains) family of RTKs includes two receptors that are almost exclusively expressed in endothelial cells and hematopoietic stem cells [236, 237]. Tie1 and Tie2 are characterized in their extracellular domains by two Ig-like loops separated by three EGF-like domains, followed by three FNIII repeats. The angiopoietins were originally identified as ligands for Tie2: Ang1 and Ang2 are the best characterized. Ang4 and its mouse ortholog Ang3 were identified later, and were found to act on human endothelial cells as Tie2 agonists and antagonists, respectively. Later studies revealed that Ang3 is instead an agonist in murine endothelial cells, indicating a species-specific activity [238]. No specific ligand has been identified for Tie1, but it has been shown that at high concentrations Ang1 binds to Tie1 through integrins [237]. While Ang1 and Ang2 bind to the same region in the extracellular portion of Tie2, only Ang1 is capable of promoting Tie2 autophosphorylation. Tie2 activation by Ang1 is required to maintain the resting state of the endothelium, whereas Ang2 destabilizes the quiescent endothelium and primes the response to exogenous stimuli [238]. Ang1 or Tie2 knockout mice are embryonic lethal and show a similar phenotype, with severe vascular remodeling defects. Interestingly, Ang2 transgenics phenocopy Ang1-deficient or Tie2-deficient mice, while inactivation of the Ang2 gene only induces a very mild phenotype [237]. There are conflicting findings concerning the role of angiopoietins in cancer, but a better understanding of the molecular mechanisms involved in their signaling could have important therapeutic outcomes, particularly for certain aspects of cancer biology, such as tumor angiogenesis, inflammation and vascular extravasation [239].

9.4.13 DDR Receptors

The discoidin domain receptor (DDR) family of RTKs includes two members that are activated by different types of collagen [240]. The discoidin domain was first identified in a protein isolated from the amoeba *Dictyostelium discoideum* and it is present in several extracellular and membrane proteins, including blood coagulation factors, enzymes and receptors [241]. The discoidin domain on the N-terminus of DDRs is necessary for the binding to collagen [242], but it has been proposed that DDRs may bind other factors, such as components of myelin in the CNS [241]. Another characteristic of this family of RTKs is the long juxtamembrane region, which includes 176 and 147 amino acids for *DDR1* and *DDR2*, respectively [240]. In certain conditions, DDR1 is processed into a membrane-anchored and a soluble subunit by proteases belonging to the ADAM family [240]. While inactivation of DDR1 and DDR2 genes in mice provokes dwarfism, the phenotypes are different. In particular, DDR1 appears to be involved in the morphogenesis and proliferation of the mammary gland, the vasculature, and the kidney, while DDR2 plays an important role in wound healing [240]. DDRs are often overexpressed in cancers of different origin, and it has been suggested that these RTKs may participate in cancer invasion and metastasis through their interaction with the collagenous extracellular matrix [240, 241]. Of note, DDR1 is a direct transcriptional target of the tumor suppressor p53, and it seems to alleviate the adverse effects of stress mediated by p53 [243].

9.4.14 Orphan Receptors

Several RTKs await the assignment of ligands. *Ros* is the cellular counterpart of the retroviral oncogene, *v-ros*, originally identified in the avian sarcoma virus UR2 [244]. The gene encodes a receptor-like PTK with an unusually large extracellular domain of nearly 2000 amino acids. It is closely related to the product of the *sevenless* gene from *Drosophila*, which determines cellular fate during development of the compact eye. However, *c-ros* does not appear to be expressed in avian or mammalian eyes [245]. In fact, in situ hybridization, studies have indicated that *c-ros* is mainly expressed in epithelial cells of the renal collecting ducts and intestinal villi and crypts [245]. A likely developmental role for *c-ros* has been inferred since expression of the proto-oncogene is detected only transiently during embryogenesis. Aberrant expression of c-ros is common in human brain tumors and a fusion of c-ros carboxy terminal domain with the protein Fused in Glioblastoma (FIG) was detected in U118MG human glioblastoma cell line, resulting in the constitutive activation of c-ros kinase domain. The c-ros-FIG fusion

protein cooperates with the loss of the tumor suppressor *Ink4a;Arf* to induce glioblastoma in mice, strongly suggesting that this orphan RTK can play a role in the onset of human brain tumors [246, 247]. The identification of a specific ligand should make it possible to better understand the functions of this protein.

Leukocyte tyrosine kinase (LTK) is expressed in B lymphocyte precursors, forebrain neurons in the mouse, as well as in placenta and hematopoietic cells in human [248]. Another member was identified as rearranged with the NPM nucleolar phosphoprotein gene in most anaplastic large-cell non-Hodgkin's lymphomas [249]. This gene, termed *anaplastic lymphoma kinase* (ALK), is normally expressed in the small intestine, testis, and brain, but not in normal lymphoid cells [250]. It has been suggested that ALK is the receptor for pleiotrophin family members [251], but this idea is still controversial.

ROR1 and ROR2 [252] define a family of receptors whose extracellular domains contain Ig-like, cysteine-rich, and kringle domains. Their tyrosine kinase domains are followed by serine/threonine-rich and proline-rich motifs. These receptors were originally identified on the basis of similarity of their TK domains to the Trk family of neurotrophin receptors. Both are widely expressed and at high levels during early rat embryonic development. Dror is the corresponding gene in *Drosophila* [253], where it is expressed specifically in the developing nervous system. The ROR receptors and NSK2 extracellular domains also show sequence similarity with the cysteine-rich domain of the frizzled proteins, which are non-tyrosine kinase receptors. Wnt ligands appear to bind this domain of frizzled. Indeed, ROR2 has been shown to bind to Wnt5a and possibly act in β-catenin-independent Wnt signaling [254, 255].

KLG and RYK represent two other distinct tyrosine kinase receptors. KLG (for kinase like gene) was isolated from a cDNA library prepared from embryonic chicken tissues using as a probe the *v-sea* oncogene [256]. KLG is a member of the immunoglobulin gene superfamily, with seven Ig-like loops in its extracellular domain. Its human homologue CCK-4, also called PTK7, was isolated from a colon carcinoma [257]. RYK (for related to tyrosine kinase) [258], a ubiquitously expressed gene, encodes a protein containing two putative transmembrane segments and two leucine-rich motifs in the extracellular domain [259]. The functional significance of these two genes is not known because efforts to demonstrate their tyrosine kinase activity have not as yet been successful. Both proteins contain several sequence substitutions in the conserved TK catalytic domain, similar to those present in the tyrosine kinase defective ErbB3. Ryk, which contains a Wnt-inhibitory factor-1 like domain in its extracellular portion, has recently been implicated in Wnt signaling [260, 261].

9.4.15 Signaling Pathways of Tyrosine Kinase Receptors

The activation of a RTK by its ligand or by other oncogenic mechanisms, such as receptor overexpression, mutation, or gene fusion, initiates a series of events that mediates the biological response in normal or cancer cells. An important role in these processes is played by a group of adaptor proteins that serve as a link between molecules of a signaling cascade and RTKs. It is generally considered that stimulation of effector proteins by RTKs can occur with three different mechanisms. In the first case, the activated receptor can induce membrane translocation of factors involved in signaling. For example, PDGF-induced stimulation of phosphatidylinositol 3 kinase (PI3K) generates the second messengers PtdIns(3,4)P2 and PtdIns(3,4,5)P3 that recruit to the membrane and activate Akt and PDK1 [PtdIns(3,4,5)P3-dependent kinase]. Another mechanism involves a conformational change, which results in the stimulation of an enzymatic activity. This is the case, for example, of Src, whose protein kinase activity is induced when its SH2 domain binds to tyrosine autophosphorylation sites of PDGFR. Finally, the signaling cascade can be triggered by RTK direct phosphorylation of the effector proteins, such as phospholipase Cγ, which can be tyrosine phosphorylated by EGF, PDGF, and FGF receptors [262] (Fig. 9.3). The signaling pathways activated by RTKs are extremely complex and interconnected. These pathways regulate fundamental processes, such as cell proliferation, survival, and differentiation, and they are frequently targeted by oncogenic events, which bypass the growth factor receptor–effector normal cascade, resulting in the constitutive activation of the signaling. For example, the oncogene Ras and the tumor suppressor PTEN are important players in two of the major signaling cascades activated by RTKs, the Ras-MAP kinase and the PI3K pathway, respectively. The limitation of space precludes a detailed discussion of the events downstream RTK activation. The last part of this chapter will focus on the role of growth factor signaling as a target for therapeutic strategies against cancer.

9.5 Implications for Cancer Therapy

We have seen in this chapter that growth factor signaling is often activated in cancer. In some cases, the activity of a particular pathway is essential for the tumor cell, a condition called oncogene addiction. In other tumors, the growth factor signaling contributes to the progression to a more aggressive disease. In both cases, the aberrantly activated signaling pathway represents a target of choice for therapeutic strategies. This type of therapy has great potential as it relies on blocking specific molecules rather than the traditional chemotherapy or

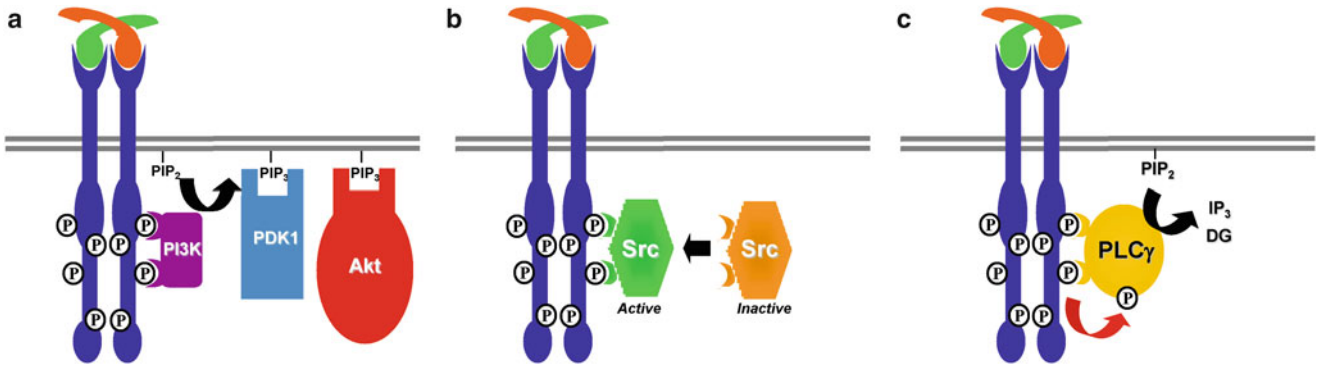

Fig. 9.3 Mechanisms for PDGFR-mediated activation of effector proteins. Simplified diagram illustrates different mechanisms of signal transduction following PDGFR activation. (**a**) PDGFR-induced stimulation of PI3K generates the second messenger PIP_3 that in turn recruits to the membrane and activates Akt and PDK1. (**b**) Src is activated by a conformational change following its binding to the PDGFR. (**c**) PDGFR can directly phosphorylate and activate PLCγ, which then generates the second messengers IP3 and diacylglycerol.

Table 9.2 Examples of Food and Drug Administration approved cancer drugs targeting RTKs

Drug	Target(s)	Disease
Monoclonal antibodies		
Trastuzumab (Herceptin)	ErbB-2	Breast cancer
Cetuximab (Erbitux)	EGFR	Colorectal cancer, head and neck cancer
Panitumumab (Vecitibix, ABX-EGF)	EGFR	Colorectal cancer
Bevacizumab (Avastin)	VEGF	Colorectal cancer, NSCLC
Small molecules		
Imatinib (Gleevec)	PDGFR, c-Kit, (ABL)	GIST
Gefitinib (Iressa)	EGFR	NSCLC
Erlotinib (Tarceva)	EGFR	NSCLC, pancreatic cancer
Lapatinib (Tykerb)	EGFR, ErbB-2	Breast cancer
Sorafenib (Nexavar)	VEGFR2, PDGFRβ, c-Kit, (Raf)	RCC, HCC
Sunitinib (Sutent)	VEGFR1-3, PDGFRα, RET, c-Kit	GIST, RCC

Some of these drugs can target non-RTK proteins. *NSCLC* non-small-cell carcinoma, *CML* chronic myeloid leukemia, *GIST* gastrointestinal stromal tumors, *RCC* renal cell carcinoma, *HCC* hepatocellular carcinoma

radiation therapy. Tremendous strides have been made in developing therapies that target oncogene products expressed at the cell surface, such as growth factor receptors using humanized monoclonal antibodies (Mabs) that either inhibit ligand/receptor interactions or cause receptor downregulation and host mediated immune responses [263–267]. One of these Mabs, Herceptin, which recognizes ErbB2, showed for the first time that a targeted therapy might be effective as a single agent and became the first clinically approved drug against an oncogene product (Table 9.2). These Mabs have been particularly effective when used in combination with traditional agents, such as in the case of Erbitux, a Mab targeting EGFR that has been approved for the treatment of colorectal and head and neck cancers in combination with chemotherapy and radiotherapy, respectively [117, 265, 268]. In addition to targeting an overexpressed receptor on which tumor proliferation is dependent, this approach could provide a means of targeting chemotherapeutic agents internalized by the receptor to sites within the tumor cell. As with other receptor targeting strategies, the efficacy of this approach would be expected to depend upon the differential magnitude of receptor expression by the tumor, as opposed to normal cells, as well as accessibility of tumor cells to the systematic administration of such agents [269].

Increased understanding of the important role of growth factor signal transduction in cancer has led to intensive efforts focused on the development of small molecule inhibitors of specific target molecules including RTKs and their

downstream effectors. The most exciting progress to date has come from investigations of Gleevec, a low molecular weight inhibitor of the tyrosine kinase activity of the PDGFR, c-kit, and the non-receptor tyrosine kinase Abl, which is translocated in chronic myelogenous leukemia (CML) as part of the Philadelphia chromosome to create the *Bcr-Abl* oncogene [270]. This inhibitor blocks ATP binding to the tyrosine kinase domain, preventing phosphorylation reactions involved in signaling [271]. Gleevec is used in the treatment of CML and it has been approved for GISTs, which contain c-kit or PDGFRA mutations [272, 273]. Other tumors with *c-kit* and *PDGFR* activating mutations are currently being evaluated for treatment efficacy by Gleevec [271, 274].

Iressa and Tarceva are examples of small molecules targeting growth factor receptors in cancer therapy. These compounds are reversible inhibitors of EGFR that have been approved for patients with advanced NSCLC who failed to respond to conventional chemotherapy. The first clinical trials showed that only a relatively small fraction of NSCLC patients responded to these drugs. Later studies revealed that sensitivity to these inhibitors correlates with activating mutations in the EGFR kinase domain, present in ~10 % of NSCLC patients, usually nonsmokers, more frequent in women and in individuals of Asian descendent [25]. Despite the initial remission, NSCLCs responsive to Iressa or Tarceva invariably develop resistance within 6–12 months of treatment, in half of the cases because of an additional mutation in EGFR (T790M) that weakens the interaction of the inhibitors with the kinase [25]. Of note, it has been shown that *MET* amplification and the resulting activation of ErbB3 is another mechanism responsible for resistance to these drugs [275], underlining the need of a therapeutic strategy that simultaneously targets different signaling pathways. Small molecules have already been generated or are under development to inhibit other growth factor receptors, such as MET [275] and IGF-R [276], as well downstream effectors, which should provide complementary therapies for a given type of cancer.

Another treatment modality that derives from increased understanding of growth factor signaling that occurs in the microenvironment of a tumor is the application of a Mab directed against the angiogenic growth factor, VEGF, which has been approved as a novel therapy in combination with other modalities. Whether this Mab acts by inhibiting tumor angiogenesis or by normalizing such vessels and actually improving access of traditional agents to the tumor is being evaluated, but there is little question that this approach can have therapeutic effects [266]. Other approaches to target the tumor microenvironment, including small molecules such as the VEGFR and PDGFR inhibitor Sunitinib, are also being used [266, 271, 277–279].

In the future, cancer treatment will most likely combine different target specific agents tailored to particular tumors. Novel therapeutics based on the knowledge of growth factor signaling pathways are already in the clinic, and there is no doubt that the number of rationally based strategies targeting these molecules will continue to grow.

Senescence, Apoptosis, and Cancer

10

Manjari Dimri and Goberdhan P. Dimri

10.1 Senescence and Cancer

In 1961, in a landmark paper, Hayflick and Moorehead suggested that normal human fibroblasts do not proliferate indefinitely in culture [1]. Their observation led to discovery of cellular senescence, which now appears to be a basic fundamental property of all normal human somatic cells. The process of cellular senescence is a function of number of population doublings (PDs) versus proliferative capacity (Fig. 10.1). At increasing PDs, the proliferative capacity of cells decreases in culture. As a result, the increase in cell number reaches a plateau after a fixed number of PDs, and cells cease to proliferate. However, in case of tumor-derived cells, the increase in cell number does not reach a plateau and cells keep proliferating indefinitely. Such cells are immortal. Although it is mostly studied in culture, cellular senescence is now known to occur in vivo and play an important role in cancer and aging [2]. The vast majority of literature suggests that cellular senescence is involved in every aspect of cancer from its development, progression to treatment [3].

10.1.1 Cellular and Molecular Features of Cellular Senescence

Cellular senescence traditionally has been confused with cell death. Contrary to cell death, senescent cells are metabolically active and resistant to apoptosis [3, 4]. Initial characterization of senescent phenotype in culture from various laboratories suggested that senescent cells stop synthesizing DNA as determined by tritium-labeled (^{3}H) Thymidine or 5-bromo-2′-deoxyuridine (BrdU) incorporation, and are irreversibly arrested with a G1 DNA content [5]. The morphological features of senescent cells include big flat and vacuolated appearance [5]. Senescent cells express a senescence-associated β-galactosidase (SA-β-gal) marker, which is biochemically detected using X-gal as a substrate at pH 6.0 in human cells [6]. Increase in this enzyme activity probably reflects an increase in lysosomal compartment of senescent cells [7, 8]. The marker offers simple yet powerful tool to identify senescent cells in culture and in vivo, and has been widely used in several cancer-related studies.

The molecular features of senescent cells include altered expression of several genes [5, 9]. For example, several proliferation-associated genes such as gene encoding c-Fos, c-Myc, cyclin A, cyclin B, polo kinase PLK, centromere-associated protein CENP-A and CENP-F, and c-Myb and c-Myc are expressed, but downregulated in senescent fibroblasts [5, 9]. On the other hand, genes which encode proteins associated with maintenance and remodeling of ECM (extracellular matrix), such as stromelysin 1, stromelysin 2, collagenase, gelatinase, human macrophage metalloproteinase (HME), tPA, uPA, PAI 1, PAI 2, cystatin M, thrombospondin, dermatopontin, fibromodulin, collagens VI and XV, elafin, cathepsin D, cathepsin L, serpin b2, and other ECM-associated proteins are upregulated in senescent fibroblasts [2, 9].

10.1.2 Types of Cellular Senescence

The senescence phenotype which Hayflick and Moorehead first described is now known as replicative senescence. Replicative senescence is caused by repeated cell division or mitoses (Fig. 10.2). The prime cause of replicative senescence is telomere shortening or dysfunction [10]. However, it is very well established that a similar phenotype also results due to non-telomeric signals such as stress signals (Fig. 10.2) [10]. For example, cellular senescence in cultured murine cells is thought to be due to stress induced by culture conditions [11]. In addition, oncogenic and mitogenic signals, such as strong oncogenic signal provided by

W.B. Coleman, G.J. Tsongalis (eds.), *The Molecular Basis of Human Cancer*, DOI 10.1007/978-1-59745-458-2_10

activated H-RAS can induce senescence in primary cells (Fig. 10.2). Thus, senescence inducing signals can be telomeric or non-telomeric (Fig. 10.2). The non-telomeric signals include oncogenic, mitogenic, DNA damage, and undefined stress signals (Fig. 10.2). Senescence induced by non-telomeric signals is termed accelerated senescence, premature senescence, *st*ress or *a*berrant *s*ignaling *i*nduced *s*enescence (STASIS), and extrinsic senescence [12, 13].

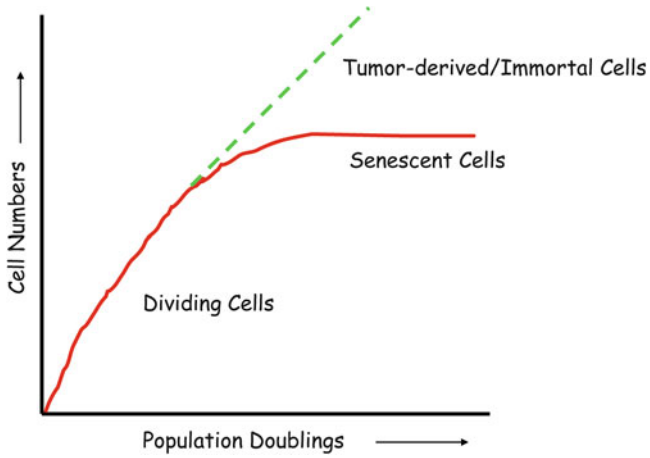

Fig. 10.1 In cell culture systems, cellular senescence is described as a decrease in proliferative capacity and eventual cessation of proliferation with increasing number of population doublings (PDs). This property of normal cells is also described as finite life span or Hayflick limit in the literature. Tumor-derived and stem cells contain telomerase activity and/or maintain telomere length. Such cells are immortal and do not exhibit cellular senescence in culture.

10.1.3 Mechanisms of Cellular Senescence

A large number of telomere binding proteins cap the end of chromosome known as telomeres, which consist of long stretch of repetitive sequences, such as (TTAGGG)*n* in humans [14]. In human somatic cells, progressive telomere shortening or telomere dysfunction appears to be the primary cause of cellular senescence [14, 15]. In most cases, the enzyme telomerase and telomere associated proteins maintain telomere homeostasis and telomere length. The catalytic subunit of telomerase (TERT) together with its RNA component (*TERC*), builds telomere repeats at the chromosome ends, which otherwise, owing to asymmetric DNA replication, are progressively lost [14].

Most human somatic cells do not contain sufficient telomerase to maintain telomere length [16], resulting in telomere shortening after each round of cell division. Consistent with this finding, exogenous expression of telomerase can either increase or stabilize telomere length in normal human cells, and in some cases results in cell immortalization [17]. It is thought that telomere dysfunction or uncapping triggers a DNA damage response, which activates p53 pathway resulting in proliferation arrest [18–20]. Consistent with this model, senescent cells are enriched in the nuclear foci of phosphorylated histone H2AX (γ-H2AX), p53 binding protein 53BP1, NBS1, the phosphoS966 form of SMC1 and MDC1, and inactivation of CHK1 and CHK2 (checkpoint kinases) can restore S phase progression in senescent cells [18–20]. Oncogene-induced senescence (OIS) has also been shown to be a DNA-damage checkpoint-response mediated by ATM and CHK2 [21, 22].

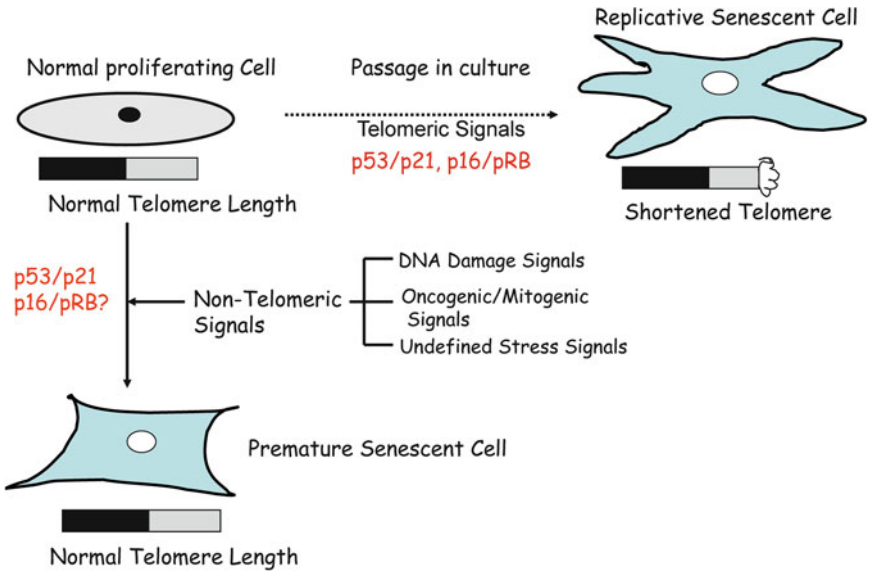

Fig. 10.2 Normal human cells undergo two types of senescence-replicative and premature senescence. Replicative senescence is caused by cell divisions (mitoses); during each cell division, telomeres shortens about 50–100 bp (base pairs). When telomeres length gets critically short to 1–2 kb (kilo base) from 8–12 kb, cells stop dividing and acquire a distinctive morphology. On the other hand, premature or accelerated senescence is caused by non-telomeric signals such as DNA damaging agents, constitutive oncogenic/mitogenic signaling, and undefined stress signals. During premature senescence, telomere length remains unchanged; however, the distinctive senescent morphology is still acquired by the cells.

The constitutive activation of p53 via ATM pathway results in induction of p53 target genes most notably p21 [23], which inhibits the activity of CDK2/cyclin E kinase. Inhibition of CDK2/cyclin E kinase activity results in hypophosphorylation of pRB (retinoblastoma tumor suppressor), which very likely mediates cell cycle arrest during senescence (Fig. 10.3). In addition to p21, other growth inhibitory p53 target genes may also play a role in cellular senescence [10]. Due to p53 and p21 activation and resulting G1 arrest, many proliferation-associated genes such as *CDK1*, *CDK2*, *cyclin A*, *cyclin B*, and *E2F1* remain repressed in senescent cells. In a parallel pathway, $p16^{INK4a}$ (CDKN2A) is upregulated during senescence [10]. $p16^{INK4a}$ inhibits the activity of other CDK-cyclin kinases such as CDK4-cyclin D1 and CDK6-cyclin D1. CDK4, CDK6, and cyclin D are expressed in senescent cells, but the activity of CDK-cyclin D complexes is lost during senescence. Thus, the repression of CDK kinases via multiple mechanisms results in hypophosphorylation of pRB. The hypophosphorylated or unphosphorylated pRB maintains permanent growth arrest phenotype of senescent cells (Fig. 10.3) [10]. Expression of $p16^{INK4a}$ is negatively regulated by BMI-1 oncoprotein [13], while p53 is negatively regulated by MDM2, PIRH2, COP1, and ARF-BP1 [24]. These regulators of $p16^{INK4a}$ and p53 are likely to impact cellular senescence and replicative life span of cells in vitro and in vivo (Fig. 10.3).

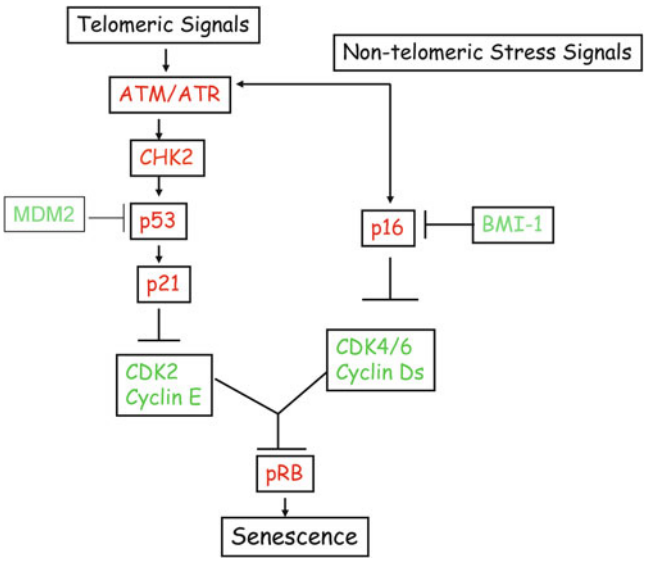

Fig. 10.3 Telomeric and non-telomeric stress signals induce senescence via tumor suppressor pathways. These signals activate a DNA damage response pathway mediated by ATM and CHK2. These DNA damage inducible kinases activate p53, which via p21 suppresses the CDK2/cyclin E activity to maintain pRB in unphosphorylated or hypophosphorylated (growth inhibitory) state. Stress signals in culture also activate $p16^{INK4a}$ (independent of p53). Very little is known about the upstream signaling molecules that mediate $p16^{INK4a}$ induction. p16 primarily inhibits CDK4/6 cyclin D activity. $p16^{INk4a}$ together with p21 and possibly other CDK inhibitors maintain pRB in a permanent growth inhibitory state, which ensures stability and irreversibility of senescent phenotype. $p16^{INK4a}$ is negatively regulated at the transcription level by polycomb proteins, in particular BMI-1. p53 is negatively regulated at the protein level by MDM2 and other ubiquitin ligases.

10.1.4 Telomere-Dependent Senescence and Cancer

Telomeres and Telomerase expression are linked to cancer in many ways. First, more than 90 % of tumors express telomerase [25] and tumor-derived cells usually maintain telomere lengths of their chromosomes. Second, several in vitro studies have shown that telomere attrition can induce senescence or apoptosis in tumor cells [26]. Third, the ectopic expression of telomerase in somatic cells prevents telomere shortening and in some cases results in immortalization of cells [17, 26], which may increase the possibility of accumulation of additional genetic abnormalities resulting in cancer initiation and progression. Indeed several studies have shown that hTERT overexpression is one of the four pivotal steps required to convert a normal human somatic cell into a cancer cell [27, 28]. These studies also showed that bypass of senescence by inactivating pRB and p53 is one of the other four requirements for in vitro transformation of human cells [10, 28, 29]. Based on these studies, one can hypothesize that telomere shortening should limit cancer progression in vivo. Until now, compelling evidence for such a hypothesis has been lacking because the laboratory mouse which is the most studied in vivo cancer model harbors very long telomeres.

Taking advantage of a mouse knockout model of telomerase ($mTR^{-/-}$), which lacks the essential RNA subunit of the enzyme telomerase, Felder and Greider recently showed that indeed short telomeres limit tumor growth in vivo by inducing cellular senescence [30]. Felder and Greider crossed $mTR^{-/-}$ mice with Eμ-Myc transgenic mice, which develop very aggressive Myc-driven Burkitt's lymphomas. It was found that at generation six (G-6), when the telomeres in $mTR^{-/-}$ mice get short enough, the progression of Eμ-Myc-induced Burkitt's lymphomas was completely blocked by apoptosis. To negate apoptosis in these animals, the investigators used Bcl-2 overexpression, and showed that short telomeres still inhibited lymphoma formation in these animals despite inhibition of apoptosis. The staining for SA-β-gal marker, $p16^{INK4a}$, and $p15^{INK4b}$ indicated that precancer cells in this setting were undergoing cellular senescence, implying that short telomere-driven senescence acts as a strong barrier to neoplasia in vivo [30]. Importantly, loss of p53 abrogated short telomere-induced senescence and promoted cancer progression [30]. Cosme-Blanco et al. also demonstrated that dysfunctional telomeres induce p53-dependent cellular senescence, which abrogated spontaneous tumorigenesis in $mTR^{-/-}$p53 (R172P) (telomerase knockout with mutant p53 knockin) mouse model [31].

Thus, telomere-dependent senescence also acts as a strong barrier to tumor-progression in vivo.

If the telomerase expression is required for oncogenesis, then inhibitors of telomerase should be considered attractive cancer therapy reagents. Indeed, inhibitors of telomerase are known to induce senescence and/or apoptosis in cancer cells. For example, Damm et al. reported that a highly selective small molecule inhibitor of telomerase caused progressive telomere shortening and induced senescence in p53-positive as well as p53-negative cancer cell lines [32]. Similarly, synthetic telomerase inhibitors MST-312, MST-295, and MST-199 were reported to induce senescence in cancer cells [33]. Riou et al. also demonstrated that a series of G-quadruplex DNA ligands can inhibit telomerase activity, cause telomere shortening, and induce cellular senescence [34]. Several other inhibitors of telomerase such as BIBR1532 and GRN163L exhibit growth suppressive and anticancer activity [35]. These studies suggest that senescence induced by telomere shortening is a tumor suppressive mechanism, and compounds that inhibit telomerase activity and induce senescence can be used as cancer therapy reagents.

10.1.5 Oncogene-Induced Senescence and Cancer

In 1997, Serrano et al. first reported that oncogenic RAS did not transform primary human cells but instead invoked a phenotype similar to cellular senescence, suggesting that senescence can be prematurely activated in response to an oncogenic stimulus [36]. This phenomenon of premature senescence by oncogenes is now popularly known as OIS [37]. Apart from oncogenic RAS, OIS is known to be induced by RAF, MYC, E2F1, and constitutive MAPK signaling in normal cells [10]. Recently, *MOS*, *cyclin E*, and *CDC6* oncogenes were also shown to cause OIS in human fibroblasts [21]. Since the discovery of Serrano et al. and others, OIS is now recognized as an important body defense mechanism against oncogenic insults. The in vivo evidence for such a role for OIS was reported in a series of papers published in 2005 [38–41]. It was found that the expression of B-RAF, K-RAS, and Eμ-N-RAS oncoproteins, or inactivation of the tumor suppressor PTEN induced a senescence response in vivo, and as a result, cancer progression was blocked at a very early stage [38–41]. Importantly, in these studies it was shown that cancer progression was only facilitated by additional mutations such as loss of p53, which caused bypass of senescence. Accordingly, malignant tumors that eventually arose in these models were largely devoid of biomarker of senescence including SA-β-gal.

Michaloglou et al. reported that benign nevi in human patients, which express oncogenic form of B-RAF, by in large are composed of senescent melanocytes as these cells express markers of senescence such as SA-β-gal and $p16^{INK4a}$, while the malignant melanomas were devoid of these senescence markers [41]. In a transgenic model of lung cancer progression by K-RAS, it was shown that the premalignant tumors but not the malignant tumors contained senescent cells [40]. In the Braig et al. study, OIS was shown as an initial barrier in lymphoma development in Eμ-N-RAS transgenic mouse model [38]. It was shown that the deficiency of Suv39h1, a methyltransferase, which silences proliferative genes to induce senescence, is required for lymphomagenesis induced by Eμ-N-RAS transgene. Finally, Chen et al. showed that PTEN inactivation per se leads to induction of p53-dependent premature senescence in vitro and in vivo [39]. It was also shown that early stage benign human prostate cancer samples but not the late stage prostate cancer samples contained senescent cells [39]. Collectively, these studies strongly suggest that OIS acts as an initial barrier to cancer progression in vivo [42].

10.1.6 Senescence and Cancer Therapy

Both OIS and telomere-based senescence are important for cancer initiation and progression. Apart from cancer initiation and progression, senescence is also important for cancer treatment. Several recent studies have shown that chemotherapeutic drugs and radiation can induce senescence in cancer cells [43]. Induction of senescent phenotype as measured by the expression of SA-β-gal marker has been reported in a number of cancer cell lines by doxorubicin [44–46], cisplatin [47–49], hydroxyurea [50–52], camptothecin [53–55], etoposide [55], and other chemotherapeutic agents.

It has been suggested that DNA-interactive chemotherapeutic drugs such as doxorubicin, aphidicolin, cisplatin, and cytrabine induce a robust senescence-like growth arrest while other cytotoxic drugs, such as taxol and vincristine, induce it only minimally [56]. Apart from in vitro studies, recent studies provide compelling evidence that cellular senescence can be induced in vivo by chemotherapeutic drugs, and that senescence induction by chemotherapy drugs might be an important mechanism of cancer growth inhibition by these drugs [55, 57, 58]. te Poele et al. reported that 41 % of breast cancers from patients who had undergone a chemotherapy regimen stained positive for SA-β-gal marker and $p16^{INK4a}$ protein, while normal tissues adjacent to tumors were devoid of senescence markers [55]. The investigators concluded that like apoptosis, senescence is a p53-induced cellular response to chemotherapeutic drugs in vivo and that it is an important factor in determining treatment outcome [55]. The induction of premature senescence by chemotherapy treatment of human lung cancer was also recently demonstrated [57].

A study by Schmitt et al. provides clear evidence for the induction of senescence by cancer chemotherapy reagents in

a mouse model [58]. The investigators generated Eμ-Myc-derived lymphomas in control-MSCV (vector), control-Bcl2, *p53* null-MSCV (vector), and *p53* null-Bcl2 mice. Mice bearing these four sets of lymphomas were treated with a chemotherapy drug CTX (cyclophosphamide). Using staining for SA-β-gal marker, $p16^{INK4a}$, and p53, the investigators showed that CTX is able to engage a senescence program when apoptosis is inhibited by Bcl2 overexpression (control-Bcl2 set) [58]. Furthermore, as a result of senescence induction, control-Bcl2 lymphomas did not progress and these animals had a better prognosis [58]. This is in contrast to *p53* null-MSCV and *p53* null-Bcl2 lymphomas, which progressed rapidly [58]. Induction of a senescence-like phenotype has also been reported in rat mammary tumors undergoing treatment with chemopreventive agents [59]. Thus, chemotherapeutic drugs can induce a senescence-like stage in vivo and in vitro by upregulating p53 and/or $p16^{INK4a}$, which may be an important mechanism of cancer growth inhibition by these drugs [10].

10.1.7 p53-Mediated Senescence in Cancer Treatment

p53 is mutated in a large number of human malignancies [60, 61]. p53 is also a major regulator of senescence and enforced expression of p53 or p21 in many cell types can induce a senescence-like phenotype [10]. Thus, it is natural to ask—does restoration of p53 in p53-deficient tumors induces senescence and stop cancer growth? Two elegant studies suggest that p53 restoration in a mouse model can cure cancer via induction of senescence and tumor clearance [62, 63]. In the first study, Xue et al. used RNA interference (RNAi) approach to conditionally regulate p53 expression in liver carcinoma in a mouse model [63]. The investigators showed that even a brief reactivation of endogenous p53 caused complete regression of the liver tumor. Importantly, the primary cause of cancer regression was not apoptosis, as one would have thought. Instead, cancer regression in this model involved induction of the cellular senescence program accompanied by the production of inflammatory cytokines [63]. The inflammatory cytokines triggered an innate immune response which enhanced tumor clearance. Thus, it was shown that p53-mediated induction of cellular senescence together with innate immune response can cure murine liver carcinomas [63].

Ventura et al. used a *Cre-loxP*-based conditional strategy to activate or inactivate endogenous p53 in a mouse model [62]. The investigators generated mice with a reactivatable p53 knockout allele by inserting a *loxP* flanked STOP cassette in the first intron of p53. This STOP cassette created a p53 null phenotype, which could be reversed to the p53-positive phenotype by removal of *loxP* sites (and STOP cassette) using a tamoxifen inducible Cre-recombinase. The p53-null mice in this setting developed lymphomas and sarcomas. After the tumors grew to a detectable size as measured by MRI imaging, the investigators restored p53 expression by administration of tamoxifen, which removed the STOP cassette and *loxP* sites. Within 24–48 h of activation of p53, it was shown that lymphomas regressed by apoptosis as determined by markers of cell death [62]. On the other hand, regression of sarcomas was only modest by 48 h and took several days for complete regression. The regressing sarcomas showed no apoptosis but rather were positive for markers of senescence such as SA-β-gal, $p16^{INK4a}$, and $p15^{INK4b}$. Thus, the investigators concluded that p53 restoration caused tumor regression in both lymphoma and sarcomas, although the outcome in the first case was based on apoptosis, and in the second case was based primarily on senescence induction [62]. The reasons for cancer clearance after senescence induction are not clear, but could involve immune response by the host.

10.2 Apoptosis and Cancer

Long before the role of senescence in pathogenesis of cancer was recognized, it was firmly believed that inhibition of apoptosis is an integral part of cancer development [64–66]. Current literature only reinforces this notion that apoptosis is an important determinant in the pathogenesis of cancer. Selective elimination of cancer cells by apoptosis is still the long sought promise of many cancer therapy drugs [67]. The process of apoptosis is irreversible and characterized by chromatin condensation, nuclear fragmentation, membrane blebbing and cell shrinkage, and formation of apoptotic bodies [68]. These properties of apoptotic cells are distinct and usually not associated with other forms of cell death such as necrosis, autophagy, and mitotic catastrophe [69]. In view of its highly regulated nature, apoptosis is also termed programmed cell death (PCD). Apoptosis is involved in many physiological processes such as embryonic development, morphogenesis and tissue homeostasis [70, 71]. It is dysregulated in many human diseases such as autoimmune diseases, AIDS, neurodegenerative diseases, and cancer [72]. Here, we briefly review the mechanisms of apoptosis, the role of apoptosis in cancer progression and induction of apoptosis by cancer therapeutics.

10.2.1 Mechanisms of Apoptosis

In mammalian cells, apoptosis is activated and executed through two major signaling pathways, the intrinsic and the extrinsic pathways (Fig. 10.4) [73, 74]. The intrinsic pathway is mitochondria-mediated and is triggered by intracellular

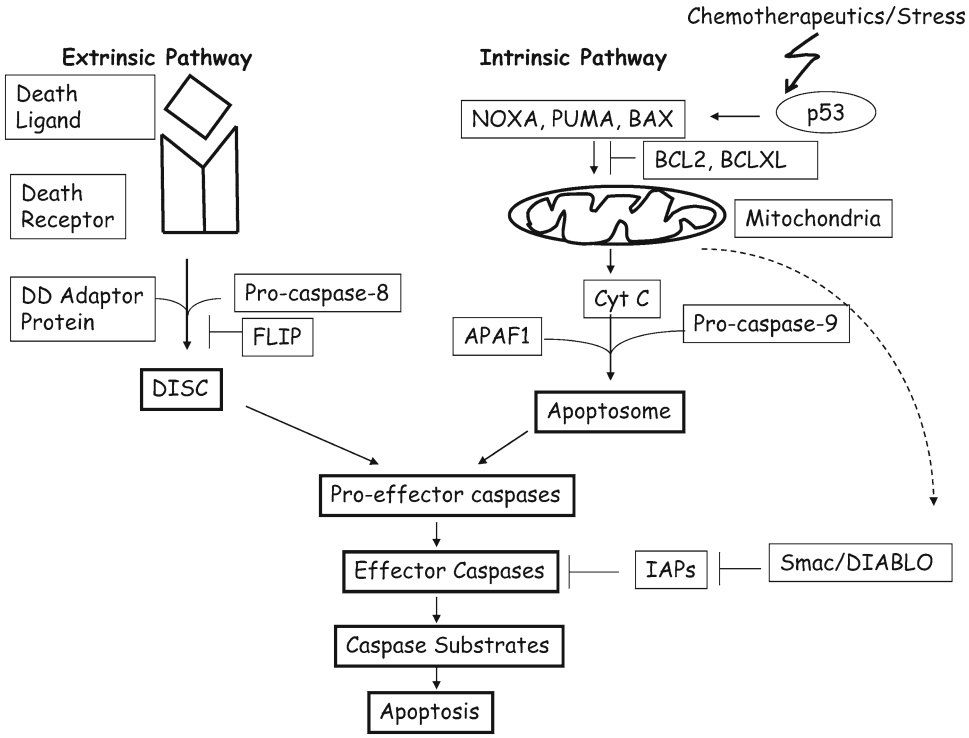

Fig. 10.4 A simplified cartoon of apoptotic pathways in mammalian cells. The extrinsic pathway of apoptosis is activated when a death ligand such as FASL, binds to pro-apoptotic receptor such as FAS. The downstream signaling is mediated by interaction of death ligand–death receptor complex with a death domain (DD) protein such as FADD. The association of these proteins with pro-caspase-8 results in DISC assembly, which activate effector caspases by proteolytic cleavage. Effector caspases cleave various caspase substrates to complete the process of apoptosis. FLIP inhibits DISC assembly by binding to caspase-8 and DD adaptor proteins. The intrinsic pathway of apoptosis is primarily mediated by mitochondrial release of Cyt-c. In response to DNA damage or other stresses, p53 is activated, which transcriptionally induce pro-apoptotic proteins such as BAX, NOXA, and PUMA. These proteins help release of Cyt-c from mitochondria. Release of Cyt-c is inhibited by BCL2 and BCLXL. Cyt-c release facilitates APAF1 and pro-caspase-9 assembly known as apoptosome, which activate casapase-9. Caspase-9 binds pro-effector caspases and activates them. IAPs negatively regulate effector caspases such as caspase-3, caspase-6, and caspase-7. Certain IAPs such as XIAP also binds and inhibits caspase-9. In response to apoptotic signals, mitochondria also releases an inhibitor of IAPs known as Smac/DIABLO. The role of these pro- and anti-apoptotic proteins is described in the main text.

cues such as DNA damage [73, 74]. The intracellular signals activated by DNA damage or other stresses result in the release of electron-transport chain intermediate Cytochrome-c (Cyt-c) to the cytoplasm from mitochondrial intermembrane space (IMS). Once released into the cytoplasm, Cyt-c facilitates the binding of procaspase-9 to APAF-1, which results in its activation and formation of the apoptosome containing activated caspase-9 [73, 74]. Release of Cyt-c from IMS is regulated by a balance between pro-apoptotic and anti-apoptotic members of the BCL2 (Bcl-2) family of proteins [74].

The detailed mechanism of action of these pro-apoptotic and anti-apoptotic proteins is still not clear. It is thought that pro-apoptotic BH3 (BCL2 homology 3)-only proteins such as BIK, BAD, BIM, NOXA, PUMA, and multi-domain BH proteins such as BAX, BAK, BCLB, BLCG, and others increase the permeability of mitochondrial membrane by forming pores. On the other hand, anti-apoptotic BCL2 family members such as BCL2, $BCLX_L$, BCLB, BCLW, and MCL1 prevent permeabilization of mitochondrial outer membrane by inhibiting the function of pro-apoptotic members of BCL2 family of proteins [74–76]. Several of these pro-apoptotic proteins such as NOXA, PUMA, and BAX are direct transcriptional targets of p53 [77–79], which is activated by DNA damage and other stress signals. p53 can also directly cause Cyt-c release from mitochondria and thus cause apoptosis without transcriptional activation of its target genes [80, 81]. Other molecules which regulate intrinsic pathway of apoptosis are IAPs (inhibitor of apoptosis) such as XIAP, which inhibits caspase-3, caspase-7, and caspase-9 [82]. XIAP in turn is inhibited by a pro-apoptotic protein Smac/DIABLO, which is released by mitochondria during apoptosis (Fig. 10.4) [83, 84].

The extrinsic pathway is death receptor-mediated and is activated at the cell surface by extracellular cues, whereby pro-apoptotic (death) ligand binds such as FASL, TNF, and TRAIL, bind and activate pro-apoptotic (death) receptors CD95/FAS, TNFR, and DR4/5 respectively [73, 74]. Death receptors contain related intracellular motifs known as death domains (DD), which interact with similar domains in corresponding adaptor molecules such as FADD and

TRADD. Through the interaction of DD of death receptors and corresponding adaptors, DISC (death-inducing signaling complex) is assembled at the plasma membrane. Adaptor molecules also contain death effector domains (DED), which help recruit procaspase-8 via its own DED domain to DISC [73, 74]. Once at DISC, high local concentration of procaspase-8 leads to its activation via autoproteolytic cleavage. Subsequently, caspase-3, caspase-6, and caspase-7 are activated, which ultimately lead to apoptosis by cleaving their substrates (Fig. 10.4) [73, 74].

Caspases belong to a family of cysteine-dependent aspartate-directed proteases [85]. There are two types of caspases, upstream or initiator caspases (caspase-8, caspase-9, and caspase-10), and effector or executioner caspases (caspase-3, caspase-6, and caspase-7) [85–87]. The upstream caspases activate effector or executioner caspases. The executioner caspases then cleave selected set of target proteins after an aspartate residue in their amino acids sequence [85–87]. The target of caspases include caspase-activated DNAse (CAD), nuclear laminins, cytoskeletal proteins, apoptosis inhibitory proteins such as BCL2 and BCL-X_L, poly(ADP-ribose) polymerase (PARP), and other proteins [85–87]. Cleavage of these various substrates ultimately results in nuclear fragmentation, membrane blebbing, and other morphological changes seen in apoptotic cells. Apart from caspases, non-caspase proteases such as cathepsins, calpines, and granzymes are also implicated in apoptosis [86, 88].

10.2.2 Apoptosis and Cancer Progression

The role of inhibition of apoptosis and cell death comes from epidemiological studies about cancer mutations, and in vivo mouse models where apoptosis related genes have been knocked out or overexpressed in transgenic models.

10.2.2.1 Apoptosis Genes and Cancer

Given the prime role of apoptosis in inhibition of proliferation and growth, and the clearance of deleterious cells, it is not surprising that many apoptosis-related genes are altered in cancer [89]. Many tumor suppressors that directly or indirectly inhibit apoptosis are mutated, deleted, or underexpressed in a variety of cancer cells. Here, we summarize genetic aberrations in few important apoptosis-related genes that are found in human cancer.

p53

The most prominent tumor suppressor in this category is p53 encoded by gene *Tp53*, which is mutated in more than 50 % of human cancers [60, 61] (also see http://p53.free.fr and www-p53.iarc.fr). Most mutations in p53 are missense and occur in its DNA binding domain (up to 80 %) [60, 61]. p53 primarily modulates intrinsic pathway of apoptosis by transcriptional control of pro-apoptotic genes such as BAX, NOXA, PUMA, and APAF-1 [79]. p53 is also involved in extrinsic pathway of apoptosis, where it transcriptionally regulates FAS and DR5 [90, 91]. Recently it was shown that p53 can also transcriptionally upregulate caspase-3 [92], which is an executioner caspase involved in both extrinsic and intrinsic pathways of apoptosis.

BCL2 and BCL2 Family Members

BCL2 (B-cell CLL/lymphoma 2) gene, which is located at chromosome 18q21.3 in human is frequently overexpressed in acute and chronic leukemia and non-Hodgkin lymphoma. It is also overexpressed in several solid cancers such as prostate, breast, lung, gastric, and renal cancers [93, 94]. It was identified as a gene located at the break point of the t(14;18) translocation found in follicular lymphoma, and the protein encoded by it was found to be a 26-kDa protein, which is homologous to a predicted Epstein-Barr virus protein [95]. BCL2 is a very potent inhibitor of apoptosis, although mechanism of inhibition of apoptosis by BCL2 is not clear. BCL2 is localized to outer mitochondrial membrane. It is thought that BCL2 preserves mitochondrial integrity by preventing oligomerization of BAX/BAK and by inhibiting the release of Cyt-c and other apoptogenic molecules from mitochondria [93, 94]. Apart from regulating the release of Cyt-c, BCL2 can also regulate the activation of initiator caspases independent of Cyt-c [96].

$BCLX_L$, a splice variant from gene *BCLX*, exhibits 44 % homology to BCL2 and protects cells from apoptosis. $BCLX_S$ another splice variant of BCLX, acts as a dominant negative inhibitor of BCL2 and $BCLX_L$, and is a pro-apoptotic protein. Increased expression of $BCLX_L$ is detected in several human cancers such as hepatocellular and renal carcinoma, and pancreatic cancer [93]. BCLW, another BCL2 like gene was found to be overexpressed in colorectal and gastric carcinomas [93]. Likewise two other anti-apoptotic protein A1/BFL1 and MCL1, with significant homology to BCL2, are overexpressed in gastric cancer and the myeloid leukemias respectively [93]. Consistent with their tumor suppressor function, the pro-apoptotic members of BCL2 family, such as BAX and BAK, are underexpressed in human cancers. For example, downregulation of BAX has been reported in breast cancer and hepatocellular carcinoma [93, 97]. In addition, loss of function and frame shift mutations in BAX have been reported in colon cancer and hematological malignancies [93]. Similarly, BAK mutations and its reduced expression have been reported in gastric and colorectal cancers [98].

APAF1

APAF1 (Apaf-1) is essential for activation of caspase-9 following Cyt-c release [99]. It is mutated, transcriptionally silenced, or downregulated in various cancers such as melanomas [100], colorectal cancer [101], bladder and kidney

cancers [102], leukemia [103], and multiple myelomas [104]. APAF1 is p53 transcriptional target and is essential for DNA damage induced apoptosis in several cell types [105].

IAPs

IAPs family of proteins acts as inhibitors of apoptosis by negatively regulating caspases. Members of IAPs family of proteins are dysregulated in numerous cancers, and are involved in tumor resistance to chemotherapeutics [106]. cIAP-2, survivin, livin, and XIAP were reported to be overexpressed in pancreatic cancer [107]. Survivin, cIAP1, cIAP2, NAIP, and XIAP are also overexpressed in esophageal cancer than in normal mucosa [108]. Livin/ML-IAP is overexpressed in lung cancer and melanomas [109]. Survivin overexpression is correlated with bladder cancer progression [110]. It is also overexpressed in breast cancer and is an independent prognostic marker of poor survival [111, 112]. Survivin is reportedly overexpressed in several other cancers such as pancreatic cancer [113], pediatric cancers [114], esophageal and squamous cell carcinomas [115], thyroid cancers [116], non-small-cell lung cancer [117], ovarian cancer [118], and gastric cancers [119]. Because of its overexpression in a variety of cancers and its role in chemoresistance and radioresistance, survivin is considered an attractive target for cancer therapy [120].

Other Apoptosis Related-Genes in Cancer

Several other genes involved in extrinsic pathway of apoptosis such as death receptors, death ligands, and adaptor proteins, and caspases are dysregulated in cancer. FAS (CD-95), which initiates the extrinsic pathway of apoptosis is mutated or downregulated in human malignancies such as gastric cancers [121], non-small-cell lung cancers [122], ovarian cancers [123], colon cancer [124], esophageal cancer [125], and lymphomas [126, 127]. Similarly, TRAIL receptors are mutated in breast and other cancers [128]. Caspases are also found to be downregulated and contain inactivating mutations in breast cancer and breast cancer cell lines [129]. Several other genes related to apoptosis and cell survival are altered in cancers; tumor suppressors such as PTEN, p14ARF, pRB, ATM, and CHK2 are often mutated, deleted, or underexpressed, while oncogenes such as *AKT*, *NF-kB*, *PI3K* subunits, and *RAS* genes are activated and/or overexpressed in various human cancers [89].

10.2.2.2 Mouse Models of Apoptosis and Cancer

A direct role for cell death or apoptosis-related genes in cancer comes from knockout and transgenic studies. It is very well established that deficiency of p53, which is a prime regulator of apoptosis, results in a wide spectrum of cancers, most notably soft-tissue sarcomas, and lymphomas in knockout mouse models [130] (also see http://p53.free.fr/p53_info/Mouse_model/p53_mouse_models.html). *Tp53*−/− mice develop normally but succumb to cancer in less than a year, suggesting that the apoptotic role of p53 is not essential for normal development, but is important for tumor suppression [130]. However, the cause of high rate of spontaneous tumorigenesis in *Tp53*−/− knockout mice is poorly understood. Recent in vivo knockin studies using wild-type or mutant p53, expression of inducible p53, and inducible/regulated knockout mice models has produced insight into the particular functions of p53 that relate to its regulation of apoptosis and senescence.

A recent surprising finding suggest that expression of human p53 in *Tp53*−/− knockout mice (SWAP mice) did not complement p53-mediated transactivation, apoptosis, and G1-S checkpoint, although the mice displayed normal p53-mediated centrosomal checkpoint and p53-mediated transrepression [131]. The SWAP mice apparently developed tumors similar to p53 deficient mice suggesting that the role p53 in spontaneous tumorigenesis does not fully rely on apoptosis [131]. However, a different study where a chimeric human-mouse p53 was used for knockin studies suggests that the chimeric p53 can fully rescue mouse p53 deficiency, restores apoptosis response to DNA damage, and blocks accelerated development of spontaneous cancers [132, 133]. Christophorou et al. investigated the tumor suppressor functions of p53 using a 4-hydroxytamoxifen (4-OHT) inducible knockin gene replacement ($p53ER^{TAM}$) mouse model [134]. It was shown that depending on the presence or absence of 4-OHT, such mice can be rapidly toggled between wild-type and p53 knockout states. Using this rapid perturbation model, authors showed that DNA damage induced apoptosis requires p53 in vivo [134]. To dissect out the function of p53 required for tumor-suppression in this model, $p53ER^{TAM}$ mice were crossed with lymphoma prone Eμ-Myc mice [135]. The composite transgenic mice could be rapidly converted into p53-deficient and p53-sufficient mice with 4-OHT. In the absence of 4-OHT, these mice rapidly developed lymphoma, while the restoration of p53 using 4-OHT significantly delayed tumorigenesis [135]. Furthermore it was shown that in this setting rapid induction of p53 induced tumor apoptosis as determined by annexin V/PI and TUNEL staining [135].

Restoration of p53 function using another 4-OHT inducible *Cre-loxP* system in mouse was shown to cause rapid regression of lymphomas by inducing apoptosis and not cellular senescence as determined by markers of apoptosis and senescence [62]. Several other p53 knockin mouse studies have clearly demonstrated that apoptosis-related function of p53 is required for its tumor suppressive function [136]. For example, Liu et al. showed that in R172P (mutant p53) knockin mice, the mutant p53 retained cell-cycle arrest function but lost its apoptotic function, and that these mice showed delayed cancer onset and stable chromosome number when

compared to Tp53−/− mice [137]. Short-telomeres in telomerase knockout mice (mTR−/−) at later generations (G-5/6) has been shown to limit tumor formation via induction of p53-dependent apoptosis [138, 139]. Furthermore, in this model, it was shown that p53 deficiency abrogates the short telomere-induced apoptotic response, and enhances tumor formation [138].

There are several reports of *BCL2* cooperating with other oncogenes such as *RAS* and *MYC* to develop tumors in transgenic mouse models [140]. BCL2 overexpression alone in B-Cells demonstrated extended survival and follicular lymphoproliferation, while the translocated BCL2 (t(14:18)) transgenic mice developed high-grade malignant lymphoma [141, 142]. BCL2 overexpression using prostate-specific Probasin promoter has been shown to facilitate multistep progression of prostate cancer in TRAMP (TRansgenic Adenocarcinoma Mouse Prostate) mice that express the SV40 early genes (T/t antigens) [143]. Similarly, cooperation between H-RAS and BCL2 has been demonstrated in multistep skin carcinogenesis in a mouse model [144]. Using a conditional BCL2 and constitutive MYC in a transgenic mouse model, Letai et al. have demonstrated that the suppression of apoptosis by BCL2 is required to enhance and maintain leukemia [145]. BCL2 also synergizes with MYC during mammary carcinogenesis in a WAP-Bcl-2/MMTV-c-Myc transgenic mouse model [146]. Overexpression of $BCLX_L$, which functions similar to BCL2 in a nonredundant way, has been shown to enhance transformation of pancreatic β cells by SV40 large T in a mouse transgenic model [147]. $BCLX_L$ also promotes chemically induced skin carcinogenesis in the transgenic mouse model [148]. Studies from several other mouse knockout and transgenic models of BCL2 family members strongly implicate apoptosis in tumor progression and tumor resistance to chemotherapy and radiotherapy reagents [93].

10.2.3 Apoptosis and Cancer Therapy

Considering the important role of apoptosis in cancer progression and maintenance of the tumorigenic phenotype, it is not surprising that the major goal of oncology companies is to facilitate apoptosis in cancer. When the survival pathways are blocked, most cells, normal or neoplastic, can be killed via induction of apoptosis, necrosis, mitotic catastrophe, and autophagy. This is what chemotherapy reagents and cytotoxic drugs do to cancer cells. Intriguingly, cancer cells are more susceptible to apoptosis than normal cells, which makes apoptosis-inducing reagents more appealing. Several cancer therapy reagents that are in preclinical or clinical trials directly affect components of apoptotic pathways. Upon administration, these ligands activate extrinsic pathway of apoptosis mediated by their respective receptors resulting in caspase activation and ultimately apoptotic cell death in cancer cells.

Death ligands such as TNFα, FASL (CD95L), and TRAIL are in clinical trials for treatment of various cancers. TNFα went through extensive clinical testing in the past but was found to be very toxic for systemic administration due to its detrimental effect on normal cells in addition to cancer cells. Similar to TNFα, FASL is also toxic when systemically administered. Clinical trials with TRAIL and TRAIL receptor agonists are now under way for the treatment of cancer [149, 150]. These reagents are less toxic to normal cells because TRAIL receptors (DR4 and DR5) are more selective to cancer cells [149, 150]. Although TRAIL therapy is promising, many cancer cells are resistant to TRAIL. Therefore, use of TRAIL in combination therapy is being developed against tumors that are refractory to treatment with either agent alone [151]. Several reagents such as COX-2 inhibitors and Casein kinase inhibitors can also sensitize cells to TRAIL and FASL by enhancing death receptor clustering, and recruitment of FADD and caspase-8, respectively [67]. Other apoptosis-related reagents that are being developed for cancer treatment include BCL2 antisense oligonucleotide, small molecule antagonist (SMA) of BCL2, $BCLX_L$ antisense oligonucleotides, SMA of $BCLX_L$, XIAP antagonists, survivin antisense oligonucleotides, and inhibitors of PI3K/AKT pathway. Apart from these reagents, p53 reactivating small molecules such as CP-31398, PRIMA-1, MIRA-1 are also being used to restore p53 functions and apoptosis in cancer [152]. Similarly, MDM2 antagonists such as Nutlin, RITA, and other compounds can be used to activate and potentiate wild-type p53 function to cause apoptosis and senescence in cancers that overexpresses MDM2 but contain wild-type p53 [153–158].

10.3 Concluding Remarks

Arguably, cancer is the most complex disease of our time. Multiple genetic pathways are deregulated in cancer. Loeb et al. have suggested that a human cancer of 10^8 cells likely contains a billion different mutations [159]. Loeb et al.'s calculations may be artificially high and are based on a postulated mutator phenotype of tumors, which may not be common to all cancers, and is debatable. However, there is no argument that cancers contain multiple mutations (perhaps not a billion) and genetic aberrations. At least four steps, which may involve several genes, are required for the conversion of normal cells into malignant tumor cells [65]. Recently, Sjoblom et al. analyzed 13,023 individual genes in 11 breast and 11 colorectal cancers to conclude that individual tumors contain an average of approximately 90 mutant genes [160].

Quite often, it is difficult to pinpoint what is the key primary mutation in the development of a specific cancer, and what are the vast majority of passenger or secondary mutations, which accumulate in a genetically unstable tumor

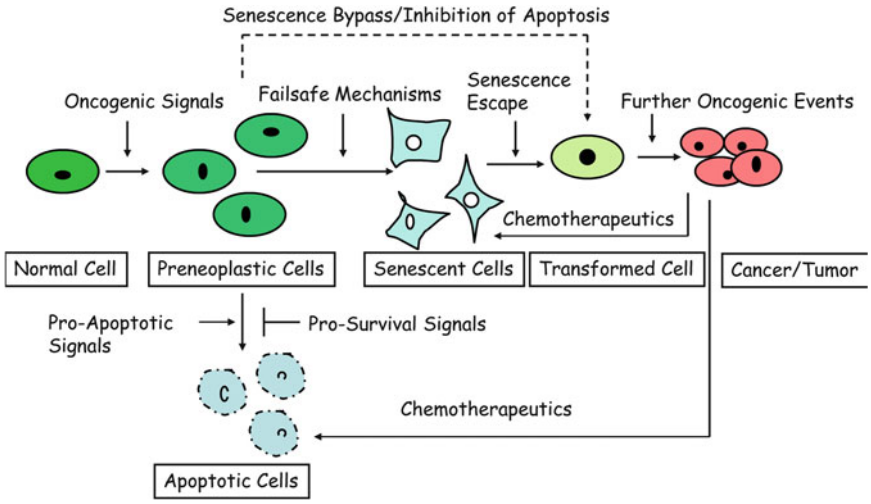

Fig. 10.5 A model of cancer progression suggesting that senescence bypass and inhibition of apoptosis due to mutations in these pathways results in cancer development. Various oncogenic signals prime a cell to a transitional stage known as preneoplastic stage. Preneoplastic cells can undergo senescence or apoptosis by fail-safe or genome surveillance mechanisms. Some cells can escape senescence and become immortal and transformed. Cells that have bypassed senescence or cannot undergo apoptosis in response to oncogenic signals become transformed. Accumulation of further oncogenic events leads to full-blown tumor capable of angiogenesis and metastasis to other organs. Treatment of tumors with chemotherapy drugs can induce either senescence or apoptosis, and ultimately tumor clearance by immunosurveillance mechanisms occur (not shown).

cell. Despite these undesirable traits of cancer cells, a few key steps are vital for cancer development, progression, and maintenance. Two of these key steps are senescence bypass and inhibition of apoptotic pathways (Fig. 10.5). Senescence bypass is essential for cancer initiation and development, while inhibition of apoptosis and induction of survival pathways is essential for cancer progression and maintenance (Fig. 10.5). Cancers achieve these goals by mutation in multiple pathways involved in these key processes. Therefore, the primary goal of cancer treatment strategies remains with the induction of apoptosis and/or senescence by interfering with the mutations that were responsible for senescence bypass and inhibition of apoptosis. Apart from these generalized treatment strategies, we now know that targeted therapies can also be used to induce senescence and/or apoptosis in tumors.

Very recent reports from laboratories of Drs. Lowe, Jacks, and Evans clearly show the promise of turning on apoptosis and senescence by a single gene *TP53* in a mouse model of cancer. Turning on *TP53* in hepatocellular carcinomas and sarcomas resulted in cellular senescence, which eventually caused regression of these tumors, and completely cured mice of these cancers [62, 63]. On the other hand, p53 induction caused apoptosis and a rapid regression of lymphoma in mice to restore normal life span [62, 135]. These reports are of extraordinary significance. We have learned a lot about cancer from animals models. We can add one more chapter of learning from these mice models that perhaps treating human cancer is not impossible; we just need to find ways to restore apoptosis and/or senescence in tumors.

Novel Cancer Therapies Targeting Angiogenesis

11

Monte S. Willis and Nancy Klauber-DeMore

11.1 Tumors Overcome Growth Limitations by Directing the Formation of New Blood Supply

There are four general strategies by which cancers can enhance their blood supply. They can (1) stimulate angiogenesis, (2) utilize existing vessels directly, (3) induce vasculogenesis, and/or (4) form vasculogenic networks without vascular cells. The secretion of proangiogenic factors and/or inhibition of antiangiogenic factors induce vascular sprouting from preexisting capillaries and venules constitutes the process of angiogenesis. This is the most common way cancers gain access to the vasculature. Cancers may also utilize existing vessels directly by growing along beside them, as is the case in astrocytomas [1]. The strategy of vasculogenesis involves the formation of blood vessels from bone marrow precursors. Vasculogenesis differs distinctly from angiogenesis in that the source of the cells that make up the vessels are from the bone marrow and not from preexisting vessels. However, many of the soluble mediators that initiate this process, notably VEGF, parallel those found in angiogenesis [2]. Lastly, tumors themselves can form lumens which can be used to transport blood, lacking endothelial cells or other vascular components. The contribution of these types of networks to cancer progression has been debated [3, 4]. Multiple strategies may be in play in a particular tumor, depending on their stage and malignancy. We focus here on the major pathways of angiogenesis as its contribution is most common as applied to therapeutic intervention.

11.2 Evidence that Angiogenesis is Necessary for Cancer Progression

The initial evidence that angiogenesis is necessary for the growth of cancer came from studies transplanting cancer cells into the avascular corneas of rabbits [5]. In these studies, tumors did not grow in rabbit corneas before sprouting vessels were able to grow to connect to the tumor. Moreover, inhibiting vessel formation would prevent cancer growth beyond 0.4 mm [5]. Other investigators similarly found that tumors placed in chicken embryo chorioallantoic membranes shrank during the first three days after placement [6]. However, new vessel formation could be seen to form from existing vessels after the cancers were placed. When these new vessels connected to the tumor, cancer growth continued. These studies not only identified a significant role of vessel formation in cancer progression but also determined that cancers elicit the growth of vessels from existing vessels. This suggests that cancer release diffusible factors that initiate angiogenesis (vessel formation from existing vasculature) to continue and maintain their growth.

The ability of cancer cells to induce angiogenesis is not a constitutive trait. In mice, the ability to induce angiogenesis appears to be initiated by tumor progression in models of pancreatic cancer [7, 8] and dermal fibrosarcomas [9–11]. The initiation of a program to induce angiogenesis also occurs in the development of human tumors. Evidence for this comes from comparing vasculature in precancerous and cancerous lesions of the breast, where the microvessel density has been reported to be relatively increased [12]. Similarly, increased capillary density has been reported to increase in cervical squamous cell carcinoma as the stage progresses [13, 14], suggesting that as a cancer becomes more aggressive, its ability to stimulate angiogenesis increases. It is believed that the switch that cancer undergo to induce angiogenesis not only come from the malignant tissue itself, but also from the surrounding tissue and infiltrating immune cells [15]. The targets of these soluble factors are endothelial cells as well as other vascular cells in the

W.B. Coleman, G.J. Tsongalis (eds.), *The Molecular Basis of Human Cancer*, DOI 10.1007/978-1-59745-458-2_11

microenvironment of the tumor [15]. The interplay between the soluble proangiogenic and antiangiogenic factors and their cognate receptors on the targets is the basis of tumor-induced angiogenesis necessary for tumors to continue their unrestrained growth. Each step in the angiogenic process presents an opportunity for targeted inhibition of angiogenesis. This review focuses on the main steps of angiogenesis for which targeted therapy is being developed.

11.3 Growth Factors/Receptor Tyrosine Kinases

11.3.1 Vascular Endothelial Growth Factor Family

An essential mediator of angiogenesis is the vascular endothelial growth factor (VEGF) family, which consists of five family members of secreted proteins (VEGFA, VEGFB, VEGFC, VEGFD, VEGFE), and platelet-derived growth factor (PDGF) [16], that bind and activate three receptor tyrosine kinases (VEGFR-1, VEGFR-2, and VEGFR-3). VEGFA stimulates endothelial cell proliferation, migration, tube formation, and vascular permeability. VEGFB was identified as an endothelial cell growth factor expressed in heart and skeletal muscle [17]; however, its function as an angiogenesis factor is not clearly defined. VEGFC and VEGFD play a critical role in lymphangiogenesis and expression has been correlated with the development of lymph node metastases [18]. Placental growth factor (PGF) promotes the survival of endothelial cells and modulates the activity of VEGF signaling [19].

Regulation of VEGF family genes expression is under the control of hypoxia, along with other forms of stress such as acidity and hypoglycemia, which stimulate transcription and increase mRNA stability, resulting in increased protein expression. Under normoxic conditions, prolyl residues in hypoxia-inducible factors (HIF) proteins are hydroxylated by prolyl hydroxylase in a reaction that uses molecular oxygen. Hydroxylation of HIF proteins targets them for ubiquitin-mediated proteolysis. Reduction in the concentration of oxygen decreases the efficiency of this process: HIF proteins are stabilized and therefore become available to bind to hypoxia-response elements in the promoters of target genes, thereby activating transcription [20].

VEGF proteins bind to receptor tyrosine kinases (VEGFR-1, VEGFR-2, and VEGFR-3) [21], which then mediate cell signaling resulting in the biologic effects of VEGF. VEGFR-1 (Flt-1) binds three of the VEGF family ligands, VEGF-A, VEGF-B, and PGF. Activation of VEGFR-1 results in embryonic vessel development, hematopoiesis, macrophage chemotaxis and recruitment of endothelial progenitor cells to tumor blood vessels from the bone marrow [22]. VEGFR-2 (Flk-1/KDR) is the key mediator of VEGF-stimulated tumor angiogenesis and is critical in embryonic vascular development. When VEGF ligands VEGFR-2, the receptor is phosphorylated and activates downstream signaling molecules including phospholipase C, protein kinase C, Raf, MAP kinase, PI3K, and FAK pathways, resulting in endothelial cell proliferation, migration, and tube formation, and anti-apoptosis [23]. VEGFR-3 binds VEGF-C and -D and is implicated in the formation of lymphatics in normal tissue and tumors [24].

In 2004 the humanized version of a monoclonal antibody to VEGFA, bevacizumab (Avastin; Genentech), became the first Food and Drug Administration (FDA)-approved antiangiogenic drug in the United States [18]. It was approved as a first-line treatment agent for metastatic colorectal cancer, in combination with 5-fluorouracil [25] and was subsequently approved for treatment metastatic non-squamous-cell lung cancer, breast cancer, and glioblastoma multiforme [26]. Ranibizumab (Lucentis; Genentech), another monoclonal antibody recognizing VEGFA, and pegaptanib (Macugen; Pfizer, New York, NY), a single-stranded nucleic acid aptamer that binds specifically to the heparin-binding domain of VEGFA165, are FDA-approved antiangiogenesis inhibitors in use for treating the wet type of age-related macular degeneration [27].

Additional FDA-approved drugs that block VEGF signaling are sorafenib and sunitinib, both receptor tyrosine kinase inhibitors, which are both administered orally. Sorafenib, in addition to blocking VEGFR signaling, also blocks FLT3, PDGFRB, and KIT signaling [28]. Similarly, sunitinib blocks signaling from VEGFR1-3, FLT3, RET, PDGFRA, and PDGFRB [28]. Sorafenib has been approved for unresectable hepatocellular carcinoma and advanced renal cell carcinoma, whereas sunitinib has been approved for gastrointestinal stromal tumors and metastatic renal cell carcinoma [18] and neuroendocrine tumors [29].

11.3.1.1 Fibroblast Growth Factor

Fibroblast growth factors (FGFs) are involved in maintaining endothelial cell function. FGF1 and FGF2 promote endothelial cell migration and proliferation and stimulate angiogenesis [30]. FGFs produce their biological effects by binding to transmembrane tyrosine kinase receptors, FGFR1 through FGFR4 [31]. FGFR can activate PLC-γ, thereby stimulating the production of diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). This, in turn, releases intracellular calcium and activates Ca^{2+}-dependent PKCs. The activation of the PI3K-Akt cell survival pathway is one of the important biological responses induced by FGF2 in endothelial cells [32].

There are several inhibitors of FGF signaling in clinical trials, including FP-1039 (FGFR1:Fc), a soluble fusion protein consisting of the extracellular domain of human fibroblast growth factor receptor 1c (FGFR1) linked to the Fc portion of human IgG1. FP-1039 prevents FGFR1 ligands from binding to any of their cognate receptors within the family of seven FGF receptors, and may mediate both direct antitumor and

antiangiogenic effects. Both E-3810 and TKI258 are dual VEGFR and FGFR tyrosine kinase inhibitors [30].

11.3.1.2 Notch

The Notch signaling pathway is important for cell-cell communication, involving gene regulation mechanisms that control multiple cell differentiation processes during embryonic and adult life. Notch signaling has been directly implicated in tumor angiogenesis and in the process of activating dormant tumors. VEGFA also induces expression of the endothelium-specific Notch ligand Delta-like 4 (DLL4). When DLL4 activates the Notch signaling pathway in adjacent cells, the effect is to inhibit dorsal sprouting. When expressed in tumor cells DLL4 can activate Notch signaling in host stromal cells, thereby improving vascular function [33]. Inhibition of DLL4-mediated Notch signaling promotes a hyperproliferative response in endothelial cells, a process that leads to an increase in angiogenic sprouting and branching. Despite this increase in vascularity, tumors are poorly perfused, hypoxia increases, and cancer growth is inhibited. Neutralizing anti-Dll4 antibodies have been demonstrated to inhibit cancer growth in vivo [34]. These findings point to the Notch pathway as a potential therapeutic target.

11.3.1.3 TGFβ

TGFβ is a paracrine polypeptide with three homologous forms (TGFβ1, TGFβ2, and TGFβ3). TGFβ is produced in latent form as a zymogen and after secretion a latency associated peptide is proteolytically cleaved to release active TGFβ. Active TGFβ signals by binding to constitutively active type 2 receptors (TGFBR2) to activate type 1 receptors (TGFBR1) in a heteromeric complex that controls transcription through the action of a family of SMAD proteins [35]. TGF-β is a strong proangiogenic agent despite the fact that TGFβ causes growth arrest and apoptosis of endothelial cells in vitro. This paradoxical behavior may be explained by the fact that TGFβ activates the secretion of fibroblast growth factor 2, which acts as an autocrine signal to stimulate the expression of VEGF. VEGF, in turn, acts in an autocrine manner through its receptor VEGFR-2 to activate the MAPK pathway (specifically p38MAPK). However, TGFβ will reverse the protective action of VEGF, promoting apoptosis, which occurs in the pruning process, to form the final vascular network [36]. Endothelial cells subsequently become refractory to TGFβ-mediated apoptosis and TGFβ then directly promotes capillary lumen formation. Therapeutic approaches for targeting TGFβ signaling include antagonism of TGFβ ligand binding to the heteromeric receptor complex with isoform-selective antibodies, such as lerdelimumab (TGFβ2) and metelimumab (TGFβ1) or the pan-neutralizing antibody GC-1008, and intracellular inhibition of the type I TGFβ receptor kinase with small-molecule inhibitors, such as LY550410, SB-505124, or SD-208 [37].

11.3.1.4 Angiopoietin/Tie Receptors

Angiopoietins are another family of endothelial cell-specific molecules that play an important role in vessel growth, maintenance, and stabilization by binding to Tie receptors [38]. There are four types of angiopoietins: Ang-1, Ang-2, Ang-3, and Ang-4. The Tie1 receptor is highly expressed in embryonic vascular endothelium, angioblasts, and endocardium, and in adult tissues expressed strongly in lung capillaries tissues [39]. The Tie2 receptor takes part in vessel maturation by mediating survival signals for endothelial cells. Ang-1 is an agonist that promotes vessel stabilization in a paracrine fashion, whereas Ang-2 is an autocrine antagonist that induces vascular destabilization. Ang-2 is increased during vascular remodeling and is implicated in tumor-induced angiogenesis and progression [40]. AMG 386 is an investigational peptide-Fc fusion protein that inhibits angiogenesis by preventing the interaction of Ang-1 and Ang-2 with their receptor, Tie2, and is being studied in clinical trials [41].

11.3.1.5 Epidermal Growth Factor

The epidermal growth factor (EGF) family consists of 11 members which bind to one of four epidermal growth factor receptors (EGFR) [42]. All of the receptors, except HER3, contain an intracellular tyrosine kinase domain [43]. Activation of EGFR contributes to angiogenesis in xenograft models [44], in addition to cellular proliferation, survival, migration, adhesion, differentiation, and cancer metastasis [43]. Activation of the EGFR pathway upregulates the production of proangiogenic factors such as VEGF, and therefore the EGFR pathway is more of an indirect regulator of angiogenesis. There are three FDA-approved EGFR inhibitors: cetuximab and panitumumab, which are monoclonal antibodies, and erlotinib, a tyrosine kinase inhibitor that specifically targets EGFR [18].

11.3.1.6 Insulin-Like Growth Factor Pathway

The insulin-like growth factor pathway plays a major role in cancer cell proliferation, survival and resistance to anticancer therapies in many human malignancies [45]. Insulin-like growth factor-1 (IGF-1) contributes to the promotion of angiogenesis through increasing VEGF expression via HIF-1a [46]. The two main strategies in development for blocking IGF signaling as an anticancer therapeutic are receptor blockade and tyrosine kinase inhibition [47]. Receptor blockade with the use of monoclonal antibody therapies against the IGF-1R (such as Figitumumab) [48] is being investigated. Tyrosine kinase inhibition is another strategy being developed. In general, these therapies will indiscriminately inhibit the kinase domains of all IGF system receptors. The exception to this is the NVP-AEW541 and NVP-ADW742, which has 15- to 30-fold increased potency for IGF-1R kinase inhibition compared to IR kinase inhibition in cellular assays [48].

11.3.2 Cell Adhesion Molecules

Integrins are heterodimer transmembrane receptors for the extracellular matrix composed of an alpha and beta subunits [49]. Integrins bind ligands by recognizing short amino acid stretches on exposed loops, particularly the arginine–glycine–aspartic acid (RGD) sequence. Upon ligation, either alone or in combination with growth factor receptors, integrins mediate signaling events that regulate angiogenesis, cell adhesion, proliferation, survival, and migration. Pathways that are activated include integrin-linked kinase, protein kinase B (PKB/Akt), mitogen-activated protein kinase (MAPK), Rac, or nuclear factor kappa B (NF-kB). In inactive vessels, integrins interact with the basal membrane, thereby maintaining vascular quiescence. During angiogenesis, integrins are essential for endothelial cell migration, proliferation, and survival. In preclinical studies, inhibition of integrin function suppresses angiogenesis and tumor growth. Of the 24 known integrin heterodimers, αVβ3 [50] and αVβ5 [51] were the first vascular integrins targeted to suppress tumor angiogenesis. Three classes of integrin inhibitors are currently in preclinical and clinical development: monoclonal antibodies targeting the extracellular domain of the heterodimer (Vitaxin; MedImmune), synthetic peptides containing an RGD sequence (cilengitide; Merck), and peptidomimetics (S247; Pfizer), which are orally bioavailable nonpeptidic molecules mimicking the RGD sequence [52].

Focal Adhesion Kinase (FAK) is a protein that plays a critical role in intracellular processes of cell spreading, adhesion, motility, survival, and cell cycle progression, and has shown to play a role in cancer angiogenesis [53]. The FAK gene encodes a non-receptor tyrosine kinase that localizes at contact points of cells with extracellular matrix and is activated by integrin (cell surface receptor) signaling. Recently Novartis Inc. developed novel FAK inhibitors downregulation its kinase activity [54]. The novel Novartis FAK inhibitor, TAE-226 was employed in brain cancer and effectively inhibited FAK signaling and caused apoptosis in these cells. Another, ATP-targeting site inhibitor of FAK, Pfizer-PF-573,228 has been described [55].

11.3.3 Calcineurin/NFAT Signaling

One of the important intracellular pathways stimulated by a variety of angiogenic growth factors, including VEGF, FGF, and a novel angiogenesis factor secreted frizzled-related protein 2 (SFRP2) [56] is activation of calcium signaling. Signaling is mediated through transient increases in cytoplasmic free calcium which activate the phosphatase calcineurin. Activated calcineurin dephosphorylates NFAT, which then translocates to from the cytoplasm to the nucleus [57]. There is increasing data supporting a critical role of NFAT in mediating angiogenic responses [58, 59]. Importantly, NFAT activation was identified as a critical component of SFRP2 [56, 60] and VEGF-induced angiogenesis and linked to the induction of cyclooxygenase-2 [61], which is also a critical player in angiogenesis. Activation of the Ca^{2+} pathway induces cell proliferation and inhibits apoptosis in cultured endothelial cells, suggesting a proangiogenic activity in vivo. FK506 is a calcineurin inhibitor that blocks NFAT activation, and has been shown to inhibit angiogenesis in vitro and tumor growth in vivo [56, 60].

11.3.4 Endogenous Angiogenesis Inhibitors

The activities of a variety of endogenous angiogenic inhibitors have been described to regulate cancer endothelial cell growth. These include thrombospondin-1 [62], angiostatin [63], endostatin [64], and 2-methoxyestradiol [65]. One of the most extraordinary developments in the discovery of endogenous inhibitors came again from the Folkman laboratory [63] via a Lewis Lung Carcinoma mouse model in which lung micrometastases seeded from primary subcutaneous cancers failed to develop further when the cancer was intact but grew rapidly after the primary cancer had been surgically removed. It was hypothesized that the primary tumor itself was producing a circulating antiangiogenic agent that inhibited blood vessel growth in the lung micrometastases. After resection of the primary cancer, the source of the endogenous angiogenesis inhibitor was removed, and the lung metastases therefore grew rapidly. O'Reilly and Folkman isolation of a protein they called angiostatin from the urine of mice with intact primary tumors. Angiostatin is a fragment of the protein plasminogen that occurs normally in the circulation, and the cleavage of plasminogen to produce angiostatin occurs in the tum or itself [63]. Purified angiostatin given daily to mice after resection of the primary tumor completely prevented the development of micrometastases. Angiostatin was subsequently shown to be active against primary cancer xenografts established in mice from inoculated human cancer cells, and it also inhibits the proliferation of endothelial cells in culture, but had no effect on cancer cell proliferation. Additional proteolytically activated antiangiogenic proteins have been isolated, including endostatin derived from collagen XVIII [64].

11.3.5 Tumor Endothelial Markers

A recent strategy to discovery novel angiogenesis targets is to explore differences in gene expression profiles between cancer and normal endothelium. This was first performed by St Croix who isolated endothelial cells using magnetic bead selection from a human colon cancer and adjacent normal colon [66].

Among the novel genes identified as being overexpressed by cancer endothelium was TEM8. TEM8 is the anthrax toxin receptor and successful targeting of this receptor in preclinical tumor models make this molecule a particularly attractive candidate for future vascular targeting studies [67]. Subsequent studies have used laser capture microdissection of blood vessels from breast cancer and normal breast tissue [68], or ovarian cancer and normal ovarian tissue [69], to identify novel targets that are presently under investigation.

11.4 Summary

Angiogenesis involves complex biological signaling pathways with a wide variety of antiangiogenic targets. Antiangiogenic therapy has been shown to increase survival in human tumors, but further research is needed to inhibit tumors that are not responsive to, or become resistant to, current antiangiogenic therapy.

Beyond the Primary Tumor: Progression, Invasion, and Metastasis

12

Danny R. Welch and Douglas R. Hurst

12.1 Introduction

The cure rate for the majority of cancer patients is >90 % if the diagnosed tumor has not spread beyond the tissue of origin. However, when tumor cells have established colonies elsewhere, the cancer is often incurable [1, 2]. Neoplasms have been diagnosed for approximately four millennia and even the earliest medical practitioners recognized that the most lethal attribute of neoplastic cells is their ability to disseminate and colonize secondary sites. Despite these well-recognized facts, the majority of cancer research funding still focuses on primary tumorigenesis. Relatively few funded grants from the NIH include the word metastasis and significantly fewer actually perform metastasis research [3]. In recognition of the need to study metastasis, a major push has been toward the last frontier of cancer research [4]. This chapter provides a brief overview of what is known regarding the cellular and molecular events of a primary tumor mass progressing to form a distinct secondary macroscopic lesion.

The evolution of a normal cell into a life-threatening metastatic cancer cell is referred to as tumor progression (Fig. 12.1). Although a secondary mass is the ultimate consequence of progression of a primary tumor cell, metastatic cells are now recognized to be behaviorally and genetically distinct from the cells remaining at the site of primary origin. These behavioral differences arise at multiple levels including the cellular level (genetic and epigenetic heterogeneity) and from the physical environment (positional heterogeneity). The molecular mechanisms underlying the phenotypic differences that characterize a metastatic cell are currently being elucidated [5, 6]. Understanding the metastatic cell and the surrounding environment may enable the design of therapeutics that target metastasis, the deadliest aspect of tumor progression [1].

12.2 Tumor Heterogeneity: Generation of a Metastatic Cell

The definition of metastasis is the dissemination of neoplastic cells to discontiguous nearby or distant secondary (or higher order) sites where they proliferate to form a mass [1, 7] (Fig. 12.2). Fortunately, this process is highly inefficient [8]. Of the millions of cells that enter the vascular compartment per gram of primary tumor per day, only small fractions (much less than 0.1 %) actually form a macroscopic mass [9, 10]. Just as most tumors are clonal in origin [5, 11, 12], each metastasis arises from a single cell [6, 13, 14]. By the time the primary mass is apparent to the individual or the diagnosing physician, it is usually composed of 10^{10} or 10^{11} cells based on the fact that a cubic centimeter of tissue contains approximately 10^9 cells. Although not all cells in a neoplasm are capable of completing the required steps for metastasis, histological examination reveals that these cells are pleiomorphic and that single cell clones isolated from a tumor vary dramatically in terms of biological behavior [5, 6, 11].

Heterogeneity describes how cancers are composed of cells which are inherently and/or behaviorally different. The basis of the behavioral differences can be genetic, epigenetic, positional, and temporal. Genetic refers to the inherent properties of tumor cells themselves. Genetic heterogeneity is demonstrated by isolation of single cell clones that stably differ for a given phenotype. Like genetic heterogeneity, epigenetic heterogeneity refers to the chemical modifications of DNA and chromatin that lead to the selective regulation of gene transcription. Epigenetic changes can occur because of position (positional heterogeneity), for example the accessibility of a cell to external stimuli (O_2, pH, growth factors, cytokines, chemokines, etc.). An example is noted with

Fig. 12.1 Hallmarks of cancer in the tumor progression continuum. The indicated phenotypes along the tumor progression continuum do (+), do not (−), or sometimes (+/−) involve the indicated properties as described by Hanahan and Weinberg [79]. Note that not all of the hallmarks are present at each stage along the entire progression. The invasion and metastasis hallmarks have been separated according to the discussion in the text. Also, the distinction has been made between the potential to form micrometastasis from development of macroscopic metastases. Examples of mouse femurs with microscopic and macroscopic metastasis are shown. The fluorescent images are from human breast cancer cells labeled with GFP that were injected intra-cardiac into athymic mice.

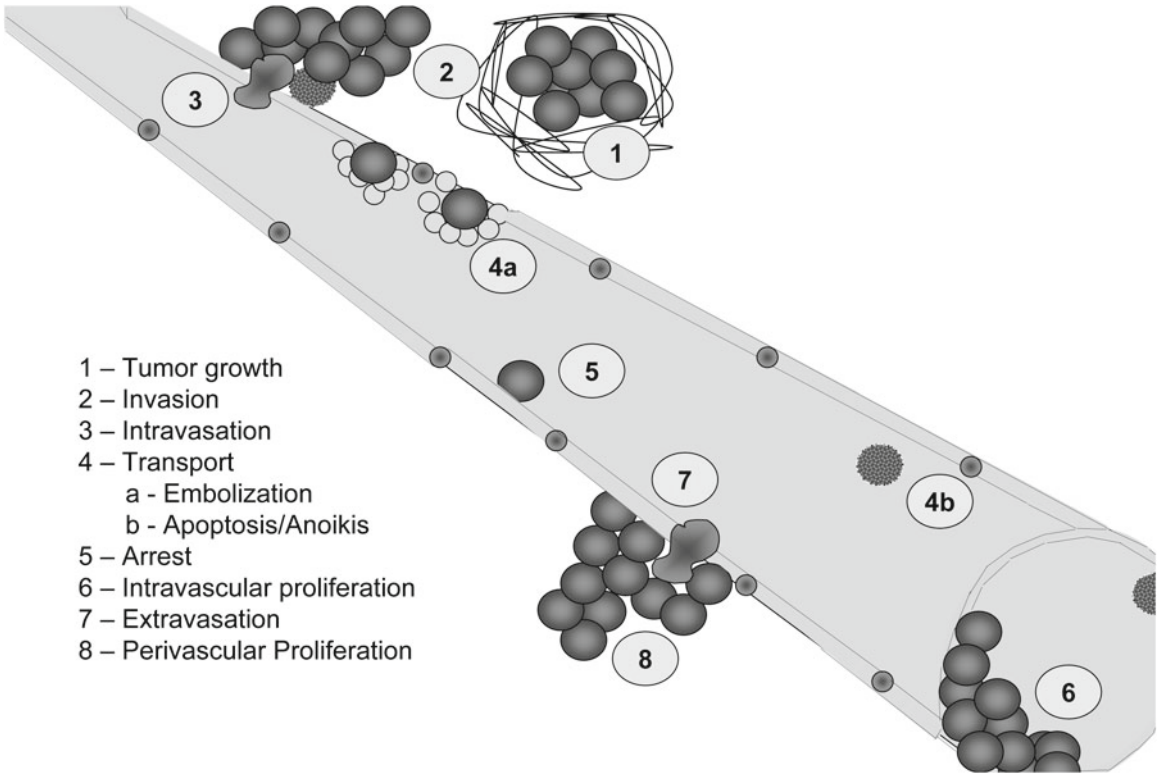

Fig. 12.2 Steps of cancer metastasis. The necessary steps for metastasis are listed in order. In the first step, tumor growth is noted with an increase in desmoplasia (1) host response to the presence of the tumor mass. Tumor cells invade away from the primary tumor (2) and eventually intravasate (3) into a circulatory compartment. Emboli involving multiple tumor cells and platelets/thrombin (4a) often occur. However, most tumor cells succumb to sheer or anoikis (4b) following entry into the vasculature. Tumor cells then specifically adhere to endothelial cells lining vessels (5), depending upon reciprocal recognition of surface molecules or arrest due to size limitations (6) at vessel bifurcations. Some cells can proliferate intravascularly (6); whereas, others extravasate (7) prior to proliferating at the secondary site (8).

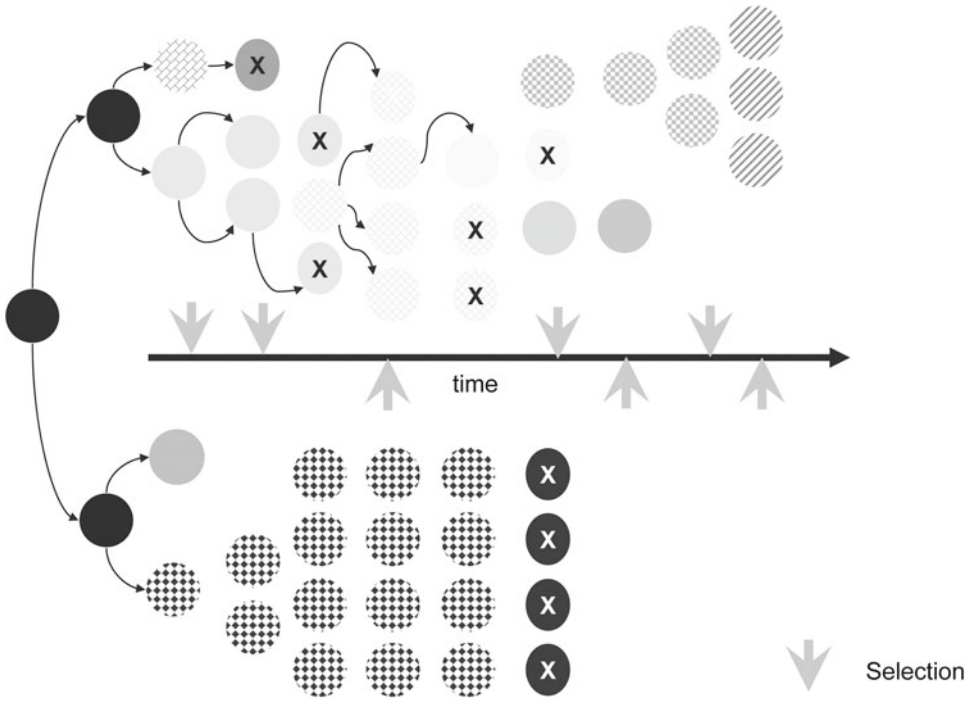

Fig. 12.3 Mutation-selection theory of tumor progression. Although mutation rates can be highly variable according to specific cell types, tumor cells generally have higher mutation rates than normal cells. Tumor cells with higher mutation rates (*upper series*) have increased chances for survival after lethal selection pressures. Variants are selected continually and are either eliminated by selection or are overwhelmed by other cells with more robust growth characteristics. Populations of cells with low mutation rates are more susceptible to lethal selection pressures (*bottom series* of cells).

radiation sensitivity being proportional to oxygenation. Thus, two identical cells would exhibit differences in radioresponse depending upon distance from a capillary since oxygen tension is inversely proportional to distance from blood. Heterogeneity can be observed temporally as well, as cells change due to cyclical signals. One example would be that cells in the G_0/G_1 phase of the cell cycle would be less sensitive than cells in S phase to drugs targeting DNA replication.

At first glance, isolation of multiple cell subpopulations from virtually every tumor mass would appear to support the hypothesis that cancers are of multicellular origin. However, tumors express either maternal or paternal isoenzymes, but rarely both, strongly supporting unicellular origination. In addition, analysis of karyotypes reveals that virtually all cells within a tumor share common abnormal chromosomal changes upon which additional karyotypic abnormalities may be superimposed. Therefore, the majority of tumors are monoclonal in origin and it is the divergence of single transformed cells into multiple phenotypically distinct progeny that generates genetic heterogeneity [5, 11].

As with most aspects of tumor biology, development of heterogeneity is not unique to tumor progression. Pluripotent hematopoietic stem cells generate cells along multiple lineages, and a zygote yields a multicellular organism with organs and tissues. Stem cells have the capacity for self-renewal and progenitor production via asymmetric cell division and are regulated by the microenvironmental niche [15, 16]. Although stem cell theory accommodates diversification, the molecular mechanisms underlying differentiation and diversification of normal cells are still being elucidated [17]. Additionally, the relevance of cancer stem cell theory is still being debated by many researchers to account for the diversification of cancer cells [18–23].

One of the first formalized conceptual frameworks of tumor progression was introduced by Peyton Rous, who described the steps involved in the transformation of skin carcinomas from the study of tar tumors in rabbits [24]. His concepts were expanded by Leslie Foulds, who studied the acquisition of hormone independence by mammary tumors. Foulds defined progression as "…*the acquisition of permanent, irreversible qualitative changes of one or more characteristics in a neoplasm*…" [25]. Both Rous and Foulds provided evidence that tumor progression occurs in a constant, unique and stepwise pattern. The trend is toward increased autonomy; however, individual characteristics within a tumor independently assort [6].

The mutation-selection theory of tumor progression proposes that genetic instability drives the process by random generation of variants (Fig. 12.3). Expanding upon Theodor Boveri's original observations that alterations of chromosomal material were significant in the generation and progression of tumors [26], Peter Nowell proposed that neoplastic cells are more genetically unstable than normal

counterparts [27]. Fluctuation analyses for a variety of genes and phenotypes show that transformed cells are significantly (frequently 10,000- to 100,000-fold, but as high as 10^7-fold higher) more genetically unstable than normal counterparts [11]. Progression is believed to occur as a result of mutation and coupled selection via Darwinian selection principles [6]. Although not formally proven, subpopulations of cells that have acquired the ability to migrate and establish themselves at other sites are thought to have a selective advantage since these tumor cells are not limited by space or location.

Isaiah "Josh" Fidler and Margaret Kripke tested these hypotheses with regard to the metastatic phenotype using combinations of cloning and Luria–Delbrück fluctuation analysis [28]. Single cell clones isolated from a single tumor varied considerably in their metastatic potentials. George Poste and colleagues later showed that highly metastatic cells, when grown in culture continuously and re-cloned, yielded populations that contained non-metastatic or poorly metastatic cells [29, 30]. Likewise, continuous culture of poorly metastatic cells yielded subpopulations that were highly metastatic. In other words, the clonal populations did not remain homogeneous.

At an organismal (i.e., tumor) level, progression typically follows a sequence (Fig. 12.1). Prior to becoming tumorigenic, cells lose the ability to differentiate fully, are no longer contact inhibited or anchorage dependent and have acquired genetic instability. The ability to form a neoplastic mass typically goes through a phase with expansile growth in the absence of invasion. While cells may be pleiomorphic at this stage, they are often encapsulated by a dense fibrous network (i.e., desmoplasia) [31, 32]. Tumors that have failed to invade through a basement membrane are referred to as benign or as carcinoma in situ. With continued generation of variants and selection, subsets of the cells acquire the ability to escape through a basement membrane, the hallmark of malignancy. Acquisition of the ability to detach from the primary tumor and move elsewhere is required for metastasis. It is important to emphasize that tumor progression is typically measured in terms of the tumor mass, rather than the individual cells within it. The stage of a tumor is defined by the most malignant cells found. Even if 99.9 % of cells are indolent, a tumor is defined as malignant if a single cell has penetrated a basement membrane.

At a molecular level, certain chromosomal and genetic changes are more prevalent in early versus late stages of tumor progression, despite unpredictability in specific genetic changes occurring within a cell. Use of this information has allowed prediction of genetic underpinnings controlling tumorigenesis, invasiveness, and metastasis [6]. The complexity of tumor progression leading to a metastatic cell, as described above, shows that a single genetic change is not enough to accurately predict whether a person will have an increased chance of a lesion becoming metastatic and defined subsets of genes have become more predictive as prognostic tools [33, 34].

However, the mutation-selection theory of tumor progression is not without its detractors. Some argue that the acquisition of invasive and metastatic behaviors is more a recapitulation of a process that occurs during embryogenesis—the epithelial–mesenchymal transition (EMT) [35]. Since invasive cells frequently dramatically change their cell shape to a non-polarized, motile, spindle shaped cell resembling a fibroblast, some hypothesize that neoplastic cells dedifferentiate to a more motile mesenchymal cell phenotype. Developmental EMT and cancer EMT are not necessarily equivalent at a molecular level, but share some characteristics. Cancer EMT is characterized molecularly by the loss of epithelial-specific E-cadherin from the adherens junctions, and a switch from the expression of keratins as the major intermediate filament to the mesenchymal intermediate filament vimentin. Ultimately, some believe that more epigenetic mechanisms may be driving tumor progression toward malignancy than mutation and selection [36].

12.3 Invasion

Invasion, the distinguishing feature of malignancy, is the capacity for tumor cells to disrupt the basement membrane and penetrate underlying stroma. Although invasion is required for metastasis, the ability to invade is not sufficient. This point is highlighted by clinical observations. Some tumors are highly aggressive, forming secondary lesions with high frequency (melanoma, pancreatic carcinoma, small cell carcinoma of the lung), whereas others are rarely metastatic despite being locally invasive (basal cell carcinomas of the skin, glioblastoma multiforme). It should be emphasized that if an invasive cell cannot complete any of the subsequent steps in the metastatic cascade, it will not form a metastasis.

The process of invasion requires major changes to the cell (morphology and phenotype) and to the surrounding environment. During invasion, three important processes are dynamically regulated that include adhesion, extracellular matrix (ECM) reorganization, and motility. Normal epithelial cells form polarized sheets that are maintained by tight junctions and desmosomes. They are anchored to the basement membrane by hemidesmosomes and their associated intermediate filaments, and integrin contacts that organize actin. Therefore, to be invasive, cells must alter cell-to-cell and cell-to-matrix adhesion in conjunction with reorganization of the ECM and cellular motility [37, 38]. The structural and functional proteins that regulate cell adhesion and migration are key downstream targets of oncogenes and tumor suppressor-controlled signaling pathways and provide insights into how oncogenic transformation results in progression to an invasive phenotype. Many of the proteins involved in tumor invasion have also been observed to affect other processes that are part of the hallmarks of cancer including cell survival, growth, apop-

tosis and angiogenesis. This highlights the intricate network of interrelated pathways controlling cell behavior [39].

The dramatic changes to a tumor cell morphologically during invasion have been referred to as EMT, which describes the conversion from an epithelial morphology to a non-polarized, motile, spindle shaped cell resembling a fibroblast [35, 40, 41]. EMT is associated with the loss of epithelial-specific E-cadherin from the adherens junctions, and a switch from the expression of keratins as the major intermediate filament to the mesenchymal intermediate filament, vimentin. EMT is influenced by the tumor microenvironment, and has been observed primarily at the edge of the tumor mass that is in contact with the tumor stroma [42]. A key regulator of EMT is transforming growth factor beta (TGF-β) signaling but other mediators include hepatocyte growth factor/scatter factor (HGF/SF), PI3 kinase signaling pathway, MAP kinases, and the transcriptional regulators Twist and Snail. Other signaling pathways implicated in stem cell maintenance that are linked to EMT are Wnt, Notch and Hedgehog. Tumor cells may also reverse the process and undergo a mesenchymal-to-epithelial transition (MET) in the absence of EMT-inducing signals. This transient nature of EMT helps explain why metastatic cells can morphologically resemble cells in the primary tumor despite the fact that they by necessity accomplished all the steps of the metastatic cascade [40, 43].

Epithelial cell–cell interactions are mediated primarily by cadherins, transmembrane glycoproteins that form calcium-dependent homotypic complexes. The loss of E-cadherin that occurs during EMT correlates with increased invasion and metastatic potential in most tumor types and reexpression in experimental models can block invasion. This observation suggests that loss of E-cadherin is causative for invasion. E-cadherin loss occurs at multiple levels including transcriptional repression and proteolytic degradation. The zinc finger transcriptional repressors Snail and Slug in particular have been implicated in regulating EMT by virtue of their ability to repress E-cadherin transcription. Cadherins are regulated by catenins (α, β, γ and p120 catenins), cytoplasmic proteins that functionally link the cadherin complex to the actin cytoskeleton. β-Catenin is both a cell adhesion protein and a transcription factor. In addition to its role in adherens junctions, it participates in canonical Wnt signaling, a signaling pathway important in development and cancer. E-cadherin levels and function are also disrupted by loss of p120 catenin, which occurs in many tumor types and may also contribute to tumor metastasis.

E-cadherin is not the only cell–cell adhesion molecule associated with invasion and metastasis. NCAM, a member of the immunoglobulin cell adhesion molecule Ig-CAM family, is downregulated in several tumor types, and NCAM loss results in an increased ability of tumor cells to disseminate [44, 45]. Other Ig-CAMs, such as DCC, CEACAM1, and Mel-CAM, also demonstrate reduced expression in specific cancer types. It should be noted, however, that not all cell–cell adhesion molecules can be viewed as potential invasion suppressors. Several are overexpressed in advanced cancers and have functions associated with cancer progression including Ig-CAMs such as L1, CEA, and ALCAM. Additionally, N-cadherin promotes cell motility. This complexity may be explained by direct or indirect signaling functions for these molecules that are distinct from their role in cell–cell adhesion. The interrelatedness of tumor growth and tumor invasion, and limitations of experimental model systems, does not always allow a distinction between growth effects that influence the appearance of an invasive phenotype and an effect on actual cellular invasion.

Cells induced to undergo EMT not only exhibit enhanced motility but are resistant to apoptosis, another key requirement for successful metastasis. However, some cancer cells use EMT independent modes of migration including collective and amoeboid [38]. Although EMT and MET are well accepted processes necessary for normal development and can be demonstrated and manipulated in many experimental tumor models, it has been questioned whether they are actual requirements for human cancer progression.

The ECM provides a scaffold for the organization of cells and spatial cues that dictate cell behavior [46]. This matrix is composed of proteins, primarily triple-helical collagens, glycoproteins such as laminins and fibronectin, and proteolgycans. The basement membrane is an organized ECM that forms a barrier separating polarized epithelial, endothelial, and muscle cells from the underlying tissue. Interstitial matrix provides the structural characteristics of connective tissues. The molecular composition of the ECM varies between tissues and organs, and provides important contextual information to cellular constituents. In addition, the ECM interacts with many secreted molecules to serve as a repository for regulatory proteins and growth factors. Thus, the interaction of cells with ECM molecules dictates their ability for survival, growth, differentiation, and migration. Moreover, selective proteolysis of ECM components leads to release of fragments that further regulate protein function and may be involved in cell signaling. These factors are collectively known as matrikines.

Adhesion of cells to their surrounding matrix occurs primarily through a family of transmembrane glycoproteins known as integrins that are assembled as specific combinations of 18 alpha and 8 beta subunits [47, 48]. Each combination of integrin subunits binds to distinct but overlapping subsets of ECM components and may be either tumor promoting or inhibitory. During tumor progression, cancer cells tend to downregulate the integrins that mediate adhesion and maintain a quiescent, differentiated state, and upregulate integrins that promote survival, migration, and proliferation. Although there is a cell-type dependency on integrin function, generally

integrins α2β1 and α3β1 are viewed as suppressors of tumor progression, while αvβ3, αvβ6, and α6β4 promote cellular proliferation and migration. Integrins mediate signals in both directions, so that changes in intracellular signaling pathways can modulate cellular adhesion, and changes in cellular adhesion can alter cellular phenotype. A well-described and important mechanism whereby integrin-ECM interactions modulate cell function is by cooperative signaling with different growth factor receptors. Many of the cellular responses induced by activation of tyrosine kinase growth factor receptors are dependent on the cells being able to adhere to an ECM substrate in an integrin-dependent fashion. Signaling in response to ECM interaction usually activates focal adhesion kinase (FAK) and non-receptor tyrosine kinases of the src-family.

The ECM is remodeled by degradative enzymes that are produced by the tumor cells themselves and additionally by the resident and infiltrating cells as a response to the tumor. These enzymes contribute to matrix degradation and facilitate tumor cell invasion. Proteolytic enzymes of many classes have been implicated in tumor cell invasion, including but not limited to the serine proteinases plasmin, plasminogen activator, seprase, hepsin, and several kallikreins, the cysteine proteinase cathepsin B, the aspartyl proteinase cathepsin D, and metal-dependent proteinases of the matrix metalloproteinase (MMP) and a disintegrin and metalloproteinase (ADAM) families. Other matrix degrading enzymes such as heparanase, an endoglycosidase which cleaves heparin sulfate proteoglycans, and hylauronidase cleavage of its substrate hylauronic acid, have also been causally associated with tumor progression and invasion.

Liotta and colleagues observed that metastatic potential correlates with the degradation of type IV collagen found predominantly in the basement membrane and focused attention on the metal-dependent type IV collagenases or gelatinases that are now recognized as MMP-2 and MMP-9. Subsequently, many of the 23 members of the MMP family of matrix-degrading metalloproteinases have been associated with tumor progression. Elevated MMP levels correlate with invasion and metastasis and poor prognosis in many cancer types, and animal models provide evidence for a causal role for MMP activity in cancer progression [49–51]. Additionally, the plasminogen activator/plasmin system has been causally implicated in cancer invasion, and urokinase plasminogen activator (uPA) and plasminogen activator inhibitor-1 (PAI-1) are validated prognostic and predictive markers for breast cancer.

Regulation of matrix proteolysis occurs at multiple levels and in addition to the expression of proteases by both the tumor cells and adjacent resident and infiltrating cells, they produce specific endogenous inhibitors including the tissue inhibitors of metalloproteinases (TIMPs), serine proteinase inhibitors (SERPINs), and cysteine protease inhibitors (CYSTATINs). Some of these inhibitors are stored in high concentrations within the ECM and paradoxically may be required for activation of the protease. The conversion of pro-MMP-2 to active MMP-2 requires the activity of MT1-MMP (MMP-14), a transmembrane MMP that is activated intracellularly by the propeptidase family member furin, and TIMP-2 (Fig. 12.4). The concentration of each of these molecules is critical for proper function and regulation. Another proteolytic cascade important for regulating protease activity during the degradation of ECM is cathepsin(s) → uPA → plasmin → MMP. Each of the proteases in this cascade is capable of cleaving components of the ECM. Therefore, activity cascades are important regulators of proteolytic function in addition to endogenous inhibitors, protease degradation, and activation.

The original view that proteolytic enzymes function predominantly to remove physical ECM barriers has been expanded with the realization that proteolysis regulates multiple steps of tumor progression. For example, MMP substrates in the matrix or on the cell surface that modulate cellular growth, differentiation, apoptosis, angiogenesis, chemotaxis, and migration have been identified. The abundant evidence for a role for MMPs in tumor progression led to the design and testing of synthetic MMP inhibitors for cancer therapy. These inhibitors proved to be ineffective in clinical trials, results that have been explained by problems with inhibitor or clinical trial design, as well as a lack of understanding of the broad range of MMP activities resulting in both cancer-promoting and cancer inhibitory effects.

In addition to ECM remodeling, locomotion of a cell occurs through the coordination of polymerization and depolymerization of the actin cytoskeleton to extend a pseudopod at the leading edge of the cell, followed by contraction associated with disassembly of cell–matrix adhesive contacts at the trailing edge [52]. Lamellipodial protrusions at the leading edge are nucleated by a branched actin network involving the Arp2/3 complex and its regulators, the WASP family, cortactin, and the GTPase Rac. Actin contractility is regulated by myosin light chain kinase and upstream small GTPases, in particular Rho and its effector ROCK. As alluded to above in the discussion of EMT, single cells migrate either with a spindle-shaped morphology, referred to as mesenchymal migration, or with the less adhesive ellipsoid shape used by leukocytes and *Dictyostelium* termed amoeboid migration. Collective migration can occur when the cells retain cell–cell junctions and clusters of cells move in single file through a tissue.

Tumor cells can secrete factors that stimulate motility in an autocrine fashion. Tumor cell-produced lysophospholipase D (autotaxin) stimulates motility, as does lysophosphatidic acid (LPA), which can be produced by lysophospholipase D activity on lysophosphatidylcholine. Hepatocyte growth factor/scatter factor (HGF/SF) interacts with its receptor, c-met, to induce chemokinetic activity of epithelial cells, resulting in an invasive phenotype. Directional motility is a chemotac-

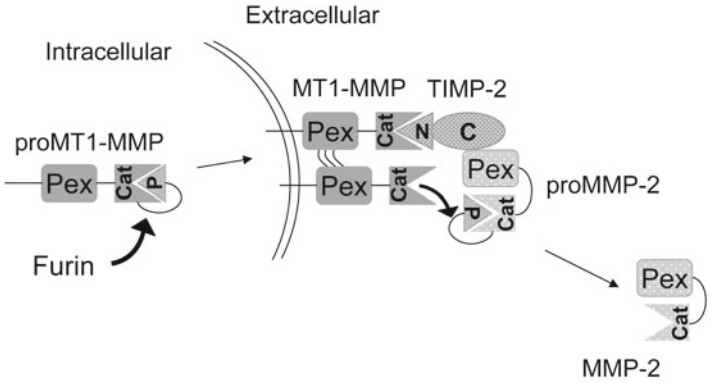

Fig. 12.4 Example of a proteolytic activation cascade. The proteolytic activities are intricately regulated at several levels during the MMP-2 activation cascade. The activation of proMMP-2 occurs by the balance of TIMP-2, MT1-MMP, and itself. MT1-MMP is activated intracellularly by furin and localized to the plasma membrane. The TIMP-2N-terminal (N) domain binds to and inhibits MT1-MMP activity and recruits proMMP-2 by interaction of TIMP-2 C-terminal (C) domain to proMMP-2 hemopexin domain (Pex). An adjacent MT1-MMP activates proMMP-2 to MMP-2 through cleavage of the pro-domain (P).

tic (following a soluble concentration gradient) or haptotactic (following an insoluble concentration gradient) effect in response to a gradient of soluble or localized factors, respectively. Chemotaxis is often the result of growth factors such as insulin-like growth factor (IGF), and chemokines of the CCR and CXC family. Haptotaxis is characterized as a response to gradients of ECM components such as laminin-5 and fibronectin, and can be modulated positively or negatively by proteolysis [53].

The coordination of cell–cell and cell–matrix adhesion, matrix degradation, and cytoskeletal activity is required for cellular invasion. The type of cell migration (collective, mesenchymal, or amoeboid) is influenced by the relative levels of adhesion mediated by cadherins and integrins, proteolytic activity, and actin contractility. Modulation of any of these factors is thought to convert one type of motility into another. Structures identified in invading cells in three dimensions that represent the physical convergence of the adhesive, proteolytic, and motility component of invasion are known as invadopodia [54]. Invadopodia are actin-rich organelles that protrude from the plasma membrane and contact and locally degrade the ECM [55–58]. Invadopodia contain adhesion molecules, including several β1 integrins and CD44, and the proteinases seprase, dipeptidyl dipeptidase IV, and several MMP and ADAM metalloproteinases. Inside the plasma membrane, invadopodia contain actin and actin assembly molecules, as well as multiple signaling molecules including FAK, src associated proteins such as p130Cas and Tks5/FISH, and the small GTPases cdc42, Arf1, and Arf6. Thus, invadopodia are implicated as key cellular structures that are used to coordinate and regulate the various components of the process of cancer invasion.

12.4 Further Steps Required for Metastasis

Invasion and metastasis are not equivalent phenotypes. Although invasion is prerequisite for metastasis, the ability to invade is insufficient to develop a metastasis. Once cells have invaded away from the primary tumor, they disseminate. Most commonly, metastasis is described in terms of hematogenous (blood-borne) dissemination. However, secondary tumors can arise because tumor cells have migrated via lymphatics (i.e., lymph nodes are common sites of metastasis for most carcinomas) or across body cavities (e.g., ovarian carcinoma cells most frequently establish secondary tumors by dissemination in the peritoneum while rarely forming metastases via hematogenous spread) [59]. Additional examples are dissemination of melanoma cells along the space between endothelium and basement membrane or perineural spread in pancreatic and prostatic carcinomas. Some question whether non-hematogenous spread is actually metastasis. We submit that the route of dissemination is irrelevant to the definition of metastasis, as long as the cells are discontinuous from the primary tumor mass. Nonetheless, for the remainder of this chapter, we will focus on blood-borne metastasis since this route is responsible for the majority of visceral metastases.

12.4.1 Intravasation

Following local invasion, the next step in dissemination is the entrance of tumor cells into the vasculature, a process termed intravasation. The mechanisms of tumor cell entry into the blood stream are not clearly understood. Both active and passive processes are involved. The growth of a tumor exerts a

hydrostatic pressure, and studies imply that tumor cell invasive cords follow lines of least resistance. Angiogenesis is likely to be a prerequisite for metastasis, but this has not been formally proven. Tumor cell entry into intact blood vessels is an active process that requires serine- and metallo-proteinase activity in an experimental model of intravasation. Tumor blood vessels, however, are highly abnormal with fewer pericytes and increased permeability compared to normal vessels, and presumably provide an easier route of entry for tumor cells. Tumor-associated lymphatic vessels are also abnormal, but their role in intravasation is unclear [60]. Irrespective of the route, tumor cells enter the circulation in great numbers: measurements of 3–4 million cells/day/g of tumor have been reported [9]. The number of tumor cells in the peripheral blood, however, does not necessarily predict if the patient will develop metastases [61–63].

12.4.2 Transport

Once tumor cells enter the blood stream, they can move actively by motility mechanisms or passively, carried or pushed along with fluid flow. Intravital microscopy has shown that most tumor cells do not float along, but rather roll like leukocytes. Despite having weak adhesion while rolling in a vessel, tumor cells are subject to anoikis, a specialized type of apoptosis in which cells that are anchorage-dependent are induced to die. In general, metastatic cells are more resistant to anoikis than non-metastatic cells.

Experiments designed to assess tumor cell fate following vessel entry often involve bioassays to quantify cells following intravenous injection. By the time it takes to remove various tissues for assay (2–3 min), the majority of cells have died. What is the basis for the cell loss? Tumor cells are killed by immune recognition, typically natural killer (NK) or monocytes. However, the majority are thought to be killed by exposure to hemostatic sheer forces.

The average tumor cell has a diameter of 20–30 μm but must navigate through vessels significantly smaller (capillaries are 6–7 μm). Therefore, tumor cells must deform and squeeze through the vascular passages. Biophysical parameters such as membrane fluidity, cellular elasticity and cytoskeletal organization influence whether the cells will remain intact or be broken by sheer. Deformability of the cell is also impacted by the hemodynamic pressures found within various tissues. In contrast to the sheer forces usually encountered in the vasculature, blood flow in bone sinusoids is sluggish (~30-fold lower than capillaries and post-capillary venules), and diameter is not limiting.

During transport, tumor cell behavior is often determined by their presence as either single cells or as emboli. Embolization can either be homotypic (tumor cell-tumor cell) or heterotypic (tumor cell-leukocyte, tumor cell-platelet, tumor cell-fibrin). The association of tumor cells with blood cells can be the result of altered cell surface glycosylation and expression of sialyl Lewis X and sialyl Lewis A on the tumor cell that permits interaction with a class of vascular adhesion molecules found on normal leukocytes and endothelium, the selectins. Alterations in the adherence of tumor cells to endothelium via E-selectin, platelets via P-selectin, and to leukocytes via L-selectin alters metastatic potential in animal models. However, the cellular specificity of adhesion to the selectins may not be so clear cut, as recent evidence indicates that bone endothelium expresses P-selectins and L-selectins. Embolus size can also contribute to the protection of the tumor cells from biophysical forces or immune attack as well. In essence, putting tumor cells into a cellular or molecular cage helps to protect them. As a result of the consequence of embolus formation, heparin, and inhibitors of selectin/glycan interactions, have been considered for anti-metastatic therapy.

12.4.3 Arrest

After tumor cells have spread to distant sites, they arrest either by physical trapping or selective adhesion to the walls of the microvasculature. Both processes have been observed, and the relative importance of these mechanisms in specific organs is debated.

In higher vertebrates, three types of endothelial structures are found—continuous, discontinuous and fenestrated. The majority of endothelial cells form tight junctions with their neighbors and have a continuous, unbroken basement membrane beneath them. However in certain organs, such as liver and spleen, the endothelial cells and the basement membrane have gaps, or discontinuities, in their structure. In the kidney, a fenestrated endothelium, there are gaps between endothelial cells but a membrane-like structure connects them and the entire structure overlaps in a continuous basement membrane. The structure of these endothelial/basement membrane barriers contribute to the normal function of the tissues and form different barriers through which tumor cells must pass. The structures also provide different ligands to which the tumor cells might adhere.

Adhesion of circulating cells to organ microvascular endothelial cells is key to metastasis, especially organ-specific metastasis. In general, higher rates of tumor cell–endothelial adhesion correlate well with metastatic potential. The initial attachment of cancer cells occurs preferentially at endothelial cell junctions and at sites of active inflammation. The latter is most likely related to endothelial cell surface alterations concomitant with inflammatory processes. In general, tumor cells utilize the same molecules and mechanisms to adhere to and traverse endothelium as inflammatory cells.

After tumor cells bind endothelium, they induce endothelial cell retraction. Eventually, the endothelial cells overlap the tumor cell. Tumor cells are then directly in contact with the basement membrane and can initiate the next step of the metastatic cascade.

12.4.4 Extravasation

Extravasation is the process of tumor cells exiting a vessel into the organ parenchyma. Extravasation was viewed as a key rate limiting step for metastasis formation, but intravital microscopy studies have indicated that extravasation can be a remarkably efficient process, at least in some situations. For example, Ann Chambers and colleagues showed that nearly 90 % of B16F1 murine melanoma cells that were injected into the mesenteric vein arrested in the liver 90 min after injection. Of the injected cells, 83 % were in the liver parenchyma by 3 days, meaning that >95 % of the arrested cells extravasated [64]. The molecular mechanisms underlying extravasation are thought to be similar to those involved in invasion, and in vitro assays for extravasation reveal a contribution of cellular adhesion molecules, proteinases, and motility factors.

There is controversy as to whether extravasation is required for metastasis. In the case of some pulmonary metastases, there is evidence that tumor cells can attach to the lung endothelium, survive and grow intravascularly [65]. Extravasation occurs in this model only when the intravascular foci outgrow the vessel.

12.4.5 Colonization

Colonization, the formation of clusters of tumor cells at ectopic sites, represents one of the most highly inefficient steps in the metastatic cascade. A tumor cell must first survive and then grow in a foreign environment. In some tumor types, it is not uncommon for metastases to arise decades after the primary tumor had apparently been treated. Those clinical observations demonstrate that tumor cells can survive in a dormant state for long times. It is unclear whether cells at these sites persist as solitary cells, or whether their overall growth rate is balanced by the rate of apoptosis or differentiation. Conversion to a clinically detectable, macroscopic metastatic lesion requires the subsequent initiation of angiogenesis.

The ability of a tumor cell to establish a metastatic lesion is very much dependent on the microenvironment. The growth of the cells is dependent on several factors, primarily soluble growth factors, present at the site of colonization. Although it is natural to focus upon molecules that promote tumor cell growth, there is ample experimental evidence showing that some tissues are hostile to tumor cells. So, resistance to growth inhibitory factors is required as well.

12.4.5.1 Organ Selectivity

There is a clear tendency for primary tumors to form metastatic lesions in specific organ sites (Table 12.1). Common regional sites of metastatic involvement can often be explained by anatomical or mechanical considerations (efferent venous circulation or lymphatic drainage). Tumor cells often arrest in the first capillary bed or lymph node encountered. Since the vast majority of tumor cells enter the vasculature in small veins or capillaries, the most common sites of metastasis are lung and liver. However, distant metastases are typically more site specific.

In 1889, Stephen Paget analyzed postmortem data of women with breast cancer and noticed a higher frequency of skeletal metastasis than would be expected based solely upon vascular perfusion. He concluded that the pattern was not simply by chance, and suggested that metastases develop only when the seed (tumor cells with metastatic potential) and the soil (organs or tissues providing growth advantages to seeds) are compatible.

Experimental data supporting Paget's "…*seed and soil*…" hypothesis is abundant, including preferential invasion and growth of tumor cells in specific organs and tissues as well as selection of tumor subpopulations with preferential sites of metastasis [66]. Furthermore, David Tarin and colleagues observed in women with advanced ovarian cancer that palliative treatment to reduce large ascites burden by peritovenous shunts did not result in disease outside the peritoneal cavity [67]. By introducing a Levine shunt, a tube that drains the peritoneal ascites into the vena cava, billions of viable tumor cells were introduced into the circulation daily. Despite this, metastases to the lung (the first capillary bed encountered) were rare. This single clinical observation highlights the inefficiency of the metastatic process and, more importantly, demonstrates that merely seeding cells in different tissues is not adequate to develop metastases.

What, then, are the molecular mechanisms underlying organotropism of tumor cells? Tumor cells adhere more selectively to organ-derived microvascular endothelial cells than large vessel endothelial cells, and variants of the B16 melanoma previously selected for metastases to brain, lung, ovary or liver adhere at a more rapid rate to brain, lung, ovary or liver endothelial cells, respectively [66]. Using phage display technology, endothelial cells in different tissues were shown to express unique markers, and tumor cells recognize the molecular addresses in order to adhere in a selective manner [68]. Tumor cells can also recognize subendothelial basement membrane differences. In vitro studies demonstrate the selective growth of tumor cells in organ-derived soluble growth factors or cells. Some tumor cells even respond to tissue derived chemotactic factors. For example, breast tumor cells that express the chemokine receptor CXCR4 preferentially metastasized to tissues that expressed the ligand, SDF1/CXCL12 [69].

While the chemoattractant data support the notion that there are soluble factors produced in different tissues to which tumor cells can respond, the process of homing has not been observed. Strictly speaking, homing would require

Table 12.1 Predilection of metastasis for certain tissues

Primary tumor	Common site(s) of metastasis
Breast	Bone, lung (pleura), liver, brain, adrenal, axillary lymph nodes, contralateral breast, ovary
Colon	Liver, lymph node, lung, direct extension into urinary bladder or stomach
Kidney	Lung, liver, bone
Lung	Bone, brain, lymph nodes, pleura, diaphragm (by direct extension), liver, kidney, adrenal, thyroid, spleen
Ovary	Diaphragm, peritoneal surfaces, lymph nodes
Pancreas	Liver, stomach (by direct extension), colon, peritoneum
Prostate	Bone (particularly vertebrae and pelvis), lymph nodes
Stomach	Liver, lymph nodes, lung, bone
Testes	Lymph nodes, lung, liver
Urinary bladder	Lung, rectum (by direct extension), colon, prostate, ureter, vagina, bone, lymph nodes, peritoneum, pleura, liver, brain
Uterine endometrium	Lung, lymph nodes, liver, ovary

Adapted from [52]

directed movement throughout the transit of tumor cells as they leave the primary tumor. Rather, tumor cells distribute according to circulatory patterns initially but may home once they are more proximate. More likely, they may be retained at sites more readily.

Some of the strongest new evidence supporting organ selectivity of cancer cells comes from data showing the selection of variants that colonize different tissues. The first selections were done by repetitive isolation of lung metastases from the B16 melanoma followed by reinjection and recolonization. Similar approaches were used to select B16 melanoma cells with brain, ovary, and liver predilection. More recently, MDA-MB-231 human breast carcinoma cells were used to select variants that colonize bone, lung and adrenal gland. Using these breast carcinoma cell lines coupled with comparison by cDNA microarray, Joan Massagué and colleagues demonstrated the requirement for coordinated expression of multiple genes for metastasis [34, 70, 71]. Transcriptomes were compared between parental and bone-selective variants and overexpressed and underexpressed genes were identified. Transfection of individual cDNAs only modestly increased site-specific metastatic efficiency, whereas co-transfection of gene combinations into the parental cells resulted in populations as efficient as the bone or lung colonizing selected variants. These data highlight that there is probably a hierarchy in the genetics of metastasis. Superimposed upon the metastasis competency transcriptome are gene expressions which determine metastasis localization.

Yet, not all organ selectivity may be determined by the seed and the soil alone. There is a recent concept that tumor cells colonize in pre-metastatic niches initiated in target organs by tumor cell-generated soluble factors that induce the migration of hematopoietic stem cells to sites where they induce expression of fibronectin by resident fibroblast-like cells [72, 73]. Bone marrow-derived cells that express the vascular endothelial cell growth factor receptor 1 and the integrin α4β1 selectively adhere to these regions, produce the proteinase MMP-9 and the chemokine SDF1/CXCL12, and provide a permissive niche for the colonization of tumor cells. In a sense, the tumor cells ensure fertilization of the soil using this mechanism.

12.5 Genetic Determinants of Metastasis

Primary tumor formation and metastasis are distinct processes—locally growing tumors can grow and progress without the development of metastases. This observation prompted the hypothesis that the molecular processes regulating tumorigenicity and metastasis are distinguishable. The existence of metastasis-controlling genes is supported by data from several laboratories showing that specific cDNAs block metastasis but not tumorigenicity [74, 75]. Such genes are termed metastasis suppressors and, by definition, are distinct from tumor suppressors (Table 12.2). Tumor suppressors block both tumor formation and metastasis since the former is prerequisite to the latter.

The identification of nm23 (non-metastatic 23), the first metastasis suppressor, provided functional evidence for the existence of molecules that specifically regulate metastasis. Subsequently, several laboratories have used various unbiased approaches to identify more than 20 metastasis suppressors. Importantly, the use of in vivo assays was required because in vitro assays were often of inadequate complexity to sufficiently model the entire process of metastasis. Several of the known metastasis suppressors block the last step of the cascade, colonization. And since there is not a reliable in vitro model of the last step of metastasis, determining the molecular underpinnings of the suppression has moved more slowly than desired.

Table 12.2 Examples of metastasis suppressors and known functions

BRMS1	Transcriptional co-repressor Component of mSin3A histone deacetylase complexes Regulates NFkB and PI3 kinase signaling Restores homotypic gap junctional intercellular communication
Cadherin-11	Cellular adhesion, cytoskeletal structure
Caspase 8	Pro-apoptotic enzyme
CD44 (family)	Cellular adhesion (hyaluronate) Potentiates HER signaling
Claudins 1 and 14	Cell–cell tight junctions
CRSP3 (cofactor required for SP1)	Transcriptional co-activator/co-repressor
CTGF (connective tissue growth factor)	Cellular adhesion (integrin binding)
DCC	Regulates cytoskeletal organization
DLC1	RhoGTPase activating protein
Drg-1	Unknown
E- and N-cadherin	Cell–cell adhesion (calcium-dependent)
GAS1	Inhibit cell cycle
Gelsolin	Actin polymerization
HUNK	Protein kinase
JNKK1/MKK4	Activates p38 MAP kinase and/or JNK kinase
KAI1/CD82	Binds DARC on endothelial cells Integrin interactions EGFR desensitization
KISS1	Ligand for G-protein coupled receptor
KISS1R	G-protein coupled receptor
KLF17	Transcription
LSD1	Chromatin remodeling
MKK6	Activates p38 MAP kinase
MKK7	Activates JNK kinase
Nm23-H1	Histidine kinase Phosphorylated kinase suppressor of Ras (KSR) Nucleotide diphosphate kinase
OGR1	GPCR signaling
p38	Stress-activated MAPK signaling
RECK	Regulates matrix metalloproteinases
RhoGDI2	Cellular motility: regulates Rho and Rac functions
RKIP	Inhibits RAF-mediated MAP/ERK kinase phosphorylation
RRMI	Increases PTEN expression; decreases FAK phosphorylation
Src-suppressed C kinase substrate	Cellular motility: regulates Rho signaling
TIMPs	Inhibit metalloproteinases; signaling
TXNIP (thioredoxin interacting protein)	Inhibitor of thioredoxin; transcriptional regulator

Adapted from [4, 48, 53, 54]

Table 12.2 lists the proteins that have bona fide metastasis suppressor activity in vivo (suppression of metastasis following ectopic expression into metastatic cell lines). Metastasis suppressors vary widely in their cellular locations and biochemical functions, and many would not have been predicted a priori based upon their known cellular functions. Many metastasis suppressors are involved in cellular responses to exogenous signals, highlighting the importance of tumor-stromal interactions. Cells respond to external stimuli in a spatiotemporal manner by utilizing a relatively limited number of signaling pathways. In this light, metastasis formation can be viewed as the result of a tumor cell's ability to respond to multiple growth milieus (i.e., orthotopic and ectopic) as opposed to being restricted to growth at orthotopic sites.

In addition to the genetic changes associated with the metastatic cell, the importance of the host genome in controlling metastasis has been elegantly demonstrated by Kent Hunter and colleagues [76, 77]. Transgenic mice expressing the polyoma middle T oncogene (PyMT) under control of the mouse mammary tumor virus (MMTV) promoter develop metastatic mammary tumors. When bred to non-syngeneic mice, metastatic potential was enhanced or inhibited, depending upon the mouse strain. Since all tumors were initiated by the same oncogene, differences in metastasis can be

explained by genetic background differences. Specific loci contributing to metastatic efficiency have been identified.

12.6 Microenvironmental Factors Influencing Metastasis

The Hunter data highlights contributions of the host to the development of metastases. As described above, metastasis is regulated by tumor and stromal interactions at every step. Tumor cells can co-opt already existing endothelial cells to create an unimpeded vascular supply. Many of the proteases involved in tumor cell invasion are produced by stromal cells rather than the tumor cells themselves. Carcinoma-associated fibroblasts can stimulate tumor cell growth and/or invasion while normal fibroblasts are growth-neutral or growth-suppressing. Adhesion to endothelium, and growth in response to organ-specific factors are all dictated by microenvironmental cues.

In experimental models, metastatic capacity is very much dependent on the site of injection. For example, human colon cancer cells injected subcutaneously do not metastasize, although the same cells colonize the liver following orthotopic injection into the GI tract. Similar findings have been observed with renal cell carcinomas, mammary carcinomas and melanomas. Although mechanical factors certainly contribute to this effect, molecular differences in the tumor microenvironment are also contributing factors.

Infiltrating immune and inflammatory cells can have dual effects on tumor metastasis. On the one hand, recognition by the immune system that a tumor cell is foreign often leads to the destruction of the tumor cell in the elimination of the cancer. However, tumor cells have been known to subvert the immune system and often take advantage of properties inherent to the inflammatory cells, such as invasion. Tumors induce macrophage and neutrophil infiltrates which have been associated with increased invasion across ECM in vitro. Recent data even indicate that tumor cells recruit hematopoietic stem cells to the primary tumor where the immune cells are activated to assist with invasion. Co-injection of tumor elicited macrophages or neutrophils increased metastasis in animal models as well. The inflammatory cells invaded through basement membranes followed by tumor cells. In addition, the inflammatory system in various tissues produces factors that are either stimulatory, or inhibitory, for tumor growth.

12.7 Therapeutic Challenges and Opportunities

The most devastating aspect of cancer cell behavior is the ability to metastasize. When tumor cells are localized, surgery is curative. However, when cells colonize secondary sites, cure rates drop precipitously. If no (neo)adjuvant therapy is given, metastases invariably kill the patient. Since the introduction of adjuvant therapies, the long-term survival rates have increased significantly (to approximately 25–30 % for breast and prostate cancers, for example). Such statistics are encouraging beginnings, but are certainly not adequate.

How, then, can understanding the molecular basis of metastasis lead to improved cancer therapies? First, by identifying what is unique about metastatic cells, one can theoretically target the therapy to the most dangerous populations of cancer cells. Unfortunately, the situation is not so simple. Cellular behavior in metastatic cells is governed by the same mechanisms that are present in normal cells and under normal physiology. The ability to invade is not unique to cancer cells. Leukocytes and neurons invade as part of inflammation and normal development, respectively. Similarly, leukocytes and stem cells exhibit intermittent adhesion as part of their normal function. And while moving around the body, they are certainly resistant to anoikis. These cells exert an influence at the secondary site. During inflammation, for example, leukocytes and fibroblasts degrade and reconstitute extracellular matrix. Proliferation of cells at two different locations would seemingly distinguish metastatic cells from normal counterparts; however, macrophages and stem cells (e.g., angioblasts, recruited hematopoietic stem cells) can proliferate at secondary sites, and in the case of stem cells they can proliferate long after initial seeding. Together, the distinctions between metastatic tumor cells and normal cells have been incredibly difficult to identify. Making matters even more complicated, metastatic cells use essentially the same molecular mechanisms for accomplishing each of the steps as do their normal counterparts.

Nonetheless, there is hope. There are some essential differences between normal cells and metastatic cells. Importantly, all of the properties necessary for metastasis must coexist within a single cell (including the properties necessary to recruit another cell to complement a specific defect) since metastases are clonally derived. Conceptually, this offers opportunities. Molecules that block adhesion to tissue-specific endothelium and/or the underlying basement membrane components offer some specificity in response. Invadopodia appear to be specialized structures found in only a limited number of normal cells, and presents an opportunity for selective targeting. In addition, unlike stem cells that can enter a secondary site, proliferate and differentiate, metastatic cells do not differentiate fully at a secondary site. Hence, another hallmark of metastatic cells is their ability to persistently proliferate without fully differentiating.

A therapeutic opportunity for controlling metastasis may not lie so much in understanding the unique characteristics of the tumor cell, as in understanding the controls exerted by the tumor microenvironment [1, 78]. Targeting normal cells, as opposed to genetically unstable tumor cells, lessens the chance of drug resistance (since normal cells are not as genet-

ically unstable). The colonization stage of metastasis offers exceptional therapeutic opportunities, since the cells can remain alive but dormant or pre-angiogenic for long periods of time. As long as the resident tumor cells do not impinge upon organ function, cancer could be rendered a chronic, controllable disease rather than an acute, deadly one.

Simple Sequence Mutations

13

Christophe Béroud

13.1 Introduction

Mutations are defined as modifications of the DNA that can be transmitted from one cell to its offspring. Thus, mutations occurring in the germ line can impact the next generation, while mutations happening in other tissues affect the host organism. We can therefore distinguish hereditary diseases resulting from germ line mutations and acquired genetic diseases resulting from somatic mutations. Indeed, hereditary forms of cancers account for a limited fraction of cancers. Moreover, cancers are complex genetic diseases characterized by multiple somatic alterations in the pathways that control cell growth, proliferation, and differentiation. Almost 25 years ago a first attempt was made to decipher the various steps of colorectal tumor development. It led to the creation of a model of colorectal tumorigenesis in which the steps required for the development of cancer involve the mutational activation of an oncogene coupled with the loss of several tumor suppressor genes [1]. This model relied on the mutational and gene expression analysis of known oncogenes and tumor suppressor genes. It was further completed with data from more recent techniques such as the Comparative Genomic Hybridization (CGH) [2] and its latest developments the cDNA microarrays [3, 4] and the oligonucleotide microarray analysis (ROMA) [5]; cDNA microarrays and oligonucleotide microarrays used to analyze gene expression [6, 7] as well as the Serial Analysis of Gene Expression (SAGE) [8], and the study of epigenetic changes that result in loss of gene expression that can be performed by various methods such as the Restriction Landmark Genomic Scanning (RLGS) [9] or DNA bisulfite treatment [10]. Recent progression models of breast, prostate, lung, and colorectal cancer have therefore been proposed [11].

Cancers are unique genetic diseases as they involve numerous somatic alterations. These alterations are subject to a selection pressure in the specific context of the human body. The study of these variations can therefore be approached both by a functional and by an evolutionary point of view. The purpose of this chapter is not to analyze all genetic variations found in cancers but instead to focus on simple mutations. These simple mutations can be defined as substitutions that can result in synonymous or nonsynonymous changes, nonsense or aberrant splicing, as well as small deletions and insertions of a few nucleotides.

The development of new sequencing technologies has led various teams to develop global approaches in order to search for new genes involved in cancer initiation and/or progression. Thus by the end of 2005, the National Cancer Institute (NCI) and the National Human Genome Research Institute (NHGRI) launched a new project called the Cancer Genome Atlas (TCGA) that is a comprehensive and coordinated effort to accelerate our understanding of the molecular basis of cancer through the application of genome analysis technologies, including large-scale genome sequencing. The first results from the pilot study on lung, brain, and ovarian cancers have been released [12]. Before this initiative, the Wellcome Trust Sanger Institute had produced a large-scale genome sequencing of 518 protein kinases in 26 primary lung neoplasms and seven lung cancer cell lines [13]. In these various sequencing projects, as expected, many sequence variations have been identified in each cancer. One major challenge is to distinguish mutations involved in tumorigenic phenotype from other randomly co-selected mutations, especially for missense mutations.

This brings us back to a fundamental concept of evolution. In 1974, the hitchhiking concept of sequence variations was proposed by Smith and Haigh [14]. It supposes that a favorable allele can co-select adjacent variations. Therefore a neutral or even deleterious allele can spread in a population only because it is in strong linkage disequilibrium

with a favorable allele. Because this phenomenon is also observed in cancer, there is selection pressure between cancer cells. Nevertheless a major difference has to be underlined: in the cancer development model, cells accumulate mutations that can result in a favorable phenotype and therefore be selected but there is no mating and recombination between different partners. Therefore hitchhiking mutations (also called passenger mutations) can be co-selected with driver (or causal) mutations without any localization constraint (linkage disequilibrium). Thus, the observation of genetic changes should mainly be driven by the mutation rate of the human genome.

Recent studies have shown that point mutation rates vary across mammalian genomes not only at the gene level [15, 16] but also when noncoding sequences are considered [17]. Analyzing a large set of genes and assuming that the rates at which neutral substitutions accumulate in protein-coding genes allows the indirect estimation of the mutation rate. Kumar et al. [18] have shown that it is approximately constant per year and largely similar among genes. They suggest that the average mammalian genome mutation rate is 2.2×10^{-9} per base pair per year. These data should be compared to results obtained from the analysis of the hemophilia B locus for which mutation rates have been estimated as follow: transitions at CpG sites 1.3×10^{-7}, other transitions 9.9×10^{-9}, transversions at CpG sites 7.3×10^{-9}, other transversions 9.4×10^{-9}, and small deletions/insertions causing frameshifts 6.5×10^{-10} with an overall mutation rate of 2.14×10^{-8} per base per generation, or 128 mutations per human zygote [19]. Data produced by these studies rely on comparison of mutations among individuals and species. Thus, these calculations take into account the final result of evolution that involves genetic drift, natural selection, mutation, and migration. The specific contribution of each basic mechanism is almost impossible to establish. The cancer situation should be viewed as a simpler model as it corresponds to the evolution of cells without resort to mating. The genetic drift is therefore reduced and we can consider that no migration influence is involved in comparison to population's migrations from the evolution theory. Thus only two mechanisms remain: (1) occurrence of mutations, and (2) selection pressure. The non-clonal compound of cancer nevertheless complicates this apparent simplicity. In fact in a cancer, the cell population constantly evolves and the genetic sequence is highly polymorphic at the individual cell level. As illustrated in Fig. 13.1, the global study of a cancer sample can give various results depending on which period the analysis is performed. In addition, these results do not give information about the genetic content of each group of cells that can be found in the cancer and thus complicate the interpretation of variations.

	A	B	C	D	E
w	100	100	100	100	100
x	-	-	14	14	4
y	-	23	53	65	78
z	-	-	-	17	37

Fig. 13.1 Genetic heterogeneity of cancer cells. All cancer cells are derived from a common ancestor cell (*black dot*) that was subject to the pathogenic mutation (w). After an initial homogenous division period, other mutations (x, y, z) appear in various cells. They are subject to selection pressure and the ratio of cells harboring a specific mutation will vary over time. The analysis of the genetic content of the tumor will reveal different results depending on the stage where is performed the analysis (A, B, C, D, or E). The interpretation of the results can thus be hazardous. In fact, x and z mutations are present at the same level at stage D (respectively present in 14% and 17% of cells) but only the z mutation will subsequently be selected while the x mutation will progressively disappear from the tumor (stage E). The x mutation could therefore be considered as a passenger mutation while the z mutation could be considered as a disease causing mutation that will contribute to the cancer phenotype.

13.2 Mutations in Human DNA

The number of somatic mutations in cancer is the sum of the mutations acquired at each round of DNA replication in the normal and neoplastic cellular lineage leading from the fertilized egg to the progenitor cell of the neoplastic clone. Variation in mutation number may therefore be determined

by variation in the number of mitoses and/or by the factors influencing the mutation rate, including mutagenic exposures and DNA repair defects.

Most analyses have been performed on germ line mutations. They have shown that the most common substitution for A (adenine) is G (guanine), for C (cytosine) it is T (thymine), for G it is A, and for T it is C. In addition, it has been shown that CpG dinucleotides mutate to TpG at a frequency five times higher than mutations in all other dinucleotides [20–22]. This event can occur on both DNA strands and can result either in C>T or G>A on the coding strand. It is therefore frequently referred to as CG>TA transitions.

Spontaneous transitions occur during DNA replication through inappropriate pairing of nucleotides, due to a shift of one of the nucleotides to a rare tautomeric form. For example adenine and cytosine can change to an imino form instead of the regular amino form. Another mechanism of transition is the deamination of a methylated cytosine residue. This is the most frequent source of transitions in eukaryotes as a significant proportion of cytosines are methylated (Fig. 13.2).

Spontaneous transversions arise through a combination of two events: tautomerization and base rotation. This rotation causes the so-called syn-conformation of DNA or Z-DNA. As only 10 % of the DNA is present in the syn-conformation at any given time, and as the transversion mechanism involves an additional step in comparison to transitions, the frequency of spontaneous transitions is reduced. Nevertheless, transitions and transversions can also result from the exposure of the DNA molecule to various carcinogens. Therefore, the mutational event spectrum of a specific gene should be viewed as a combination of both spontaneous and induced mutations.

Deletions or insertions of a few nucleotides are also common in the human genome. Data from the Human Gene Mutation Database (HGMD) (http://www.hgmd.cf.ac.uk), which contained by February 2007 an excess of 67,030 different lesions detected in 2478 different genes [23] show that small deletions and insertions account for 15 % and 6.6 % of germ line mutations, respectively. Germ line deletions of 1–3 base pairs (bp) account for 70 % of small deletions and frequently result in an alteration of the reading frame (78 %). The mechanisms by which these micro-rearrangements occur remains unknown, but it has been shown that (1) deletion of one or a few nucleotides frequently occurs in runs of the same nucleotide [24], and (2) larger deletions involve inverted repeats and symmetric elements [25, 26]. Micro-insertions are three times less frequent than micro-deletions, and nearly half of these involve the insertion of only one nucleotide.

Somatic mutations are acquired in somatic tissue during the subject's lifetime and predominantly result in neoplastic disease. These mutations can either be spontaneous or induced by exogenous compounds such as UV, carcinogens, or radioactivity.

The analysis of somatic mutations extracted from the UMD-TP53, UMD-APC, and UMD-VHL databases reveal that micro-deletions represent respectively 8 %, 51.4 %, and 28.6 % of somatic mutations, while micro-insertions account for 2.6 %, 12.2 %, and 7.5 % [27–29]. As for germ line mutations, an excess of deletions is observed with an average ratio

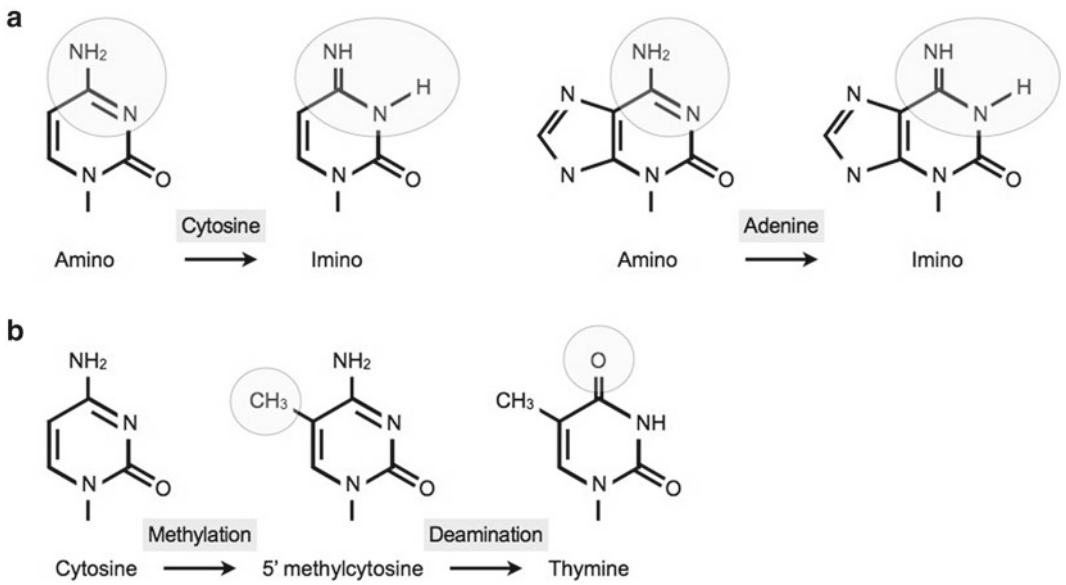

Fig. 13.2 The most frequent events that lead to a transition. (**a**) Shift to a tautomeric form cytosine and adenine shift to an imino form. (**b**) Schematic presentation of the transversion from a cytosine to a thymine after methylation and oxidative deamination.

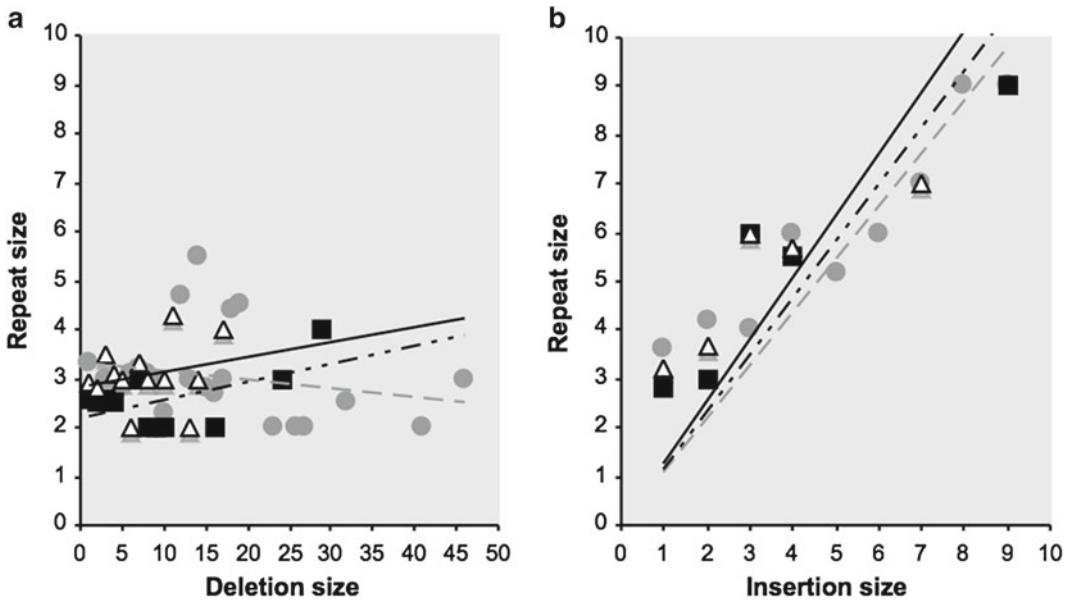

Fig. 13.3 Distribution of repeated elements surrounding deletions (**a**) and insertions (**b**). *Dark squares* = data from the VHL gene; *grey circles* = data from the TP53 gene and *white triangles* = data from the APC gene. *Dotted line* = fitting curves for VHL, *grey lines* = fitting curves for TP53, and *black lines* = fitting curves for APC.

of 3.4 deletions per insertion (this ratio is close to 3 for germ line mutations reported in HGMD). The study of repeated sequences surrounding the deletion reveals that the size of the deletion is not related to the size of the repeated sequences (Fig. 13.3a). In contrast, the study of micro-insertions show that the insertion is sequence dependent and will result in the creation of a repetition of whom the size is directly proportional to the insertion size (Fig. 13.3b).

13.3 Consequences of Mutagen Exposure

Mutagens are usually defined as chemical agents that increase the rate of genetic mutation by interfering with the function of nucleic acids. A clastogen is a specific mutagen that causes breaks in chromosomes. Mutagens that specifically result in nucleotides substitutions usually have a two step mechanism. The first event is the production of a DNA adduct, the second one being the inability of the cell to correctly repair this abnormal complex. In fact DNA adducts are chemical complexes that result from various chemical reactions between DNA and small molecules able to induce these reactions. These DNA adducts mostly involve one or more nucleotides, such as pyrimidine dimers, from a single DNA strand resulting in a mismatch between the two DNA strands. To preserve the genomic integrity, eukaryotic cells employ complex surveillance mechanisms called checkpoints to counteract DNA damage. The complex DNA damage checkpoint network is composed of DNA damage sensors, signal transducers, and various effector-pathways, and its major components are the phosphoinositide 3-kinase related kinases (PIKKs), ATM (ataxia telangiectasia mutated), ATR (ATM and Rad3-related), and DNA-PK (DNA-dependent protein kinase) [30–34]. ATM with its regulator MRN (Mre11-Rad50-NBS1) complex to sense double-strand breaks (DSBs) [35] whereas ATR with its regulator ATRIP (ATR-interacting protein) sense single-strand DNA (ssDNA) generated by processing of DSBs, as well as ssDNA present at stalled replication forks. Both kinases then initiate a signaling cascade that includes mediators, transducers, and effectors. About 25 ATM and ATR substrates have been identified [36]. Depending on DNA lesions, activated checkpoints can then mediate cell cycle arrest in G1, S, or G2 phases, DNA repair or even cell death by apoptosis. Matsuoka and coworkers have performed a large-scale analysis to identify proteins phosphorylated in response to DNA damage [37]. They have identified more than 700 candidate proteins that are involved in various biological processes (Fig. 13.4). Progress made in the decoding of these extraordinarily complex pathways reveal that the DNA-damage response network profoundly alters the cell.

In addition to this first level of response to DNA damage, a second barrier against cell alterations has been identified, oncogene-induced senescence [38–41]. Oncogene-induced senescence belongs to a heterogeneous group of cellular responses that include replicative senescence, which is induced by telomere attrition and depends of the activation of the DSB checkpoint [42]. In contrast, oncogene-induced senescence is a telomere-independent form of senescence associated with precancerous lesions [43]. Indeed, it is

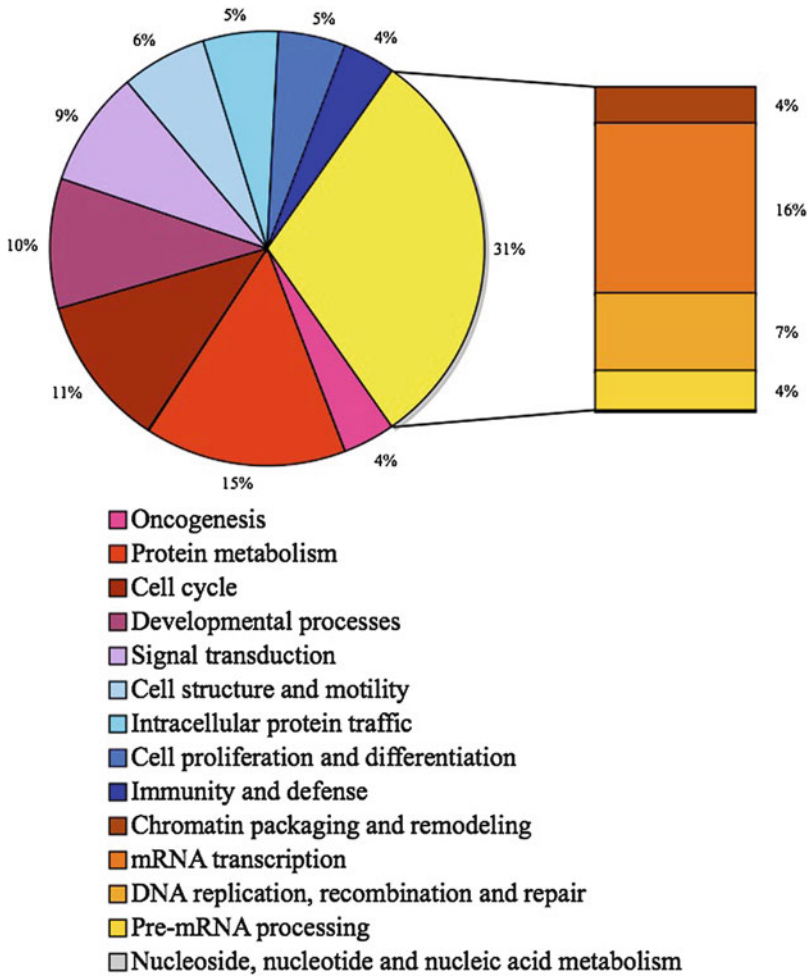

Fig. 13.4 Biological process of the more than 700 candidate ATM and ATR substrate proteins. Data adapted from Matsuoka et al. [37].

believed that this senescence is recruited to terminate a pre-malignant condition before a fully transformed stage can develop. Various experiments have clearly demonstrated that senescence can act as a key barrier to oncogene-mediated transformation in vitro but only few data have been collected in vivo. Melanie Braig and coworkers have provided a nice example about lymphoma development. They have shown that Ras-induced lymphomagenesis can be efficiently regulated by the histone methyltransferase Suv39h1 that methylates H3K9 into H3K9me creating binding sites for HP1 proteins to form constitutive heterochromatin locally. Thus, mice lacking at least one Suv39h1 allele developed lymphomas, whereas most transgenic control animals remain free of lymphoma. They also showed that this phenomenon is dependent on ARF and p53. Thus, an alteration of one of these two senescence regulators leads to the development of lymphomas [44].

Eukaryotic cells harbor complex and efficient networks to avoid mutations. These networks integrate a recognition step that will target DNA damage/intermediates such as uracil, 7,8-dihydro-8-oxoguanine (8-oxoG), 3-methyladenine, apurinic/apyrimidinic (AP) sites, and SSBs followed by: the excision of the inappropriate base moiety (e.g., 8-oxoG), the incision at the resulting abasic site, the replacement of the excised nucleotide, the cleanup of the terminal end(s), and the sealing of the final nick [45]. One of the most studied pathways is the repair step that involves the uracil-DNA glycosylase (UNG), which is responsible for the removal of uracil from DNA. This uracil is usually the result of an erroneous incorporation of dUMP opposite to adenine during the DNA synthesis or the result of a deamination of a methylcytosine (Fig. 13.5) that results in a mispairing between U and G and ultimately to a C to T transition if a DNA polymerase replicates across the mismatch [46]. UNG is a highly conserved enzyme found in many species from *E. coli* to human. All UNG appear to have very similar properties: they are able to cleave uracil from both single- and double-stranded DNA, whether it is in a U/A base pair or any type of base mismatch [47]. This enzyme hydrolyzes the N-glycosidic bond linking the uracil to the sugar and initiates the base excision repair (BER) process [48]. Other base alterations are frequently found in DNA. Among them, the 7,8-dihydro-8-oxoguanine (8-oxoG), also called 8-hydroxyguanine, is a by-product of normal aerobic metabolism. It is strongly mutagenic and

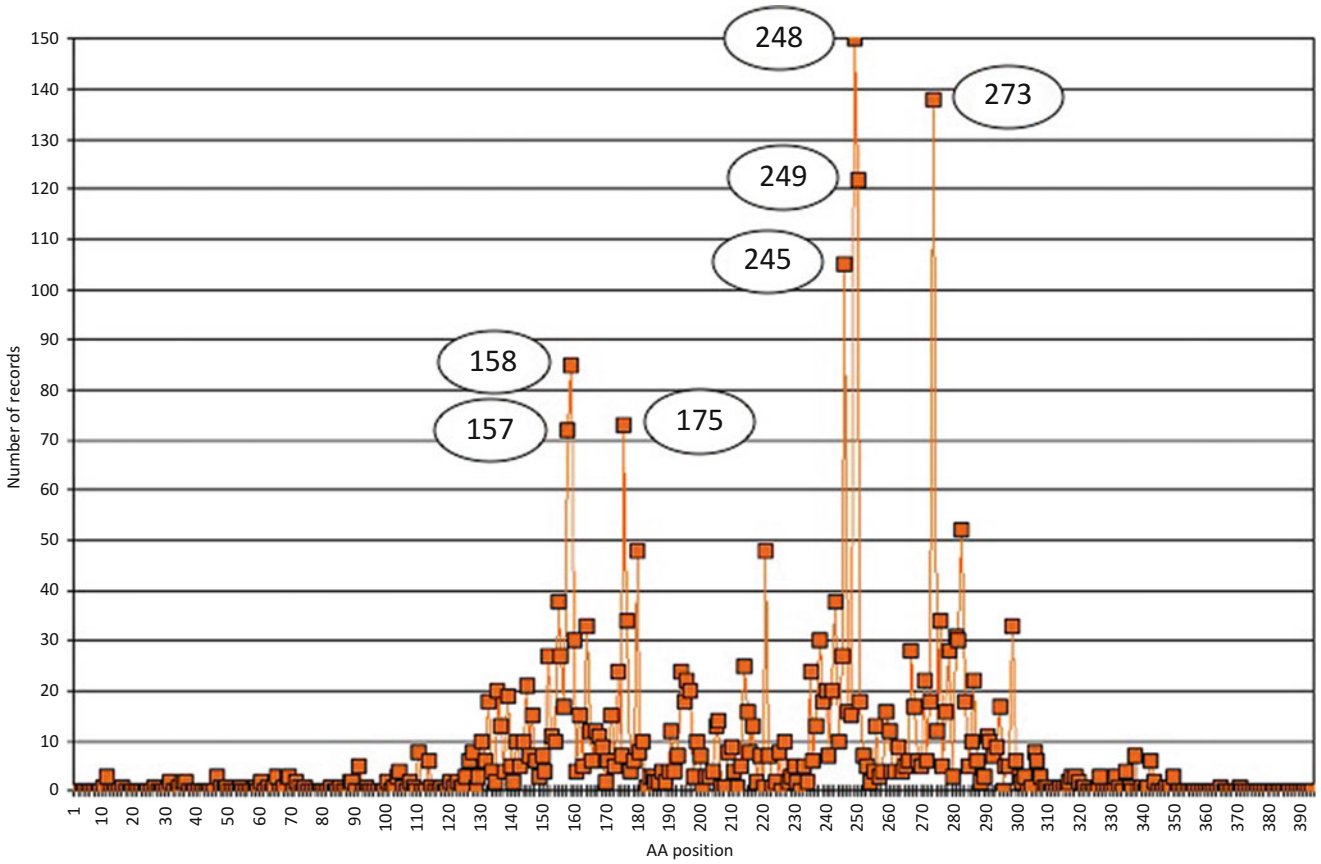

Fig. 13.5 Distribution of TP53 gene mutations in lung cancers. Data were extracted from the UMD-TP53 (http://www.umd.be) that contains 2784 mutations from lung cancers (July 2007 release). *X*-axis = amino acid residues, *Y*-axis = number of records. *Circles* indicate hotspot positions.

able to base pair with adenine and cause G:C → T:A transversion mutations. The OGG1 DNA glycosylase is the major activity excising 8-oxoG from DNA [49].

13.4 Gene Targets

Because of the high efficiency of the BER, the DNA damage checkpoint network, and the oncogene-induced senescence mechanisms, the probability for a mutation to arise is very low. Therefore, mutation of key genes from one of these pathways, as well as oncogenes or tumor suppressor genes, will more efficiently be selected and they are therefore good candidates for cancer-associated genes.

Historically, the identification of cancer genes relied on virus and linkage analysis using large kindreds with a high incidence of cancers. These two approaches led to the identification of oncogenes and later on to tumor suppressor genes associated with a predisposition to develop cancers. The first human retrovirus HTLV-1 was discovered in the late 1970s) [50], and the first tumor suppressor gene identified was the RB1 gene involved in retinoblastoma [51]. More recently, mismatch repair genes (hMLH1, hMSH2, and others) involved in microsatellites instability and colorectal tumors were discovered [52, 53]. These early discoveries paved the way to the identification of a large set of genes associated with cancers. The list being now too long to be printed here, additional information can be found at the Cancer Genome Anatomy Project (http://cgap.nci.nih.gov/Genes) where more than 220 oncogenes and 260 tumor suppressor genes are recorded.

Concomitantly to these efficient approaches to identify genes involved in the early steps of cancer development (i.e., genes involved in the cancer initiation), three other approaches have been developed to identify cancer genes.

13.4.1 DNA Adducts

A DNA adduct is the first step to DNA damage that will eventually result in a mutation. Various examples have shown that levels of DNA adducts vary with a number of lifestyle, environmental, and chemical exposure factors. It has also been shown that increased dietary intake of antioxidants and essential metals, especially zinc, is protective. The detection of DNA adducts as pro-mutagenic markers could enable an understanding of cancer risk. In fact, cancers with

poorly defined etiology may be explained once DNA adducts have been identified. Various assays and in vivo protocols are available to evaluate the mutagenicity of a single agent but, as for drugs interactions, the evaluation of complex mixtures for mutagenicity is difficult. In addition, it is often challenging to predict if the mutagenic compound identified in vitro will reach the target organ at a sufficient concentration. The short-lived positron-emitting radionucleides molecular imaging is an approach as well as the use of IR microspectroscopy that can be used as a high-throughput technology [54], but the need for an inexpensive in vitro system remains [55]. Despite these limitations, numerous studies have been able to demonstrate a relation between DNA adducts and mutations at the gene level. An interesting illustration is given by the study of chromium in the context of lung cancers. Chromium (Cr) is a ubiquitous environmental contaminant that is also used in various occupations (artistic painting) or industries (chemical industry, anticorrosion paints, and others). In addition, Cr is also present in cigarette smoke. Hence, it has been suggested that chromium exposure and cigarette smoke may have a synergistic or additive effect in inducing lung carcinogenesis [56]. In addition, while the direct exposure to Cr (III) is not harmful as this compound is not able to penetrate human cells, the exposure to other compounds such as Cr (VI) will ultimately lead to the production of Cr (III) after various intracellular reducing reactions. This intracellular Cr (III) is then able to form covalent binary and ternary DNA adducts that have mutagenic potencies [57]. It has been shown that these DNA adducts preferentially form in NGG sequences, which include codons 245 (GGC), 248 (CGG), and 249 (AGG) of the p53 gene, the mutational hotspots in cigarette smoke-related lung cancer. While polycyclic aromatic hydrocarbons (PAHs), the major carcinogen found in cigarette smoke, bind to the p53 mutational hotspots for lung cancers including codon 157 (GTC), 158 (CGC), 245 (GGC), 248 (CGG), and 273 (CGT), while codon 249 (AGG) is not a preferential site for PAH binding [58, 59].

The finding that Cr (III) strongly binds at codon 249 suggests that the etiological agent for lung cancer with codon 249 mutations is Cr (III). Mutations involving this codon account for 4.4 % of mutations from lung cancers. Mutational events involving this residue are presented in Fig. 13.6.

Mutations involving the second base of codon 249 are more frequent for smokers (21/41–51.2 %) than for nonsmokers (17/67–25.4 %). However, results show that Cr (III) binds at the second base two times more frequently than at the third base of this codon. It has thus been suggested that the Cr (III)–DNA adducts formed at the second and third bases of this codon are repaired with different efficiencies and/or that they affect the fidelity of DNA replication differently [60]. The DNA adducts approach is usually restricted to the study of a particular component and its relationship with mutations from a previously identified gene. It is thus not frequently used to identify new cancer genes.

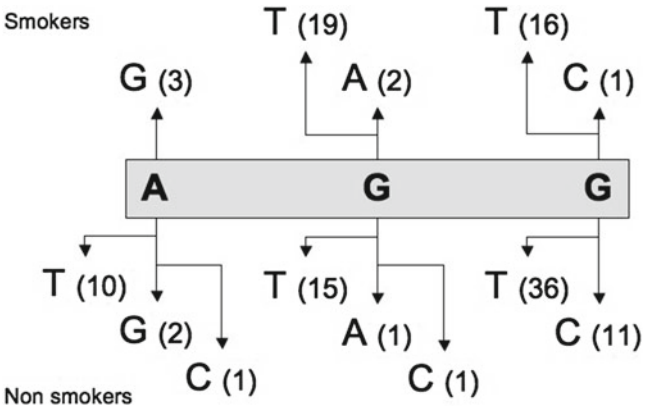

Fig. 13.6 Simple mutational events involving codon 249 of the TP53 gene in lung cancers. *Top* = mutational events reported in smokers; *Bottom* = all mutational events. Data were extracted from the UMD-TP53 (http://www.umd.be) that contains 2784 mutations from lung cancers (July 2007 release).

13.4.2 Cancer Transcriptome

Another approach is the analysis of the cancer transcriptome. With the completion of the Human Genome project [61], life scientists were challenged with the task of analyzing the expression levels on a global scale. In 1995, microarrays were developed as a high-capacity system to monitor the expression of numerous genes in parallel. These microarrays were prepared by a high-speed robotic printing of cDNAs on a glass support. This matrix was further used for quantitative expression measurements of the corresponding genes [62]. In parallel to these microarrays produced by a deposition of cDNA fragments or oligonucleotides on slides, a new in situ synthesis technology that combines photolithography and chemical DNA synthesis was developed [63–65]. This technology enabled a further miniaturization of the assay and the manufacturing of high density oligonucleotide microarrays. The GeneChip® Human Gene 1.0 ST Array is a product in the family of Affymetrix expression arrays offering whole-transcript coverage. It includes 764,885 25-mer probes to address each of the 28,869 genes with an average of 26 probes per gene (http://www.affymetrix.com).

These technical developments allowed testing of the hypothesis that identification of cancer subtypes could be accomplished through detection of all genetic modifications found in cancer cells. This was driven by the fact that cancer cells accumulate genetic abnormalities and that, while they share common genetic defects, specific alterations will be found only in a homogeneous subtype of tumors. The implications of this hypothesis would range from diagnosis (development of classifications on the basis of gene expression patterns) to therapeutic (patient prognosis and the response to a particular treatment). The hundreds of analyses performed have shown that known types and subtypes of cancer can be distinguished by their gene-expression profile. In addition,

new molecular subtypes have been discovered that are associated with various properties such as the propensity to metastasize. While microarrays can be used to search for cancer genes among a list of candidate genes, the two main foci of microarray investigations are to improve our understanding of the pathophysiology and/or the molecular etiology of a specific cancer and the detection of genetic markers that could improve the differential diagnosis. Early results were very promising [66]. With the accumulation of data from various teams, limitations of the technology were soon recognized. In fact, the power of microarray studies depends not only on the quality of the array design and production, but also on the statistic and bioinformatics approaches used to analyze the data. Thus, because this technology offered the possibility to investigate a multitude of genes in a small number of samples, it also introduced the most challenging problem of microarray analysis, which is the problem of multiple comparisons. Therefore the Westfall-Young step-down permutation correction should be mandatory. In addition, hierarchical cluster analysis has become the most popular and most frequently used multivariate technique to analyze microarray data. This method defines a distance between two tumors based on the difference in gene expression. It produces a complete tree with leaves as individual patterns and the root as the convergence point of all branches. However, given enough genes, the genes will always cluster. Therefore, there is only minor scientific value in the fact that there are genes that behave in a similar way. It has been shown that these approaches have numerous limits and that clustering trees can even be produced when starting with very poor quality signals questioning about the significance of reported data [67]. Similarly, it has been recognized that the clustering is today overused to interpret microarray data [68].

In 2005, Rhodes reported the clinical utility of array-based gene profiles in breast cancer based on data from van de Vijver et al. [69], 2 years later a review by Michiels et al. [70] gave quite different conclusions. They underlined that most prediction rules using gene expression have not provided a substantially and significantly improved prognostic classification when compared to conventional prognostic factors [71, 72]. Thus they concluded that these results could be interpreted as disproving the initial assumption and stated that if published results are correct to the extent that published combinations of genes have some prognostic value, many other gene combinations would be as good. Besides, none have been shown to add much to the clinical information that is routinely available. The example of breast cancer illustrates a problem that is central to the interpretation of microarray data. Studies with a solid experimental design and large sample sizes are required before gene expression profiling can be used in the clinic to predict outcome [70].

Eszlinger et al. arrived at similar conclusions in the context of thyroid malignancies [73]. Reviewing microarray data they reported that the use of different platforms and experimental designs (intra-individual or inter-individual comparisons) as well as the use of various control tissues (non-nodular healthy tissue or benign lesions such as goiter or follicular adenoma) complicate cross-analysis. In addition, the studies are characterized by strong differences in data analysis methods, which vary from simple empiric filters to sophisticated statistic algorithms.

Microarray technology is still in its early days of development. In order to standardize its usage strong improvements have to be made to standardize experimental designs and analysis. Quality controls [74] need to be defined and the various platforms should include common probes to allow meta-analysis. Despite these limitations, this technology is promising and should in the next years give valuable information to improve understanding of the pathophysiology and/or the molecular etiology of cancers and the detection of genetic markers that will improve the differential diagnosis and the prognosis of drug response. This technique is not the method of choice to search for cancer genes mutated in tumors as most of the down-regulated or up-regulated transcripts are the result of loss of cellular differentiation in cancer.

13.4.3 Large-Scale Sequencing of Human Cancers

A third approach to identify cancer genes is to perform a systematic resequencing of cancer samples. Ideally, a normal tissue from the same patient is also sequenced in order to identify somatic mutations. A proof-of-principle for this approach was given by work from Stephens et al. who sequenced the gene encoding the transmembrane protein kinase ERBB2 in a series of 120 primary lung cancers [75]. They identified mutations in 4 % of samples and 10 % in the adenocarcinoma subtype. This previous study was followed by a larger analysis of the whole protein kinase gene family or kinome, which is of primary interest as targets for inhibition in cancer treatment. Thus, in 2005 were published results from the sequencing of 518 protein kinases representing about 1.3 Mb of DNA per sample [76]. As underlined by Collier et al. many of the samples used in this work were cell lines and the interpretation of data should thus be done with caution [77]. In fact, 89 % of breast cancer cell lines displayed at least one kinome mutation while only 25 % of primary breast cancers possessed one. These results could be linked to the fact that cells were forced to grow in culture and thus accumulate somatic mutations. In addition, the physiological significance of most mutations remains unclear, and only a functional validation of these mutant alleles could reveal their pathogenic effect. Nevertheless, these early high throughput-sequencing projects demonstrated the ability to

identify somatic mutations in cancers. The same group from the Wellcome Trust Sanger Institute released their data from the sequencing of the 518 protein kinases in 210 diverse cancers. For this analysis they used 169 fresh cancer specimens with matched normal DNA in order to avoid artifacts mentioned by Collier et al. [77] regarding the use of cell lines. Cancers types were: acute lymphoblastic leukemia, bladder, breast, colorectal, gastric, glioma, head and neck, lung, melanoma, ovarian, renal, and testis. During this analysis a total of 274 Mb of cancer genome was sequenced and 1007 somatic variations identified. As expected the number of somatic events varied between cancers with a higher prevalence for cancers with defective mismatch repair or from patients previously treated with anticancer drugs known to induce mutations. About 30 % of other cancers showed no somatic mutations while the mutation rate varied between 4.2 per Mb (lung carcinomas) to 0.2 per Mb (breast cancers) [78]. In order to evaluate the number of driver or passenger mutations the investigators examined the observed ratio of nonsynonymous and synonymous mutations compared with that expected by chance alone [79, 80]. This approach is different from the one reported by Sjoblom et al. who did not take into account the synonymous mutations [12]. The overall approach of these 2 large-scale sequencing projects is shown in Fig. 13.7.

Large-scale sequencing projects mostly rely on bioinformatics tools to extract driver mutations from among all variations detected. Thus, in the project from Sjoblom et al., during the first round they identified 816,986 putative mutations, and after various selection steps they discarded 99.84 % of these mutations (Fig. 13.7). Almost all large-scale sequencing projects rely on the same selection procedure. The first model is known as a codon substitution model and account for potential factors in the mutation process. It is based on the assumption that the genetic code allows some codons to mutate to missense or stop codons more readily than others. Yang et al. have thus developed a new codon-based method to estimate the relative rate of substitution and of nonsense versus missense mutations in different functional domains [79]. It includes differences in mutation rates between transversions and transitions, as well as between silent and non-silent mutations. This model is based on a continuous-time Markov processes, reflecting the hypothesis that mutations are random events that occur independently of one another.

Greenman et al. [80] recently described a second model where the selection is explicitly separated from the mutation. They used an approach related to phylogenetic methods. The basic principle is that silent (synonymous) somatic mutations are passenger mutations. The set of silent mutations can thus be used as a control group to estimate the number of non-silent mutations that would be expected to occur by chance, under the null hypothesis of no association between mutations and cancer development.

The limit of these statistical approaches is that they were validated with small data sets (somatic mutations of the *TP53* gene for example). As proteins have usually specific

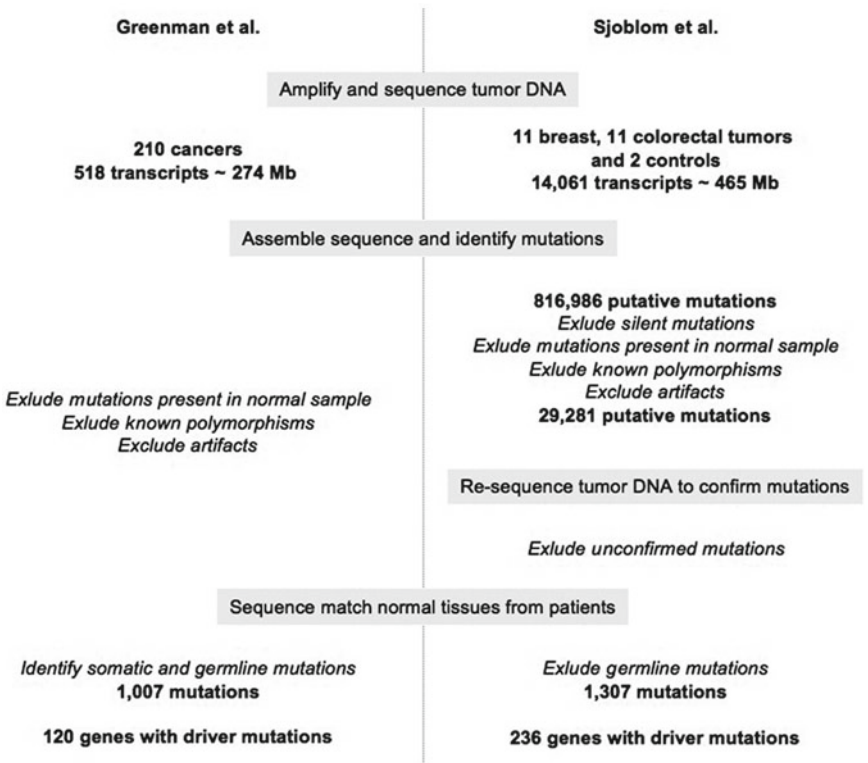

Fig. 13.7 Schematic of mutations detection for the two main large-scale sequencing projects. *Left* = steps for the kinome study by Greenman et al. [78]. *Right* = steps from the study of a major fraction of human genes in two common tumor types, breast and colorectal cancers by Sjoblom et al. [12].

features this approach can result in the misinterpretation of many putative mutations. In addition, as underlined by Greenman, they consider that synonymous mutations are passenger mutations. Recent progress in our knowledge of germ line mutations have shown that these synonymous, but also at least 15 % of missense mutations in fact do affect splicing either by the creation of a new donor or acceptor splice site but also by the inactivation of an exonic splicing enhancer or the creation of an exonic splicing silencer [81].

Overall, these large-scale sequencing projects appear to be the most efficient approach to identify cancer genes in the future. The preliminary results show that the patterns of somatic mutations in human cancers are highly variables. Thus, it is necessary to study large sets of homogenous subtypes of cancers to identify specific signatures and decipher the mutagenic process of cancer progression. In addition, as most somatic mutations are passenger mutations, new tools need to be developed to efficiently recognize driver from passenger mutations. The development of Locus Specific Database (LSDB) [82] will facilitate the rapid interpretation of mutations from common cancer genes and specific tools to predict the pathogenic impact of missense mutations integrated to LSDB software such as the UMD tool will be of valuable help in the selection process [83, 84].

13.5 How These Simple Sequence Mutations Contribute to Cancer Development?

The last 30 years of cancer research has generated enough information about cancer development to build a global model. Thus, it is today recognized that cancer cells have defects in regulatory process that govern cell proliferation and homeostasis. Despite the highly variable set of genes involved in a specific cancer, most abnormalities can be classified in six major alterations in cell physiology as suggested by Hanahan et al. [85] (Fig. 13.8).

The mechanisms by which a cell can detect and correct a DNA damage are numerous and efficient. It is therefore not surprising to observe a multistep progression of cancer cells that will progressively acquire new capacities in order to avoid defense mechanisms. Depending on the cancer progression stage (Fig. 13.1) only few of these mechanisms could be involved but ultimately almost all cancers will acquire these new capacities. The number of genetic changes necessary to acquire these new capacities will vary among cancers. Thus, in some situations the alteration of a single gene will confer several capabilities simultaneously, while for other cancers the alteration of multiple genes will be necessary to acquire a single capacity. In addition a single capacity may be acquired by different ways.

Because the mechanisms and pathways involved in cancers are too numerous to be included in this chapter, we will focus on the example of the discovery of the Insulin-like growth factor binding protein 2 (*IGFBP2*), which plays a major role in the development of astrocytomas.

IGFBP2 was initially reported to be a gene that is overexpressed in high-grade gliomas, and overexpression was associated with poor patient survival [86, 87]. While in vitro studies showed that IGFBP2 promotes glioma cell migration and invasion, it has not been determined whether IGFBP2 plays a causative role in glioma development in vivo. We were thus facing the central question about cancer genes: Because this gene is associated with cancer does that mean that it is actually a cancer gene? To answer this question, Zhang et al. used a viral gene transfer delivery agent known as RCAS that infect only glial cells. They found that the delivery of IGFBP2 alone did not lead to glioma development, but that the co-delivery of IGFBP2 with the activated K-Ras oncogene led to development of astrocytomas [88]. These data can be compared to previous reports that neither K-Ras nor Akt alone are enabled to cause brain cancers while the association of K-Ras and Akt is [89]. Therefore, they tried the combination of Akt and IGFBP2 and no tumor formed, suggesting that these two genes belong to the same molecular pathway. In addition, they showed that the combination of IGFBP2 and the platelet-derived growth factor beta (PDGFB) results in a higher-grade form of the cancer than that caused by PDGFB alone. As PDGFB has been previously shown to initiate oligodendroglioma formation independently from the Akt pathway [90], they thus postulated and demonstrated that IGFBP2 activates the Akt pathway. This was further confirmed by the use of an Akt inhibitor, which killed more IGFBP2-PDGFB infected cells than those infected only with PDGFB.

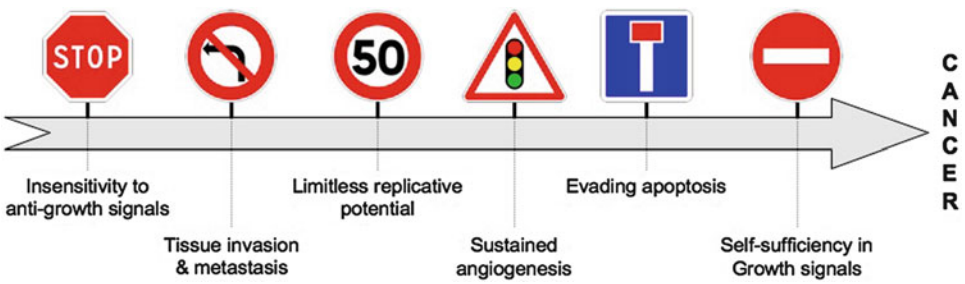

Fig. 13.8 Major acquired functional capacities for cancer cells. Most cancer cells during their development acquire functional capacities that allowed them to ignore regulation signals.

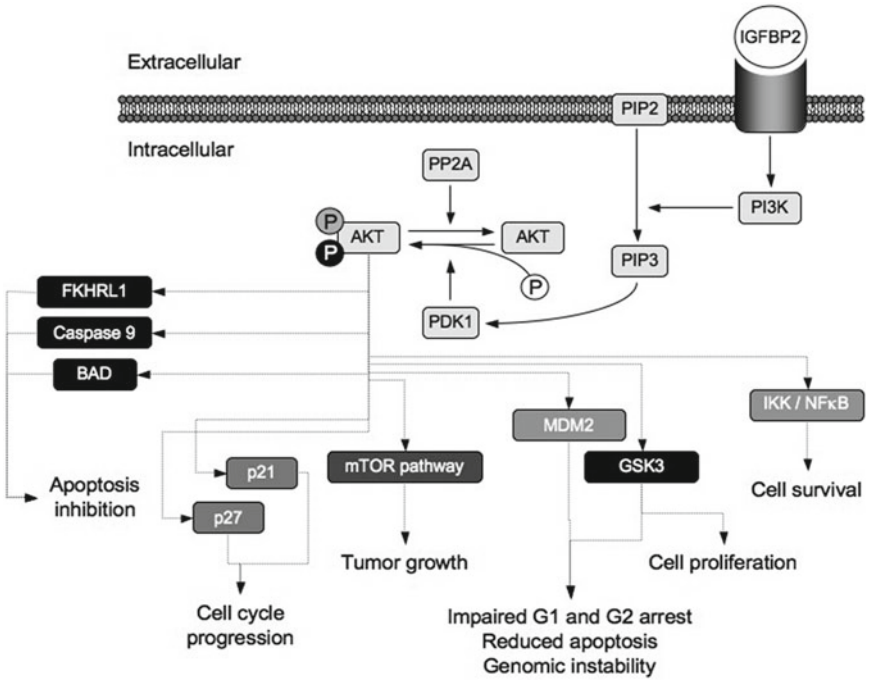

Fig. 13.9 IGFBP2 and PI3K/AKT pathway and its potential roles in cancer. AKT = v-akt murine thymoma viral oncogene homolog 1; BAD = BCL2-antagonist of cell death; FKHRL1 or FOXO3A = forkhead box O3A; GSK3 = glycogen synthase kinase 3 beta; IKK = Ikappa-B kinase; mTOR = mammalian target of rapamycin; NFkB = nuclear factor of kappa light polypeptide; p21 or CDKN1A = cyclin-dependent kinase inhibitor 1A; p27 or CDKN1B = cyclin-dependent kinase inhibitor 1B; mdm2 = transformed 3T3 cell double minute 2, p53 binding protein; PIK3 = phosphoinositide-3-kinase; PIP3 = phosphatidylinositol 3,4,5-trisphosphate; PDK1 = 3-phosphoinositide dependent protein kinase-1; PP2A = protein phosphatase 2. The IGFBP2 circulating protein binds to cell-surface receptors that will induce the production of second messengers via the activation of PI3Ks. PIP3 signals then activates the kinase PDK1, which in turn activates the kinase AKT, also known as protein kinase B. Proteins phosphorylated by activated AKT will play key roles in cancer development: (1) AKT promotes cell survival and opposes apoptosis by a variety of routes: BAD is a protein in the Bcl-2 gene family that opposes Bcl-2 to induce apoptosis. Similarly, phosphorylation of the protease caspase 9 or forkhead transcription factors by AKT block the induction of apoptosis by these factors; (2) The Akt-dependent phosphorylation of p21 prevents the complex formation of p21 with PCNA and decreases the binding of the cyclin-dependent kinases Cdk2 and Cdk4 to p21. Similarly, the phosphorylation and the cytosolic retention of p27 contribute to cell cycle progression; (3) The phosphorylation of the ribosomal protein S6 kinase (p70S6K) and the eukaryotic translation initiation factor 4E binding protein (4EBP) by mTOR and the downstream phosphorylation of the ribosomal protein S6 (RPS6) and the eukaryotic translation initiation factor 4B (EIF-4B) stimulate translational initiation and contribute to cell growth; (4) AKT plays a critical role in controlling of Mdm2-p53 signaling pathway by regulating Mdm2 stability; (5) AKT phosphorylates and deactivates Gsk3-beta, thus subsequently resulting in cell proliferation; (6) The phosphorylation of IKKs lead to activation of the transcription factor NF-kB to oppose apoptosis. Data were extracted from the Kyoto Encyclopedia of Genes and Genomes (KEGG) website (http://www.genome.jp/kegg/kegg2.html) and the Biocarta website (www.biocarta.com).

Concomitantly to this discovery, Carpten et al. announced the identification of a recurring mutation of the *AKT1* (v-akt murine thymoma viral oncogene homologue 1) gene in breast, colorectal, and ovarian cancers [91]. To identify the AKT1 mutation, the researchers analyzed 162 tumor samples from patients with either breast [62], colorectal [51] or ovarian cancer [50]. They showed that 8 % of breast, 6 % of colorectal and 2 % of ovarian tumors had the c.49G>A (p.Glu17Lys) AKT1 mutation. They also demonstrated that this missense mutation can cause tumor proliferation and may play a role in making cells resistant to certain types of therapies.

It has been known for many years that hormone and growth factor stimulations of phosphoinositide 3-kinases (PI3-Kinases) result in the production of lipid second messengers at the plasma membrane, which initiate a complex network of signaling pathways that have been implicated in cell growth, cell survival, cell proliferation, and cell migration [92]. Class IA PI3-Kinases are activated by a series of cell surface tyrosine kinase receptors such as insulin growth factor receptor and platelet-derived growth factor receptor. Upon growth factor receptor activation, PI3-Kinases promote the phosphorylation of Akt at Serine 473 and/or Threonine 308. Akt then activates a series of cancer-related functions such as cell proliferation, cell migration, invasion, and decrease of cell death in human tumors [93].

Although AKT1 is central to pathway activation, for years its role in cancer has been that of an intermediary between mutated upstream regulatory proteins and downstream survival signaling proteins. The demonstration of an existing cancer causing mutation is the first evidence of a direct role of

AKT1 in human cancer. This discovery was made possible by the sequencing of clinical samples from cancer patients, while a mutation from this gene has never been detected in cancer cell lines. These data together with the ones from IGFBP2 allow drawing a new pathway linking these two proteins (Fig. 13.9).

The identification of simple sequence mutations has been driven for years by oncogenes identification using viral vectors and by human genetics to isolate oncogenes and tumor suppressor genes by linkage and positional cloning. If these approaches have been fruitful and our knowledge of human cancers has made tremendous progresses, a new area is now opened to search for cancer genes. In the next few years, the large-scale sequencing projects will be able to identify thousands of mutations in each tumor samples. The development of efficient bioinformatics and biological tools to extract driver mutations from passengers ones will allow the establishment of databases of somatic events. The collection of these mutations from thousands of samples will then allow the characterization of molecular signatures of types and subtypes of cancers. These signatures will then be useful both for diagnosis and for the development of new therapeutics. Other strategies such as the analysis of the cancer transcriptome and the DNA adducts studies will be favorably combined to draw the various pathways that can be activated or inactivated in cancer cells and their relationship to exposure to various environmental factors.

Single Nucleotide Polymorphisms and Cancer Susceptibility

14

Richard A. Hubner and Richard S. Houlston

14.1 Introduction

Cancer susceptibility is determined by exposure to environmental factors and inheritance of genetic factors, which act either alone or in combination to influence likelihood of disease. For most common cancers relatives of affected individuals have an approximately twofold increased risk of developing the disease themselves, which may be a due to shared environment, inherited factors, or a combination of both [1]. However, twin studies have provided evidence that the familial aggregation of cancer results from inherited factors, in particular for prostate, colorectal, and breast cancer [2]. Known highly penetrant rare mutations account for some but not all of this familial risk. For example, mutations in the breast cancer susceptibility genes *BRCA1* and *BRCA2* account for less than 20 % of the excess risk in relatives of breast cancer patients [3], and similarly less than 5 % of colorectal cancer can be ascribed to high penetrance mutations in *APC*, mismatch repair (MMR) genes, and *MYH*. The nature of the remaining familial risk is unknown, but multiple-case families have failed to provide evidence of linkage to novel loci in recent studies, and it is more plausible that a substantial proportion will be conferred by a number of low-penetrance genetic variants with relatively high population frequency [4]. Individually these polymorphisms will confer only modest increases in risk, but when considered collectively, and in combination with relevant environmental factors, they may confer substantial susceptibility. This concept has been termed the common disease-common variant hypothesis, and single nucleotide polymorphisms (SNPs), which are the most abundant sequence variation in the human genome, are thought to account for the majority of such common low-penetrance cancer susceptibility variants.

14.2 Distribution of SNPs and Linkage Disequilibrium in the Human Genome

A SNP is a DNA sequence variation that occurs when a single nucleotide in the genome varies between two individuals or between paired chromosomes in the same individual. SNPs are a consequence of point mutations occurring in the reproductive cells of an individual which are passed onto their offspring, and after many generations become established within a population. Each SNP has two alleles, the original sequence and the mutated copy. The less common (minor) allele should have a population frequency of at least 1 % for the genetic variant to be termed a polymorphism, but the frequency of SNPs may vary widely between different geographical populations and ethnic groups [5]. There are estimated to be over 10 million SNPS in the human genome, collectively accounting for over 90 % of sequence variation [6]. They are distributed throughout the genome, occurring approximately every 100–300 base pairs but with marked regional differences, and the vast majority lie in untranslated regions outside of known genes [7].

Adjacent SNPs in the same chromosomal region are not inherited randomly but as a combination of alleles which form haplotype blocks [8]. This phenomenon is termed linkage disequilibrium (LD), and the strength of LD between two adjacent SNPs is dependent on the physical distance between them along the chromosome. Two SNPs that are very close to each other will be tightly linked due to the low probability of a meiotic chromosomal break occurring between them resulting in recombination and loss of linkage. In contrast, widely spaced SNPs will exhibit low LD since recombination during meiosis is more likely. However, the degree of LD between two adjacent SNPs cannot be simply predicted by the chromosomal distance between them since the pattern of LD within the human genome is not uniform [9, 10]. Distinct blocks of high LD occur, and are interspersed with regions in which LD breaks down rapidly [11].

Linkage disequilibrium underlies the principle of gene mapping by association analysis. Linkage disequilibrium

W.B. Coleman, G.J. Tsongalis (eds.), *The Molecular Basis of Human Cancer*, DOI 10.1007/978-1-59745-458-2_14

between a marker allele and a disease susceptibility allele will result in both alleles being inherited together over many generations, thus the same marker allele will be detected in affected individuals in multiple apparently unrelated families. Recombination between the marker and disease susceptibility allele will eventually dissipate the association (as can further mutational events) with the rate of decay being primarily dependent on the distance between the two alleles and the number of generations that has passed [12, 13]. However, the slowness of this decay makes allelic association a useful tool. Additionally, the complexity of analysing a number of different SNPs within a particular gene or locus can be significantly reduced if there is strong LD between them, since the genotype of all the SNPs within the haplotype block can be inferred by the genotyping of only one or a few marker SNPs or tagging SNPs [14]. Thus, linkage disequilibrium can be further exploited in association studies by using tagging SNPs to reduce the number of SNPs that require genotyping, significantly lowering laboratory costs.

14.3 Biological Consequences of SNPs

The likely functional effects of a SNP are dependent on the location and nature of the sequence change. Those occurring in exonic regions of genes are generally thought most likely to confer functional effects. However, SNPs occurring in the 5′ untranslated region (UTR) and 3′ UTR may influence gene transcription or mRNA stability, whilst SNPs in intronic regions of genes or in non-gene regions may also have as yet unknown or poorly defined consequences [5].

Of the exonic SNPs nonsense or frame shift changes that result in protein truncation have the most serious deleterious effects, often resulting in total loss of protein function. Non-synonymous SNPs that result in a change in the amino acid sequence can also have deleterious effects, the functional effects being dependent on the similarity of the original and mutant amino acid, its location within the protein, and consequences to the tertiary structure. Algorithms have been developed to aid prediction of the functional consequences of non-synonymous SNPs. Examples include the Grantham Scale which categorises codon replacements into classes of increasing chemical dissimilarity [6], and the PolyPhen algorithm which predicts the functional impact of amino acid changes by considering evolutionary conservation across different species, physiochemical differences, and proximity of the substitution to predicted functional domains and structural features [15]. Such algorithms can at best only give a very general prediction, placing amino acid changes into a hierarchy of four or five categories of likely functional significance. To provide more detailed data in vitro experiments with different enzyme isoforms are required, and even where such experiments have been performed extrapolation to the in vivo situation may be problematic [16]. The consequences of synonymous SNPs that do not change the amino acid sequence, intronic SNPs, and SNPs outside of gene regions are unknown. Carriage of these variants may still result in cancer susceptibility, either through mechanisms as yet undiscovered or though linkage disequilibrium with an unknown functional variant. For example, a synonymous SNP in the human dopamine receptor D2 gene has been demonstrated to influence mRNA stability resulting in altered expression [17].

14.4 The Association Study Design for Identifying Low Penetrance Susceptibility Alleles

14.4.1 Linkage Versus Association

Highly penetrant cancer susceptibility alleles result in extensive pedigrees and are most readily localised through linkage studies in which genetic markers co-segregate with disease. Low penetrance alleles conferring more modest risks, typically twofold or less, will rarely cause multiple-case families, and will not be identified efficiently through linkage strategies [18]. The search for low penetrance cancer susceptibility alleles has therefore focused on the association study design where the frequencies of candidate alleles are compared in cancer cases and cancer-free controls. A marker allele is said to be associated with a disease if the allele is found more frequently among cases than in the general population, or in a group of unaffected individuals. Association between a marker allele and disease can be a consequence of either a direct biological action of the marker allele, or linkage disequilibrium between the marker allele and a disease-causing allele [19]. The association study design is advantageous since large numbers of case and control samples may be readily obtained, providing adequate power to detect relatively small effects. To detect a gene with a population frequency of 10 % which confers a twofold increased cancer risk, linkage analysis would require about 10,000 affected sibling pairs, whereas an association study would require 500 unselected cases and 500 controls [20].

In most association studies the risk conferred by a specific variant is estimated by using carrier frequencies in case and controls to derive an odds ratio (OR). Usually the frequencies of the three possible genotypes (homozygous wild-type, heterozygous, and homozygous mutant) are compared using homozygous wild-type individuals as the reference group. Where homozygous mutant individuals are rare they may be combined with heterozygotes in the analysis, but this is only efficient if a dominant model can be assumed [20]. Similarly, combining homozygous wild-type and heterozygous individuals is only appropriate if the allele is acting recessively.

14.4.2 Failure to Replicate Positive Associations

The relative ease of collecting DNA samples from unselected cases and controls and the extensive range of genetic variants that could plausibly be associated with cancer susceptibility has made association studies very popular. However, few reported associations have been established beyond reasonable doubt, and in most instances initially significant associations cannot be replicated in subsequent sample sets [21–23]. This is most likely due to type I errors, the spurious association of genetic variants with disease, compounded by publication bias [24]. The levels of statistical significance appropriate in other contexts ($P=0.05$ or $P=0.01$) may not be suitable for association studies, since the number of possible genetic polymorphisms that could be tested is very large and the prior probability that any particular polymorphism will be associated with disease is low, thus most variants achieving a modest level of statistical significance will be false positives [24]. The false-positive rate can be reduced by setting more stringent levels of statistical significance or by improving the selection of candidate SNPs to increase the prior probability of association.

A second possible explanation for the failure to replicate initially positive associations is inadequate statistical power in the replication study, leading to type II errors or false negatives [20]. For example, fewer than 40 % of the colorectal and breast cancer association studies reviewed by Houlston and Tomlinson [23] and Dunning et al. [21] had 80 % or more power to detect a twofold difference in risk at the 0.05 significance level. Very large sample sizes, in the order of thousands or tens of thousands, are required to identify and confirm, or conclusively refute, genetic variants conferring modest cancer susceptibility.

14.4.3 Population Stratification

A further common explanation for spurious association is population stratification, the existence of multiple population subgroups in what was assumed to be a homogeneous population in which allele frequencies vary between the different subgroups [25]. If cases and controls are selected differentially from these subgroups then allelic association will occur in the absence of a true biological association. One way to circumvent this problem is to use family-based approaches, such as the transmission disequilibrium test (TDT), which assess the evidence for preferential transmission of one allele over another in heterozygous parents. Outside the context of childhood cancers this approach is not suitable since it involves genotyping the affected case and both parents who are often not available, and use of other family members severely reduces power [26]. In reality there are few actual examples to support the suggestion that population stratification is a frequent cause of non-replicable associations, indicating that this problem has probably been overemphasised and that other factors such as type I errors and publication bias are more important [5]. Alternatively, failure to replicate associations may occur if there is genuine heterogeneity in risk in different populations. This could occur if there were population differences in LD patterns, allele frequencies of interacting genes, or interacting environmental exposures [24].

14.4.4 Enriching for Genetic Susceptibility

The population frequency of a putative susceptibility allele is an important consideration when designing an association study, since allele frequency markedly influences power to detect an association, and hence the required number of cases and controls (Fig. 14.1). Assuming two controls per case, 800 unselected cases would be required to achieve 90 % power at a significance level of 0.01 to detect a dominant allele with a population frequency of 5 % conferring a twofold increased risk [20]. In contrast, if the population frequency were only 1 % then 3700 cases would be required to achieve the same level of statistical power. Thus the use of unselected cases in association studies is satisfactory for the evaluation of common alleles, but has limited power if the population frequency is less than 5 %. However, power can be increased in association studies by selecting cases that are enriched for genetic susceptibility by virtue of a family history of cancer (Fig. 14.2). The sample size required is typically reduced by more than twofold if cases with an affected first-degree relative are selected, and by more than fourfold if cases with two affected first-degree relatives are used [27, 28]. In the example above, the number of cases required would be reduced from 3700 to 700 if cases with two affected first-degree relatives were selected.

The identification of the rare protein truncating variant 1100delC in the cell-cycle-checkpoint kinase 2 (*CHEK2*) gene in breast cancer patients illustrates the potential of association studies using familial cases to detect rare susceptibility alleles conferring modest relative risks. This variant has a population frequency of less than 1 % and confers a 1.7-fold increase in breast cancer risk [29]. Among unselected breast cancer cases the frequency of *CHEK2* 1100delC was not significantly increased, but in familial cases not carrying *BRCA1* or *BRCA2* mutations the frequency was markedly increased. Subsequently the relative risk in pooled unselected cases has been demonstrated to be 2.3 [30]. Enrichment for genetic factors may also be achieved by selecting cases with an early age of onset, although this has limited effects on power to detect associations in comparison to family history [28].

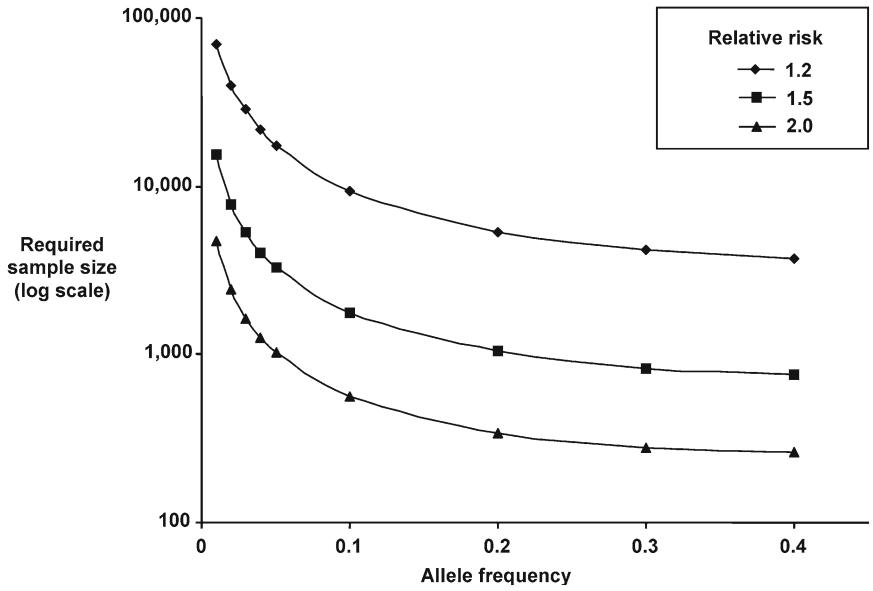

Fig. 14.1 Effect of allele frequency and relative risk on the required sample size to generate 90 % power to show significant associations ($P = 0.01$) for co-dominant susceptibility alleles, assuming one control per case.

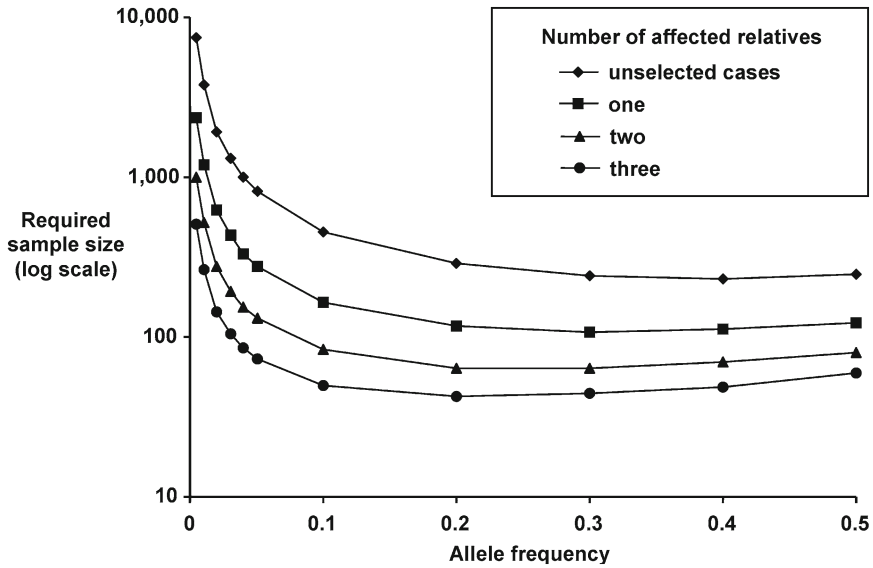

Fig. 14.2 Effect of affected family members on sample sizes required to generate 90 % power to show significant associations ($P = 0.01$) for co-dominant susceptibility alleles conferring a relative risk of 2, assuming one control per case.

14.5 Applications of SNP Genotyping in Cancer Susceptibility Gene Discovery

14.5.1 Direct Association Studies

Most of the known disease alleles in Mendelian cancer syndromes are SNPs within coding regions that result in protein truncation and hence total or very severe loss of function [6]. Ninety-five per cent of germ line mutations in the *APC* gene giving rise to the colorectal cancer susceptibility syndrome familial adenomatous polyposis (FAP), for example, are protein truncating [31]. Low penetrance cancer susceptibility alleles are similarly most likely to be coding variants, and the majority of analyses performed to date have been direct association studies which focus on SNPs that are thought to alter protein function or gene expression [18]. The analysis of functional SNPs has the potential to be a powerful method of cancer gene discovery since the number of common coding SNPs is only a fraction of the total number. It is estimated that there are 50,000–250,000 SNPs which confer a biological effect, most of which are distributed in and around the 30,000 genes [5]. Most cancer association studies have

focused on functional SNPs in candidate genes that encode proteins thought to be involved in carcinogenesis, such as those involved in apoptosis, cell-cycle control, carcinogen metabolism, or DNA repair, or those known to be somatically altered in cancer [24]. Candidate genes may also be identified from linkage analysis, expression array analysis, and comparative genomics. The disadvantages of the direct association approach are that it relies on existing knowledge to select candidate genes, identify potentially functional SNPs within these genes through database searching, and accurately predict their functional effects.

The association between the *MTHFR* C677T polymorphism and colorectal cancer (CRC) risk can be seen as an illustration of the successful application of the direct association paradigm. Folate metabolism impacts on both DNA methylation and DNA synthesis and repair, and aberrations of both these processes are known to be important in colorectal carcinogenesis [32]. Epidemiological studies lend further support for a role of folate metabolism in CRC development with high folate intake individuals generally showing a reduced CRC incidence [33]. The methylenetetrahydrofolate reductase (MTHFR) enzyme occupies a pivotal position in the folate metabolism pathway, directing the flow of one-carbon moieties towards DNA methylation and away from DNA synthesis (Fig. 14.3). Thus, there is strong a priori evidence that genetic variants in folate metabolism genes, and in the *MTHFR* gene in particular, might confer susceptibility to CRC. In vitro studies have demonstrated that the C677T polymorphism in the *MTHFR* gene gives rise to an enzyme with 35 % of normal activity, making this SNP an attractive candidate for direct association studies [34]. A number of such studies in a variety of different populations have been performed, and the pooled estimate from a recent updated meta-analysis indicated that compared to the homozygous wild-type genotype the *MTHFR* 677TT genotype was associated with a 17 % reduction in CRC risk [OR 0.83; 95 % confidence interval (CI): 0.75–0.93] [35]. Although an OR of 0.83 is modest, because of the high frequency of the wild-type allele conferring an increased risk (0.68 in Caucasian populations) this translates into a relatively high population attributable risk, and it was estimated that *MTHFR* C677T genotype contributed to approximately 15 % (95 % CI: 9–22 %) of the total incidence of CRC. It is noteworthy that only a few of the studies included in this meta-analysis individually showed a significant association with CRC risk, and pooling of data from over 12,000 individuals with CRC was required to demonstrate a significant association. This illustrates the order of magnitude of the sample sizes required to generate adequate statistical power to reliably identify low penetrance susceptibility alleles.

The assembly of adequately sized sample sets has been a frequent obstacle to identifying low penetrance susceptibility alleles. Pooling of data from a number of different studies that have analysed the same SNP in independent sample sets has therefore been a popular method of generating adequate statistical power [21, 23, 36]. Examples of genetic variants with evidence from pooled analyses for association with colorectal and breast cancer risk are listed in Table 14.1.

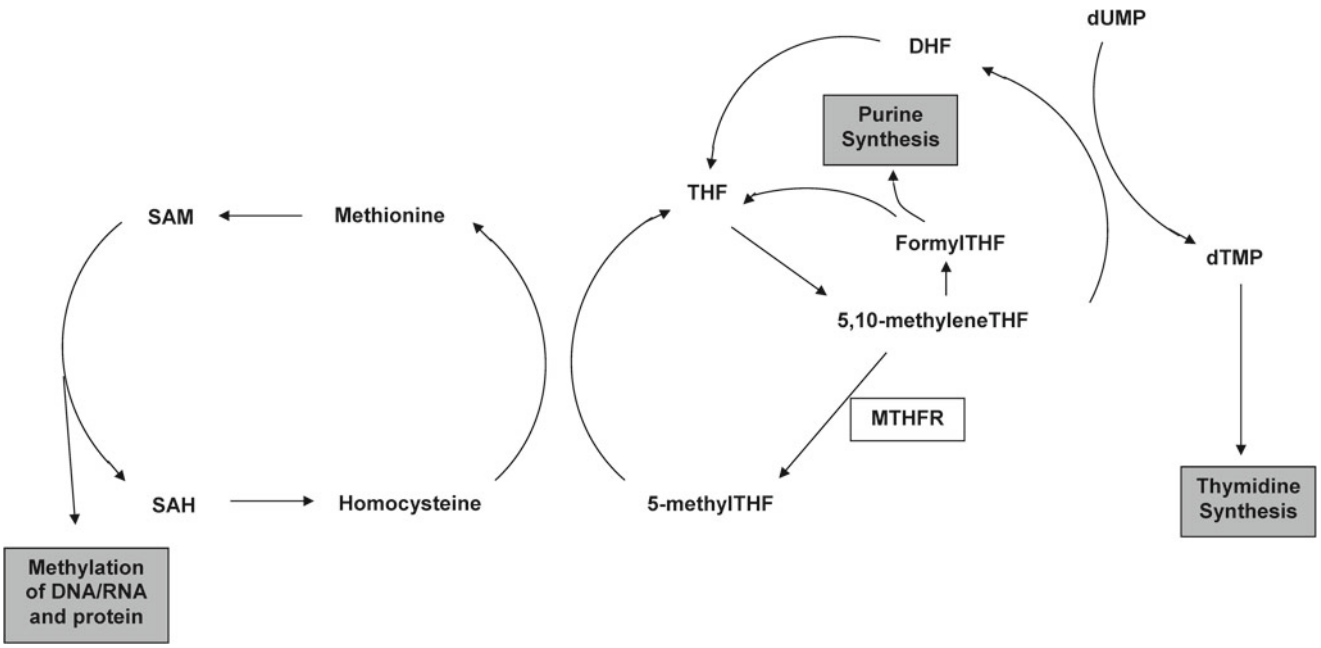

Fig. 14.3 Schematic representation of folate metabolism. *MTHFR* methylenetetrahydrofolate reductase, *THF* tetrahydrofolate, *DHF* dihydrofolate, *dUMP* deoxyuridine monophosphate, *dTMP* deoxythymidine monophosphate, *SAM* S-adenosylmethionine, *SAH* S-adenosylhomocysteine.

Table 14.1 Summary of significant associations in pooled analyses between specific polymorphisms and risk of colorectal and breast cancer

Cancer	Polymorphism	Number of studies (total number of cases)	Risk group	Pooled OR (95 % CI)	Reference
Colorectal	*APC* I1307K	3 (670)	K carriers	1.58 (1.21–2.07)	[23]

[a]Breast Cancer Association Consortium
[b]Relative risk for each copy of rare allele carried compared to common homozygote

When considering such pooled analyses it is important to identify methodological issues which may affect their reliability. Firstly, an extensive search of all studies potentially suitable for inclusion in the pooled analysis should be performed, and few, if any, exclusion criteria applied in order to avoid ascertainment bias. Authors should be contacted where necessary, if the required data has not been presented in publications. Secondly, evidence of significant heterogeneity between the individual studies included in the analysis makes interpretation of the pooled estimate problematic [40]. Where there is evidence of such between-study heterogeneity, attempts should be made to identify potential sources, such as differences in study design, in particular the use of hospital-based rather than population-based control subjects, differences in ethnicity or geographic location of study subjects, and the methods of genotyping employed [41]. Thirdly, an assessment of publication bias should made, since significant publication bias means the pooled estimate is unlikely to reflect the true influence of the genetic variant under study [42]. Despite these potential methodological problems, carefully designed pooled analyses remain a useful tool, and most of the low penetrance cancer susceptibility alleles identified to date have been confirmed by data-pooling.

14.5.2 Indirect Association Studies

The identification of large numbers of SNPs across the human genome has allowed association studies to progress from the analysis of a small number of specific candidate SNPs, to assessing a much greater proportion of the genetic variation within a particular gene or gene region to detect any allelic association. Such indirect association studies rely on LD between multiple SNPs across a small region, allowing analysis of all SNPs within the LD block through the genotyping of one or a few tagging SNPs. With indirect association studies it is assumed that any cancer causing SNP within the region is unlikely to be analysed directly, rather SNPs in the same LD block will be genotyped, and hence show association with disease. The recent rapid advances in our knowledge of polymorphic variation, and the availability of this information in public databases, has allowed the development of methods and software to select SNPs spanning gene regions such that at least one SNP per LD block is chosen for analysis [43, 44]. This set of tagging SNPs can then be genotyped in a series of cases and controls to test for association. If an association is found, the component SNPs within the LD block should be examined to determine the causal variant, a process that may involve genotyping of additional SNPs to better define the haplotype structure.

Recent indirect association studies have found evidence that common variation in *BRCA2* confers significant susceptibility to breast cancer [45], whilst common variation in *BRCA1* does not [46]. Other significant associations include base excision repair genes and squamous oesophageal cancer [47], *MIC-1* and prostate cancer [48], and *TP53BP2* and gastric cancer [49].

14.5.3 Genome-Wide Association Studies

Until very recently extension of the indirect association approach to evaluation of the whole genome was prohibitively expensive, due to the need to analyse several hundred

thousand SNPs to achieve adequate coverage of the entire human genome. However, the development of novel SNP genotyping technologies means that 500,000 SNPs can now be genotyped simultaneously on a single array at a cost of only a few hundred dollars per sample, making genome-wide studies economically feasible. Evaluation of such large numbers of SNPs presents new problems in terms of interpretation, in particular in relation to thresholds for statistical significance. If 500,000 SNPs are genotyped, a P value of 0.01 for statistical significance will result in 5000 SNPs showing an association by chance alone. Although setting lower thresholds for significance or compensating for multiple tests can help to address this issue, the employment of a multistage study design may be a more efficient solution to this problem [24]. In the first stage of such studies cases and controls are genotyped for the entire set of SNPs. Polymorphisms that are below a nominal level of significance are then selected for genotyping in a second, larger, series of cases and controls to identify the true-positives and false-positives from the first stage. The SNPs that still remain significantly associated may then be tested in a third sample set where available. Genetic variants that are significantly associated with cancer risk in multiple, large, independent sample sets are likely to be genuine low penetrance susceptibility alleles even where there is no a priori evidence for association, probably through LD with unidentified functional variants.

Initial small-scale genome-wide studies provided encouraging results. For example, in a study of squamous oesophageal cancer analysing 11,555 SNPs in samples from 50 cases and 50 controls, significant association with SNPs in 33 different genes was demonstrated [50]. Very recently the results of the first large-scale genome-wide cancer association studies have been published, all of which investigated prostate cancer susceptibility [51–54]. Initially, a study genotyping 1068 microsatellite markers in 871 Icelandic men with prostate cancer reported association with a variant at chromosome 8q24, which was replicated in two independent sample sets, one of prostate cancer cases from Sweden and the second in cases of European American descent [51]. This association was further replicated in a separate study in prostate cancer cases of African American descent [52]. Subsequently two independent studies genotyping 550,000 and over 315,000 SNPs across 1172 and 1453 cases respectively identified a second prostate cancer susceptibility variant also located at 8q24, which showed association independently of the first variant [53, 54]. Interestingly, this association was strengthened when calculations were restricted to cases with an early age of diagnosis, a group in which an increased genetic effect would be expected. Combining the results of these studies indicates extraordinarily strong associations with prostate cancer (adjusted P values $= 4 \times 10^{-29}$ and 1×10^{-19} respectively for the two independent variants), and although the associations are individually relatively modest both risk alleles are relatively frequent, especially among African Americans, thus the estimated population attributable risks are high, ranging from 6–68 % depending on the variant and population considered [55]. The success of these studies highlights the value of genome-wide approaches and the importance of performing multiple complimentary studies in independent populations. The results of similar studies in other cancers are eagerly awaited.

14.5.4 Copy Number Variation

Alterations in gene copy number can lead to loss of tumour suppressor gene function or amplification of oncogenes, thus identification of genomic regions showing such copy number variation can be very informative for identifying novel cancer-related genes. Such allelic imbalances can be identified by analysis of microsatellite markers in paired tumour and normal DNA samples, however genotyping of SNPs may be a more effective method [56]. The abundance of SNPs and the ease and efficiency of high throughput SNP genotyping technologies means that a much denser analysis of a gene region of interest can be performed. Sequential SNPs all yielding homozygous genotypes may indicate loss of heterozygosity, whilst microdeletions may result in stretches of SNPs where no signal is observed. The availability of genome-wide SNP genotyping technologies has allowed extension of this approach to the entire genome. Similar to genome-wide association studies the major advantage of genome-wide copy number variation studies is that a priori knowledge of cancer related genes or chromosomal abnormalities is not required. Studies of this nature have identified novel areas of allelic imbalance in breast cancer [57], prostate cancer [58], ovarian cancer [59], and small cell and non-small cell lung cancers [57, 60].

14.6 Gene–Environment Interactions

Functional SNPs in genes coding for enzymes involved in drug or carcinogen metabolism may not directly influence cancer risk, but may modify the effect of environmental factors, and in this manner alter cancer susceptibility in exposed individuals. Such effects have been termed gene–environment interactions, and are interesting since they may not only confer cancer susceptibility but may also modify an individual's response to anticancer therapies [61]. Investigation of gene–environment interactions can be included in association studies by appropriate measurement of the environmental factor of interest, and analysis of the effect of genotype on disease risk following stratification by exposure.

Examples of gene–environment interactions include the *MTHFR* C677T polymorphism and folate status, and variant uridine diphosphate glucuronosyltransferase 1A6 (*UGT1A6*) genotypes and aspirin use [62, 63]. In both examples the genetic variant has been demonstrated to interact with the environmental exposure to determine colorectal cancer risk. Individuals with the less common *MTHFR* 677TT genotype are at reduced risk of CRC if they have adequate folate status, but at paradoxically increased CRC risk if they have inadequate folate intake [62, 64]. The UGT1A6 enzyme participates in the metabolism of aspirin and other non-steroidal anti-inflammatory drugs, and functional polymorphisms of *UGT1A6* which result in reduced enzyme function, have been reported to modify the protective effect of aspirin on colorectal adenoma (CRA) risk [63]. Individuals with wild-type *UGT1A6* genotypes did not gain benefit from taking aspirin, whilst those with the reduced function genotypes had a lower risk of developing CRA but only if they were exposed to long-term aspirin.

Identification of further gene–environment and gene–gene interactions, where the effect of one genetic variant is modified by the presence or absence of a further variant, will be assisted by the simultaneous analysis of multiple genetic variants within the same metabolic pathway and accurate measurement of appropriate environmental exposures. The only caveat being that adequate assessment of interactions requires sample sizes a further order of magnitude greater than those required for investigation of the main effects of either genotype of environmental exposure separately [61].

14.7 Conclusions

A significant proportion of inherited susceptibility to cancer remains unaccounted for and it is likely that SNPs will be responsible for an as yet unknown fraction of this risk. Alternatively, multiple rare variants could account for the remaining susceptibility, identification of which will require large-scale high-throughput resequencing. The lessons learned from early association studies will aid the design of future studies, and in particular the assembly of multiple, large sample sets will generate the required statistical power to reliably identify low penetrance susceptibility polymorphisms. The advances in SNP genotyping technology have made genome-wide association studies a reality, and it remains to be seen whether such studies will fulfil their promise and identify further low penetrance polymorphisms, perhaps in genes that have not so far been considered as cancer susceptibility candidates.

Chromosomes and Chromosomal Instability in Human Cancer

15

Kazuma Ohyashiki, Masahiko Kuroda, and Junko H. Ohyashiki

15.1 Introduction

Human cancers show chromosome abnormalities, some of which are frequent and specific cytogenetic changes associated with certain forms of cancer. The most striking findings are nonrandom chromosomal changes in human hematologic neoplasia [1–3]. Specific cytogenetic changes are associated with the diagnosis of leukemia, clinical implications, and prognosis. Since some chromosomal changes in human hematologic neoplasms are simple and linked to molecular changes that create fusion products, such anomalies are currently being utilized as therapeutic markers. These findings have emerged gradually over the last 40 years as increasingly better techniques, for example fluorescence in situ hybridization (FISH), have become available for preparation and analysis of human chromosomes. More recently, small molecules that target fusion protein created by chromosomal changes are clinically available. Thus, detection and monitoring of chromosomal alterations in human cancer cells, especially in human hematologic neoplasms, are important in clinical practice. Nevertheless, the biological and clinical significance of nonrandom cytogenetic changes in neoplasms and chromosomal instability are still unresolved.

15.2 Overview of Chromosomal Abnormalities in Human Cancer

Chromosomal abnormalities in human cancer can involve both the number, and more frequently, the structure of chromosomes [4]. Cytogenetic changes can be categorized as numerical changes and structural changes. Structural changes include reciprocal translocations (no change in dosage of chromosomal materials), and deletion or addition of chromosomal materials. Numerical changes are sometimes associated with structural changes, as additional cytogenetic changes. Thus, primary cytogenetic changes (termed prototype) are suggested to be essential molecular alterations in carcinogenesis.

In general, chromosomal changes fall into three categories [3]. The first category is reciprocal translocation, which is an exchange of chromosomal materials between two chromosomes. This rearrangement can result in the abnormal expression of translocated genes as a consequence of their new location in the genomes, or it can alter the structure of genes at the site of translocation. The second category involves nonreciprocal exchanges of chromosomal material. These exchanges can result in either deletion or addition of chromosomal regions. Although such changes are frequently observed in tumors, the consequences of this type of chromosomal aberrations are known in only a few instances. For example, deletions at 17p, 13q, or 11p are associated with loss of the tumor-suppressor genes p53, pRB, or WT1, respectively. The third category involves an increasing amount of DNA in a specific region of a chromosome. The increased genetic material results in areas on chromosomes referred to as homogeneously staining regions (HSRs) or double minute chromosome. HSRs are associated with extensive gene amplification [5]. Although the form of gene amplification leads to chromosomal abnormality called double minutes chromosomes (DMs). DMs appear as two small dots of dark staining material in a standard metaphase preparation. It is generally believed that DMS represent the first

W.B. Coleman, G.J. Tsongalis (eds.), *The Molecular Basis of Human Cancer*, DOI 10.1007/978-1-59745-458-2_15

stage in gene amplification and that HSRs result from the integration of DMs into the chromosomes.

Chromosomal abnormalities are designated according to the International System for Human Cytogenetic Nomenclature [6]. To describe the karyotype or chromosomal complement of a cell type or tumor, the total chromosomes number is listed first, followed by the sex chromosomes, and then a complete list of any chromosomal abnormalities.

15.3 Chromosomal Abnormalities in Myeloid Leukemias

15.3.1 Myeloproliferative Neoplasm

Damshek proposed that the entity of chronic myeloproliferative disorders (CMPD) encompassed chronic myelogenous leukemia (CML), polycythemia vera (PV), essential thrombocythemia (ET), and chronic idiopathic myelofibrosis (CIMF). In 2001, the new WHO classification proposed the CMPD entity to be associated with constitutive upregulation of tyrosine kinase [7] and most recently the entity is called as myeloproliferative neoplasm (MPN), thus the category includes classical MPN, chronic neutrophilic leukemia (CNL), hyper-eosinophilic syndrome (HES), and unclassifiable chronic myeloproliferative disease. Based on this concept, some novel pathways involving tyrosine kinase activity have been identified; some of them were initially found as cytogenetic change (Table 15.1) [7].

The first specific chromosome abnormality found to be associated with cancer was the Philadelphia (Ph) chromosome in CML of which the minute chromosome (22q-) identified as Ph chromosome [8] was a reciprocal translocation between chromosomes 9 and 22 [t(9;22)(q34;q11)], i.e., Ph translocation [9]. This cytogenetic change is present in the leukemic cells of at least 95% of patients with CML, and 30% of adult acute lymphoblastic leukemia and less than 5% of acute myelogenous leukemia [10]. The Ph translocation occurs in a pluripotent stem cell that give rise to cells of both lymphoid and myeloid lineages. The genetic consequence of the Ph translocation is the translocation of the *ABL* proto-oncogene on chromosome 9 to a location on chromosome 22, termed the breakpoint cluster region (or *BCR* locus) [11–13]. The detection of Ph translocation is still important in determining cytogenetic response even in the imatinib era [14–16], and molecular determination of the reduction level of *BCR-ABL* mRNA is currently a powerful marker in managing Ph-positive leukemia patients, including CML, and predicting imatinib resistant CML [16, 17]. Recently, discontinuation study of tyrosine kinase inhibitors (TKIs), including imatinib and second generation TKIs, after long-lasting complete molecular remission (CMR), the so-called treatment-free remission (TMR), is reported: these results open new avenue for treatment strategy for CML patients [18], though the STOP-TKIs studies are yet under control.

In 2003, Cools et al. reported nine cases of HES with interstitial deletion leading to the formation of the *FIP1L1-PDGFRA* fusion gene; this change was originally detected in HES patients with 4q12 abnormality [19]. This fusion gene encodes an active tyrosine kinase that is able to transform hematopoietic cells and is inhibited by imatinib mesylate. The frequency of the *FIP1L1-PDGFRA* fusion gene in HES has been reported to vary from 0 to 100%, and this anomaly is not detectable by using conventional cytogenetic analysis, thus RT-PCR or FISH analysis is required [20]. The detection of this anomaly is therefore important for determining the indications of imatinib therapy.

Another important discovery in MPN is $JAK2^{V617F}$ mutation in almost all patients with PV and approximately 50% of ET and CIMF. The presence of $JAK2^{V617F}$ mutation in MPN has been speculated, since some PV patients have 9q24 (terminal portion of 9p) changes when the JAK2 gene locates [21–25]. Approximately 30% of PV patients have the homozygous $JAK2^{V617F}$ mutation, therefore, this change could result from mitotic recombination of the 9q region [21]. Again, this mutation is not visible by the microscope, thus cytogenetic change, in combination with JAK2 mutation, might be important in managing MPN patients. In addition there is a possibility to identify new tyrosine kinase involvement in MPN based on cytogenetic studies. More recently, the frequent mutations in the calreticulin gene (*CALR*) occur in MPN has been found, and related study shows that somatic mutations in *CALR* exist in the majority of patients with JAK2 wild-type MPN [26–28].

In CNL, a breakpoint cluster region, referred to as micro-*BCR* (or μ-*BCR*), has been identified, and this reciprocal translocation results in a BCR-ABL fusion protein of 230KD

Table 15.1 Cytogenetic and molecular change in chronic myeloproliferative disorders

Diagnosis	Cytogenetic change	Molecular change	Additional changes
Chronic myeloid leukemia	t(9;22)(q34;q11)	*210KD BCR-ABL*	
CML-AP/BP	t(9;22)(q34;q11)	*210KD BCR-ABL*	+8, +Ph, +19, i(17q), t(3;21)(q26;q22)
Polycythemia vera		$JAK2^{V617F}$ (>90%)	+8, +9, del(20q), del(13q), del(1p11)
Essential thrombocythemia		$JAK2^{V617F}$ (50%)	+8, del(13q)
Idiopathic myelofibrosis		$JAK2^{V617F}$ (50%)	+8, del(20q), −7/del(7q), del(qq1), G15del(13q)
Hypereosinophilic leukemia		FIPL1-PDGFa	+8, dic(1;7), 8p11
Chronic neutrophilic leukemia		*230KD BCR-ABL*	+8, +9, del(20q), del(11q14)
CMPD unclassifiable			

[29]. Maxon et al. demonstrated that activating mutations in the gene encoding the receptor for colony-stimulating factor 3 (*CSF3R*) in approximately 60% of CNL or atypical CML. These mutations segregate within two distinct regions of *CSF3R* thus lead to preferential downstream kinase signaling through *SRC family-TNK2* or *JAK* kinases and differential sensitivity to kinase inhibitors [30].

15.3.2 Acute Myeloid Leukemia

Detection of cytogenetic changes in acute myeloid leukemia (AML) is a powerful tool for determining diagnosis and therapeutic strategy, as well as prognosis [1–3]. Currently mutiplex-PCR is widely used in the detection of known translocation-type cytogenetic changes in acute leukemia. However, cytogenetic analysis is also important in detecting minor populations with additional cytogenetic changes, rare chromosomal change, and numerical chromosome changes. These abnormalities are also important in clinical practice. The genes involved in nonrandom chromosomal translocations are listed in Table 15.2.

Most of all patients with acute promyelocytic leukemia (APL: AML-M3 by the FAB) show t(15;17)(q22;q21) resulting in *PML/RARA* (retinoic acid α receptor); the fusion protein interferes with normal myeloid cell differentiation, possibly through dominant negative effects against the transcriptional activity of RARA [31, 32]. The detection of this cytogenetic change is important in the diagnosis of AML-M3, especially in cases of the variant form of the AML-M3, and to establish the likelihood of therapeutic response to retinoic acid. In contrast, rare AML-M3 patients show t(11;17)(q23;q21) resulting in *PLZF/RARA* fusion, and they are resistant to retinoic acid treatment [33].

In AML, patients with t(8;21)(q22;q22) and inv(16)(p13q22) are now called CBF (core-binding factor) leukemia, and they respond well to cytarabine therapy [34, 35]. The t(8;21)(q22;q22) creates *RUNX1-RUX1T1* (previously designated as *ETO /AML1)* [36] and inv(16)(p13q22) does *CBFβ/MYH11* [37]. Although there are some other chromosome changes, t(15;17)(q22;q21), t(8;21)(q22;q22) and inv(16)(p13q22) are known as favorable cytogenetic change in AML [38, 39]. Intermediate risk cytogeneitc category includes numerical and structural abnormalities, while poor cytogenetic category for AML patients basically includes those with complex cytogenetic changes (more than 3 chromosomes abnormalities. Of note is that the deletion of the long arm of chromosome 7 is categorized as intermediate cytogenetic change, while monosomy 7 is classified as poor cytogenetics (Table 15.3). Other recurring translocations, including t(6;9) [40], abnormalities at 3q26 [41, 42], and abnormalities at 11q23 [43, 44], and the genes involved are listed in Table 15.2.

Detection of normal karyotypes in AML patients is important: these patients are currently separately categorized by the presence of FLT3 internal tandem repeat (FLT3-ITD) and mutation of the nucleophosmin (NPM) gene [45, 46]. These data may show that both cytogenetic analysis and molecular examination are important to predict prognosis and molecular target therapy.

15.3.3 Myelodysplastic Syndromes

Cytogenetic changes in myelodysplastic syndrome (MDS) are currently used in determining the prognosis [47]. Based on the IPSS (International Prognostic Scoring System), chromosomes in MDS are categorized into three groups, i.e., good cytogenetics [normal karyotype, del(20q), del(5q), and −Y], intermediate cytogenetics (other than good or poor cytogenetics) and poor cytogenetics (complex abnormalities: ≥3 chromosomal changes or −7/del(7q) [48]. More recently, detailed cytogenetic classification and survival risk stratification is proposed [49] and thereby revised International Prognostic Scoring System (IPSS-R)

Table 15.2 Chromosomal translocation involving transcription factors in myeloid leukemia

Translocation	Genes	Disease phenotypes
t(8;21)(q22;q22)	*RUNX1-RUNX1T1*	M2
t(3;21)(q26;q22)	*RUNX1-MDS1*	AML
inv(3)(q21q26.2) or t(3;3)(q21;q26.2	*RPN1-EVI1*	AML with thrombocytosis
inv(16)(p13.1q22) or t(16;16)(p13.1;q22)	*CBFB-MYH11*	M4Eo
t(15;17)(q24.1;q21.1)	*PML-RARA*	M3
t(11;17)(q23;q21)	*PML-RARA*	M3
t(12;22)(p13;q22)	*TEL-AML1*	AML, MDS
t(1;22)(p13;q13)	*RBM15-MKL1*	AML (megakaryoblastic)
t(6;9)(p23;q34)	*DEK-NUP214*	M2 (M4) with basophilia
t(7;11)(p15;p15)	*NUP98-HOXA9*	M2 (M4)
t(8;1)(p11.2;p13.3)	*KAT6A-CREBBP/CBP*	Therapy-related AML
t(9;11)(p22;q23)	*KMT2A-MLLT3*	AML-M5
t(11;19)(q23;p13.1)	*HRX (MLL)-MEN*	AML
t(6;21)(q11;p22)	*FUS-ERG*	AML

Table 15.3 Prognosis of acute myeloid leukemia and chromosome abnormality

Risk	Chromosome changes	CR rate (%)	5-year survival (%)
Good	t(8;21)(q22;q22)	98	69
t(3;21)(q26;q22)	t(15;17)(q22;q21)	85	63
	inv(16)(p13q22)	88	61
Intermediate	del(9q)	100	60
	+22	91	59
	+8	84	48

Poor	Complex	67	21
	del(3q)	63	12
	del(5q)	57	11
	−7	54	10
	−5	42	4

Table 15.4 Revised international prognostic scoring system for myelodysplastic syndromes

IPSS-R score[a]							
Variable	0	0.5	1.0	1.5	2.0	3.0	4.0
Cytogenetics[b]	Very good		Good		Intermediate	Poor	Very poor
BM blasts (%)	≤2		>2–<5		5–10	>10	
Hemoglobin (g/dL)	≥10		8–<10	<8	–		
Platelets ($\times 10^9$/L)	≥100	50–<100	<50	–	–		
ANC ($\times 10^9$/L)	≥0.8	<0.8					

Good = normal, del(5q), del(12p), del(20q), double including del(5q); Int. = del(7q), +8, +19, i(17q), other single or double independent clones; poor = −7, inv(3)/t(3q)/del(3q), complex (3 abnormalities); very poor = complex (>3 abnormalities)
[a]IPSS-R risk groups: very low ≤1.5; Low 1.5–3; intermediate 3–4.5; high 4.5–6; very high >6
[b]Very good = −Y, del(11q)

is utilized for exact prognosis for untreated MDS patient (Table 15.4) [50]. Due to accumulation of cytogenetic data, in combination of hematologic parameters (number of cytopenias and percentage of blasts in the marrow), the prognosis of MDS patients could be predictive and therapeutic strategy is formulated based on this prognostic system, thus indicating that determination of cytogenetic change in MDS patients again is a powerful tool in managing patient care.

15.3.4 Secondary Acute Leukemia/ Myelodysplastic Syndromes

In the WHO classification, secondary AML/MDS was categorized as a separate entity from de novo AML or MDS [51]. Secondary AML/MDS patients are usually classified into two categories based on the causative agents, i.e., alkylating agent/radiation-related and topoisomerase II-inhibitor-related AML/MDS. The alkylating agent/radiation related disorder usually occurs 5–6 years following exposure to the mutagenic agents, and often presents initially as an MDS with low percentage blasts (25 % of this type of patients were refractory anemia with excess blasts 1 or 2), and have short survival. They have unbalanced translocations or deletions involving chromosomes 5 and/or 7 consisting of loss of all or part of the long arm of the chromosomes, and usually show multiple chromosomal abnormalities, referred to as complex cytogenetic changes. Importantly, the prognosis and cytogenetic changes of the secondary AML/MDS are quiet different between these two types. Another type, topoisomerase II-inhibitor-related AML/MDS occurs 12–130 months (median of 33–34 months) after exposure. They usually show AML without a preceding MDS, and predominant cytogenetic finding is a balanced translocation involving 11q23 (the *MLL* gene), primary t(9;11), t(11;19) and t(6;11), or t(8;21) or t(3;21) involving band 21q22 (*AML1* gene). They respond to initial therapy in a manner similar to that of de novo AML.

15.4 Chromosomal Abnormalities in Lymphoid Leukemias

15.4.1 Acute Lymphoid Leukemia

Chromosomal translocation in ALL could be separated into two types, i.e., dysregulation type and chimeric fusion type (Table 15.5) [52–57]. The former group represents involvements of immunoglobulin genes or T-cell receptor genes. Approximately 25 % of T-ALL patients show involvement of T-cell receptor (*TCR*) genes, i.e., *TCRδ* (14q11), *TCRβ* (7q32-36), and altered transcriptional level of involving genes, including *c-MYC* (located at 8q24), *LOM1* (11p15), *LOM2* (11q13), *HOX11* (10q24), *TAL1/SCL* (1p32).

The correlation of cytogenetic changes with morphology in AML leads to the identification and characterization of specific disease-associated chromosome abnormalities, while the correlation between morphology and cytogenetic change is not striking in ALL, except for the 8q24 (c-*MYC*) and ALL-L3 by the FAB classification. In ALL-M3 or Burkitt lymphoma, translocations invariably involve chromosome 8q24 and one of the three chromosomes that carry the immunoglobulin light (2p12: λ-light chain gene and 22q11: k-light chain gene) or heavy chain genes (14q32: heavy-chain gene). These translocations rearrange one allele of *c-MYC* proto-oncogene at 8q24, which encodes a transcription factor consisting of a basic region helix–loop–helix zipper (bHLH) motif, into the immunoglobulin locus carried on one of these chromosomes, resulting in dysregulation of *c-MYC* expression through the strong enhancer of immunoglobulin genes [55, 56].

Table 15.5 Chromosome abnormalities in lymphoid leukemia

Dysregulation		
B-cell lineage		
t(8;14)((q24;q32)	*c-MYC/IgH*	B-ALL
t(14;19)((q32;q13)	*BCL3/IgH*	B-CLL
T-cell lineage		
t(8;14)((q24;q11)	*c-MYC/TCRa*	T-ALL
t(11;14)(p15;q11)	*Rhom-1 (TTG1/LOM1)/TCR δ*	T-ALL
t(11;14)(q13;q11)	*Rhom-2 (TTG2/LOM2)/TCR δ*	T-ALL
t(10;14)(q24;q11)	*HOX11 (TCL3)/TCR δ*	T-ALL
t(1;14)(p32;q11)	*SCL (TAL1,TCL5)/TCR δ*	T-ALL
t(7;9)(q23;q34.4)	*TAN/TCR β*	T-ALL
t(7;9)(q23;q32)	*TAN2/TCR β*	T-ALL
t(4;11)(q21;p15)	*NUP98/RAP1GDS1*	T-ALL
Chimeric fusion gene		
t(1;19)(q23;p13)	*E2A-PBX1*	PreB-ALL
t(17;19)(q22;p13)	*E2A-HLF*	PreB-ALL
t(9;22)(q34;q11)	*BCR-ABL*	cALL
t(12;21)(p21;q22)	*TEL-AML1*	PreB-ALL
t(4;11)(q21;q23)	*MLL-AF4(MLLT2)*	MLL
t(11;19)(q23;p13)	*MLL-ENL (MLLT1)*	MLL

T-cell leukemias (T-ALLs) have a number of different recurring translocations. Most of these involve putative transcription factors, and are not normally expressed in T-cells. As example of this is the *HOX11* gene, located on chromosome 10q24, which is activated by translocations t(10;14)(q24;q11) and t(7;10)(q35;q24) in T-ALL. The *HOX11* gene shares homology with other homeobox-containing genes that normally code for sequence-specific DNA-binding proteins [57]. The t(1;14)(p32;q11) chromosome translocation has been observed in 3 % of T-ALL patients. This translocation results in the juxtaposition of the *SCL* gene (also called *TAL1*) from chromosome 1q32 with the TCRα/δ chain locus on chromosome 14q11 [58]. The *SCL* gene encodes DNA-binding protein containing the bHLH motif, which can dimerize with protein E47. The chromosomal translocation probably causes ectopic *SCL* protein expression, activating specific target genes that are transcriptionally silent in normal T cells.

Another chromosomal translocation type in ALL is chimeric protein formation, for example t(1;19) and t(9;22). The t(1;19)(q23;q13) chromosome translocation affects approximately 25 % of pre-B ALLs, and fuses the N-terminal part of the transcription factor E2A, carrying a transcription domain, to the DNA-binding homeodomain of the transcription factor PBX, replacing the bHLH region of E2A [59, 60]. The E2A PBX fusion protein is recognized by the homeodomain of PBX and can strongly activate transcription, whereas PBX cannot. Target genes that bind the PBXC homeodomain in the E2A/PBX fusion protein may be activated and initiate leukemogenesis.

Translocation (12;21)(p13;q22) is found in 20–30 % of childhood ALL, in contrast to 3–4 % in adult ALL, with favorable prognosis. The translocation results in *TEL (ETV6)-AML1 (CBF2)* fusion and consists of the dimerization domain (HLH) of the *TEL* gene and the most part of the *AML1* protein [61], thus suggesting that homodimer of the *TEL-AML1* or heterodimer suppresses the normal *TEL* function due to a dominant negative effect.

Chromosomal aberrations involving 11q23 is found in 60 % of infantile leukemia (the so-called *MLL* acute leukemia), possibly due to trans-placental chemical exposure [62]. This anomaly is also characterized by (1) acute leukemia with both lymphoid and myeloid phenotypes, and (2) frequently found in therapy-related adult acute leukemia related with topoisomerase II-inhibitor [63]. The *MLL* gene is translocated to more than 30 gene loci, and frequent involvements in adult acute leukemia are t(9;11)(p22;q23), following t(6;11)(q27;q23), t(10;11)(p12;q23), t(11;19)(q23;p13) (Table 15.6) [64]. The *MLL* gene is believed to act to maintain transcription, and the breakpoints of *MLL* gene in 11q23-leukemia are clustered within 8.5-kb spanned exon 5 to exon 11. The 11q23 translocation creates chimera between the 5′-side of the *MLL* region including AT-hook and targeted genes, and loss of the zinc finger domain of the *MLL*

Table 15.6 Translocation involving MLL genes

Trasnslocation	Genes	Function
t(1;11)(p32;q23)	*AF1p*	a-helical coils
t(1;11)(q21;q23)	*AF1q*	Unknown
t(4;11)(q21;q23)	*AF4/FEL*	Transcriptional activating domain
ins(5;11)(q31;q13q23)	*AF5q31*	Partially homologue to AF4
t(6;11)(q27;q23)	*AF6*	a-helical coils, GLGF repeat
t(6;11)(q21;q23)	*AF6q21*	Forkhead DNA binding domain
t(9;11)(p22;q23)	*AF 9*	Homology to ENL
t(10;11)(p12;q23)	*AF10*	Leucine zipper
t(10;11)(p11.2;q23)	*ABL-1*	Homology to c-ABL binding protein
t(11;14)(q23;q24)	*GPHN*	Scaffold protein
t(11;16)(q23;p13)	*CBP*	Transcription co-activator
t(11;17)(q23;q21)	*AF17*	Leucine zipper
t(11;17)(q23;q25)	*MSF/AF17q25*	Septin/GTP binding domain
t(11;19)(q23;p13.1)	*ELL/MEN*	RNA polymerase II transcription
t(11;19)(q23;p13.3)	*ENL*	Transcription domain
t(11;19)(q23;p13)	*EEN*	a-helical coils
t(11;22)(q23;q11.2)	*hCDCrel*	Homology to CDC binding protein
t(11;22)(q23;q13)	*p300*	Transcription co-activator
t(X;11)(q13;q23)	*AFX*	Forkhead DNA binding domain
ins(X;11)(q24;q23)	*SEPTN6*	GTP binding domain

gene might be important in the generation of this type of leukemia [65].

The detection of Ph translocation in ALL is diagnostically and therapeutically important. Ph translocation is also detectable in 30 % of adult ALL. This translocation creates the *BCR-ABL* oncoprotein; some of which have 210KD$^{BCR-ABL}$ (fusion between *ABL* and major *BCR*) which is the transcript similar to those of Ph-positive CML and most patients have 185KD$^{BCR-ABL}$ (fusion between *ABL* and minor-*BCR*). Ph-positive ALL patients have poor prognosis. However, current molecular target therapy, including imatinib or dual SRC-kinase inhibitor, dasatinib, followed by allogeneic stem cell transplantation has yielded promising data for the possibility of obtaining complete remission and maintaining prolonged survival [66, 67], therefore detection of Ph translocation at the ALL diagnosis and incorporation of target therapy is essential in treating such ALL patients.

15.4.2 Malignant Lymphoma

B-cell malignant lymphomas have translocation involving chromosome 14q32, which contains the immunoglobulin heavy (IgH) chain gene. Two specific translocations involving this locus have been characterized. The chromosomal rearrangements occur at precise locations on chromosomes 11 and 18 at the *BCLl* and *BCL2* loci, respectively. The *BCL1* gene, which is aberrantly expressed as a consequence of the t(11;14)(q13;q32) encodes cyclinD1 notable in mantle cell lymphoma (MCL). Cyclin D1 forms a complex with a cyclin-dependent kinase (cdk), and function in cell-cycle regulation [68, 69]. The *BCL2* gene is consistently associated with t(14;18) chromosomal translocation observed in a large percentage of B-cell follicular lymphomas. The *BCL2* gene product is suggested to mediate inhibition of cellular apoptosis [70, 71]. Thus, constitutive activation of the *BCL2* gene may contribute to the formation of follicular lymphoma by blocking programmed cell death.

Anaplastic large cell lymphoma (ALCL) is a variant of non-Hodgkin's lymphomas composed of large pleomorphic cells that usually express the CD30 antigen and is characterized by frequent cutaneous and extranodal involvement. This type of lymphoma frequently exhibits the t(2;5)(p23;q35) chromosomal translocation that fuses the NPM gene (nucleophosmin) on the 5q35 region to the *ALK* (anaplastic lymphoma kinase) on the 2p23 chromosomal region [72, 73]. The *ALK/NPM* fusion protein has tyrosine kinase activity and induces tumorigenesis. ALCL patients with the *ALK/NPM* fusion protein have favorable prognosis compared to those without the fusion protein, thus indicating the presence of a prognostic factor in ALCL patients.

15.4.3 Chronic Lymphoid Leukemia

Trisomy 12 in chronic lymphoid leukemia (CLL) is well known. The t(14;19)(q32;q13.1) chromosomal translocation is noted in some B-CLL. This result in divergent orientation (head-to-head) of the immunoglobulin heavy-chain gene (14q32) and *BCL3* (19q13) [74–76]. The *BCL3* gene is a dis-

tinct member of the IkB family, may function as a positive regulator to NF-kB activity. Thus, overexpression of *BCL3* gene by the translocation may alter the transcriptional activity of NF-kB.

15.4.4 Multiple Myeloma

Conventional metaphase cytogenetic studies are successful in only 40 % of multiple myeloma (MM) patients studied, due to a slowly proliferation of mature B cells. Using metaphase cytogenetics, only one-third of patients show an abnormal karyotype and the remaining two-thirds have normal metaphase cytogenetics. However, current studies utilizing FISH demonstrated that the large majority of such patients have an aneuploid DNA content and abnormal cytogenetics and impact on prognosis. Well known abnormalities in MM are (1) hyperdiploid (≥48 chromosomes), (2) chromosome 13 deletion, (3) an involvement of 14q32 (*IgH*) region, i.e., t(11;14)(q13;q32), t(4;14)(p13;q32), and t(14;16)(q32;q23) [77, 78]. Rare translocations t(6;14) and t(14;20) are also notable. Hyperdiploid MM is associated with improved prognosis, and negative prognostic effector in this group is the concomitant presence of high-risk immunoglobulin heavy chain (IgH) translocation. Chromosome 13 deletion is detectable in approximately 50 % of MM patients with abnormal karyotypes (10–20 % of all MM patients), and associated with shorter survival and lower response rate to treatment. The t(11;14) is associated with oligo-secretary or light-chain-only MM, CD20 expression, and amyloidosis (50 %) and IgM MM (>90 %) [77]. The t(11;14)-MM patients show improved or neutral survivals when treated with high-dose chemotherapy and stem cell transplantation. Translocation (4;14) is found in 15 % of MM patients and this translocation results in *FGFR3* to the IgH switch region locus. Recently, t(14;16), del(17p), and t(4;14) are known to be linked to poor prognosis after conventional therapy, and thereby it is recommended to utilize fluorescent in situ hybridization to detect these genetic changes, in combination with standard metaphase cytogenetics [79].

15.5 Chromosomal Abnormalities in Solid Tumors

15.5.1 Ewing Family of Tumors

Sarcomas are soft tissue tumors that often have chromosomal rearrangements encoding tumor-specific fusion oncoproteins (Table 15.7). Ewing tumors, a subset of sarcomas, occur predominantly in the long bones of children and young adults. Extraskeletal Ewing sarcomas typically involve the soft tissues of the chest wall, paravertebral region, retroperitoneum, and lower extremities. The histogenetic origin of these tumors is now suspected to be neural, a discovery linking Ewing's sarcoma to more differentiated tumors, known as peripheral primitive neuroectodermal tumors (PNET) or neuroepitheliomas [80]. Approximately 80 % of Ewing family tumors exhibit a balanced chromosomal translocation between chromosome 11 and 22, t(11;22)(q24;q12). Molecular analysis revealed that the chromosome 22 breakpoint present in Ewing tumors is located within the *EWS* gene, while the chromosome 11 breakpoint is located within the *Fli1* gene [81, 82]. Reciprocal translocation between these two chromosomes creates a new chimeric protein combining portions of the EWS and Fli1 proteins. The *EWS* gene, located on 22q12, plays a recurrent role in several chromosomal translocations found in soft tissue and bone tumors. This gene is involved in all of the alternative translocations identified in Ewing sarcoma/PNET and in distinct translocations found in desmoplastic small round cell tumors, clear cell sarcomas (soft tissue melanomas), cases of extraskeletal myxoid chondrosarcoma, a subset of angiomatoid fibrous histiocytomas, and rarely in myxoid liposarcomas [83, 84]. The *EWS* and related *TLS/FUS/FUS* gene products have features typical of RNA-binding proteins; their C-termini, which are deleted from fusion oncoproteins, contain R-G-G repeats flanking a highly conserved RNA-binding domain of the RRM type [85, 86]. The *FLI1* gene encodes a DNA-binding protein, Fli1 [85], that appears to function as a transcription factor [81]. The human Fli1 protein shares approximately 70 % sequence identity with the protein encoded by the *ETS1* gene. The EWS-Fli1 fusion protein contains the N-terminal domain of EWS and the DNA-binding domain of Fli1. Evidence suggests that DNA-binding activity and subsequent transcriptional activation of various target genes by the EWS-Fli1 fusion are essential for tumorigenesis of Ewing sarcoma [87]. While other chimeric partners of the *EWS* gene, such as *ERG* [88], *ETV1* [90], ETV4 and *E1AF* [91], are involved as fusion partners less commonly than *FLI1*, and all share homology with *ETS1*.

15.5.2 Myxoid and Round Cell Liposarcoma

Myxoid and round cell liposarcomas are almost invariably associated with translocations involving the *CHOP* gene on chromosome 12q13.1 [92]. The vast majority of tumors contain a reciprocal balanced translocation, t(12;16)(q13;p11), that fuses the 5′ half of the *TLS/FUS* gene (also known as *FUS*) to the *CHOP* coding region, giving rise to a *TLS/*FUS-CHOP oncogene [93, 94]. Rarely, myxoid and round cell liposarcomas are associated with a different translocation, t(12;22)(q13;q12), that fuses the 5′ half of *EWS* to *CHOP* [95]. The clinicopathological features of disease associated with this variant translocation do not differ from those

Table 15.7 Chromosome abnormalities in solid tumors

Type	Genes involved	Tumor type
t(11;22)(q24;12)	*EWSR1, FLI1*	Ewing sarcoma/PNET
t(21;22)(q22;q12)	*EWSR1, ERG*	Ewing sarcoma/PNET
t(7;22)(p22;q12)	*EWSR1, ETV1*	Ewing sarcoma/PNET
t(17;22)(q21;q12)	*EWSR1, ETV4*	Ewing sarcoma/PNET
t(16;21)(p11;q22)	*FUS, ERG*	Ewing sarcoma/PNET
t(2;22)(q33;q12)	*EWSR1, FEV*	Ewing sarcoma/PNET

observed with the typical t(12;16). The *CHOP* gene encodes a member of the CCAAT/enhancer-binding family, which contains a leucine zipper-type dimerization motif and a putative DNA-binding domain [96]. Normally, the CHOP gene product may function in a dominant-negative manner by dimerizing with and inhibiting other transcription-factor complexes. The *TLS/FUS* gene is homologous to both *EWS* and *RBP56/hTAFII 68*; the TLS/FUS gene product contains a glutamine-serine-tyrosine-rich segment, three glycine-rich stretches, and an RNA-binding domain [93]. Of note, a large number of sarcomas are associated with fusion oncoproteins that contain either an EWS, TLS/FUS, or RBP56/hTAFII 68-type N-terminal domain. These include Ewing family tumors associated with EWS-Fli1, EWS-ERG [89], EWS-ETV1 [90], and EWS-E1AF [91], clear cell sarcomas associated with EWS-ATF1 [97], desmoplastic small round cell tumors associated with EWS-WT1 [98], myxoid chondrosarcomas associated with EWS-TEC (also known as EWS-CHN) [99, 100] and RBP56/hTAFII 68-TEC [101], and two tumors associated with TLS/FUS fusions, myxoid liposarcoma (TLS/FUS-CHOP) [93, 94] and myeloid leukemia (TLS/FUS-ERG) [102, 103]. The molecular epidemiology and transforming properties of TLS/FUS-CHOP and EWS-Fli1 point to an important role for TLS/FUS/EWS-type N-terminal domains in oncogenesis [104].

15.5.3 Synovial Sarcoma

Synovial sarcoma is an aggressive tumor that accounts for approximately 10 % of soft-tissue tumors [81] that commonly occur adjacent to limb joints or tendons in children and young adults [81]. A t(X;18) is detected cytogenetically in greater than 90 % of synovial sarcomas, regardless of histologic subtype. At the molecular level, the t(X;18)(p11.2;q11.2) produces a fusion of the *SYT* gene on chromosome 18 with the *SSX* gene on chromosome X, resulting in SYT-SSX fusion gene transcripts [105]. The Xp11 region contains a cluster of closely related *SSX1-SSX5* genes. Although the Xp11 breakpoint typically involves either *SSX1* or *SSX2,* which map to Xp11.23 and Xp11.21, respectively, other members of the cluster can be involved [106]. *SYT* encodes a protein of 387 amino acids; all but the C-terminal eight amino acids are fused to SSX as a result of this translocation. The normal SYT protein does not exhibit homology to any known protein sequences [105, 107, 108]. The *SSX1* and *SSX2* genes encode similar 188 amino-acid proteins. As neither SYT nor the SSX proteins possess recognizable DNA-binding domains, they are presumed to function as transcriptional regulators whose actions are mediated primarily via protein–protein interactions. The SSX2 protein has been shown to exhibit transcriptional repression [109]. Therefore, the SYT-SSX chimeric proteins may be involved in the transcriptional deregulation of specific target genes. Microarray analysis recently identified various genes that are downregulated in synovial sarcoma cell lines [110, 111]. The target genes regulated by endogenous intact SYT and SSX proteins through direct or indirect protein–protein interactions with specific transcription factors are currently unknown.

15.5.4 Clear Cell Sarcoma

Clear cell sarcoma (CCS, malignant melanoma of soft tissue) is an uncommon soft tissue sarcoma that occurs in tendons and aponeuroses, typically of the lower extremities and CCS rarely arises from in the gastrointestinal tract. This tumor is believed to be of neural crest origin. CCS in soft tissue typically possesses the t(12;22)(q13;q12) [112], on the other hand, CCS in gastrointestinal tract shows t(2;22)(q34;q12) . Molecular analyses of the t(12;22) breakpoints have demonstrated that the *EWS* gene on chromosome 22 becomes fused to the *ATF-1* gene on chromosome 12, which encodes a protein containing a leucine-zipper domain and a basic DNA-binding domain [97]. On the other hand, t(2;22) breakpoints have demonstrated that the *EWS* gene on chromosome 22 becomes fused to the *CREB1* gene on chromosome 2 [113]. This translocation produces a fusion transcript in which the RNA-binding domain of the EWS protein is replaced by ATF-1 protein leucine-zipper and DNA-binding domain. In CCS, the DNA-binding and dimerization activities of the fusion protein likely lead to the transcriptional activation of ATF-1 targets.

15.5.5 Alveolar Rhabdomyosarcoma

Rhabdomyosarcoma is a malignant skeletal muscle tumor occurring primarily in children and adolescents. The alveolar subtype (ARMS), the most aggressive, has the poorest prognostic outcome [114]. The typical cytogenetic finding in ARMS is the t(2;13)(q35-37;q14), which has been detected in as many as 70 % of cases [115–117]. A variant translocation, t(1;13)(p36;q14), was identified in a smaller subset of ARMS [118, 119]. These translocations fuse the *FKHR* locus on chromosome 13 to either *PAX3* on chromosome 2 [120] or *PAX7* on chromosome 1 [120]. *PAX3* and *PAX7* encode members of the paired box (PAX) transcription factor family, which is characterized by a conserved paired box DNA-binding domain first identified in *Drosophila* segmentation genes [121]. The FKHR gene product contains a fork head domain, a sequence first identified as a 100 amino-acid region of similarity between *Drosophila fork head* and the rat HNF-3 proteins. This domain was subsequently identified in a large family of genes in multiple species, ranging from

yeast to humans [122]. Of the FOX family of proteins, FKHR is the prototype of a subfamily with highly similar fork head domains and additional regions of sequence similarity [123–125]. Recently, a mouse model of ARMS was developed, in which PAX3-FKHR expression is conditionally activated in developing skeletal muscle [126]. Tumor incidence in these mice increases with the introduction of additional genetic defects, such as deletion of the Ink4A/ARF locus and p53 gene mutations [127]. Thus, PAX3-FKHR plays a primary role in muscle cell transformation and may function at multiple stages in ARMS development.

15.5.6 Desmoplastic Small Round Cell Tumor

The desmoplastic small round cell tumor (DSRCT) is a type of sarcoma characterized by an aggressive clinical course with widespread abdominal involvement and a peculiar histological appearance with prominent desmoplasia [128]. Cytogenetics and molecular characterization of DSRCT have identified a unique chromosomal rearrangement, t(11;22)(p13;q12), in these tumors [129–132]. This translocation involves the *EWS* gene at 22p12 and the Wilms tumor suppressor gene (WT1) at 11p13. The resulting chimeric gene generates a fusion cDNA transcript encoding an aberrant transcriptional regulatory factor containing the N-terminal region of *EWS* and the *WT1* C-terminus [133]. This fusion transcript is similar to other tumor-specific fusions of the *EWS* gene described in other human sarcomas, such as the prototype joining of *EWS* with *ETS* gene family members (*FLI-1, ERG,* or *ETV1*) in Ewing family tumors. In all of these rearrangements, resulting transcripts possess the N-terminal effector region of *EWS* with replacement of the RNA-binding C-terminus by the fusion partner [132, 133]. The chimeric product, which is often transforming, likely functions by dysregulating a critical group of target genes [134, 135].

15.5.7 Dermatofibrosarcoma

Dermatofibrosarcoma protuberans (DP) is a soft tissue tumor typically found in the deep dermis [80]. While it can arise at any site, DP preferentially arises in the subcutaneous tissues of the trunk and proximal extremities. DP typically occurs during early and mid-adult life [80]. Although authentic DP may occur in children, the distinct entity of giant cell fibrosarcoma (GCF) is considered to be the juvenile form of DP [80, 126]. Cytogenetically, DP and GCF both exhibit a unique chromosomal rearrangement, t(17;22)(q22;q13) [136–140]. This translocation, involving the *PDGFB* gene at 22q13.1 and the *COL1A1* gene at 17q22 [141], results in the deregulation of *PDGFB* expression. Unregulated expression of the ligand leads to continuous activation of the PDGF receptor (PDGFR) protein tyrosine kinase, which promotes DP cell growth [142].

15.5.8 Thyroid Cancer

The thyroid gland manifests a wide spectrum of malignant neoplasms. Follicular cell-derived thyroid carcinoma consists of several morphological subtypes, including papillary (PTC), follicular (FTC), Hürthle-cell (HCC), and anaplastic (ATC) carcinomas. These subtypes are phenotypically distinct, exhibiting extremes of malignant potential, from the indolent PTC to the highly aggressive ATC. While chromosomal alterations generating fusion oncoproteins are common in leukemias/lymphomas and sarcomas, they are relatively rare in human carcinomas; such fusions are almost exclusively found in well-differentiated thyroid carcinomas [143]. FTC, which accounts for approximately 20 % of all thyroid cancers, was recently found to contain a genomic rearrangement involving a t(2;3)(q13;p25). This translocation fuses the thyroid-specific transcription factor *PAX8* with *PPARγ*, a ubiquitously expressed transcription factor [144]. The resulting paired box-8 (*P*AX8)/peroxisome proliferator-activated receptor (PPAR)-γ fusion protein (PPFP) has been identified in approximately 50 % of FTC and a smaller proportion of follicular adenomas, the putative precursor lesion. PAX8, which is required for normal thyroid development, is involved in the maintenance of differentiated follicular cell function. As is typical for *pax* family genes, its expression is tightly regulated and controlled. Thus, aberrant expression of PPFP is likely to have oncogenic effects simply by downregulating endogenous PAX8 expression, an effect that has been observed for other fusion genes containing *pax* family genes [145]. In PTC, a single mutation in BRAF, the gene encoding the B-type Raf kinase, changing valine to glutamic acid at position 600 (V600E) is responsible for disease in 40–50 % of patients, especially in older people. This mutation is associated with a poorer clinicopathological outcome. Another important cause of PTC is rearrangements in the RET tyrosine kinase receptor (RET/PTC), which typically recombine the C-terminal region of the RET gene with the promoter and N-terminal domain of a partner gene. This fusion gene results in a protein product exhibiting constitutive activation of RET tyrosine kinase. This rearrangement is responsible for disease in 20–30 % patients, with a higher incidence in younger patients and those receiving radiation [146–149].

15.5.9 Renal Cell Carcinoma

Renal cell carcinoma (RCC) constitutes a heterogeneous group of tumors; specific chromosomal aberrations present in these tumors are important for defining RCC subtypes. The

most common RCC subtypes are clear-cell, papillary, and chromophobe carcinomas, which account for 75, 10, and 5% of malignant kidney tumors, respectively [150]. The most frequent genetic change in clear-cell RCC is loss of the short arm of chromosome 3, which can be caused by terminal deletions, intrachromosomal rearrangements, or unbalanced translocations. Papillary RCCs, which constitute as many as 10% of human kidney tumors, are rare in children. Cytogenetic studies usually identify trisomy or tetrasomy 7 or trisomy 17, 12, 16, or 20 [151]. A subset of papillary RCC exhibits abnormalities at Xp11 in the presence of t(6;11)(p21;q12) [152] or other translocations [153]. The t(6;11)(p21;q12) results in fusion of the 5′ portion of the *ALPHA* gene (11q12) to the transcription factor *TFEB* (6p21) [154, 155].

15.5.10 Other Solid Tumors

Congenital fibrosarcoma (CFS) and cellular mesoblastic nephroma (CMN) are two closely related spindle cell malignancies seen in infancy and young childhood. In addition to clinical and histopathological similarities [156, 157], these tumors share several common genetic abnormalities, including trisomy 11 [158, 159] and expression of the t(12;15)(p13;q25)-associated *ETV6-NTRK3* gene fusion [160].

Several additional neoplasms exhibit distinct genetic abnormalities that are critical in tumorigenesis. Almost all meningiomas exhibit hemizygosity for chromosome 22. Loss of these chromosome 22 loci, specifically the inactivation of the *NF2* tumor-suppressor gene at 22q12, is a critical step in meningioma tumorigenesis [161]. Almost all forms of retinoblastoma contain abnormalities of chromosome 13q14; in a subset of cases, a deletion at 13q14 can be visualized karyotypically. The molecular consequence of this deletion is loss of the *Rb1* tumor suppressor gene. Wilms tumor, a kidney tumor of childhood, typically exhibits deletion or mutation of the short arm of chromosome 11, which inactivates the *WT1* tumor-suppressor gene, located at 11p13 [162]. Inactivation of the *APC* tumor-suppressor gene at 5q21-22 is a critical step in colorectal tumorigenesis [163].

In addition to translocations and deletions, tumor cells often exhibit increases in chromosomal material, with identification of double minutes (DMs) or homogeneously staining chromosomal regions (HSRs). Human neuroblastomas were the first tumors demonstrated to harbor DMs and HSRs; in these tumors, gene amplification involves the *N-MYC* gene [164]. Such amplification of *N-MYC* is typically seen in more advanced tumors (stage III and IV). Amplified *L-MYC* genes in DMs and HSRs [165] have also been found in a subset of small cell carcinomas, typically in the late stages of tumor progression. Additional gene amplifications involving *EGFR, c-ERBB2*, or *BCL1* have been described in various solid tumors.

15.6 Overview of DNA-Repair and DNA-Replication Process

Maintaining genetic stability requires not only an extremely accurate mechanism for replicating the DNA before a cell divides, but also mechanisms for repairing the many accidental lesions that occur in DNA. Most spontaneous changes in DNA are temporary because they are immediately corrected by the various cellular DNA repair processes. There are a variety of repair and replication mechanisms, each catalyzed by a different set of enzymes. DNA repair (including replication-coupled repair mechanisms) involves at least four processes: (1) the altered portion of a damaged DNA strand is recognized and removed by enzymes called DNA-repair nucleases; (2) DNA polymerase binds to the 3′-OH end of the cut DNA strand and fills in the gap by making a complementary copy of the information stored in the residual template strand; (3) during DNA replication, proofreading occurs through the $3' \rightarrow 5'$ exonuclease activity of the DNA polymerase enzyme; (4) post-replication or mismatch repair (MMR), remove any replication errors that were missed by the proofreading exonuclease and remain in the newly synthesized DNA. Inactivation of any of these DNA-repair processes can result in a large increase in spontaneous mutability, and in the case of humans, predisposition to cancer development.

15.7 Nucleotide Excision Repair and Cancer

15.7.1 Mechanism of DNA Excision Repair

There are two main mechanisms for excision of DNA damage. These mechanisms are base excision repair (BER) and nucleotide excision repair (NER) [166]. In general terms, BER removes and abnormal base from the DNA strand. Release of the damaged base from the DNA is catalyzed by the class of enzymes called DNA glycosylases. Each glucosylase is specific for a particular type or class of DNA lesion. The resulting apurinic or apyrimidinic site is cleaved by an AP endonuclease, DNA polymerase fills the gap, and DNA ligase seals the remaining nick.

Another model for damaged DNA excision is NER, which involves the removal of the section of DNA containing the lesion, followed by repair synthesis using the remaining intact DNA strand as a template for restoring the gap [166–168]. Once a bulky DNA lesion is found, the phosphodiester backbone of the abnormal strand is cleaved on both sides of the distortion, and the portion of the strand containing the lesion is peeled away from the DNA double helix by a DNA helicase enzyme. The gap produced in the DNA helix is then repaired in the usual manner by DNA polymerase and DNA

ligase. The importance of these repair processes is indicated by the large investment that cells make in DNA-repair enzymes. Individuals with the genetic disease xeroderma pigmentosum (XP), for example, are defective in a NER process that can be shown by genetic analysis to repair at least seven different gene products [167, 168].

15.7.2 Proteins Involved in NER

Most proteins involved in NER have been discovered through analysis of XP [169]. These proteins are summarized in Table 15.8. The damage recognition step involves the DNA-binding proteins XPA and XPE [170, 171]. Mammalian XPA and XPE proteins show a preference for binding damaged over undamaged DNA. Differential recognition by XPA may be an important factor in determining faster repair. The next step of NER involves the introduction of two incisions into the damaged DNA strand, one on each side of the DNA lesion. The size of the repair patch formed during NER is about 25–30 nucleotides long. Two different nucleases are used to create the dual incisions. In mammalian cells, these are the XPG/ERCC5 protein, which makes the 3′-incision [172], and the complex consisting of XPE/ERCC4 and ERCC1, which makes the 5′-incision [173]. The portion of the strand containing the lesion is peeled away from the DNA double helix by a DNA helicase enzyme. These processes combine to remove the damaged segment of DNA, leaving a single-strand gap in the DNA at the site of the lesion. This gap is subsequently filled through the action of DNA polymerase enzymes.

The multiprotein complex TFIIH participates in both basal transcription and in NER. TFIIH is normally found in the initiation complex at promoters transcribed by RNA polymerase II. Known NER proteins are components of TFIIH [174, 175]. Human TFIIH contains the XPB (ERCC3) and XPD (ERCC2) proteins. XPB and XPOD contain seven conserved helicase domains, and they have $3' \rightarrow 5'$ and $5' \rightarrow 3'$ DNA helicase activities, respectively. TFIIH also contains a kinase, composed of cdk7 and cyclin H. TFIIH may regulate transcription initiation by phosphorylating DNA polymerase II. It has been reported that the p53 tumor-suppressor protein interacts both physically and functionally with the TFIIH complex [176]. This interaction might provide an immediate and direct link between p53 and the multiple function of TFIIH in transcription.

15.7.3 Mutations of NER and Cancer Family Syndromes

Defective excision repair in human in association with some autosomal recessive diseases strongly predispose to malignant disease [177]. XP is caused by absence or greatly reduced levels of excision inheritance. The clinical manifestations of XP result from DNA damage from exposure to the defective NER in these patients. Cell-fusion studies have identified 7 XP complementation groups, XPS. A through XPG, suggesting that many distinct gene products are involve in NER [178].

Bloom's syndrome (BS) is a rare disorder with autosomal recessive inheritance, and major clinical manifestations are growth deficiency, unusual facies, and sun-sensitive facial erythema [179]. Increased sister chromatid changes (SCE) and chromosomal instability are typical in vitro findings demonstrable in lymphocyte and fibroblast cultures from BS patients [180]. These patients also have an increase susceptibility to cancer [181]. The tumor spectrum exhibited by BS patients includes various rare tumor types, acute leukemias and lymphomas. The first step in positional cloning effort to isolate the BS gene (BLM) was to identify genetic linkages between the BLM locus and mapped polymorphic markers [182]. BLM protein is a member of a growing helicase subfamily, including *recQ* in *Escherichia coli*, *RECQL* in human, *SGS1* in yeast, and the gene product encoded by the Werner syndrome (WS) gene *WRN*. RecQ genes are suppressors of illegitimate recombination in E. coli and would lead to DNA instability in humans. Gene products of SGS1 and WRN are especially similar to BLM, and contain the 7 conserved helicase motifs [183]. These proteins are likely to play similar roles in DNA metabolism. Because helicase activity is important for the DNA excision-repair process, cancer susceptibility in BS patients may result from abnormality of the DNA-repair system.

Table 15.8 The polypeptides required for excision repairs in humans

XP protein	ERCC protein	Yeast homolog	Activity	Comments
XPA	–	RAD14	DNA binding	Binds damaged DNA
XPB	ERCC3	RAD25	Helicase	3′ to 5′ DNA helicase in TFIIH
XPC	–	RAD4	DNA binding	Binds ssDNA
XPD	ERCC2	RAD3	Helicase	5′ to 3′ DNA helicase in TFIIH
XPE		–		Binds damaged DNA?
XPF	ERCC4	RAD14	Nuclease	Complex with ERCC1, 5′-incision
XPG	ERCC5	RAD25	Nuclease	3′-incision
–	ERCC1	RAD10	Nuclease	Complex with ERCC4, 3′-incision

15.8 Replication Error and Cancer

15.8.1 Proofreading and MMR

An overview of DNA replication is illustrated in Fig. 15.1. Human cells require a high-fidelity DNA-replication and -repair mechanisms to ensure the integrity of the approximately 3×10^9 base pairs of DNA contained in the genome. The fidelity of DNA replication is extremely high, with about 1 error made for every 1×10^9 base pairs of DNA replicated. This level of fidelity is much higher than might be expected, given that the standard complementary base pairing (AT and GC) observed in mammalian DNAs are not the only ones possible. The high fidelity of DNA replication depends on several proofreading and MMR mechanisms that act sequentially to remove errors [184].

One proofreading process depends on specific properties of the DNA polymerase enzyme [185, 186]. Several DNA polymerase enzymes are known in mammalian cells (Table 15.9), DNA polymerase enzymes are able to correct mismatched nucleotides by means of a separate catalytic subunit that removes unpaired residues at the primer terminus. Excision by this $3' \rightarrow 5'$ proofreading exonuclease activity continues until enough nucleotides have been removed from the 3′-end to regenerate a base-paired terminus that can prime DNA synthesis. In this way, DNA polymerase functions as a self-correcting enzyme that removes its own polymerization errors as it moves along the DNA.

Another mechanism that removes replication errors missed by the proofreading exonuclease is the MMR system. In E. coli, two MMR genes are well known, namely *MutS* and *MulL* proteins with the heteroduplex activates a latent endonuclease associated with MutH protein, which cleaves the unmethylated strand at a d(GATC) site. Although little is known about the reaction responsible for unbiased correction of continuous heteroduplexes, nick-directed MMR in humans has been extensively examined. This type of repair depends on the gene products of *MLH1, MSH2, MSH3, MSH6* (or *GTBP*), *PMS1*, and *PMS2*, implicating these human homologous of *MutS* and *MutL* in the reaction [187]. Available evidence suggests that mismatch recognition in human cells is mediated by the MSH2-MSH6 protein het-

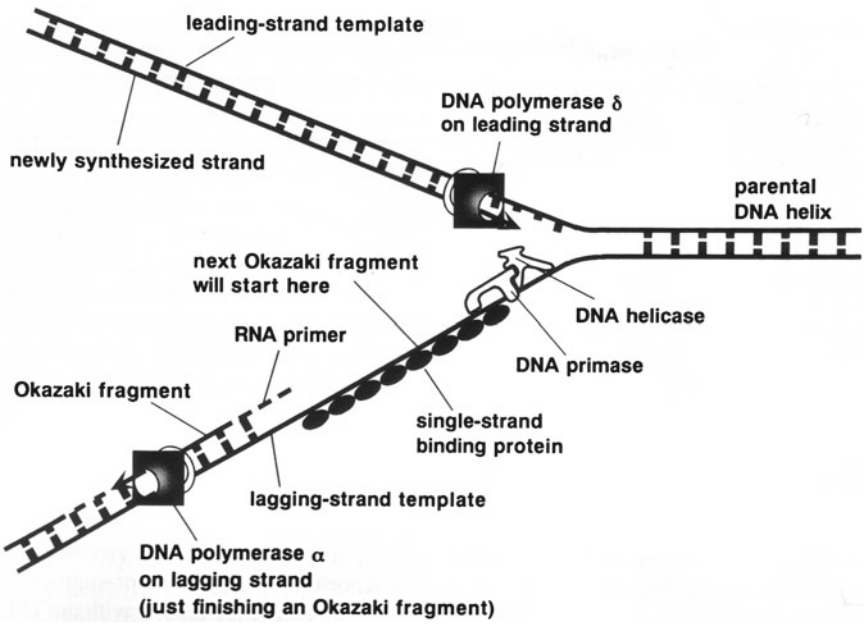

Fig. 15.1 A mammalian replication fork during DNA replication. The major types of proteins that act at a DNA replication fork are illustrated, showing their positions on the DNA. The replication fork makes use of two DNA polymerase enzymes; one for the leading strand and one for lagging strand. The leading-strand polymerase is designed to keep a tight hold on the DNA, whereas that on the lagging-strand must be able to release the template and then rebind each time a new Okazaki fragment is synthesized.

Table 15.9 Properties of DNA polymerase in eukaryotic cells

Exonuclease type	Distributions	3′–5′ Activity	Function
α	Nuclei	–	Synthesis of Okazaki fragment in lagging
β	Nuclei	–	Base excision repair
γ	Mitochondria	+	Replication of mitochondrial DNA repair Proofreading activity
δ	Nuclei	+	Synthesis of reading strand Joining of Okazaki fragment Proofreading activity
ε	Nuclei	+	Replication? Proofreading?

erodimer (designated hMutSa), with the MLH1-PMS2 protein heterodimer (hMutLa) providing MutL function [188].

15.8.2 Microsatellite Instability in Human Cancer

The human genome is punctuated with repetitive nucleotide sequences or microsatellites. These repetitive dinucleotide, trinucleotides, and tetranucleotides are frequently, but not invariably, located between genes and have been classified as junk DNA. Because microsatellites are usually less than 100 bp long and are embedded in DNA with unique sequences, they can be amplified in vitro using the polymerase chain reaction (PCR). Microsatellites are easy to clone and characterize, and they display considerable polymorphism due to variation in the number of units [189, 190]. Microsatellite instability (MSI) may reflect replication error (RER), because RER results in accumulation of changes in the length of microsatellites and other short repeat sequences (Fig. 15.2).

In studies on hereditary non-polyposis colorectal cancer (HNPCC) and sporadic colorectal cancer patients, frequent mutations in the microsatellite-repeat sequences were first described [189–191]. These mutations are typically tumor-specific and indicative of a somatic origin. Since the original description of MSI in HNPCC tumors and sporadic colon cancer, MSI has been described in a significant fraction of sporadic tumors, including colorectal, endometrial, stomach, ovarian cervical, pancreatic, esophageal, and small-cell lung cancer [192–195]. These data suggest that RER followed by MSI could be a common mechanism involved in neoplastic transformation. Moreover, it is demonstrated that a frequent occurrence of MSI in the evolution of CML [196, 197], indicating MSI to be a later genetic event in the evolution of CML to blast crisis. On the other hand, Kaneko et al. reported that MSI contributes to the pathogenesis of myelodysplastic syndromes (MDS) in some patients, especially as an early genetic event [198]. MSI has also been observed in other hematologic malignancies including CLL, Burkitt lymphoma, and HIV-associated lymphomas [199–201].

15.8.3 Mutations of MMR Genes in Human Cancer

The basis of the MSI phenotype has been clarified by genetic analysis of HNPCC families and biochemical assay of tumor cell lines that express MSI. Four genes have been implicated to date in HNPCC: *MSH2, MLH1, PMS1,* and *PMS2* [202, 203]. The majority fraction of HNPCC examined harbor mutations in MSH2 or MLK1, whereas PMS1 and PMS2 mutations appear to be responsible for only a small fraction of HNPCC patients. These data suggest that MSI in tumors arising in patients with HNPCC is due to the presence of mutations in 1 of 4 known (*hMSH2, hMLH1, hPMS1, and hPMS2*) DNA MMR genes. Isolation of *hMutSa* have implicated *MSH6* in mismatch repair, but mutations in the *MSH6* locus have not been identified in HNPCC kindred. However, *MSH6* defects have been identified in several sporadic MSI-positive colorectal cancers [204].

Mutation analysis of these four MMR genes in endometrial carcinomas displaying microsatellite instability revealed that two of nine tumors contained *hMSH2* mutations, suggesting that mutations in these four MMR genes are not responsible for MI in the majority of sporadic endometrial carcinomas [205].

Hangaishi et al. examined alterations of *hMLH1* gene in a total 43 human leukemia cell lines by PCR-SSCP: mutations of the hMLH1 gene were detected in three cell lines from lymphoid leukemias, suggesting that disruption of MMR may play an important role in the development of human lymphoid leukemias [206].

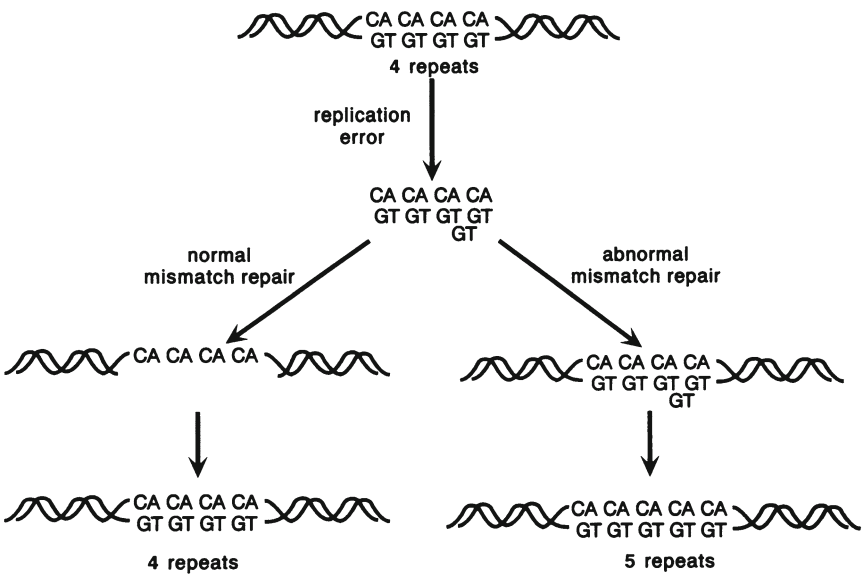

Fig. 15.2 The principle of microsatellite alterations in the disruption of mismatch repair system. During DNA replication, slippage occurs and CA repeats could be altered and not be removed, if the repair system is damaged.

15.8.4 Target Genes of Mismatch Repair Defects

Markowitz et al. demonstrated a strong correlation between defects in the *type II TGF-β receptor* (*TGFβRII*) gene and expression of MSI in tumors cell. The mutations responsible defective TGFβRII function in thee tumor cells were located in microsatellite-repeat units with the coding sequence of the gene, and consisted of expansion (insertions) mutations in an $(A)_{10}$ repeat in several cases and a $(GT)_3$ repeat in one case [207]. Because failure to respond to TGF-β growth inhibition is a characteristic of certain cancers, these findings directly link to RER and a mutational hot spot in a growth control locus. Other genes that are targets for mutations in MSI-positive cells during the course of carcinogenesis have proven elusive. Ouyang et al. examined mutations of the *insulin-like growth factor-2 receptor (IGF2R)* gene in MSI-positive cancers occurring at various primary sites, and found frameshift mutations in some populations of gastric, endometrial, and colorectal cancers expressing MSI [195].

15.8.5 Mutation of DNA Polymerase Enzymes in Human Cancer

In the hereditary form, mutations of MMR genes are usually responsible for instability. However, in many sporadic tumors, mutations of the known MMR genes are apparently absent. Da Costa et al. investigated whether defects in the proofreading DNA-repair function of DNA polymerase δ might contribute to the RER phenotype [208]. They found a variation in exon III of *polymerase* δ was observed in 3 of 8 MMR-positive colorectal cancer cell lines, suggesting that the RER phenotype might be related to mutations in the exonuclease domain of DNA polymerase. DNA polymerase α expression correlates with the extent of malignancy and survival in non-SCLC patients and is therefore considered to be a useful prognostic marker [209]. Moreover, mutations in the gene coding DNA polymerase β were detected in a high percentage of human colorectal cancer [210]. DNA polymerase β gene mutations are also detected in prostate and bladder cancer, although with relative low frequency [211].

15.8.6 Telomere Attrition and Chromosome Instability

Telomeres, the ends of chromosomes, consist of simple tandem repeats. In humans, 10–15 kb of (TTAGGG) repeats are found at the termini of all chromosomes and function to protect chromosomal ends from chromosomal recombination [212–216]. Since telomere overhang does not replicate without the presence of telomerase [217–219], consisting of a RNA component (hTERC) [220], a catalytic subunit (hTERT) [221] and associated proteins [222–225], telomere length progressively shortens on every cell division. Progressive telomere shortening without telomerase activity (or low level telomerase activity) results in chromosomal instability and produces telomere association, for example, dicentric chromosomes or DMS [226, 227]. In normal somatic cells, telomerase activity is only detectable in regenerating tissues, like hematopoietic cells, intestinal cryptic cells, and hair follicle cells. Reduction of telomere length is calculated by the telomere-binding protein (POT-1) and then telomerase activity is controlled via several telomere-binding proteins (TRF-1, TRF-2) [228–230].

In cancer cells, upregulation of telomerase activity was evident and is believed to protect from ultimate telomere shortening that induces cell death [231, 232]. Therefore, telomere loss due to cell division induces chromosomal instability. However, to avoid cell senescence, telomerase activity is upregulated and then tumor cells obtain consistent growth with relatively short but stable telomere length in hematologic neoplasms [233–235]. Although it has been suggested that telomere attrition (and chromosome abnormality) and microsatellite instability cooperate in cancer cells, it remains unresolved whether telomere reduction and telomerase upregulation actually contribute to chromosome abnormalities or instability in cancer cells, especially in solid tumors. Currently, targeted therapy for telomerase or telomere structure has been attempted to reduce telomere length and induce cell death, in combination with chemotherapy [236].

15.9 Cell-Cycle Checkpoints in Cancer

15.9.1 Cell-Cycle Checkpoints and Chromosomal Instability

Cell-cycle checkpoints mechanisms ensure that all process in one phase of the cell cycle are completed before the next phase begins. Such checkpoints are not activated unless an impediment to cell-cycle progression is detected. Therefore, it is natural that DNA damage can trigger cell-cycle checkpoint controls, because DNA damage can interfere significantly with cell-cycle processes and diminish their accuracy.

It has demonstrated been demonstrated that cell-cycle checkpoint abnormalities can lead to the generation of chromosomal aberrations [237, 238].for example, a defect in the S/M checkpoint can result in the improper segregation of chromosomes owing to the incomplete separation of sister chromatids before DNA replication is successfully completed. Defects in the surveillance of the integrity of DNA can cause chromosomal rearrangements, such as deletions, amplifications, and translocations. Defects in spindle surveillance can lead to nondisjunction, generating whole chromosome gain or loss, whereas defects in the surveillance of the spindle poles can lead to change in chromosomal number, i.e., aneuploidy. In such

cells with defective checkpoint machinery, the replicated DNA may not be segregated in time into the daughter cells, which lead to aneuploidy and chromosomal instability However, aurora-kinase inhibitor (target for spindle surveillance) is now ongoing for possible target therapy for various cancers, including Ph-positive leukemia with T315I mutation [239–241].

15.9.2 p53 Gene

Mice deficient for p53 have a predisposition to cancer in multiple organs systems [242]. In human, tumor cells in the Li–Fraumeni syndrome have defects in both copies of p53, whereas the non-tumor cells have a defect in only one. Furthermore, more than 50 % of sporadic cancer patients are found to have p52 mutations [243]. The gene product of the p53 tumor-suppressor gene is a checkpoint factor that mediates G_0/G_1-cell cycle arrest of apoptosis in response to DNA damage. p53 also harbors an intrinsic exonuclease activity and binds to Rad51 recombinase, a factor that facilitates DNA repairs, indicating that p53 is indirectly involved in the DNA repair mechanism [244]. Moreover, p53 seems to be involved in the regulation of chromosome replication and the prevention of DNA replication when a mitotic-spindle inhibitor hampers chromosome replication [245, 246]. Therefore, the loss of p53 function cause enhanced gene amplification, and chromosomal instability [247].

15.9.3 MicroRNA in Cancer

Most currently, it is well known that microRNAs (miRNAs, small noncoding RNAs ranging from 18 to 24 nucleotides in length) regulate gene expression by the RNA-induced silencing complex, resulting in a reduction of the translation and stability of target messenger RNAs [248–250]. Recent studies have shown the presence of miRNA alterations in various human cancers, suggesting that mRNAs play important roles in carcinogenesis and disease progression [251–253]. Moreover, some miRNAs are known to control not only expression of fusion product that creates from chromosomal translocation but also genes link to cell cycle. In the near future, the whole story will be disclosed, in combination with chromosome changes and miRNA profiling, for understanding cancer biology, and thereby contribute to therapeutic approach.

Epigenetic Mechanisms in Cancer Development

16

José Ignacio Martín-Subero and Manel Esteller

16.1 Introduction

Epigenetics literally means *upon genetics* and comprises various mechanisms that regulate both gene expression and genome stability without modifying the DNA sequence itself [1, 2]. The most widely studied epigenetic changes are DNA methylation of cytosines within CpG dinucleotides and a growing number of chemical modifications at different amino acid residues of histone tails including acetylation, methylation, phosphorylation, and ubiquitination [2–5]. Additionally, other epigenetic factors like nuclear positioning, noncoding RNAs, and microRNAs are also associated with gene regulation and chromatin structure [6–8].

Epigenetics plays a key role in multiple physiological processes like development, establishment of tissue identity, imprinting, X-chromosome inactivation, chromosomal stability, and gene transcription regulation [2]. Therefore, it is not surprising that alterations in the epigenetic code are associated with a wide variety of malignant and nonmalignant diseases [3, 9–13]. Furthermore, multiple environmental factors, e.g., nutrition, exposure to metals, or maternal behavior in early childhood, are able to induce epigenetic changes [9, 14]. These environmentally induced epigenetic changes are in turn related to susceptibility to several diseases in adults, including cancer [15]. Interestingly, there is evidence showing that monozygotic twins acquire epigenetic and phenotypic changes throughout life [16], which supports the concept that lifestyle influences the phenotype through epigenetic modifications.

CpG dinucleotides are not randomly distributed across the genome but concentrated in the promoter regions of genes (called CpG islands) and in repetitive genomic sequences [3]. In general, it can be said that repetitive sequences are heavily methylated in normal cells whereas most promoter regions associated with CpG islands are unmethylated, which allows gene expression if the appropriate transcriptional activators are present [3]. However, only approximately 70 % of genes contain CpG island-associated promoters. In the remaining 30 % of genes, transcriptional regulation is mostly achieved through histone modifications and not by DNA methylation. But this rule has several exceptions. For instance, expression of some genes lacking the established criteria for CpG islands, e.g., Maspin, is strongly regulated by DNA methylation [10].

As compared to epigenetic patterns in normal cells, cancer cells are characterized by an intense disruption of the epigenomic machinery, which is reflected in multiple aberrations affecting both content and distribution of DNA methylation and histone modifications [3, 10, 11, 17–19]. The aim of this review is to provide an overview on the role of epigenetic modifications in cancer development as well as in cancer management and treatment.

16.2 Gene Expression Regulation by Epigenetic Mechanisms

DNA methylation and histone modifications are tightly regulated by DNA methyltransferases (DNMTs) [20] and a large number of histone modifying enzymes [5], respectively. The best characterized DNMTs are DNMT1, DNMT3A, and DNMT3B. Although DNMTs were originally classified as maintenance or de novo DNMTs (depending on their ability to methylate hemimethylated or unmethylated substrates), several lines of evidence indicate that all three DNMTs not only cooperate, but also may show both de novo and maintenance functions in vivo [21–23]. The knockout cell lines for DNMT1, DNMT3B, and both enzymes demonstrated that in

W.B. Coleman, G.J. Tsongalis (eds.), *The Molecular Basis of Human Cancer*, DOI 10.1007/978-1-59745-458-2_16

single knockouts no effective CpG island demethylation and restoration of gene expression were observed, but the double knockout of DNMT1 and DNMT3B showed complete hypomethylation at the studied CpG islands and corresponding gene activation [22, 24]. The double-knockout cell line has also been shown to be a useful tool for identifying new hypermethylated genes in human cancer [24] thanks to the use of global genomic methylation strategies, such as AIMS and CpG island arrays [3, 25]. Taken together, these results strongly suggest that both enzymes, DNMT1 and DNMT3B, are necessary for effective CpG island methylation.

The information for gene silencing contained by methylated CpG islands is in part read by methyl-CpG-binding proteins (MBDs). MBDs mechanistically link DNA methylation and histone-modifying enzymes that establish a transcriptionally inactive chromatin environment. This family of proteins consists of five well-characterized members (MeCP2, MBD1, MBD2, MBD3, and MBD4) [26]. MBD proteins are associated with hypermethylated CpG island promoters of tumor-suppressor genes and their transcriptional silencing [26], showing remarkable specificity in vitro [27] and in vivo [28–30]. In fact, most hypermethylated promoters are occupied by MBD proteins, whereas unmethylated promoters generally lack MBDs, with the exception of MBD1 [29]. Several promoters are highly specific in recruiting a particular set of MBDs, while other promoters seem to be less exclusive. Thus, it can be speculated that the specific profile of MBD occupancy is gene-type and cancer-type specific [29].

DNA methylation and histone modifications are not independent epigenetic events but function in an orchestrated manner to achieve a chromatin structure associated with gene silencing or gene expression. For instance MeCP2 represses transcription of methylated DNA by recruiting a histone deacetylase (HDAC)-containing complex [31, 32]. Most histone modifications occur in their protruding N-terminal tails. So far, over 60 different residues on histones targeted by modifications like methylation, acetylation, phosphorylation, and ubiquitination have been identified [5]. A specificity in the pattern of modifications under particular conditions led to the proposal of the histone code hypothesis, according to which histone modifications act sequentially or in combination to form a code that may be read by nuclear factors [4, 33]. Several modifications are compatible with gene silencing whereas others are associated with gene activation. In general, histone deacetylation leads to gene silencing whereas histone acetylation leads to gene activation. Other modifications like histone methylation lead to silencing or activation depending on the amino acid targeted, e.g., methylation of lysine 9 of histone 3 leads to repression whereas methylation of lysine 4 of the same histone results in gene activation [5]. Additional connections between DNA methylation and histone modifications have been found: DNMTs are able to recruit HDACs [34, 35], while on the other hand, both DNMTs and MBDs recruit histone methyltransferases (HMTs) that modify lysine 9 of histone H3 [36, 37]. Also, it has been reported that EZH2, a member of the polycomb repressor complex leading to methylation of lysine 27 of histone 3, associates with DNMTs and might be involved in establishing DNA methylation in a subset of target genes [38].

In conclusion, gene expression is highly regulated by various epigenetic mechanisms. Active genes are associated with lack of DNA methylation, acetylation of H3 and H4, and methylation of lysine 4 of H3, whereas inactive genes show deacetylation of histones H3 and H4, methylation of lysine 9 of histone H3, and demethylation of lysine 4 of histone H3 (Fig. 16.1). In cancer, these patterns are profoundly distorted (Fig. 16.1).

16.3 Technical Approaches to Detect Epigenetic Changes

Techniques for the detection of epigenetic changes have dramatically evolved during the last 30 years [39–43]. The initial efforts in the 1970s were focused on the measurement of global DNA methylation content and the study of particular sequences by Southern blot analyses using methylation-sensitive restriction endonucleases. The limitations of the latter method (e.g., large amounts of high-quality DNA, sequence biases, and problems with incomplete digestions) made the study of specific sequences time consuming and not widely applicable. It was not until 1992, with the introduction of the sodium bisulfite conversion technique, that DNA methylation analyses made a revolutionary step forward [44]. Sodium bisulfite has the property of converting unmethylated cytosine into uracil, whereas methylated cytosine remains unmodified. The combination of this chemical modification with genomic sequencing and methylation-specific PCR (MSP) made the study of DNA methylation changes widely available, and a large number of studies, especially dealing with CpG island hypermethylation of tumor-suppressor genes in cancer, were published in the late 1990s [45]. However, these PCR-based approaches are restricted to the study of few candidate genes and are not suitable as screening techniques to identify novel markers. To overcome this, techniques like Amplification of InterMethylated Sites (AIMS) and Restriction Landmark Genomic Scanning (RLGS), which combine the use of methylation-sensitive restriction endonucleases with one-dimensional or two-dimensional electrophoresis were established [46, 47]. These techniques are time consuming, and every new fragment identified as differentially methylated between a control and a test sample has to be cloned and sequenced.

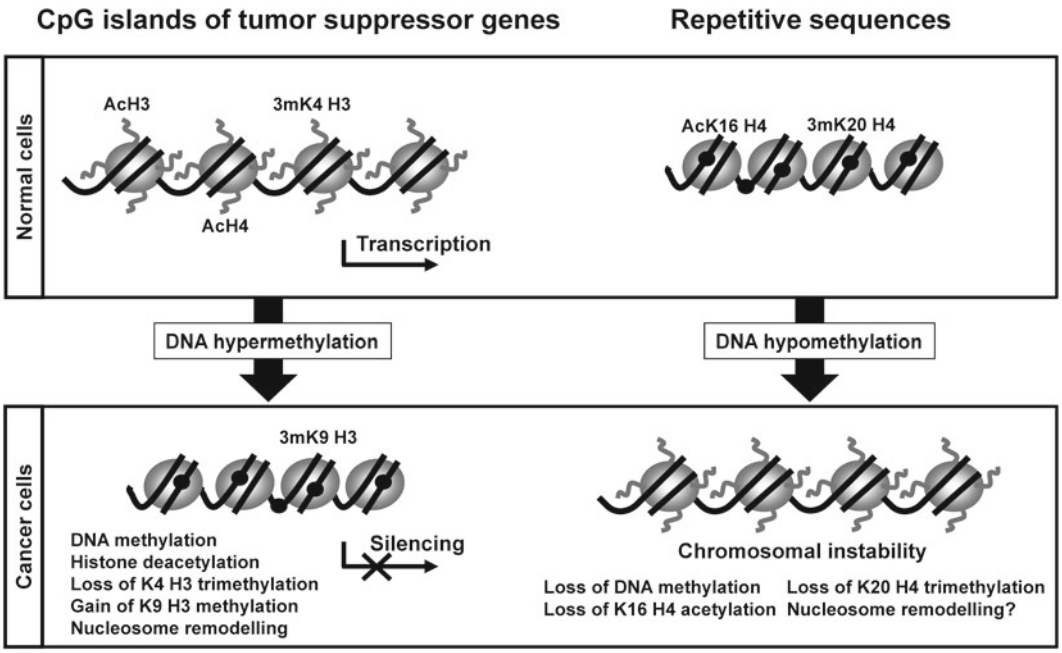

Fig. 16.1 Graphical display of the most common epigenetic changes in CpG islands of tumor suppressor genes and DNA repeats in normal and cancer cells.

An important step forward was been made in recent years with the introduction of the microarray technology [48], which allowed the simultaneous study of epigenetic changes of thousands of known sequences. Some of these array-based DNA methylation techniques are based on the enrichment of methylated DNA and sequential hybridization onto a dedicated microarray containing thousands of promoters or CpG islands, or even a tiling path array containing the whole genome [49–51]. Enrichment for methylated DNA can be achieved by immunoprecipitation of methylated sequences with an antibody specific for 5-methylcytosine (MeDIP) [52] or by methyl-CpG immunoprecipitation (MCIp), which uses a recombinant protein made of the methyl-CpG-binding domain of the MBD2 protein and the Fc fraction of the human IgG1 to directly isolate methylated DNA [53, 54]. Methylated DNA can also be isolated by digestion with methylation-specific endonucleases [50, 55, 56]. One of the limitations of these methods is that they only provide a blurry picture of the methylome and it is not possible to determine the methylation status of specific CpGs. This problem can be overcome by combining bisulfite treatment of the DNA and microarrays able to differentiate methylated and unmethylated alleles [57–59].

These methods allow a direct detection of DNA methylation patterns. However, there is an additional, but indirect, way for detecting hypermethylated genes. This method applies gene expression profiling before and after treatment with DNA demethylating agents like 5-aza-2′-deoxycytosine (5-AZA), so that hypermethylated genes become reactivated after treatment [60, 61]. Although this technique has allowed the detection of novel cancer-related hypermethylated genes, 5-AZA is highly toxic to the cells and can alter the expression levels of many genes regardless of their methylation status, leading to a high false-positive and false-negative rates, and a thorough and time-consuming data validation [43].

With regard to histone modifications, global alterations can be detected by isolating histone fractions by high-performance liquid chromatography (HPLC), and then analyzing them by high-performance capillary electrophoresis (HPCE) and liquid chromatography–electrospray mass spectrometry (LC–ES/MS) [62]. Specific modifications at each amino acid residue can also be characterized using antibodies in western blots, immunostaining [63], or tandem mass spectrometry (MS/MS) [62]. If the goal is to detect histone modifications at specific DNA stretches, a different strategy is necessary. DNA can be crosslinked to the associated histones and in a second step precipitated with antibodies specific to certain histone modifications (technique called chromatin immunoprecipitation or ChIP) so that a DNA fraction enriched for that specific histone modification can be isolated. Then, a PCR using primers for the region of interest can be used. Alternatively, a genome-wide picture of histone modifications can be obtained by the ChIP-on-chip technique. By means of this technique, the immunoprecipitated fraction can be labeled and directly hybridized onto a microarray or compared with the input DNA in two-color hybridization [64, 65].

In spite of the potential of microarrays to characterize DNA methylation and histone modifications across the genome, they are limited either by resolution, type and number of

sequences analyzed, or by their quantification accuracy. In any case, the complete characterization of the human epigenome of a given sample requires the quantification of the methylation status of each of the ~55 million CpG dinucleotides per diploid cell and the distribution of histone marks of every DNA region, and today this is far from possible using the current microarray platforms. The development of a new generation of sequencers is now revolutionizing both genomics and epigenomics [66–68]. These new sequencing technologies are based on pyrosequencing using millions of picoliter-scale reactions, sequencing by synthesis and sequencing by ligation [66], and are able to sequence up to 2 gigabases of DNA (and the human genome is made of ~3.1 gigabases) in a single experiment. The initial applications of these technologies in the epigenomics field have enabled profiling of the distribution of 20 different histone methylation marks in human CD4+ T-cells [69] or the chromatin state (using six different histone marks) of mouse embryonic stem cells and lineage-committed cells like neural progenitor cells and embryonic fibroblasts [70]. With regard to the detection of DNA methylation changes by high-throughput sequencers [71], the reduction from 4 to 3 bp of unmethylated sequences (C is transformed to U and then to T in the PCR reaction) after bisulfite treatment poses a methodological problem to identify the origin of the sequenced fragments. Therefore, current technologies do not yet allow direct sequencing of bisulfite-treated whole genomic DNA, although this will be most likely achieved in the near future.

16.4 DNA Hypomethylation in Cancer

One of the initial epigenetic changes discovered in cancer is that, in comparison to normal cells, cancer cells are characterized by a global hypomethylation of the DNA [18, 72, 73]. Such global loss of methylation mainly targets repetitive DNA sequences, coding regions, and introns. So far, it has been reported that DNA hypomethylation leads to generation of chromosomal instability, reactivation of transposable elements, and loss of imprinting in cancer [74]. Hypomethylation of DNA repeats results in a more open chromatin at those genomic regions and renders the DNA more susceptible to suffer DNA breaks by mitotic recombination of homologous repetitive sequences in different chromosomes (Fig. 16.1) [75–77]. This leads to chromosomal rearrangements, which represent one of the genetic hallmarks of cancer. Also, germline mutations in the *DNMT3B* gene in humans are associated with the ICF (immunodeficiency, centromeric region instability, facial abnormalities) syndrome, which displays DNA hypomethylation of repeats (like satellite 2), and chromosomal instability [78]. Hypomethylation of DNA in malignant cells can reactivate endoparasitic DNA, such as L1 (long interspersed nuclear elements), and Alu (recombinogenic sequence) repeats [79, 80]. These unmethylated transposons can be transcribed or translocated to other genomic regions so that chromosomal instability is further generated. The loss of methyl groups from DNA can also disrupt genomic imprinting. For instance, the hereditary Beckwith-Wiedemann syndrome shows loss of imprinting of *IGF2* (the insulin-like growth factor gene) and individuals affected with this syndrome have an increased risk of cancer [81].

16.5 Gene Silencing in Cancer by DNA Methylation

Tumor-suppressor gene silencing by CpG island hypermethylation is perhaps the best studied epigenetic change in cancer development (Fig. 16.1) [10, 11, 17, 82, 83]. The presence of CpG island promoter hypermethylation affects genes regulating virtually all important cellular functions, such as cell cycle (*p16INK4a*, *p15INK4b*, *RB1*, *p14ARF*), DNA repair (*BRCA1*, *hMLH1*, *MGMT*, *WRN*), cell adherence and invasion (*CDH1*, *CDH13*, *EXT1*, *SLIT2*, *EMP3*), apoptosis (*DAPK*, *TMS1*, *SFRP1*), carcinogen metabolism (*GSTP1*), hormonal response (*RARB2*, *ER*, *PRL*, *TSH* receptors), Ras signaling (*RASSF1A*, *NOREIA*), and microRNAs, among others [82]. Table 16.1 shows a summary of the most common hypermethylated genes in human cancer.

Some of the genes hypermethylated in cancer are common to most cancer subtypes, whereas others are considered to be cancer subtype specific [83, 84]. Hierarchical cluster analysis of DNA methylation profiles of tumor suppressor genes in different cancers leads to a classification according to diagnosis and therefore, each cancer type can be assigned a specific DNA *hypermethylome*. Such patterns of epigenetic inactivation occur not only in sporadic cancers but also in inherited cancer syndromes [85], in which hypermethylation can be the second lesion in the classical Knudson's two-hit model of cancer development [85, 86].

So far, most of epigenetic studies have targeted known tumor-suppressor genes. However, with the advent of the science of epigenomics, a more precise and less biased delineation of the cancer cell epigenome is becoming accessible. This strategy is already providing a complete new generation of epigenetic markers in cancer. An increasing number of microarray-based studies have focused on the detection of differentially methylated biomarkers associated with specific types of solid tumors like breast cancer [87–90], colorectal cancer [91–94], prostate cancer [95–97], lung cancer [98–101], head and neck cancer [49], oligodendroglioma [102], medulloblastoma [103], and Wilms tumors [104]. In hematological cancers, due to the large number of different cell types of the hematopoietic system, a wide range of different leukemias and lymphomas have been identified by means of morphological, immunohistochemical, and genetic features [105]. Now, several groups are using microarray-based DNA

Table 16.1 Summary of the best characterized genes silenced by CpG island promoter hypermethylation in human cancer (adapted from [3])

Gene	Function	Location	Cancer type
APC	Inhibitor of beta-catenin	5q21	Aerodigestive tract
AR	Androgen receptor	Xq11	Prostate
BRCA1	DNA repair, transcription	17q21	Breast, ovary
CDH1	E cadherin, cell adhesion	16q22.1	Breast, stomach
CDH13	H cadherin, cell adhesion	16q24	Breast, lung
COX2	Cyclooxygenase-2	1q25	Colon, stomach
CRBP1	Retinol-binding protein	3q23	Colon, stomach, lymphoma
DAPK	Pro-apoptotic	9q34.1	Lymphoma, lung, colon
DKK1	Extracellular Wnt inhibitor	10q11.2	Colon
ER	Estrogen receptor	6q25.1	Breast
EXT1	Heparan sulfate synthesis	8q24	Leukemia, skin
FAT	Cadherin, tumor suppressor	4q35	Colon
GATA4	Transcription factor	8p23	Colon, stomach
GATA5	Transcription factor	20q13	Colon, stomach
GSTP1	Conjugation to glutathione	11q13	Prostate, breast, kidney
HIC1	Transcription factor	17p13.3	Multiple types
HOXA9	Homeobox protein	7p15.2	Neuroblastoma
ID4	Transcription factor	6p22.3	Leukemia
IGFBP3	Growth-factor-binding protein	7p13	Lung, skin
Lamin A/C	Nuclear intermediate filament	1q21.2	Lymphoma, leukemia
LKB1/STK11	Serine–threonine kinase	19p13.3	Colon, breast, lung
MGMT	DNA repair of 06–alkyl-guanine	10q26	Multiple types
MLH1	DNA mismatch repair	3p21.3	Colon, endometrium, stomach
NORE1A	Ras effector homologue	1q32	Lung
p14ARF	MDM2 inhibitor	9p21	Colon, stomach, kidney
p15INK4B	Cyclin-dependent kinase inhibitor	9p21	Leukemia
p16INK4A	Cyclin-dependent kinase inhibitor	9p21	Multiple types
p73	p53 homologue	1p36	Lymphoma
PR	Progesterone receptor	11q22	Breast
PRLR	Prolactin receptor	5p13.2	Breast
RARB2	Retinoic acid receptor-beta2	3p24	Colon, lung, head, and neck
RASSF1A	Ras effector homologue	3p21.3	Multiple types
RB1	Cell-cycle inhibitor	13q14	Retinoblastoma
RIZ1	Histone/protein methyltransferase	1p36	Breast, liver
SFRP1	Secreted frizzled-related protein	18p11.21	Colon
SLC5A8	Sodium transporter	12q23	Glioma, colon
SOCS1	Inhibitor of JAK–STAT pathway	16p13.13	Liver, myeloma
SOCS3	Inhibitor of JAK–STAT pathway	17q25	Lung
SRBC	BRCA1-binding protein	1p15	Breast, lung
SYK	Tyrosine kinase	9q22	Breast
THBS1	Thrombospondin-1, anti-angiogenic	15q15	Glioma
TMS1	Pro-apoptotic	16p11	Breast
TPEF/HPP1	Transmembrane protein	2q33	Colon, bladder
TSHR	Thyroid-stimulating hormone receptor	14q31	Thyroid
VHL	Ubiquitin ligase component	3p25	Kidney, hemangioblastoma
WIF1	Wnt inhibitory factor	12q14.3	Colon, lung
WRN	DNA repair	8p12	Colon, stomach, sarcoma

methylation profiling to characterize the epigenome of this heterogeneous group of diseases and to identify diagnostic epigenetic marks. These studies have shown differential methylation profiles between mantle cell lymphoma (MCL) and follicular lymphoma (FL) [106], B-cell chronic lymphocytic leukemia (B-CLL), MCL, and FL [107, 108], cutaneous T-cell lymphoma and normal T-cells [109], acute lymphoblastic leukemia (ALL) and acute myeloid leukemia

(AML) [110], AML and normal monocytes [54], and ALL and normal peripheral blood [111]. Taken together, these studies and our recent unpublished experiments indicate that cancer cells, depending on the tumor subtype, might contain up to 2000 hypermethylated gene promoters.

The acquisition of differential methylation in cancer, like hypermethylation of tumor-suppressor genes, is thought to provide the tumor clone with a selective (e.g., proliferative) advantage. However, recent reports have proposed that there is an instructive mechanism behind aberrant DNA methylation in cancer [112, 113]. Keshet and colleagues performed a MeDIP-on-chip study in colon and prostate cancer and as well as identifying differentially methylated genes, they studied whether these genes show distinct biological features [112]. They discovered that genes differentially methylated in cancer are enriched for functional categories (e.g., cell adhesion, cell-cell signaling, signal transduction, and ion transport) and that the expression of some of them is already repressed (or expressed at low levels) in cells from matched normal tissues [112]. Furthermore, they detected a significant enrichment of sequence motifs and a significant clustering of such genes in chromosomal regions [112]. In line with this finding, another study has shown that large stretches of DNA containing several genes can become hypermethylated in cancer [114].

Various independent studies have recently provided further evidence for an instructive mechanism leading to selective methylation of certain groups of genes in most types of cancer. These studies took advantage of ChIP-on-chip data generated using antibodies against members of the polycomb repressor complex 2 in embryonic stem cells [115, 116]. The investigators found that a highly significant proportion of genes that become hypermethylated in cancer were already repressed at the embryonic stem cell stage by PcG marks [117–120]. These findings suggest that epigenetic changes of polycomb target genes occurring in a cell with stem cell features might represent the initial event in tumorigenesis (Fig. 16.2), which supports the cancer stem cell theory [10, 113, 121].

16.6 DNA Methylation also Targets miRNAs in Cancer

Aberrant repression of gene expression in cancer not only targets coding sequences but also small non-coding RNAs like miRNAs. These are made of short stretches of 22 nucleotides that are able to regulate gene transcription of target genes by sequence-specific base pairing in the 3′ UTR regions and subsequent degradation of the target mRNA or inhibition of translation. Target genes of miRNAs are involved in cellular functions like cell proliferation, differentiation, and apoptosis [122, 123]. Therefore, it is not surprising that miRNA expression has been found to be deregulated in cancer development [124, 125]. The role as tumor suppressors of miRNAs has been investigated in more detail for particular cases. For example, the downregulated let-7 and miR-15/miR-16, and miR-127 are known to target the oncogenic factors RAS and BCL-2, respectively [126, 127]. This may be explained by the failure of these miRNAs during post-transcriptional regulation in cancer cells [128], but additional mechanisms such as CpG island hypermethylation could also be involved. For instance, it has been observed that 5 % of human miRNAs are upregulated by treatment of bladder cancer cells with DNA demethylating agent and HDAC inhibitor [129]. In particular, miR-127 expression was induced by a decrease in DNA methylation levels around the promoter region of the miR-127 gene, and the proto-oncogene BCL6, a potential target of miR-127, was translationally downregulated after treatment [129]. Additionally, using a genetic approach that takes advantage of the genomic disruption of DNMT1 and DNMT3B in cancer cells, we have demonstrated that CpG island hypermethylation is a mechanism that can account for the downregulation of miRNAs in human cancer [130]. Most importantly, the epigenetic silencing of miR-124a, one of the DNA methylation-associated silenced miRNAs isolated using this approach, leads to activation of cyclin D kinase 6 (CDK6), a bona fide oncogenic factor, and phosphorylation of the retinoblastoma (RB1) tumor-suppressor protein [130].

16.7 Histone Modifications in Cancer Cells

Although less studied than DNA methylation, histone modification patterns are also highly disrupted in cancer. One of the best studied alterations is the acetylation of histone H4, which is globally hypoacetylated in esophageal squamous cell carcinoma [131, 132], gastric cancer [133], testicular cancer [134], and acute promyelocytic leukemia (APL) [135]. Furthermore, monoacetylated lysine 16 of H4 is globally reduced in various types of cancer [62], and lower levels of acetylated lysine 12 of H4 are an indicator of recurrence in prostate cancer [63]. Interestingly, exposure to the carcinogen Ni2+ induces a clear decrease in histone acetylation [136]. Another histone H4 modification, the trimethylation of lysine 20 of H4, which is enriched in differentiated cells [137] and increases with age [138], is commonly reduced in cancer cells [62, 139]. Global alterations of histone H3 modifications in cancer have been less thoroughly investigated. One study found that low levels of acetylation at lysines 9 and 18 of histone H3 are associated

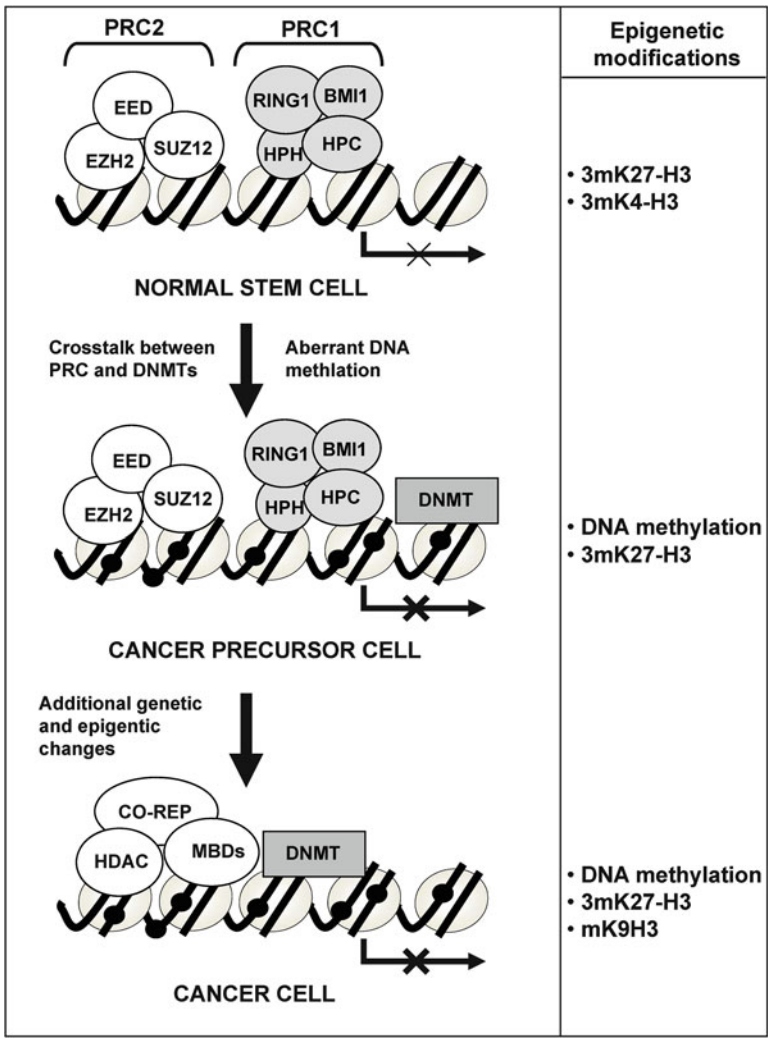

Fig. 16.2 Model of tumorigenesis by which cancer is initiated by a polycomb repressor complex (PRC)-associated DNA methylation followed by additional genetic and epigenetic changes (adapted from [120]).

with high recurrence of prostate cancer [63]. In two recent studies, H3 acetylation has been found to be reduced in colon cancer [140] and in several human colon cancer cell lines [141].

Hypermethylation of the CpG islands in the promoter regions of tumor-suppressor genes in cancer cells is associated with a particular combination of histone markers: deacetylation of histones H3 and H4, and methylation changes at various amino acid residues of H3, like loss of trimethylation at lysine 4, and gain of methylation at lysine 9 and trimethylation at lysine 27 [10, 30]. The presence of the hypo-acetylated and hypermethylated histones H3 and H4 silences certain genes with tumor-suppressor-like properties, such as p21WAF1, despite the absence of hypermethylation of the CpG island [142]. On the other hand, silencing of SIRT1, a histone deacetylase, leads to increased H3 and H4 acetylation of cancer genes that become reactivated despite full retention of DNA hypermethylation [143].

16.8 Interaction Between Genetic and Epigenetic Changes in Cancer Development

After decades of cancer research, it is now widely accepted that genetic and epigenetic mechanisms closely interact in carcinogenesis [144]. This interplay between genetic and epigenetic changes can be clearly observed in the case of tumor-suppressor gene inactivation, which can be caused by genetic (mutation, deletion) or epigenetic (DNA hypermethylation) means. For instance, the *VHL* gene is mutated in 60 % of the renal carcinomas and hypermethylated in 20 % of the remaining cases [145]. In the case of the *E-cadherin* gene, mutations and methylation are mutually exclusive in breast cancer [146]. Besides, genetic alterations (e.g., translocations and amplifications) targeting genes directly involved in the regulation of DNA methylation or histone

modification processes (e.g., *HDAC2*, *MML*, *MOZ*, *MORF*, *NSD*, and *GASC1*) are frequent in cancer [3]. Some genes of the polycomb repressor complex like *BMI1*, *EZH2*, and *SUZ12* are also targets of chromosomal changes [147, 148]. Interestingly, transgenic mice overexpressing the polycomb member Bmi1 develop lymphomas, and this process of lymphomagenesis is accelerated in double transgenic mice overexpressing Bmi1 and Myc, the latter is frequently translocated in lymphomas [149, 150]. The close interaction between genetic and epigenetic changes is also supported by the discovery of epigenetic changes that affect the stability of the genome. For instance, hypomethylation of DNA repeats leads to chromosomal changes by inducing chromosomal instability. Also, genes targeted by DNA hypermethylation are involved in DNA repair pathways like *BRCA1*, *hMLH1*, *MGMT*, and *WRN* [82]. In these cases, silencing of the DNA-repair gene blocks the repair of genetic mistakes, thereby opening the way to neoplastic transformation of the cell. Overall, these data show that (1) genetic and epigenetic changes represent alternative mechanisms targeting the same genes in cancer, (2) genetic changes of epigenetic genes can lead to epigenetic modifications (and vice versa), and (3) epigenetic changes of DNA repair genes can lead to genetic alterations.

16.9 The Origin of Cancer from a Genetic and Epigenetic Perspective

Two of the main issues in cancer research are (1) to discover the primary change triggering tumorigenesis and (2) to identify the type of cell that acquires such a change and clonally expands to give rise to an overt cancer.

With regard to the primary change, several lines of experimental evidence support the feasibility of an epigenetic origin of cancer [121]. For instance, epigenetic changes affecting genes known to be hypermethylated in cancer (e.g., *CDKN2A/p16*, *SFRP1/2/5*, *GATA4/5*, and *HIC1*) [10, 151, 152] can be observed in pre-neoplastic tissues, and in the case of *CDKN2A/p16*, its germline loss in transgenic mouse models increases the stem cell life span. Additionally, loss of imprinting by aberrant DNA methylation of the *IGF2* gene in Beckwith-Wiedemann syndrome is associated with cancer risk and expansion of progenitor cells [121].

There are also data clearly supporting a genetic origin of cancer. A strong argument for this hypothesis is that transgenic mice bearing chromosomal translocations and gene mutations develop cancer [153, 154]. Also, the existence of familial predisposition to cancer linked to the presence of inherited mutations provides strong evidence for a genetic origin of cancer [155].

With regard to the cell of origin, recent data on dysregulation of the polycomb system might indicate a relationship between cancer and stem cells. In stem cells, the polycomb group is involved in repressing genes involved in cell differentiation so these cells maintain their pluripotent state [148]. EZH2, a member of the polycomb group, is able to recruit DNMTs and direct DNA methylation towards specific genes [38]. Most interestingly, it was recently discovered that genes hypermethylated in cancer are indeed repressed in stem cells by proteins of the polycomb group, which strengthens the link between cancer, stem cells, and DNA methylation [117–120]. This finding strongly supports the concept that the initial cell acquiring epigenetic changes should have a kind of stem cell features [113, 121]. Further support for a stem cell involvement in the origin of cancer is that stem cells are more susceptible to genetic changes than differentiated cells [156].

The arguments shown above obviously indicate that genetic and epigenetic alterations collaborate in early stages of tumorigenesis and that cancer cells might originate from cells with stem-cell features (Fig. 16.2). In spite of all these findings, the order of the temporal occurrence of genetic or epigenetic changes is currently unknown. The available experimental data can support several possible temporal relationships, depending upon context. Interdisciplinary studies analyzing genetic, epigenetic, and transcriptional features in the same cancer biopsies and experimental models are required to shed light into the interaction between genetic and epigenetic factors in cancer.

16.10 Epigenetic Changes in the Clinical Management of Cancer Patients

The detection of epigenetic changes in cancer not only helps us to understand cancer biology but also have applications in the clinical management of patients. DNA hypermethylation markers can potentially be used as diagnostic tools, prognostic factors, and predictors of responses to treatment. For instance, the glutathione S-transferase gene (*GSTP1*) is de novo methylated in 80–90 % of patients with prostate cancer [157–159]. Thus, the detection of *GSTP1* methylation could help to distinguish between prostate cancer and a benign process. Analysis of CpG island hypermethylation has potential diagnostic applicability for carriers of high-penetrance mutations in tumor suppressor genes. For example, identification of DNA hypermethylation in a breast-biopsy specimen from a carrier of a *BRCA1* mutation could be useful when the pathological diagnosis is uncertain [85]. Analysis of several hypermethylated genes detects twice as many cancer cells in breast ductal fluids as conventional cytologic analysis [160], and hypermethylated genes can be found in exfoliated cells at different stages in the development of cervical cancer [161]. Aberrant DNA methylation of some genes is also associated with clinical outcome in patients with cancer. For instance hypermethylation of the death-associated protein

kinase (*DAPK*), *p16INK4a,* and epithelial membrane protein 3 (*EMP3*) has been linked to poor outcomes in lung, colorectal, and brain cancer, respectively [3]. Additionally, DNA methylation profiling by microarrays has also identified differential methylation patterns associated with prognosis in ovarian cancer [162] and breast cancer [163].

Hypermethylation of particular genes is potentially a predictor of the response to treatment. A classic example is the methylation-associated silencing of *MGMT*, coding for a DNA-repair protein, in gliomas [164]. MGMT reverses the addition of alkyl groups to the guanine base of DNA and is thus a point of attack for alkylating agents [165]. Two studies have shown that the hypermethylation of *MGMT* is an independent predictor of a favorable response of gliomas to carmustine (BCNU) [166] or temozolomide [167]. These findings have been confirmed by others [168]. Moreover, the hypermethylation of *MGMT* in untreated patients with low-grade astrocytoma and other cancer types is a marker of a poor prognosis [169], and it is probably related to the accumulation of mutations in these cancers [170]. The potential of the methylation status of *MGMT* and other DNA-repair genes to predict the response to chemotherapy has also been observed with cyclophosphamide (with the *MGMT* gene) [171], cisplatin (with the *hMLH1* gene) [172], methotrexate (with the reduced folate carrier gene *RFC*) [173], and irinotecan (with the *WRN* gene) [174].

16.11 Epigenetic Therapies of Cancer

One of the major promises of epigenetic changes in cancer is that, in contrast to genetic mutations, DNA methylation and histone modifications are reversible [10]. The fact that de novo DNA methylation is so prevalent in cancer has led to the development of novel therapeutic approaches aimed at reversing DNA methylation-induced gene silencing [175–177]. It is possible to re-express genes silenced by DNA methylation in cancer cell lines by using demethylating agents, like inhibitors of DNMTs, and to rescue their functionality [3, 178]. DNA-demethylating drugs in low doses have clinical activity against some tumors. Two such agents, 5-azacytidine (Vidaza) and 5-aza-2′-deoxycytidine (Decitabine), have been approved as treatments for myelodysplastic syndromes and acute myeloid leukemias [177, 179]. However, these demethylating agents have not yet been shown to have clinical activity against solid cancers [180]. Histone deacetylase (HDAC) inhibitors can induce differentiation, cell cycle arrest, and apoptosis in vitro [181], although it has not been possible to pinpoint a specific mechanism that explains these effects. In clinical trials, HDAC inhibitors are associated with a low incidence of adverse events [180]. The first drug of this type, suberoylanilide hydroxamic acid (Vorinostat), has been approved by the Food and Drug Administration for the treatment of cutaneous T-cell lymphoma [182]. The efficacy of HDAC inhibitors in the treatment of other cancers is limited. The nonspecific effects of DNA-demethylating agents and HDAC inhibitors could have unintended consequences with regard to gene expression, and as a paradoxical result, they could have growth-promoting effects on a cancer by DNA hypomethylation-associated chromosomal instability. Interestingly, directed epigenetic-specific therapy using transcription factors that target particular gene promoters is under development [183]. For instance, the engineered zinc finger proteins target unique sequences in the *MASPIN* promoter; these proteins not only reactivate the epigenetically silenced gene but also inhibit tumor growth in vitro [184]. Until now, therapy with DNA-demethylating agents and HDAC inhibitors has been based on classic protein-coding tumor-suppressor genes, but the possibility of rescuing the growth-inhibitory effects of miRNAs by means of DNA-demethylation treatment [129, 130] suggests new epigenetic treatment strategies that are worthy of further exploration.

MicroRNAs and Cancer

17

Phong Trang, Joanne B. Weidhaas, and Frank J. Slack

17.1 Introduction

17.1.1 miRNAs Represent a Paradigm Shift in Our Understanding of Gene Expression

MicroRNAs are small noncoding RNAs, belonging to a novel class of regulatory molecules found in plants and animals that control gene expression by binding to complementary sites on target messenger RNA (mRNA) transcripts. Individual miRNAs are generated from large RNA precursors (termed pri-miRNAs) that are processed in the nucleus by the RNase III enzyme, Drosha, into ~70 nucleotide pre-miRNAs, which fold into imperfect stem-loop structures [1]. The pre-miRNAs undergo an additional processing step within the cytoplasm and mature miRNAs of 18–25 nucleotides in length are excised from one side of the pre-miRNA hairpin by another RNase III enzyme, Dicer [2, 3].

MicroRNAs have been shown to regulate gene expression in two ways. First, miRNAs that bind to protein-coding mRNA sequences that are exactly complementary to the miRNA induce the RNA-mediated interference (RNAi) pathway. Messenger RNA targets are then cleaved by ribonucleases in the RNA-induced silencing complex (RISC). This mechanism of miRNA-mediated gene silencing has been observed mainly in plants [4, 5], but an example is known from animals [6]. In the second mechanism, work from our laboratory and others has shown that miRNAs exert their effect by binding to imperfect complementary sites within the 3′-untranslated regions (3′UTRs) of their target protein-coding mRNAs, and repress the expression of these genes at the level of translation [7–13]. miRNAs identified in both plants and animals use this mechanism to exert translational control of their gene targets [14].

17.1.2 The First miRNAs Identified, lin-4 and let-7, Control Timing of Cell Differentiation

The founding members of the miRNA family, *lineage defective-4 (lin-4)* and *lethal-7* (*let-7)* [10], were identified in the nematode, *C. elegans* [10, 11], where they are members of the heterochronic pathway of genes regulating developmental timing. *C. elegans* growth and development is divided into three major stages called embryo, larva, and adult. Larval growth is subdivided into four larval stages (L1, L2, L3, and L4). Each larval stage ends in a molt and ultimately the animal matures into an adult. Mutations in the *lin-4* and *let-7* miRNAs result in inappropriate reiterations of the first larval stage (L1) and the fourth larval stage (L4) fates, respectively, and these defects lead to disruptions in cell cycle exit [10, 11]. For example, in wild-type animals, specialized skin cells, known as seam cells, divide with a stem cell pattern and terminally differentiate at the beginning of the adult stage. The seam cells fail to terminally differentiate in *lin-4* and *let-7* mutant animals, and instead reiterate the larval fate and continue to divide, a hallmark of cancer.

The expression patterns for *lin-4* and *let-7* correlate with their role in directing developmental timing. *lin-4* RNA accumulates during the L1 stage and is responsible for the

L1/L2 transition in nematodes by inhibiting the expression of *lin-14* and *lin-28,* repressors of post-L1 fates [11, 12, 15–17]. Likewise, *let-7* RNA accumulates during the L4 stage and is responsible for the L4/Adult transition by downregulating the expression of *lin-41*, *hbl-1*, and *RAS* [8, 9, 18, 19] through binding complementary sites in the 3′UTR.

17.1.3 miRNAs Are Abundant Throughout Animal Genomes

Hundreds of other miRNAs have recently been identified in the fly, worm, plant, and mammalian genomes. Because almost all of these were found through cloning and bioinformatic approaches [20–27] the biological role for the majority of miRNAs remains unknown, although those with known roles are all important regulatory molecules in a variety of developmental and metabolic processes. It is likely that the uncharacterized miRNAs also act as important gene regulators during development to coordinate proper organ formation, embryonic patterning, and body growth.

Our lab and others have found that *lin-4* and *let-7* miRNAs are evolutionarily conserved in higher animals, including humans and are also temporally expressed [28], indicating a universal role for these miRNAs during animal development [21, 29]. There are three exact copies of the mature *let-7* sequence in the human genome (referred to *as let-7a1, let-7a2, let-7a3*) under control of separate promoters and a variety of close homologues that differ from *let-7* at certain nucleotide positions (e.g., *let-7c*). The nematode, fly, and human *let-7* genes are processed from a precursor form (pre-*let-7*) that is predicted to form a stem-loop structure, which is also conserved.

17.1.4 miRNA Biogenesis and Cancer

Studies have shown that the miRNA and RNAi pathways may intersect [2, 3]. miRNAs copurify with components of the RNAi effector complex, RISC, suggesting a link between miRNAs and siRNAs involved in RNAi [30–32]. There is also an indication that some protein factors may play a role in both the miRNA ribonucleoprotein (miRNP) and RISC and that genes encoding these proteins are linked to cancer. For example, the Argonaute protein-coding genes *hAgo3, hAgo1,* and *hAgo4* reside in region 1p34–35, often lost in Wilms tumors, and *Hiwi* an additional Argonaut gene is located on chromosome 12q24.33, which has been linked to the development of testicular germ cell tumors [33]. In addition, *DICER*, the enzyme which processes miRNAs and siRNAs, is poorly expressed in lung cancers [34]. Expression levels of *DICER* and *DROSHA* in 67 non-small-cell lung cancer (NSCLC) samples were examined in the study and reduced expression of DICER was found to correlate with shortened postoperative survival. Kumar et al. [35] substantiated the indication that DICER might be able to prevent the transformation of lung tissue in a later work. This study showed that mouse lung cancer cells expressing short hairpin RNAs (shRNAs) targeting DICER had a decrease in the global miRNA levels and a more pronounced transformed phenotype [35]. Furthermore, deletion of DICER enhanced tumor development in both a xenograft model and a K-Ras-induced mouse model of lung cancer [35, 36].

17.2 miRNAs as Oncogenes and Tumor Suppressors

17.2.1 Evidence for the Role of miRNAs in Cancers

Recent studies from different laboratories have shown roles for the miRNAs themselves in human cancer (Table 17.1) [37]. The human miRNAs, *mir-15* and *mir-16*, are preferentially deleted or downregulated in patients with a common form of adult leukemia, B-cell chronic lymphocytic leukemia [38]. This observation suggests that miRNAs may function as tumor suppressor genes.

For years researchers were perplexed as to how the BIC RNA could consistently produce lymphomas and induce the overexpression of the MYC oncogene [39]. After analyzing the phylogenetically conserved region in BIC, Metzler et al. found that a high homology region in fact codes for the pri-miRNA of miR-155 [40]. Further studies by this group showed that miR-155 expression is upregulated 100-fold in pediatric Burkitt lymphoma, in addition to Hodgkin's lymphoma and primary mediastinal and certain subsets of large B-cell lymphoma [41, 42]. The etiological role of miR-155 in lymphoma development was further established by Costinean et al. from their work with transgenic mice carrying a miR-155 transgene with B-cell targeted expression [43]. The transgenic mice from this experiment developed preleukemic pre-B-cell proliferation at as early as 3 weeks of age and developed high-grade B-cell malignancies at 6 months of age. However, the oncogenic role of miR-155 is not limited to B-cell lymphoma as other studies have reported its upregulation in breast, lung, colon, and thyroid cancers [44, 45].

Another potentially oncogenic cluster of miRNAs is the polycistron miR-17-92, containing seven miRNAs: miR-17-5p, miR-17-3p, miR18a, miR-19a, miR-19b-1, and miR-92-1. This cluster was found to be overexpressed in samples of many kinds of lymphoma samples compared with normal tissues [46]. Using a mouse B-cell lymphoma model, He et al. found that the miR-17-92 cluster in conjunction with

Table 17.1 MiRNA expression and signature for various cancers

Tumor type	miRNAs	Comments	Reference(s)
Brain, GBM	miR-21, miR-221, miR-222, (up)	miR-21 upregulated in all high-grade tumors	[45, 47]
Breast cancer	miR-21, miR-155b (up) miR-125b, miR-145 (down)	Expression levels correlate with biopathological features and proliferation index	[59]
Cervical cancer	miR-21 (up) miR-143 (down)		[103]
Cholangiocarcinoma	miR-21, miR-141, miR-200b (up)		[103]
Chronic lymphocytic leukemia (CLL)	miR-15a, miR-16-1 (down) miR-29a-2, miR-29b-2, miR-29c (down)	Downregulated in 68 % of CLL patients	[59]
Colorectal cancer	miR-143, miR-145, miR133b (down) miR-31, miR-135b, miR-96, miR-183 (up)	miR-31 expression level correlates with cancer stage	[68]
Hepatocellular cancer	miR-18, miR-224 (up) miR-199a, miR-195, miR-200a, miR-125a, miR-122 (down)	Higher miR-18 expression level is inversely correlated with tumor differentiation	[104]
Lung, NSCLC	*let-7 (down)* *miR-21, miR-155 (up)*	Low *let-7* and high miR-155 expression levels correlate with poor survival	[18, 51, 52]
Lymphoma (B cells)	miR-155 (up)		[38, 39]
Pancreatic cancer	miR-21, miR-107 (up) miR-155, miR-103 (down)	Overexpression of miR-21 correlates with high proliferation index	[71]
Prostate cancer	let-7, miR-125b, miR-143, miR-145 (down)	Profile can separate between androgen positive versus androgen negative tumor	[72]
Testis, germ cell tumors	miR-372, miR-373 (up)		[105]
Thyroid, papillary ca (PTC)	miR-221, miR-222, miR-146b (up)		[41]
Thyroid, anaplastic ca (ATC)	miR-125b, miR-26a (down)	miRNA profile can separate ATC from normal and (PTC)	[67]

MYC accelerated tumor development [46]. At the same time, O'Donnell et al. independently identified the mir-17-92 cluster as a group of potentially cancer-related genes [47]. The group found that MYC activates the expression of this cluster and two miRNAs in this cluster, miR-17-5p and miR-20a, act to downregulate the transcription factor E2F1, which is also a MYC transcriptional target, promoting cell cycle progression. This feedback cycle allows MYC to control the accumulation of E2F1 and drive the cell toward proliferation, since E2F1 is known to sensitize cells to apoptosis at high concentrations.

Various studies reported that miRNAs are also aberrantly expressed in brain tumors. During the analysis of a global expression level of 245 miRNAs in glioblastoma multiforme (GBM), Ciafre et al. observed that miR-221 was highly upregulated [48]. In recent work, Gillies et al. reported that miR-221 and miR-222 directly target $p27^{Kip1}$, a key negative regulator of the cell cycle, in glioblastoma [49]. In another study, Chan et al. also observed that miR-21 was strongly overexpressed (5-fold to 100-fold) in highly malignant glioblastoma tumor tissues [50]. The investigators also found that knockdown of miR-21 in cultured glioblastoma cells activated caspases and resulted in more cell death by an apoptotic pathway. In a comprehensive analysis of miRNA expression signature of human solid tumors, Volinia et al. found that overexpression of miR-21 is shared by all six solid tumors studied, including breast, colon, lung, pancreas, prostate, and stomach [45]. This finding suggests that miR-21 plays an important regulatory role in a pathway shared by all of these cancer types. Despite the evidence that mutant miRNAs cause cancer, little is known about the mechanism of these miRNAs and how they affect cancer progression.

17.2.2 let-7 Regulates and Suppresses Activated RAS in *C. elegans*

Our lab recently showed that *let-7* regulates *let-60*, the *C. elegans RAS* oncogene homologue [18, 19]. *let-60/RAS* is best understood for its role in *C. elegans* vulval development [51]. During vulval development, a LIN-3/EGF signal from the anchor cell is received by the LET-23/EGFR receptor on

the vulval precursor cells (VPCs), P5.p, P6.p, and P7.p. The P6.p cell receives the most LIN-3 and activates a *RAS*/MAPK signal transduction pathway to adopt the primary induced (1°) fate. P5.p and P7.p receive less LIN-3 and also receive a second, lateral signal (involving LIN-12/Notch) from the 1° cell that induces them to the 2° fate. *let-60/RAS* contains multiple *let-7* complementary sites in its 3′UTR, and *let-60(lf)* suppresses *let-7* mutants. We found that the *let-60/RAS* 3′UTR is sufficient to restrict *let-60/RAS* expression only to the P6.p. In a normal animal, a *let-7* family member, *mir-84*, is expressed in all the VPCs except the primary induced cell, and represses *let-60/ras* expression in these cells. In *C. elegans* animals carrying activating *let-60/RAS* mutations more than one VPC is induced to differentiate into the 1° cell fate, leading to excess vulvae (thought of as vulval tumors), called a multivulva phenotype (Muv). We found that overexpression of *mir-84* suppressed the Muv phenotype of activating mutations in *let-60/RAS*.

17.2.3 let-7 Negatively Regulates Human RAS and Other Oncogenes

Many activating mutations in the human *NRAS, KRAS,* and *HRAS* genes alter the same amino acid affected by the *C. elegans let-60/RAS* activating mutation. Since *C. elegans RAS* is a target of *let-7*, and both human *RAS* [36, 52, 53] and *let-7* [18, 54] are implicated in lung cancer, our laboratory tested the hypothesis that human *RAS* is also a target of *let-7*. Our results show that all three *RAS* oncogenes have *let-7* complementary sites in their 3′UTRs and that *let-7* can reduce their expression in a 3′UTR-dependent manner [18] in vitro. We next evaluated the relationship between *let-7* and *RAS* in lung tumors and found that *let-7* was consistently downregulated in lung cancers relative to normal adjacent tissue (NAT), mirroring a recently published report about *let-7* [54]. We also found that in lung cancer tissue, where *let-7* levels are low, *RAS* protein levels are elevated relative to the NAT. Supporting the significance of our findings, a correlation was found where lung cancer patients with the least *let-7* expression were most likely to die from lung cancer [54, 55]. A similar correlation was seen when just the lung adenocarcinoma patients were followed [54].

let-7 has also been recently reported to be involved in the regulation of two other oncogenes, MYC and HMGA2. Sampson et al. showed that overexpression of pre-*let-7*a in a Burkitt lymphoma cell line led to downregulation of MYC expression and reverted MYC-induced growth in this cell line [56]. Interestingly, *let-7*a overexpression not only resulted in a decrease in MYC protein (75 %), but also its mRNA level (70 %), suggesting that *let-7*-mediated repression of MYC may act through the mRNA degradation pathway and not the translational inhibition pathway.

HMGA2 encodes a small, nonhistone chromatin-associated protein that plays a critical role in growth during embryonic development by altering chromatin architecture [57]. It is normally expressed at low levels in adult, but disruption of the gene by chromosomal translocation at 12q15 results in benign and malignant transformation in various tissues [58]. Several groups reported that this chromosomal translocation event removes the 3′UTR of HMG2A and results in the deletion of miRNA-binding sites [59–61]. Mayr et al. [59] and Lee et al. [60] showed that the HMG2A 3′UTR contains seven predicted conserved *let-7* binding sites, and a luciferase reporter assay using this 3′UTR confers repression by *let-7*. The two groups also demonstrated that overexpression of *let-7* inhibited proliferation in H1299 lung cancer cells and disruption of the pairing between *let-7* and HMGA2 led to enhanced tumor formation in a mouse xenograft model [59, 60].

These findings support the role of *let-7* as a tumor suppressor. It has been hypothesized that similar to its role in *C. elegans*, *let-7* functions during late stage embryonic development to maintain differentiated states by suppressing expression of embryonic genes (such as HMGA2) that are expressed in de-differentiated tissues [61]. When *let-7* repression is lost, embryonic genes are upregulated and trigger neoplastic transformation with characteristic of embryonic cells. Taken together, these studies suggest that *let-7* replacement may be a potentially useful cancer treatment, especially in lung cancer.

17.2.4 Mir-34 and the p53 Network

The *mir-34* family is an evolutionary conserved miRNA family first identified in *C. elegans*. It is located at a fragile site region at 1p36 and has been found to be frequently deleted in various cancers including breast and lung cancer [62]. Recently, numerous independent reports showed that miR-34 is a part of the p53 network and is a direct transcriptional target of p53 [63–67]. miR-34 is directly induced by p53 in response to DNA damage and oncogenic stress. miR-34 by itself has been shown to mimic p53 action to a certain extent, as evident by its anti-proliferation and apoptosis-inducing properties when overexpressed in primary fibroblast and some tumor cell lines [63, 65]. Microarray analysis showed that the induction of the miR-34 family led to the downregulation of hundreds of mRNAs. Some validated targets of miR-34 include CDK4, CDK6, cyclin E2, and E2F3. This was the first time that a miRNA was found to be an integral part of an established oncogene and tumor suppressor network, and suggests that there are other miRNAs belonging to these networks as well. These findings could partially explain why alterations affecting miRNAs are so prevalent in cancers.

17.3 miRNA Profiling: Diagnostics, Classification, Prognosis, and Treatment

miRNA expression profiling studies using microarray and other methods can differentiate normal from cancer tissues via a unique miRNA signature. These differences can classify different cancer types and cancer grades. Certain miRNA signatures are correlated with prognosis and could potentially be used someday to determine the specific course of treatment [44, 54, 55, 68–70].

Using a novel bead-based miRNA microarray assay, Lu et al. examined the expression profile of 217 miRNAs in a panel of 334 samples that included primary tumors, tumor-derived cell lines, and normal tissues [68]. The investigators found that miRNA profile can discern between normal and cancer tissues, separate different cancer types, stratify cancer differentiation state, and cluster sample groups according to their embryonic lineage. Moreover, miRNA profiles were more accurate than mRNA profiles in classifying cancer types and were able to categorize 17 poorly differentiated tumors of cancers of unknown primaries where histological appearance was not diagnostic, into their specific tissue lineages.

Studying colorectal cancer, Michael et al. were the first to recognize aberrant miRNA expression in solid tumors as the investigators identified 28 different miRNAs in colonic adenocarcinoma and normal mucosa, and found that miR-143 and miR145 were consistently downregulated in colon cancer [71].

Analyzing the miRNA expression in 104 pairs of primary lung cancers and corresponding noncancerous tissues, Yanaihara et al. found that a set of 43 unique miRNAs were able to discriminate normal from tumor tissues [55]. Among the miRNAs from the signature, high miR-155 and low *let-7*a-2 expression independently correlated with poor survival for adenocarcinoma patients. In a comparable study, Takamizawa et al. [54] found that *let-7* miRNA expression can classify 143 postoperative lung cancer patients into two prognosticator groups. Those with low levels of *let-7*a had significantly shorter survival after surgery [54].

In breast cancer, the first miRNA profiling study showed that a set of 15 miRNAs correctly predicted normal versus cancer tissues with 100 % accuracy, with the most significantly deregulated miRNAs being miR-125a, miR-125b, miR-145, miR-21, and miR-155 [72]. miR-21 and miR-155 were upregulated and the others were downregulated. miR-125a and miR-125b regulate the expression of the receptor tyrosine kinases ERBB2 and ERBB3 and their overexpression in SK-BR3 cells induced impaired anchorage-dependent growth and reduced invasion capacities [73]. Furthermore, miRNA expression was correlated with specific breast cancer pathological features, such as estrogen and progesterone receptor expression, tumor stage, and vascular invasion.

Papillary thyroid carcinoma (PTC) is the most common malignancy in thyroid tissue. Profiling of PTC by He et al. yielded a signature of five miRNAs (which included miR-221, miR222, and miR-146) that could separate PTC and normal thyroid tissue [44]. The investigators found that upregulation of miR-221, miR-222, and miR-146 corresponded to a dramatic decrease in KIT mRNA and protein levels. This suggests that these three miRNAs negatively regulate KIT and may contribute to PTC. Interestingly, in a separate study, Visone et al. [70] showed that another type of thyroid cancer, thyroid anaplastic carcinomas (ATC), has a completely different miRNA signature from PTC that clearly differentiates ATC from normal tissues and from PTC.

In the case of pancreas and prostate cancers, researches have also shown the presence of miRNA signatures that differentiate these cancers from normal tissues. Bloomton et al. showed that a signature of 21 upregulated and 4 downregulated miRNAs correctly differentiated pancreatic cancer from benign pancreatic tissue in 90 % of samples [74]. In the profile, two commonly malignancy-associated miRNAs, miR-21 and miR-155, were uniquely overexpressed in pancreatic cancer versus normal pancreas. Additionally, a subgroup of 6 miRNAs was able to predict long-term survival, in contrast to one, miR-196a-2, which predicted for poor survival. In the profiling of prostate cancer, Porkka et al. [75] found that there was differential expression of 51 individual miRNAs between benign prostatic hyperplasia (BPH) and prostrate carcinoma—37 miRNAs showed downregulation and 14 were upregulated in carcinoma samples [75]. Among the downregulated miRNAs are some familiar ones, including *let-7*a, miR-125b, miR-143, and miR-145. Furthermore, the miRNA expression patterns could classify the tumors according to their androgen dependence (hormone naïve versus hormone refractory). This finding indicates that miRNAs could be useful in diagnosis and perhaps in subsequent treatment decisions.

miRNA profiling is a powerful method that cannot only classify normal and cancer tissues, but also can discern between different cancer subtypes. It could potentially become an important tool for the pathologist with difficult cases such as poorly differentiated metastatic cancers of unknown primary.

17.4 The Cause of Aberrant miRNA Expression in Cancer

17.4.1 miRNAs at Chromosomal Fragile Sites

Several studies have evaluated the cause of altered expression of miRNAs in cancer. In one study, Calin et al. [62] identified the location of 186 miRNAs and compared this to the location of previously reported nonrandom genetic

alterations in cancer. The investigators found that overall, 98 of 186 (52.5 %) of miRNA genes are in cancer-associated chromosomal fragile sites, such as minimal regions of loss of heterozygosity, minimal regions of amplification, and common breakpoint regions. One example is miR-15a and miR-16-1 which are often deleted or downregulated in chronic lymphocytic leukemia (CLL) and are located within the intron of a noncoding RNA gene of unknown function, called deleted in lymphocytic leukemia 2 (DLEU2). Deletion of this 30 kb region within the 13q14 chromosomal locus is seen in more than 65 % of CLL cases, in 50 % of mantle cell lymphomas, 16–40 % of multiple myelomas, and 60 % of prostate cancers. The implication that miR-15a and miR-16-1 function as a tumor suppressor in CLL is further supported by Cimmino et al. [76] showing that these two miRNAs negatively regulate BCL2, an antiapoptotic gene that was reported to be overexpressed in many types of human cancers, including leukemias, lymphomas, and carcinomas. Additionally, *let-7g*, a miRNA that is often downregulated in lung cancer, maps to 3p21, a well-known region deleted early in the progression of lung cancer [77].

To examine the relationship between miRNA DNA copy number abnormalities and cancer, Zhang et al. employed a high-resolution array-based comparative genomic hybridization assay to study 283 known human miRNA genes in 227 human ovarian cancer, breast cancer, and melanoma specimens [78]. The results show that a significant number of genomic loci containing miRNA genes exhibit DNA copy number alterations in ovarian cancer (37.1 %), breast cancer (72.8 %), and melanoma (85.9 %). A total of 41 miRNA genes with gene copy number changes were shared among the three cancer types (26 with gains and 15 with losses). The same study also found high frequency copy number abnormalities of Dicer1, Argonaute2, and other miRNA associated genes in all three cancer types [78]. Findings from these studies support the notion that genetic instability resulting in copy number alterations of miRNAs and their regulatory genes is highly prevalent in cancer and could partially explain miRNA aberrant expression in cancer.

17.4.2 Epigenetic Regulation of miRNAs

It is well known that epigenetic control of gene expression by DNA methylation and covalent histone modification play an important role in tumorigenesis, as tumor cells can acquire epigenetic abnormalities that result in altered patterns of gene expression from normal cells [79]. miRNAs have been hypothesized to be susceptible to epigenetic control as one study showed that 155 out of 332 human miRNA genes analyzed were associated with CpG islands, which are targets of the DNA methylation machinery. Furthermore, the methylation frequency of miRNA genes seemed to be at least an order of magnitude higher than the methylation frequency of protein-coding genes [80]. Several recent studies have confirmed that this mechanism exists to regulate miRNA expression in various cancers.

Using miRNA array analysis, Scott et al. profiled miRNA levels in response to the histone deacetylase inhibitor (HDACi) LAQ824 in the breast cancer cell line SKBr3. After 5 h of exposure, significant changes were observed in 40 % of the >60 different miRNA species expressed in SKBr3 cells with 22 miRNA species downregulated and 5 miRNAs upregulated [81]. Additional antisense experiments targeting a downregulated miRNA, miR-27, showed that one of its potential targets is the proapoptotic protein RYBP [81].

In one of the first studies to clearly demonstrate epigenetic alterations of miRNA expression in human cancer cells, Saito et al. analyzed miRNA expression in T24 human bladder cancer cells and normal fibroblasts after treatment with the DNA-demethylating agent 5-aza-2′-deoxycytidine (DAC) and an HDAC inhibitor 4-phenylbutyric acid (PBA) [82]. Expression profiling revealed that 17 out of 313 human miRNAs studied showed more than threefold upregulation, with miR-127 showing the biggest change at a 49-fold increase [82]. MiR-127 is constitutively expressed in normal human fibroblasts and tissues as part of a miRNA cluster, but is downregulated or silenced in bladder, breast, cervix, pancreas, lung, and colon cancer cell lines, and prostate, bladder, and colon primary cancer tissues. miR-127 was found to be hypermethylated in both normal and cancer cells, and treatment with PBA and DAC led to specific induction of mir-127 within the cluster, with more pronounced upregulation of the miRNA observed in TP24 cancer cells. The investigators furthermore demonstrated that the proto-oncogene BCL6 is one of the targets of miR-127, as epigenetic reactivation of miR-127 resulted in a corresponding downregulation of the BCL6 protein level [82]. These results suggest that miR-127 may function as a tumor suppressor and that its epigenetic regulated gene expression is altered in various cancers.

In another study, Lujambio et al. showed that miR-124a is another potential tumor suppressor miRNA that is susceptible to altered epigenetic regulation in cancers [83]. In this study, miRNA expression profiling of the wild-type colon cancer cell line HCT-116 and a genetically engineered double knockout of DNA methyltransferase 1 (DNMT1) and DNMT3b HCT-116 cell line (DKO) showed 18 out of 320 miRNAs were upregulated more than threefold in DKO cell line. Of these miRNAs, miR-124a was analyzed further and found to be embedded in CpG islands, but was unmethylated in normal colon tissues. In contrast this miRNA is inactivated by promoter hypermethylated in various human cancer cells and tissues, including colon, breast, lung, leukemias, and lymphomas. Epigenetic silencing of miR-124a resulted in the upregulation of its target, CDK6, an oncogenic factor that targets the Rb (retinoblastoma) tumor suppressor protein

for phosphorylation and inactivation [83]. These studies confirm epigenetic regulation of miRNAs as another mechanism for control of miRNA gene expression and deregulation of this process could play a role in the etiology of cancer as a result of altered miRNA and cellular gene expression. This also presents an opportunity for therapeutic intervention, and indeed HDAC inhibitors are currently emerging as a promising class of anticancer drugs [84–86].

17.4.3 Single-Nucleotide Polymorphism of miRNAs

Base pairing between the mature miRNA and its target mRNA 3′ UTR is known to be highly conserved. Using genome-wide analysis to discover single-nucleotide polymorphisms (SNPs) located in the miRNA-binding sites of the 3′ UTR of various human genes, two studies concluded that miRNA-binding site SNPs are negatively selected in predicted conserved miRNA-binding seed sequences compared to other conserved motifs and the entire 3′ UTR [87, 88]. However, natural genetic variants do exist in the population and can predispose certain carrier groups to disease, as one study found 79 different SNPs within putative miRNA-binding sites present in the 3′ UTR of 129 genes involved in pathways commonly acknowledged as important in cancer [89]. In another example, when comparing the dbSNP database against human cancer specimens, Yu et al. found that 12 miRNA-binding site SNPs display an aberrant allele frequency in human cancers [88].

SNPs within the miRNA coding regions or within miRNAs binding sites are likely to be deleterious and can have an impact on an individual's risk to develop diseases such as cancer. In one of the first studies to illustrate this, He et al. observed that in 5 out of 10 thyroid cancer cases analyzed, where upregulation of miR-221, miR-222, and miR-146 was highest, there was a corresponding loss of KIT transcript and Kit protein in addition to germline SNPs in the two 3′UTR binding sites in KIT for these miRNAs [44]. Due to high familial incidence, these SNPs are hypothesized to predispose this group of carrier to thyroid cancer.

17.5 Therapeutic Applications of miRNAs

17.5.1 Strategies for miRNAs Inhibition

With miRNAs emerging as important oncogenic and tumor suppressive genes, therapy to inactivate or supplement specific miRNAs is a strategy to perhaps inhibit tumor progression [54, 76, 90]. Since pri-miRNAs, pre-miRNAs, and mature miRNAs are long and short oligonucleotides, all these molecules can be targeted by the antisense technology. Many groups have shown that anti-miRNA oligonucleotides (AMOs) with or without 2′ sugar modification (including 2′-O-methyl, 2′-O-methoxyethyl, and 2′-fluoro) can be effective inhibitors of miRNAs in cell culture and animal models [50, 91–94]. Si et al. showed that anti-miR-21 oligonucleotides can suppress both cell growth in vitro and tumor growth in the xenograft mouse model with MCF-7 breast cancer cells [94]. Furthermore, this anti-miR-21-mediated cell growth inhibition was associated with increased apoptosis and decreased cell proliferation, which is hypothesized to be the result of downregulation of the antiapoptotic Bcl-2 genes.

Locked nucleic acid (LNA)-based oligonucleotides have been shown to be more stable and less toxic in inhibiting endogenous miRNAs in *Drosophila melanogaster* cells, leading to upregulation of the cognate target protein [95]. Modified AMOs that are conjugated with cholesterol termed antagomirs have been shown to be effective in targeting miRNAs in vivo and can discriminate between single-nucleotide mismatches of the targeted miRNA [96, 97]. When antagomir targeting the liver-specific miR-122 was delivered intravenously in mice, the AMO efficiently inhibited the mature miRNA in various organs and increased levels of miR-122 target mRNAs were observed in the liver [97]. Additionally, since miR-122 plays a role in cholesterol biosynthesis, reduced levels of plasma cholesterol were also observed in treated mice. Most impressively, a single injection of 240 mg/kg of body weight conferred silencing for up to 23 days. As an alternative to AMOs, Ebert et al. recently developed microRNA inhibitors called microRNA sponges [98]. These molecules are transcripts expressed from strong promoters, containing multiple, tandem binding sites to specific miRNAs and competitively inhibit them. One advantage of this system is that one could construct sponges with combination of seed binding sites to inhibit an entire miRNA family or a miRNA cluster [98].

17.5.2 Strategies for miRNA Replacement

Strategies to overexpress miRNAs that function as tumor suppressors, such as the *let-7* and miR-34 families, could be employed to treat specific cancer types. Similar to siRNAs, modified matured miRNAs could be delivered in vivo by liposome or cholesterol conjugation. Kim et al. showed that by using a cholesterol conjugated siRNA their group was able to effectively inhibit tumor growth in colon adenocarcinoma [99]. Alternatively, a gene therapy approach can be used for miRNA replacement therapeutics. This involves expressing the pre-miRNA hairpin and flanking sequences from a polymerase II or III promoter in a viral vector, which is then processed by the endogenous miRNA machinery for proper target gene repression. One concern with this strategy is that while abundant expression ensures effective target

knockdown, it can overwhelm the miRNA pathway to the detriment of the host [100]. Thus, tissue-specific and control on/off expression of miRNAs would be the most prudent approach.

The use of miRNA therapy to complement traditional anticancer treatments appears to have great potential as reported for the first time from two groups that miRNAs can enhance response and suppress resistance to anticancer cytotoxic therapies. Meng et al. reported the use of anti-miR-21 and anti-miR-200b AMOs to increase the susceptibility of cholangiocarcinoma cells to the chemotherapy drug gemcitabine [101]. Recent work from our own laboratory showed that increasing levels of the *let-7* family of miRNAs can radiosensitize A549 lung cancer cells and a *C. elegans* in vivo model of radiation-induced cell death, while decreasing *let-7* levels causes radioresistance [102]. Significantly, these two papers also showed that chemotherapy and radiation treatment alter miRNA expression, perhaps as a part of the cellular damage repair pathway. As resistance to cytotoxic therapy accounts for the majority of failed cancer treatments and recurrences, it would be interesting to profile the miRNA differences between resistant and sensitive populations of cells to identify miRNAs that are involved in the resistant mechanisms or pathways, which then can be used to re-sensitize tumors to available treatments.

17.6 Conclusion

miRNAs are emerging as major players in the etiology of cancer. Some are authentic oncogenes or tumor suppressors as they function in controlling cell differentiation and apoptosis directly, while others are part of the existing oncogenic pathways. Beyond this miRNAs appear to play a role in the response to cancer therapy. Elucidating their regulation and targets will enhance our understanding of cancer biology and provide us with new targets for cancer diagnosis and therapy.

Erionite and Asbestos in the Pathogenesis of Human Malignant Mesotheliomas

18

Mutlay Sayan and Brooke T. Mossman

18.1 Introduction

Epidemiologic and animal studies indicate that exposure to asbestos or erionite fibers can result in pulmonary and pleural fibrosis, lung cancer, and malignant mesotheliomas (MM), unique tumors associated predominantly with human exposures to these fibers [1]. Recent studies have shown that erionite also causes these diseases, especially MM in families in Cappadocia, Turkey who are genetically predisposed to mineral fiber carcinogenesis [2]. In these circumstances, residents are exposed to high levels of erionite due to its incorporation into their homes. Soils in these areas also have erionite contamination, another source of environmental exposures. In contrast, asbestos-induced diseases have been usually associated with occupational exposures to these fibers in the past workplace before regulation of exposure levels. However, para-occupational MMs also have been detected in family members of asbestos workers and in individuals living in asbestos mining communities. Understanding the critical chemical and physical properties of asbestos and erionite fibers, including how fibers interact with target cells of disease, and how these interactions contribute to the pathogenesis of fibroproliferative and malignant diseases are critical to designing preventive and therapeutic approaches in high-risk individuals. This review focuses on similarities and differences among asbestos and erionite fibers, their effects on the pathogenesis of MM, and key pathways in cell signaling that are linked to fiber toxicity, cell proliferation, inflammation, and other features of carcinogenesis.

18.2 Properties of Erionite and Asbestos

Erionite is a naturally occurring fibrous mineral belonging to a classification of minerals called zeolites that are often used industrially. [Note that a fiber is defined by most regulatory agencies as having ≥3:1 length-to-diameter ratio, whereas particles (<3:1 length-to-diameter ratio) can be spheroid, platy, or irregular in shape]. Zeolites usually occur in cavities in basic volcanic rocks and in other late stage hydrothermal environments such as those found in the Cappadocian region of Turkey and at other geological sites including parts of the western USA [3]. These minerals have a very large internal surface area resulting from the particular configuration of their crystalline lattice [4] and are able to exchange water molecules and cations without major changes to their structure. Most zeolites are non-fibrous. However, erionite is fibrous and occurs in needle-like bundles that resemble amphibole types of asbestos (Fig. 18.1) [5]. Fibrous morphology largely dictates their unique cancer-inducing properties.

Erionite has gas adsorption, ion exchange, and catalytic properties that are highly selective depending upon the molecular size of the adsorbed compounds [6]. The integral composition of erionite is made up of an interlocking tetrahedral of silicate aluminate which is negatively charged, allowing it to bind cations [7]. In addition, erionite adsorbs iron after inhalation and interacts with the respiratory epithelium. This adsorbed iron is associated with the toxicity of erionite [8].

Three types of erionite have been identified based upon differences in their levels of Ca, Na, and K (the predominant cations) and the amounts of Mg, Fe, Sr, and Ba in the structure. The general formula for the erionite-Ca type mineral is $(Ca_{3.56}K_{1.95}\ Na_{0.27}Mg_{0.30})\ (Si_{25.78}\ Al_{10.28}\ Fe_{0.01})\ O_{78}$, for the erionite-Na type mineral is $(Na_{4.00}\ K_{2.40}\ Ca_{1.13}Mg_{0.24})\ (Si_{26.69}\ A_{19.11}Fe_{0.22})\ O_{72}$, and for the erionite-K type mineral is $(K_{2.80}Na_{1.66}Ca_{1.03}Mg_{0.51})\ (Si_{28.21}\ A_{17.39}\ Fe_{0.41})\ O_{72}$ [9].

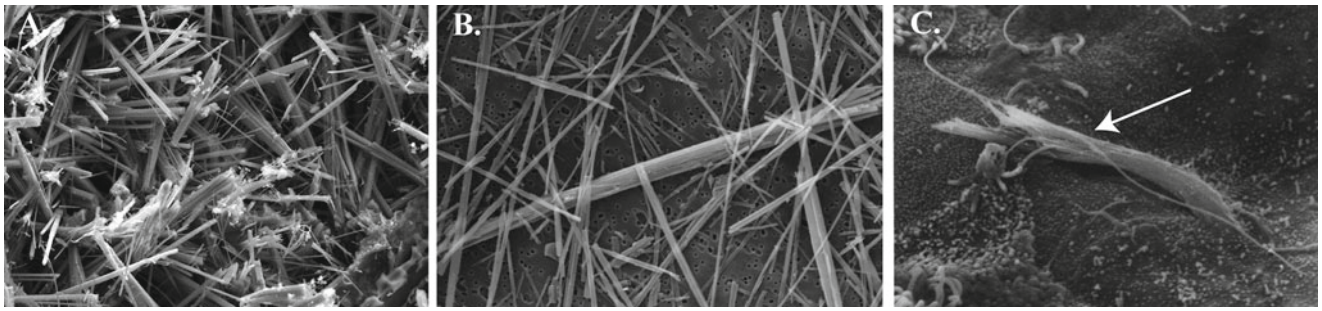

Fig. 18.1 Scanning electron microscopy (SEM) micrographs showing the morphology of erionite fibers, crocidolite asbestos, and chrysotile fibers. (**a**) Erionite fibers from Pine Valley, NV (courtesy of Dr. Ian Steele, Department of Geoscience, University of Chicago, Chicago, IL). (**b**) NIEHS reference sample of crocidolite asbestos. (**c**) A bundle of chrysotile fibers (*arrow*) interacting with the tracheal epithelial cell surface in organ culture (from [86]).

Asbestos is a commercial term for another group of naturally occurring crystalline fibers. Each group has its own distinctive structure and chemical composition. There are two subgroups: (1) a serpentine group, consisting of chrysotile [$Mg_6Si_4O_{10}$ $(OH)_8$]; and (2) the amphiboles, five groups of rod-like fibers including crocidolite [$Na_2(Fe^{3+})_2(Fe^{2+})_3$ $Si_8O_{22}(OH)_2$], amosite [$(Fe,Mg)_7Si_8O_{22}(OH)_2$], tremolite [$Ca_2Mg_5Si_8O_{22}(OH)_2$], anthophyllite [$(Mg,Fe)_7$ $Si_8O_{22}(OH)_2$], and actinolite [$Ca_2(Mg,Fe)_5Si_8O_{22}(OH)_2$] [10]. These fibers may exist in deposits with each other or other minerals and may adsorb other metals or organic compounds to their surfaces during mining or processing.

The potential of asbestos fibers to cause cancers and fibrosis has been linked primarily to their fibrous geometry and size—longer, thinner fibers being most bioreactive because of their incomplete phagocytosis, release of oxidants from cells, and their ability to act as a platform for cell proliferation [11, 12]. However, in addition to size, the chemical composition of asbestos fibers also plays an important role in determining the cytotoxicity, durability, and biopersistence of asbestos types [13]. Amphibole fibers, especially crocidolite and amosite asbestos, have the greatest carcinogenic potential in MMs in comparison to chrysotile in asbestos-exposed human populations. The increased pathogenicity of amosite and crocidolite asbestos may reflect their greater durability in the lung or pleura after inhalation as well as the high iron content of these amphiboles (20–30 % by weight) [13]. They also form ferruginous asbestos bodies in the lung in contrast to chrysotile fibers which may be iron-free or acquire iron naturally in trace amounts. Amphibole asbestos fibers also have a sharp, needle-like structure which causes their alignment with airways after inhalation and allows more effective penetration into the deep lung. In contrast, chrysotile fibers have a curly, snake-like structure (Fig. 18.1c) and break down into smaller fibrils over time. A number of studies have shown that smaller fibers or fragments (<5 μm) of asbestos, regardless of type, are less cytotoxic, carcinogenic, and fibrogenic than longer asbestos fibers [14]. This may be in part because they are more easily cleared from the lung over the long latency periods of asbestos-induced diseases.

On an equal weight basis, chrysotile fibers are more cytotoxic than amphibole fibers due primarily to their positive surface charge and greater surface area whereas amphiboles are neutral or slightly negative in charge [15]. Hydrated magnesium molecules are located on the apical oxygens of chrysotile accounting for its highly polar properties as well as dissolution of the mineral when magnesium is leached from the fiber. In nature, these structures are arranged as loose bundles that break down into smaller fibrils in tissue [1, 16].

For reasons that are unclear, erionite is more carcinogenic in rodents than asbestos, regardless of source [7]. Experimental studies indicate that erionite is 300–800 times more carcinogenic than chrysotile and 100–500 times more carcinogenic than crocidolite asbestos when administered through intrapleural routes. In intraperitoneal injection studies, erionite is 20–40 times more potent than chrysotile, and 7–20 times more potent than crocidolite in tumor induction [17]. These trends have also been observed in inhalation studies [18]. One theory is that erionite has a hexagonal structure with an internal surface of 200 m^2/g that is 20 times larger than crocidolite asbestos, thus allowing erionite to absorb many small molecules and to have a higher catalytic activity [19]. It was also found that on an equal weight basis, erionite induces more reactive oxygen species (ROS) than asbestos fibers [20].

18.3 Links Between Erionite, Amphibole Asbestos, and Malignant Mesothelioma

18.3.1 Features of Malignant Mesothelioma

Malignant mesothelioma (MM) is an aggressive tumor originating from the lining cells (mesothelium) of the pleural and

peritoneal cavities, as well as the pericardium and the tunica vaginalis. Although the main risk factor is exposure to asbestos or erionite, other factors such as Simian virus 40 (SV40) infection and inheritance of susceptibility genes likely play roles in initiation and progression of MM [21, 22]. MM may acquire many phenotypic forms (epithelioid, biphasic, and sarcomatoid) which makes them difficult to diagnose without multi-panel histochemical stains.

The combination of an accurate patient history, physical examination, radiology, and the confirmation of pathology is essential in the diagnosis of mesothelioma. Typical presenting features invariably occur in late stages of disease and include chest pain, dyspnea, and breathlessness due to pleural effusion [23, 24]. Treatment strategies include chemotherapy, radiotherapy, gene therapy, extrapleural pneumonectomy, surgical resection of tumors, or combined therapies. However, no effective therapies have been developed for MM, and because they are most often diagnosed at end stages of disease, clinicians often focus on palliation of symptoms and/or end-of-life care [25].

The latency period for development of MM is often 30–40+ years from initial exposure to asbestos fibers [13]. Because of difficulties in treatment and management, life expectancy in pleural MM is grim with median survival varying between 8 and 14 months [21]. However, peritoneal MM patients can survive 5 years or longer [26].

18.3.2 Malignant Mesothelioma in Turkey

18.3.2.1 Epidemiologic Studies

Annual asbestos-related mesothelioma cases in Southeast Turkey are reported to be 50 per million [27]. However, the annual incidence of mesothelioma related to environmental exposure to erionite was found to be from 2200 to 8000 cases per million in several villages such as Karain, Tuzkoy, and Sarihidir in the Cappadocia region of Turkey. This incidence rate is much higher than any other reported incidence of MM worldwide [28]. In 1987, Baris reported the epidemic of mesothelioma among residents of Karain, Tuzkoy, and Sarihidir [28]. The estimated incidence of pleural MM was indicated as 996 per 100,000 inhabitants [28]. It was noted that more than 50 % of deaths were caused by MM in these three villages [29]. A study based on 162 Turkish immigrants from Karain to Sweden also shows a strong correlation between erionite exposure and MM. Fourteen deaths were reported due to MM among the 18 (78 %) total deaths during the period between 1965 and 1997. The standardized incidence rates found in this study were 135 times higher among the males and 1336 times higher among the females compared to the general population of Sweden [30].

A mortality study between 1994 and 1997 suggested that MM might also occur in some of the other villages near the known three erionite villages in Cappadocia. These other villages are Cokek, Karlik, Karacaoren, Boyali, and Yesiloz. These investigators reported 53 deaths due to mesothelioma from the three erionite villages, Karain, Tuzkoy, and Sarihidir, and 11 deaths from the other four villages [31]. It was noted that MM cases were more prevalent in the erionite villages compared to the nearby villages despite the environmental contamination of erionite, which was often used in dwellings in the region [27].

In 2006, a study from 1979 to 2003 based on residents of two erionite-exposed, and one nearby control village, was published [32]. In this study, a total of 891 men and women, aged 20 years or older, were included, a total of 230 residents in villages without known exposure to erionite. Mortality data were obtained from hospital records and death certificates. During the 23-year follow-up, 119 deaths occurred from MM, the cause of 44.5 % of all deaths in the exposed villages. Seventeen patients had peritoneal mesothelioma; the remainder died of pleural mesothelioma. Only two cases of MM, one of each type, occurred in the control village, both in women born elsewhere [32].

18.3.2.2 Gene: Environmental Interactions

In Karain, Tuzkoy, and Sarihidir, MM occurs only in certain houses. Pedigree analyses revealed that in MM villages, MM was more frequent in certain families compared with others. However, in some families, MM developed among individuals who married into the affected family. For example, in one family, 17 of 30 members died of MM. Among the 17 MM, 5 occurred in individuals who married into this family [2]. This finding initially argued against a theory of genetic predisposition. However, it was found that those who married into a MM family and developed MM were also from MM families. When members of a family with high incidence of MM married into families with no history of MM, descendants developed MM [2].

To test the hypothesis that genetics alone could cause MM in certain families, 24 descendants from one family (ages 26–45 years) born and raised outside the village of Sarihidir were identified. No MM developed in this group. Instead, three MM cases were observed in the same age group among 29 members of a family born and raised in Sarihidir and exposed to erionite. These pedigree studies indicate that the MM epidemic in three Cappadocian villages is caused by genetic predisposition and may make certain individuals more susceptible to the carcinogenic effects of erionite exposures [2]. A team of US and Turkish investigators is now attempting to isolate the putative MM susceptibility gene(s). This gene(s) may be mutated or otherwise altered in

Cappadocian families and also may be affected in sporadic familial MMs in the Western world [32].

18.3.3 Epidemiology of Asbestos-Induced Malignant Mesothelioma

18.3.3.1 Historical Studies

Although adverse health effects of asbestos were first recognized by 1899 [33], dust control legislation for mines was not enacted in North America until 1971 by the Occupational Safety and Health Administration (OSHA). In 1935, the suggestion that mesothelioma resulted from occupational exposure to asbestos was first made by Gloyne [34], and the first clear evidence of a link between amphibole asbestos exposure and primary malignant tumors of the mesothelium was shown by Wagner in 1960 [35]. Wagner's observation was based on 33 cases of pleural mesothelioma in the Northwest Cape Province of South Africa, 28 in persons who had lived close to the crocidolite mines, mostly as children [35]. Confirmation was provided by eight case-control studies published in 1965–1975, based on a total of 657 cases, predominantly male, exposed to asbestos mainly in shipyards, heating trades, insulation, and factory work [36]. It was also shown that the hazards of asbestos dust were not confined to heavily exposed workers in asbestos factories but extended to insulation workers, other users of products containing asbestos, and people who lived close to asbestos factories [37–40].

The role of SV40, a polyomavirus, as a cofactor with asbestos fibers in the induction of malignant mesothelioma is controversial. A review by Gazdar indicates that some investigators have detected SV40 viral DNA sequences and oncoproteins in human pleural MMs [41]. Even though there are technical concerns about some of these findings [42], a role for SV40 as a carcinogen or co-carcinogen is biologically believable on much cellular data and results of animal models [43]. This suggestion is also supported by many of the molecular mechanisms of action of these viral oncoproteins [41].

18.3.3.2 Libby, Montana

Although approximately 2500 cases of MM are reported in the USA annually, a cluster has been noted in Libby, MT, a town with a population of ~2700, with nearly 12,000 people in the surrounding area. Libby had one of the world's largest vermiculite mines in operation from the 1920s to 1990. The Libby vermiculite had useful insulating and soil conditioning properties. However, ore from the mine was contaminated with fibrous and nonasbestiform amphiboles in veins throughout the deposit [44]. After 70 years of mining amphibole-contaminated vermiculite, amphibole asbestos related contamination was seen in areas surrounding the abandoned mine and in other areas throughout the town. For example, tree bark samples contain varying levels of amphibole contamination in Libby in the EPA-restricted mine area [45]. Amphibole fiber concentrations range from 41 to 530 million fibers per gram of bark while a bark sample collected ~11 km west of town along the railroad line had concentrations of 19 million fibers per gram [46]. This indicates that there is a potential exposure to asbestos during harvesting or disturbing contaminated woods in the Libby area. Libby was added to the Environmental Protection Agency's (EPA) National Priorities List in October 2002 for Superfund sites [47].

It is reported that nearly one million homes in the USA have used vermiculite-based insulation from the Libby mine [48]. Even though vermiculite is not classified as one of the six types of asbestos, Libby amphibole has been described as a tremolite-containing transition fiber, and exposure of residents and past workers at the Libby vermiculite mine has been associated with the development of pleural plaques and numerous asbestos-related diseases including asbestosis, pleural fibrosis, and MMs [49]. In this region, asbestos-related deaths are reported to be 40–80 times greater than reference populations in the USA [49]. Thus, Libby amphibole fibers may also be potent in the pathogenesis of MMs.

18.4 Mechanisms of Action of Asbestos and Erionite in the Development of Malignant Mesothelioma

18.4.1 Modern Concepts of Carcinogenesis

Several decades ago, it was thought that all carcinogens were mutagens, and a number of cell assays, including those using bacteria (the Ame's test), were developed with the hopes of identifying critical mutations and short-term testing of agents for carcinogenicity in lieu of expensive lifetime animal studies. Subsequently, it became clear in 2000 that multiple, sometimes common, mutations (i.e., in oncogenes) were required for the development of most cancers [50]. It also had become apparent that several of these mutations were spontaneously induced during aberrant cell replication when DNA repair was compromised, causing DNA damage and genome instability [51]. Carcinogens causing mutations in vitro by direct interaction with DNA or after metabolism and formation of DNA adducts are often termed initiators of cancer, although it is clear that genomic instability also occurs during the long latency periods (progression) of most cancers. Genetic instability is augmented by tumor promoters that induce cell proliferation and inflammation, chronic stimuli necessary for the development of cancers. In lung cancers, it is clear that asbestos fibers function primarily as co-carcinogens and tumor promoters, as mutations by asbestos are not observed in human bronchial epithelial cells or

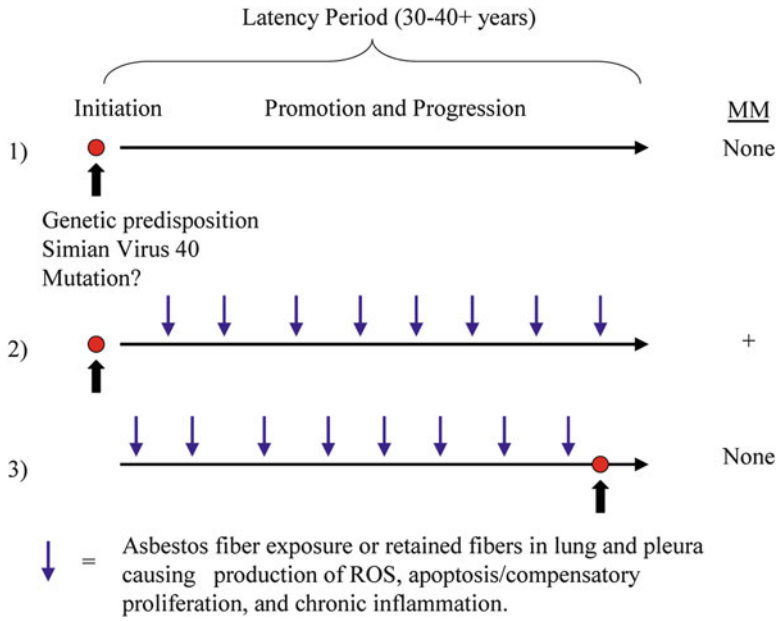

Fig. 18.2 A hypothetical schema for the development of human malignant mesotheliomas after exposures to amphibole asbestos fibers that are retained in the lung during the long latency period of these tumors. The sequence of events and outcomes of MM development in #1–3 are consistent with modern concepts of multi-stage carcinogenesis and the many observations that asbestos fibers play critical roles in tumor promotion and inflammation as opposed to initiation of cancers by mutations. Consistent with observations in mouse skin and other models of carcinogenesis, initiation alone does not cause tumors in the absence of tumor promotion that is characterized by chronic episodes of cell proliferation and inflammation. Moreover, initiation must be followed sequentially by these phenomena for MM to occur.

other epithelial cells in general [52]. In this scenario, polycyclic aromatic hydrocarbons (PAH) associated with smoking classically cause DNA adduct formation whereas asbestos fibers act as co-carcinogens to adsorb PAH and increase their delivery to lung epithelial cells [53]. On the other hand, asbestos fibers act on tracheal epithelial and mesothelial cells as tumor promoters (analogous to phorbol esters in mouse skin) in that they induce inflammation and IL-1B dependent cytokine production that is triggered by activation of the inflammasome [54]. Chronic cell proliferation is triggered by activation of growth factor receptors and protein kinases, increased cyclin D1 and induction of cycling cells [55], stimulation of ornithine decarboxylase [56], and hydrolysis of phosphatidylinositol, increases in diacylglycerol, and activation of protein kinase C at the plasma membrane [57–59]. Moreover, asbestos increases numbers of tumors at low, nontumorigenic concentrations of PAH in tracheal graft models [60]. None of these alterations are observed using nonfibrous, chemically similar analogs of asbestos. Moreover, longer fibers cause more striking alterations than shorter fibers or fragments.

Figure 18.2 depicts a hypothetical model of how amphibole asbestos fibers might promote the development of MMs initiated by tumor susceptibility gene alteration(s) or interaction with SV40, a DNA virus. This schema is supported by studies showing that mutations by asbestos fibers in vitro are large scale chromosomal deletions observed only at toxic amounts of fibers and dissimilar to clonal mutations detected in MM.

18.4.2 Methylation and Tumor Suppressor Genes

Asbestos fibers have not been detected in the nuclei of rodent or human mesothelial cells in situ nor are they mutagenic in a number of studies. An exciting recent development is the observation that gene locus-specific methylation alterations occur in human pleural MM, supporting the concept that epigenetic dysregulation is a crucial mechanism of action in the induction of MM [61]. Indeed, several putative tumor-suppressor genes have been reported in MM [61, 62]. It has also been reported that somatic mutations in the neurofibromatosis type 2 (Nf2) gene occur in 50 % of human MM [63]. After intraperitoneal injection of asbestos fibers, the susceptibility to induction of peritoneal MM increased in heterozygous Nf2-deficient mice [64]. Li-Fraumeni syndrome is a rare heritable cancer-susceptibility disorder characterized by carrying a mutant allele of the p53 gene. Even though mutations in the p53 tumor-suppressor gene are rare in human MMs, individuals with Li-Fraumeni syndrome show increased susceptibility for MM [65]. Susceptibility and accelerated progression of asbestos-induced mesotheliomas also are enhanced in heterozygous

p53-deficient mice [66]. These two models support a role of inactivation of the Nf2 and p53 tumor-suppressor gene pathways in the pathogenesis of asbestos-induced MM [67].

18.4.3 Cell Signaling Pathways Activated by Asbestos Fibers

Since asbestos fibers initially contact the cell membrane after addition to cell cultures, injection, or inhalation, work in our laboratory has focused on the pleiotropic effects of asbestos on cell signaling pathways that regulate cell injury, proliferation, and cell fate. As shown in Fig. 18.3, asbestos fibers may interact via the production of reactive oxygen or nitrogen species (ROS or RNS) [68] or directly with receptors such as the epidermal growth factor receptor (EGFR) [69] or tumor necrosis factor receptor (TNFR).

Direct interaction of asbestos fibers with the epidermal growth factor receptor (EGFR) activates Ras-Raf-extracellular signal-regulated kinase (ERK) pathways of the mitogen activated protein kinases (MAPKs). These pathways control expression and transcriptional activity of the Fos family members, including Fra-1, that comprise heterodimers with Jun family members to form the activator protein-1 (AP-1) transcription factor [70, 71]. Activation of ERK5 by asbestos may also regulate c-Jun family members that form homodimers or heterodimers with Fos proteins [72]. Both Fos and Jun proteins are encoded by early response proto-oncogenes that are induced transcriptionally by asbestos fibers in a dose-responsive fashion [73]. Even though linking increased expression of AP-1 subunits such as Fos and Jun to specific gene expression and phenotypic endpoints remains a challenge, it has been shown that increased expression of c-Jun by asbestos is critical to proliferation and transformation of tracheal epithelial cells [74].

Through possibly redundant phosphorylation cascades, the ERK1/2 and ERK5 pathways govern AP-1-dependent gene expression that regulates cell proliferation, cell migration, and aspects of neoplastic transformation. Activation of the phosphoinositol-3 kinase (PI3K)/AKT pathway by asbestos [75] may also promote cell survival through mTOR or the transcription factor, Nuclear Factor-KappaB (NF-kB) [76, 77] that is also classically linked to activation of TNFR and production of cytokines. Studies on isolated human MM cells and data from our laboratory using an SCID mouse xenograft model after injection of human MM [78, 79] sup-

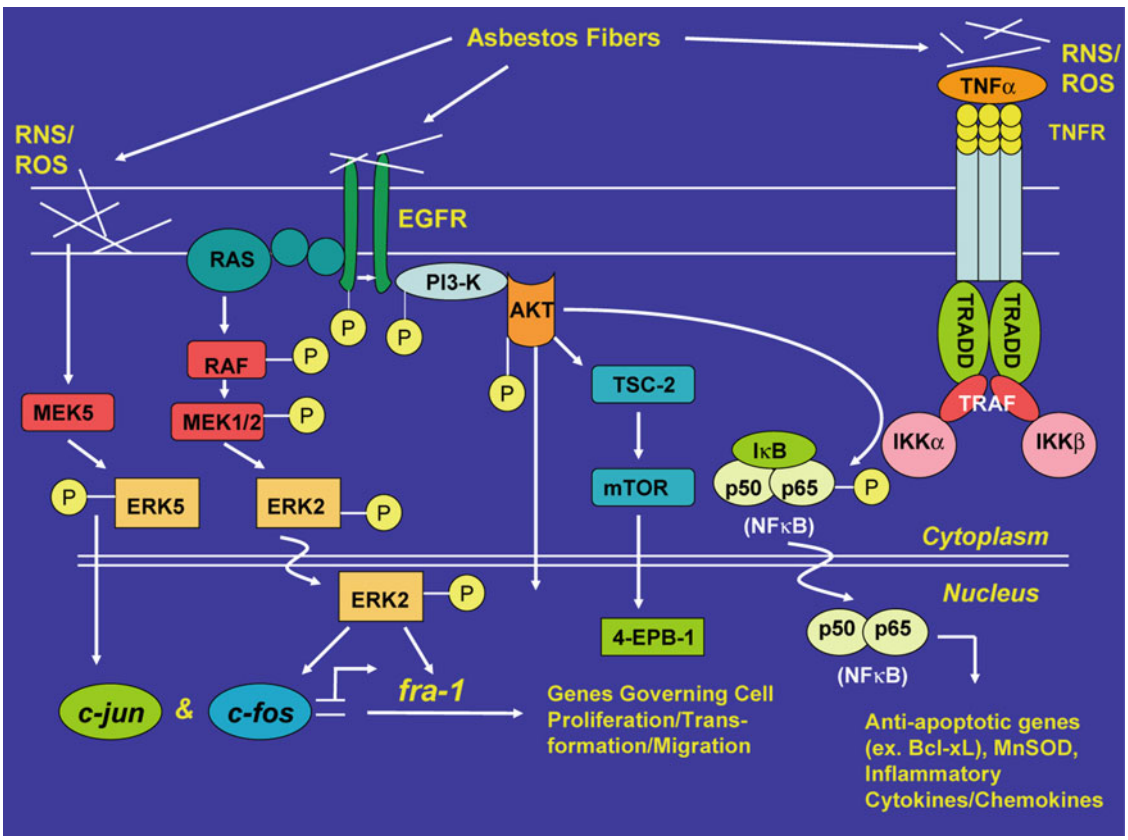

Fig. 18.3 A synopsis of known receptor activation and signaling cascades activated by asbestos fibers and leading to transcriptional activation of gene expression critical to cell proliferation, inflammation, and transformation of mesothelial and lung epithelial cells (modified from [67]).

port the concept that asbestos fibers via activation of NF-kB and other transcription factors cause autocrine production of inflammatory cytokines, growth factors, and angiogenic factors in human mesothelial cells that are recapitulated in a model of tumorigenesis.

After administration of asbestos, NF-kB is activated by asbestos fibers in rodent tracheal epithelial and mesothelial cells in vitro, and in the lungs of rats after inhalation [76, 77]. Furthermore, asbestos fibers cause transcriptional activation of a number of NF-kB-dependent genes, including *c-myc*, another early response proto-oncogene through an oxidant-dependent pathway [76]. Activation of NF-kB is critical in up-regulating the expression of many genes linked to proliferation, apoptosis, and chemokine/cytokine production, and is a critical transcription factor in modulation of chronic inflammation, a feature of asbestos-related diseases [67].

18.4.4 Mechanisms of Erionite-Induced Malignant Mesothelioma

Although studied less widely, it has been shown that the mechanisms of carcinogenesis by erionite are similar to mechanisms of carcinogenesis by amphibole asbestos fibers [59, 80]. For example, exposure to erionite fibers leads to generation of ROS from macrophages [59] and increases mRNA levels of the early response *c-fos* and *c-jun* proto-oncogenes in rodent mesothelial cells [80]. It has been recently shown that erionite is less cytotoxic in contrast to crocidolite asbestos, inducing proliferation and high growth rate in human mesothelial cells [81]. After short-term erionite exposure (24 h or 48 h), DNA synthesis is observed. In contrast, crocidolite asbestos causes initial apoptosis in rodent mesothelial cells that is followed by compensatory proliferation at these time points [82]. After long-term erionite exposure (30 days and 60 days), human mesothelial cells derived from foci of morphologic transformation express HGFR/Met, EGFR, and PDGFR to a higher extent than untreated human mesothelial cells. These growth factor receptors are known to be stimulated by crocidolite asbestos in mesothelial cells [69–71, 83, 84]. Analogous to our observations [67], erionite also induced AKT, ERK1/2, and NF-kB activities at higher levels in morphologically transformed as compared to untransformed human mesothelial cells [81].

18.5 Conclusions

In brief, the phenotypic and functional outcomes of asbestos or erionite exposures in mesothelial cells are related to fibrous geometry and fiber dose. Moreover, the multiple signaling and survival pathways activated by these diverse fibers are similar and may be induced by direct interaction of fibers with receptors or production of ROS or NOS. In general, both fiber types promote robust and persistent activation of signaling through ERK and other redox responsive kinase cascades in comparison to rapid and transient activation by growth factors or phorbol esters. The molecular mechanisms of carcinogenesis due to asbestos and erionite exposure are still under investigation in several laboratories and may yield unique pathways of erionite-induced tumorigenesis that explain its greater potency.

It is perplexing why erionite, a fibrous zeolite, has a higher carcinogenic potency relative to asbestos fibers based on both rodent studies and epidemiology. However, MM does not occur in all individuals exposed to erionite, but in the members of certain families. These findings suggest that MM may be caused by the combined effect of environmental exposure to erionite and susceptibility due to unknown genetic traits [2, 26, 32, 85]. Since familial MM occurs in some families in the US, and erionite and amphibole asbestos are environmental contaminants in some US soils, future research should focus on fiber exposures in these high-risk groups, specifically gene profiling and gender influences. A logical approach to future research should include strategies to reduce environmental exposures and mechanistic and clinical investigations to develop novel and effective therapies for MM.

Viral Mechanisms in Human Carcinogenesis

19

Paul F. Lambert

19.1 General Principles of Virally Induced Cancer

Infectious agents, including viruses, bacteria, and parasites, are thought to be the etiologic agents in approximately 20 % of human cancers. Human oncogenic viruses include hepatitis B and hepatitis C viruses (associated with hepatocellular carcinoma), Epstein–Barr virus (associated with B-cell lymphomas, nasopharyngeal, and gastric carcinomas), human papillomaviruses (associated with cervical carcinoma, other anogenital cancers, and a subset of head and neck cancers), human T-cell lymphotropic virus I (HTLV-1; associated with Adult T-cell lymphomas), human herpesvirus type 8 (associated with Kaposi's sarcoma and primary effusion lymphomas), and the newest identified human tumor virus, Merkel cell carcinoma-associated polyomavirus. The initial recognition that viruses cause cancer arose from studies of animal viruses. In the early twentieth century, transmittable agents were demonstrated to cause tumors in chickens and in rabbits. The respective agents were later identified to be Rous sarcoma virus (RSV), the first studied RNA tumor virus, and Shope papillomavirus, the first studied DNA tumor virus. Much of our understanding of viral oncogenesis derived initially from the study of such animal viruses. In recent years, much attention has been focused on the study of human tumor viruses as etiological roles of such viruses in human cancers have been elucidated. The study of virally induced cancers in animals and in humans has provided many basic insights into cancer, the most important of which is the identification and functional characterization of two fundamental types of genes important in cancer: oncogenes and tumor-suppressor genes. From these collective studies several generalizable principles of virally induced cancer have arisen. First, the onset of virally associated cancer is characterized by long latent periods following initial infection. This suggests that the viruses alone are not sufficient to cause cancer. Also, given this long latency, oncogenic viruses must be able to persist in the host for long periods of time. Second, the cancers induced by viruses do not constitute a natural part of the viral life cycle. Rather, virally associated cancer appears to be a dead-end street for most viruses—by-products of the natural infection that provide no advantage to the virus evidenced by the fact that it is uncommon for progeny virus to be produced in the associated tumors. The third principle is that viral properties that contribute to the induction of tumors often play critical roles in the life cycle of the virus. In the following sections are described the basic properties of RNA and DNA tumor viruses and the major insights gained regarding how they contribute to cancer.

19.2 RNA Tumor Viruses

The field of tumor virology initially arose from the study of retroviruses that cause tumors in birds and mammals other than humans. The oncogenic retroviruses can be divided into three classes: (1) transducing retroviruses, (2) insertionally mutagenic retroviruses, and (3) true oncoretroviruses. Transducing retroviruses are ones that acquire genetic information from the host genome. RSV is one example. Most other examples also were isolated from avian hosts, although others have been isolated from feline, murine, and simian hosts. The cellular genetic information being transduced is a cellular proto-oncogene which, as present in and expressed from the transducing retrovirus, has oncogenic activity, i.e., it contributes to tumor formation in vivo and cellular transformation in tissue culture. The study of transducing retroviruses led to the discovery of more than a dozen oncogenes, including *src, ras,* and *myc*. The discovery of these virally encoded oncogenes, and their detailed study helped define numerous cellular signaling pathways that play fundamental roles in

normal cell physiology and when altered, in carcinogenesis. It was not recognized until the 1970s that these viral oncogenes actually had been picked up by the virus from the host organism through genetic recombination, which arises as a by-product of reverse transcription. This led to the recognition that animals encode oncogenes. The cellular copies of these genes were initially referred to as proto-oncogenes because it was recognized that the viral copies of these genes had undergone genetic changes that led to the increased expression and/or activity of the encoded gene product. These changes led to the oncogenic nature of the virally transduced gene. In contrast, the cellular homologs do not contribute to cancer in their wild-type state. For example, the virally encoded *src* and *ras* genes have amino acid substitutions at positions in these proteins that lead to their constitutive activity in signal transduction pathways, and the virally encoded *myc* gene is missing regions of the cellular gene that normally lead to a tight regulation of its expression at the transcriptional and post-transcriptional levels. No examples of transducing retroviruses have been found for human cancers; rather, most such viruses were identified from the evaluation of laboratory stocks of retroviruses that infect laboratory animal species. Generally, these transducing, oncogenic retroviruses are replication-defective because of the disruption of one or more essential viral gene by the insertion of the cellular proto-oncogene. The rare exception is RSV, which is a replication-competent virus in which the transduced cellular *src* gene did not disrupt function of any viral gene. How a transducing oncogenic retrovirus arises remains unclear. It likely results from a provirus that integrates close to a cellular proto-oncogene. This could result in the formation of a chimeric RNA of viral and cellular origin which, when packaged into progeny retrovirus and on reverse transcription, undergoes recombination with a co-packaged, intact viral transcript to produce the actual transducing viral genome.

Insertionally mutagenic retroviruses are ones that, as a consequence of insertion of the proviral genome into the host chromosomes, alter the structure and/ or expression of a cellular proto-oncogene or tumor suppressor gene. These retroviruses are also known as the weakly oncogenic retroviruses since they only rarely cause cancers in laboratory animals, reflective of the low likelihood that the provirus insertion occurs at or near a cellular proto-oncogene or tumor suppressor gene. There are several mechanisms by which insertion of provirus can lead to activation of a cellular proto-oncogene. First, the virus may integrate upstream of the cellular gene in the same sense orientation such that read-through transcription from the viral promoter leads to the generation of chimeric viral:cellular mRNAs that can encode the cellular proto-oncogene. Second, the viral transcriptional enhancer can upregulate the activity of the cellular gene's own transcriptional promoter. Finally, the virus can disrupt the integrity of the cellular mRNA leading to the loss of negative regulatory elements such as mRNA instability elements in the mRNA encoding the cellular protooncogene. Examples of each of these three cases exist in the literature. Many of the insertionally mutagenic retroviruses cause lymphomas/ leukemia in their natural host. In these tumors, the provirus is found nearby to the c-*myc* locus, leading to increased expression of the c-*myc* gene product. Insertionally mutagenic retroviruses can also integrate within alleles of tumor suppressor genes and disrupt their expression, thereby leading to cancer. The identification of such events is much less frequent than those that lead to the activation of cellular proto-oncogenes, presumably because of haplosufficiency.

True oncoretroviruses are ones that, through virally encoded activities, alter the host cell or the host cell environment, thereby making cells more susceptible to cancer development. There are only a few cases of true oncoretroviruses. One is HTLV-1, which causes T-cell lymphomas in humans.

19.3 DNA Tumor Viruses

Whereas the study of RNA tumor viruses was largely responsible for the discovery of oncogenes, the study of DNA tumor viruses led to the discovery and elucidation of the function of cellular tumor suppressor genes, most notably *p53* and *pRb*. Much of the initial knowledge about DNA tumor viruses came from the study of SV40, a simian virus. SV40 efficiently transforms cells in tissue culture and can cause tumors in hamsters, but not its natural host. Several viral gene products were found expressed in these transformed/tumorigenic cells and were identified because hamsters made antibodies against them. Most notable of these was the SV40 large tumor antigen (TAg). This protein is one of the most potent oncogenic factors known [1]. Its oncogenic activity is multifactorial, largely arising from its ability to bind and inactivate the cellular tumor-suppressor proteins p53 and pRb. p53 is now recognized to be functionally disrupted in most human cancers. The protein was originally identified by virtue of its association with SV40 TAg. Initial cloning and functional analysis of *p53* led to its designation not as a tumor suppressor gene but an oncogene. This was due to the fact that the initial *p53* clones were isolated from cell lines, i.e., populations of cells that had acquired an immortalized phenotype. In these cell lines the *p53* gene had undergone mutations that cause the encoded gene product to possess dominant-negative activity; that is, it could inactivate the normal p53 protein when put back into cells. It was not until the late 1980s that the wild-type *p53* gene was recognized to be a tumor-suppressor gene [2]. *p53* is thought to play an important role in orchestrating the cellular responses to certain forms of stress, including insult from DNA-damaging agents. Activation of *p53* leads either to growth arrest, which is believed to allow cells time to repair damaged DNA, or apoptosis (programmed

cell death). Without functional *p53,* cells have a greater propensity for undergoing genetic alterations, some of which can contribute to tumorigenesis. It is now understood that when SV40 TAg binds the wild-type p53 protein, it inactivates the latter's function [1]. SV40 TAg also can bind the gene product of the retinoblastoma tumor susceptibility locus (Rb) [3]. Rb and the related pocket proteins, p107 and p130, are critical regulators of the cell cycle. In the G1 stage of the cell cycle pRb binds to and inactivates a family of transcription factors, E2Fs, that regulate the activity of cellular genes involved in DNA synthesis and cell cycle control. Normally, pRb's activity is regulated by cyclin-associated kinases, which phosphorylate pRb and lead to its dissociation from E2Fs. TAg upon binding to pRb or its relatives p107 and p130 can also cause this dissociation and thereby lead to cell cycle deregulation.

The insights gained from the study of SV40 provided many insights about how human papillomaviruses cause carcinoma of the anogenital tract and head/neck region in humans, and potentially also shed light on the oncogenic activities of the recently discovered Merkel cell carcinoma associated polyomavirus. However, it would be an oversimplification to think that targeting p53 and pRb are the only means by which DNA tumor viruses transform cells or cause tumors in organisms. Much like what was learnt from the study of transducing oncoretroviruses that express mutated forms of cellular proto-oncogenes, there are many varied cellular pathways targeted by DNA tumor viruses that, when altered, contribute to transformation in tissue culture and tumorigenesis in vivo.

19.4 Human Tumor Viruses

19.4.1 Human Papillomaviruses

Papillomaviruses are small DNA viruses that infect the epithelial lining of their host and for the most part cause benign proliferative lesions such as warts that support production of progeny virus. There are over 100 defined human papillomavirus genotypes that can be subdivided into two classes, those that primarily infect cutaneous epithelia such as the epidermis lining the hands and feet, and those that primarily infect mucosal epithelia including that lining the anogenital tract and the oral cavity. The latter, mucosotropic HPVs, are the most common sexually transmitted pathogens in humans; greater than half the human population have been exposed to these HPVs in their lifetime. A subset of these mucosotropic HPVs that cause human cancers such as cervical cancer, anal cancer, and head and neck cancers. The recent generation of highly efficacious, prophylactic vaccines against two of the most common of these cancer-causing HPV genotypes, HPV16 and HPV18, provides the potential of reducing the incidence of human cancers caused by these viruses. However, their impact on global health is significantly limited by their availability, largely for socio-economical reasons.

Papillomaviruses are non-enveloped icosahedral viruses that contain a double-stranded DNA genome of about 8000 bp that encodes early and late genes. These viruses infect the poorly differentiated basal cells within stratified epithelium wherein the viral genome is established as a low copy, nuclear plasmid and a subset of viral genes are expressed The papillomavirus life cycle is intricately tied to the differentiation program of the host tissue. Progeny virus are only produced when the infected basal cell undergoes cell division and a daughter cell initiates terminal differentiation. This triggers amplification of the viral genome and expression of structural genes that encode the capsid proteins resulting in the production of progeny virus. The virus must manipulate the differentiating epithelia to facilitate its own life cycle. Many of these manipulations to the differentiating host cell are caused by the same viral genes that contribute to cancer.

Professor Harald zur Hausen and his colleagues at the German Cancer Center in Heidelberg are responsible for first uncovering the etiological role of HPVs in human cancer when they reported the presence of DNA of specific HPV genotypes in human cervical cancers [4]. This revelation earned Dr. zur Hausen the Nobel Prize in Medicine. A causal role of these same HPVs has since been established in other anogenital cancers including that of the vagina, vulva, penis, and anus, as well as the head and neck region, particularly the oropharynx. In many of these cancers, the viral DNA is found integrated into the cellular genome and no progeny virus is produced. The viral integration event almost always leads to a disruption in the E2 translational open reading frame (ORF). The E2 ORF encodes proteins involved in viral transcription and replication and its disruption leads to derepression of the viral transcriptional promoter that directs expression of the viral oncogenes, E6 and E7 [5]. Integration also disrupts an mRNA instability element, and this also facilitates increased expression of E6 and E7 [6]. Even in cancers where the genome remains extrachromosomal, E6 and E7 expression is reported.

E6 and E7 are directly implicated in oncogenesis. E7 can cooperate with E6 or the activated ras oncogene to transform fibroblasts in tissue culture, and E6 and E7 contribute to the immortalization of epithelial cells in tissue culture [7]. The expression of E6 and E7 was shown to be required for the continued proliferation of HPV-positive cervical and head/neck cancer cell lines; thus, E6 and E7 are thought to be required for the onset as well as persistence of HPV-associated cancers. When the expression of E6 or E7 is directed to stratified squamous epithelia of transgenic mice, including the epidermis, the mice exhibit thickening of the skin and spontaneously develop squamous cell carcinomas [8]. When treated persistently with exogenous estrogen,

these same mice, which also E6 and E7 in the epithelia lining the cervix and vagina, develop cervical and vaginal cancers (whereas nontransgenic animals do not) [9]. Furthermore, these mice are more susceptible than nontransgenic mice to head and neck cancers when treated with an oral carcinogen, again owing to the expression of viral oncogenes in the epithelia lining the oral cavity, oropharynx, and esophagus [10].

Even though E6 and E7 are well accepted to be the main oncogenes for HPV, more recent evidence implicates the E5 viral protein as a possible contributor to carcinogenesis, at least in the cancers where its expression is retained (integration of the viral genome in the host chromosome often leads to a reduced expression of E5). E5 is the main transforming oncogene of bovine papillomavirus (BPV). BPV E5's transforming activity correlates with its ability to activate the PDGF receptor in a ligand independent manner [11]. E5's role in HPV-associated cancers is less clear. In tissue culture HPV E5 acts as a weak oncogene. Nevertheless, a large fraction of cervical cancers still express E5. In recent studies, transgenic mice expressing E5 were found to be more susceptible to skin and cervical cancers implicating its role in HPV-associated human cancers [12]. The mechanism underlying HPV E5's role in cancers remains unclear.

As is the case with SV40 and adenoviruses, papillomaviruses have the ability to inactivate tumor suppressors. E7 binds to and induces the degradation of the tumor suppressor, pRb [7, 13]. The inactivation of pRb allows E2F transcription factors to be constitutively active, which likely accounts in large part for the increased proliferation seen in E7-expressing cells/tissues. The regions of E7 required for its inactivation of pRb have been mapped to conserved regions (CR) 1 and 2, so named because of their similarity to pRb-binding regions in the adenovirus oncoprotein E1A [7] . The CR1 and CR2 domains of E7 are both necessary for E7's induction of tumors in animals and transformation of cells. An exception is that when the CR1 and CR2 domains of E7 are mutated in the context of the whole papillomavirus genome, cells transfected with the genome still undergo transformation [14]. This suggests that E7 possesses transforming activities mediated by other activities besides inactivation of pRb. In vivo studies have confirmed that E7's carcinogenic phenotypes both in the cervix and the head and neck of the mouse cannot be attributed merely to its inactivation of pRb. E7 also inactivates proteins related to pRb, p107 and p130, which like pRB modulate the activities of E2F transcription factors. Studies now underway suggest that inactivation of both pRb and either p107 or p130 increases the susceptibility of mice to cervical and head/neck cancers in mice. E7 also can bind to and inactivate p21 and p27, inhibitors of cyclin-associated kinases that play critical roles in the control of the cell cycle [15, 16]. E7's inactivation of p21 has now been demonstrated to contribute to its oncogenic potential in the cervix [17]. Thus E7 causes cancer at least in part through its ability to disrupt the function of multiple cellular factors that are involved in the regulation of the cell cycle. E7 is known to associate with over 100 cellular factors in addition to the ones described above. Which of these interactions also contribute to E7's oncogenic potential remains unclear [18].

The discovery of the ability of E6 to inactivate the tumor suppressor, p53, was prompted by the oncogenic similarities between papillomaviruses and SV40 and adenovirus. E6 was found to form a tertiary complex with p53 and a cellular ubiquitin ligase, E6-AP [19, 20]. This leads to the ubiquitination of p53, which is then targeted for proteasomal degradation. The p53 tumor suppressor is involved in the G1 to S phase transition of the cell cycle and is induced in response to cellular stresses such as DNA damage. Although the importance of p53 in other cancers suggests that it is important in papillomavirus-associated cancers, inactivation of p53 cannot fully substitute for the activities of E6. For example, E6 was found to abrogate differentiation of skin epithelial cells in tissue culture. However, when the p53 in these cells was inactivated by overexpressing a dominant-negative form of p53, the cells could still differentiate. Also, p53-null mice differ from E6 transgenic animals in that they do not display thickened skin or spontaneously develop skin tumors. The alpha-helix-binding domain of E6, through which E6 associates with E6AP has been shown to be important for E6 oncogenic activities in mice, suggesting that the inactivation of p53 contributes to this process. Consistent with these results, E6 is unable to cause cervical cancers on an E6AP-null background [21].

E6 has been shown to bind a variety of protein partners, including E6-BP, paxillin, E6-TP, bak, and the human homolog of Drosophila disc large (DLG) tumor-suppressor gene [22]. The ability of E6 to associate with proteins correlates with its ability to induce aberrant DNA synthesis, transform cells in tissue culture, and contribute to carcinogenesis in mice. The binding partner responsible for those phenotypes has not been identified but candidates include Dlg, Scribble, and MUPP1, all of which have been reported to bind E6 through the PDZ domain. Interestingly, E6 causes destabilization of these PDZ proteins much like it does p53, and this is at least in part mediated by E6AP.

In addition, E6 can activate telomerase, the enzyme which extends the number of telomere repeats to the ends of chromosomes. This activity is thought to contribute at least in part to E6's ability to immortalize cells [23]. Thus, as with E7, E6 contributes to transformation in tissue culture and oncogenesis in vivo through multiple means. In addition to the cellular targets described above, E6 can associate with at least two dozen additional cellular factors. Their importance in E6-mediated oncogenesis remains to be unraveled.

19.4.2 Merkel Cell Polyomavirus

The most recently identified human tumor virus is a novel human polyomavirus identified in Merkel cell carcinomas, a rare cancer arising in a specialized cell of the skin involved in sensory transduction [24]. This polyomavirus encodes for two putative oncogenes, large tumor antigen and small tumor antigen, which bear similarities with the like genes of SV40 and murine polyomaviruses. The Merkel cell carcinoma associated polyomavirus is often found to be integrated into a human chromosome in the cancers, and because of frame-shift or nonsense mutations in its large tumor antigen gene, the virus is defective in its ability to replicate as a nuclear plasmid, its normal genomic state. These mutations lead to the expression of truncated forms of large tumor antigen gene product. Interestingly, the truncated large tumor antigens expressed in the cancers retain an ability to bind pRb and pRb-like proteins, leading to the prediction that this retained activity contributes to Merkel cell carcinoma development. Like other polyomaviruses, Merkel cell polyomavirus also encodes a small tumor antigen gene product that is predicted to modulate the activity of PP2A. In the case of SV40 and murine polyomavirus, small tumor antigen contributes to their transforming activity through their modulation of PP2A. As with HPVs, continued expression of Merkel cell polyomavirus-encoded tumor antigens is necessary for the continued growth and transformation properties of Merkel cell carcinoma derived cell lines in tissue culture [25]. Merkel cell polyomavirus represents an exciting new field of study in human tumor virus biology.

19.4.3 Epstein–Barr Virus

In the 1950s, while working as a missionary doctor in Africa, Denis Burkitt described the childhood tumor Burkitt's lymphoma (endemic BL) and postulated that an infectious agent could possibly act as the etiologic agent of BL [26]. In 1961, a collaboration among Denis Burkitt, Tony Epstein, and Yvonne Barr resulted in the establishment of BL-derived cell lines in culture. Electron microscopy examinations of the cell lines showed herpesvirus-like particles that are biologically and antigenically dissimilar to other human herpesviruses. Subsequent seroepidemiological studies indicated that the candidate human tumor virus named Epstein–Barr virus (EBV), also named human herpesvirus 4, presents ubiquitously throughout the human populations in two different types and is persistently infectious. The strong association between the virus and BL, its ability to transform primary human B lymphocytes into permanent lymphoblastoid cells, and a predominance of a single glycoprotein in the viral outer surface further differentiate EBV from other herpes members. All three subtypes of BLs—endemic, sporadic, and AIDS related—are thought to be associated with EBV infection. Early-onset endemic BL, the most common childhood cancer in equatorial Africa, occurs with an unusually high incidence of 5–10 cases per 100,000 individuals per year. Virtually all of the malignant cells of every analyzed endemic BL tumor are EBV genome positive. The sporadic BL, more commonly found in the United States and other Western countries, has a 50-fold to 100-fold lower incidence in comparison to the endemic BL with about 15–25 % EBV genome-positive tumors. Also, sporadic BL tumors have a slightly later age of onset, a different pattern of presentation, and frequently involves the abdomen and bone marrow instead of the jaw, as in the cases of the endemic BL. AIDS-related BL develops in approximately 10 % of AIDS patients in Western societies and reflects both early-onset and late-onset B-cell malignancies. However, even with such a high incidence of AIDS-related BL tumors, only 30–40 % of these are EBV genome positive. Remarkably, all known forms of BL have the t(8:14), t(2:8), and t(8:22) chromosomal translocations that are likely deleterious to B lymphocyte development. In addition to BL, EBV-associated malignancies also include immunoblastic B-cell lymphomas in immunosuppressed individuals, nasopharyngeal carcinoma, a subset of gastric carcinoma, Hodgkin's disease, and EBV-associated T-cell lymphomas.

Acute infection with EBV causes mononucleosis [27]. How EBV initially infects an individual is not clear, but it may do so through infection of epithelial cells lining the oral cavity. Usually, EBV infections become persistently latent, in which the viruses induce B-lymphocyte proliferation concurrently with viral DNA replication. Stable retention of EBV episomes is mandatory for the continual growth of EBV-positive BL cells. The viral protein EBNA1 is critical for the maintenance of the EBV replicon in infected cells and for the continued growth of BL cells [28, 29]. EBNA1 contributes both to the replication of the viral genome, and its efficient inheritance during cell division.

How EBV contributes to human cancer is not well understood. In tissue culture, EBV can efficiently induce the immortalization of B lymphocytes, a property that is likely to be related to its oncogenic properties in vivo [30]. The EBV genome is a 172 kbp linear, double-stranded DNA. In infected cells the EBV genome is maintained as a circular episome. Although the EBV genome can encode many genes, the fact that in EBV-immortalized B cells only a handful of viral genes are expressed helped researchers identify the genes relevant for immortalization. One viral gene, latent membrane protein 1 (LMP1), has been demonstrated to be critical for EBV's immortalization of B lymphocytes and in transgenic mice is sufficient to induce lymphomas. As its name implies, LMP1 is an integral membrane protein found in the cytoplasmic membrane of latently infected cells.

LMP1 has characteristics of a cell surface receptor; it displays a rapid turnover that is associated with endocytosis and it signals to NF-kappaB through association with TRAFFs and TRADDs [31]. This signaling capacity of EBV appears to be required for its capacity to induce B lymphocyte proliferation. In this regard, LMP1 is functionally analogous to CD40, a cellular receptor normally expressed in B lymphocytes which can induce B lymphocyte proliferation upon stimulation by its ligand. Unlike CD40, LMP1 is not known to have an associated ligand; consistent with this, LMP1 lacks a prominent extracellular domain to which an extracellular ligand could bind. Rather, LMP1's signal transduction activity appears to be constitutively active. In the past, LMP1 has been argued to cause the immortalization of B lymphocytes in part by inducing expression of the cellular anti-apoptotic factor Bcl-2. However, it is unclear whether the increased levels of Bcl-2 found in some EBV-infected cells are a direct consequence of LMP1 action or an acquired phenotype that correlates with improved survival of those cells in tissue culture. Another EBV-associated gene, EBNA2, has been shown to be critical for EBV's immortalization of B lymphocytes. However, its role is likely indirect through its ability to activate the transcription of LMP1.

With the recent advances in understanding the role of EBNA1 in the persistence of the EBV genome in human cells and the role of LMP1 in EBV's immortalization of B lymphocytes, scientists now have two relevant targets for developing novel antiviral therapies that could reduce the incidence of EBV-associated malignancy in the future.

19.4.4 Kaposi's Sarcoma-Associated Herpesvirus

Kaposi's sarcomas (KS) is a relatively rare disease that came into the limelight because of its prevalence amongst AIDs patients [32]. Chang, Moore, and colleagues used an enrichment procedure based on PCR to identify DNA sequences present in KS but absent in normal cells. They identified a new herpesvirus, Kaposi's sarcoma associated herpesvirus (KSHV, also termed human herpesvirus 8, HHV-8) present in these cancers [33] that is related to EBV, another human tumor virus. KSHV has also been detected in body-cavity-based lymphomas or primary effusion lymphomas (PEL) [34] and in an atypical lymphoproliferative disorder termed multicentric Castleman's disease (MCD) [35]. KSHV is now accepted as contributing causally to KS and PEL.

KSHV encodes genes with homology to cellular genes, some of which are candidates for contributing to viral oncogenesis. For example, KSHV encodes its own cyclin [36, 37]. KSHV cyclin can foster progression of nuclei isolated from cells in G1 to undergo DNA synthesis and induce cells to undergo apoptosis. Mice transgenic for KSHV cyclin and p53-null develop T-cell and B-cell lymphomas with a mean latency of 3 months, a latency shorter than that for the p53-null mice alone [38]. KSHV also encodes its own inhibitors of apoptosis, viral Bcl-2 and viral FLIP (an inhibitor of cellular FLICE, a protein-mediating Fas ligand-induced cell death). The viral Bcl-2 shares its limited sequence homology with cellular Bcl-2 in those regions critical for inhibiting apoptosis and fails to dimerize with cellular Bcl-2 and Bcl-XL thus avoiding regulation by potential cell-binding partners [39]. Viral FLIP inhibits apoptosis mediated by the Fas pathway and induced by cytotoxic T-lymphocytes [40]. Finally, KSHV encodes homologues of cytokines and cytokine receptors. Its viral IL-6 may promote proliferation of PEL cells, although they appear to be dependent on cellular IL-6 and not viral IL-6 for their continued growth [41]. KSHV also encodes a G protein-coupled receptor, viral GPCR, that, when expressed in endothelial cells in mice, leads to KS-like tumors [42].

19.4.5 Human T-Cell Leukotropic Virus Type 1

HTLV-1 is an oncogenic retrovirus associated with a variety of human diseases, including adult T-cell leukemia/lymphoma (ATL) [43]. The epidemiology of ATL suggests that cumulative genetic defects may be responsible for the acute T-cell malignancy. HTLV-1 transforms human T-cells in vivo and in cell culture. The development of T-cell transformation can be divided into two stages. In the early stage, the virus induces interleukin-2 (IL-2)-dependent T-cell proliferation, which mimics the action of antigens. In the normal T-cells, antigen-stimulated T-cells cease growth after a few weeks. However, HTLV-1-infected T-cells show infinite proliferation (i.e., immortalization). The uncontrolled cell proliferation is believed to facilitate secondary genetic changes. Therefore, the immortalized T-cells can progress to the second stage of transformation, which has a typical property of IL-2-independent growth. Recent evidence suggests that HTLV-1 not only induces the proliferation of host T-cells, but also protects the infected cells from undergoing apoptosis.

The HTLV-1 provirus genome is 9032 bp long and contains gag, pol, and env genes that encode the viral matrix (capsid and nucleocapsid proteins), enzymes (reverse transcriptase, integrase, and protease), and envelope protein (surface glycoprotein and transmembrane protein), respectively. The HTLV-1 genome contains unique regulatory genes, the Rex and Tax genes (analogous to the HIV rev and tat genes), at the 3′ end of the genome that are not common in other retroviruses. Rex is a 27-kDa nuclear phosphoprotein that regulates viral RNA processing. Rex enhances the expression of single-spliced mRNA and unspliced viral genomic RNAs encoding the gag-pol and env gene products but reduces the expression of double spliced tax/rex mRNA. At the early stage of viral gene expression in the viral life cycle, double-spliced mRNAs for Tax and Rex proteins are mainly

produced. Newly synthesized Tax protein transactivates the transcription of HTLV-1. However, accumulated Rex protein enhances the accumulation of unspliced and single-spliced viral RNAs and suppresses the accumulation of tax/rex mRNA. Therefore, Tax and regulate viral expression both positively and negatively. Transient expression of the viral genes may be one of the mechanisms to escape from immune surveillance of the host. Tax protein is a 40-kDa nuclear phosphoprotein and is considered an oncogenic viral protein that transactivates the transcription of HTLV-1 and also binds to cellular transcription factors or other cytoplasmic cellular molecules involved in the fundamental cell function such as IL-2, IL-2R, and c-fos and the parathyroid hormone related peptide. The oncogenic property of Tax protein is well documented in the development of ATL [43]. Indirect evidence showed that the 3′ end of the HTLV-1 genome (Tax gene) is necessary and sufficient for cell immortalization. In addition, co-transfection of Tax with Ras can also induce transformation of primary rat embryo fibroblasts. Finally, Tax transgenic mice develop several pathologies, including leukemia, mesenchymal tumor, and neuro-fibromas.

HTLV-1 is passed from male to female via semen, and from mother to child by breast milk. The latter route has been demonstrated prospectively. Encouraging carrier mothers to refrain from breast feeding has decreased transmission of HTLV-1 to their children by 80 % [44].

19.4.5.1 Hepatitis B Virus

Infection by hepatitis B virus (HBV) is strongly associated with the development of hepatocellular carcinoma (HCC), one of the ten most common carcinomas in the world [45]. This oncogenic association categorizes HBV as a tumor virus. HBV is a hepatotropic, circular, partially duplex DNA virus of 3.2 kb and replicates via an RNA intermediate and reverse transcription. Infection by HBV can lead to liver damage and such pathological diseases as chronic hepatic insufficiency and cirrhosis, leading to HCC. HCC is a difficult cancer to treat because symptoms occur late in the development of the carcinoma, often too late for clinical intervention. Unfortunately, the survival rate for individuals diagnosed with HCC is low. The association of HCC and HBV was determined from worldwide epidemiological studies [46]. In those areas of the world where a higher incidence of HCC was observed (e.g., sub-Saharan Africa and Southeast Asia), there was a higher rate of HBV. Though HBV-induced HCC is relatively rare in the USA and Europe where HBV infection rates are low, it is a leading cause of cancer in those areas where HBV infection rates are high. Studies in animal systems have also demonstrated a correlation between infection with HBV and the occurrence of HCC. For example, 100 % of woodchucks infected with woodchuck hepatitis virus (WHV) develop HCC. There is a long latency period of at least 30 years between infection by HBV and the development of HCC in humans. During this time, the virus integrates into the host genome and viral protein expression is ablated. Infection by HBV can lead to either acute or chronic hepatitis. Acute infection involves symptoms such as fever, fatigue, anorexia, and nausea, which are soon followed by jaundice. In adults, the disease is usually cleared by an immune system response to viral surface antigen. However, in 1–8 % of infected adults infection persists and the virus undergoes active replication. Chronic infection rates are much higher (approximately 90 %) in the case of perinatal and early childhood infections. It is these chronically or persistently infected patients that are at highest risk for developing HBV-associated HCC. Persistently infected individuals may be asymptomatic for years, although the HBsAg surface antigen can be detected during this time. In other patients, chronic hepatitis B occurs, with symptoms including fatigue, anxiety, and anorexia, associated with hepatocellular necrosis and inflammation. A fraction of those patients with chronic hepatitis will develop cirrhosis of the liver. Cirrhosis can then lead to HCC. How HBV causes HCC is a matter of debate, although there are two main pathways by which HBV might be acting: directly through a viral protein or integration or indirectly, as an consequence of chronic liver damage due to viral infection and host-immune responses to it. HBV may directly induce HCC either in trans, by an activity of one of its gene products early on in cancer development, or by a cis, as a result of viral integration (i.e., akin to insertionally mutagenic retroviruses). For HBV to cause oncogenesis through a trans-acting mechanism, it must be actively undergoing transcription. Since most advanced HCCs display no viral gene expression, this putative pathway must act primarily at the initial stages of cancer cell growth while viral genes are still being expressed. There are multiple viral gene products which have been argued to play a role in promoting uncontrolled cell growth. It is common to find HBV genomes integrated into the host chromosome in HCC. These integrations commonly lead to the retention of a portion of the viral genome, including the X and preS/S regions [47]. The X gene product of HBV has transcriptional activation activity. The activity of X in the context of the in vivo viral life cycle is unclear, although X has been shown to activate many promoters in reporter gene assays, including the herpes simplex virus (HSV) tk promoter, the HIV long-terminal repeat (LTR), and the HBV Enl. Cellular promoters activated by X include those for MHC class I, c-myc, and RNA polymerase III. It is possible that X activates cellular oncogenes, leading to uncontrolled cell growth. X has also been shown to inhibit nucleotide excision repair, leading to accumulated mutations. This could cause an increased mutation rate induced by chemical carcinogens such as aflatoxin B1. X has also been found to bind to the p53 tumor suppressor protein and may therefore interfere with the latter's role in DNA damage response [48]. Some mice transgenic for X driven by the X promoter develop HCC. However, this effect is not seen using heterologous promoters or subgenomic or genomic HBV DNAs containing the X region.

HBV alternatively may lead to cancer via a *cis*-acting mechanism, whereby the integration of the virus into the host genome can cause interruption of a tumor suppressor gene or activation of an oncogene. An example of insertional activation is observed in WHV-induced HCC. Using Southern blotting analysis, WHV has been found to be integrated near to the N-myc loci in 40 % of HCCs. Using the more broad-scanning technique of pulse-field gel analysis, an even higher percentage of tumors have been found to be integrated near N-myc. However, insertional activation by HBV has not been regularly demonstrated in human HCCs using either technique. However, this does not mean that this phenomenon is not occurring because current techniques allow detection only within a few kilobases of a gene of interest.

Another major school of thought is that HBV can lead to HCC via an indirect pathway. Infection of the liver by HBV can cause liver damage, which leads to a chronic proliferative response in the liver to replace lost cells. The resulting increase in DNA synthesis increases the probability of mutations occurring, leading to uncontrolled cell growth. This theory is supported by the fact that most diseases of the liver leading to liver damage, such as HCV infection, alcoholic cirrhosis, and Wilson's disease, are associated with an increased risk for the development of HCC. The Large S (L) protein product of HBV, when expressed, is toxic to cells and can lead to liver damage. Transgenic mice engineered to overexpress the HBV L protein display hepatocellular necrosis and regeneration, which eventually leads to HCC [49]. Although this result is potentially informative, it should be interpreted carefully because the levels of L protein in these mice are much higher than those in an HBV infection. HBV induced liver damage alternatively could be the result of host immune responses to viral gene products.

Although the association of HBV infection with the development of HCC is high, the mechanism by which the virus causes cancer clearly is still a matter of debate. It is possible that a combination of pathways described above are contributing to the oncogenic activity of HBV. Further clarification of this effect will pave the way for more effective treatments of HCC associated with HBV. Meanwhile, efforts are underway to eradicate HBV infections through mass immunizations.

19.4.6 Hepatitis C Virus

Human hepatitis C virus (HCV) is another etiological agent for hepatocellular carcinoma (HCC). Approximately half of the cases in the USA are ascribed to HCV [50]. HCV represents the most common chronic viral infection among bloodborne pathogens in the U.S., where the rate of infection during the period from 1988 to 1994 was estimated to be 1.8 % [51]. The World Health organization estimates the worldwide infection rate at 3 %. Infection is thought to arise from contaminated blood, use of shared needles among intravenous drug users, organ transplantation, hemodialysis, sexual transmission, and vertical transmission. As with people chronically infected with HBV, HCC in HCV-positive individuals correlates with chronic hepatitis and cirrhosis. 2–7 % of chronically infected people develop HCC [52]. The hyperproliferative state induced by chronic hepatitis and cirrhosis is argued to lead to an accumulation of genetic changes and contribute to the onset of liver cancer. How HCV contributes to liver carcinogenesis is not known.

HCV is a flavivirus. As such it is unique among the human tumor viruses for having RNA as its only genetic material. HCV contains a 9.6 kb, positive-stranded RNA as its genome, which encodes a single translation product of approximately 3000 amino acids. This polyprotein is cleaved by proteases to yield at least ten proteins [53]. The study of HCV has been daunting for at least two reasons. Its sequence varies in infected people such that there are six recognized genotypes with multiple subtypes among patients and a spectrum of quasi-species within any one infected individual. Members of these quasi-species within one patient vary by 1–2 % in their sequence [54]. In addition, there is no available cell culture for HCV. Researchers have made heroic efforts to overcome this latter hurdle and have met with partial success. In 1999 Bartenschlager and colleagues described the replication of a subgenomic derivative of HCV in a cell line derived from a human HCC [55]. These subgenomic replicons were difficult to establish, but once established exhibited bona fide characteristics of flaviviral nucleic acid replication. One to five thousand molecules of plus-strand RNA were present in each cell; minus-strand RNA was present at 10–20 % of the level of the plus strand; and this viral RNA replication was insensitive to treatment of cells with actinomycin D [55]. This mode of nucleic acid replication in cells will allow the elucidation of the cis and trans elements it requires, but with an unexpected twist. The efficient replication of the subgenomic derivatives of HCV requires mutations in at least two viral genes that enhance replication in cells but abrogate infectivity of intact HCV RNA [56].

19.4.6.1 Evidence for a Direct Role of HCV in HCC from Studies of the HCV Core Protein

The HCV core protein can cooperate with an activated form of the ras oncogene to transform primary rodent cells in tissue culture and mice transgenic for the HCV core protein develop HCC. Several potential mechanisms have been invoked to explain the transforming potential of HCV Core protein. It has been found to enhance cell proliferation through the stimulation of the mitogen-activated protein kinase [57, 58]. More recently, the core protein has been found to activate STAT3, and this activation may contribute

to its transforming potential [59]. Whether the HCV core protein contributes directly to human HCC is uncertain. Neither replication of subgenomic replicons in cell culture nor infection of chimeric mice populated with human hepatocytes will allow ready testing of the possible role of the core protein in HCV's oncogenesis.

Hormonal Carcinogenesis: The Role of Estrogens

20

William A. Ricke, Karin Williams, Jalissa Wynder, Ganesh Palapattu, Yuzhuo Wang, and Gerald R. Cunha

20.1 Background: Estrogens

In animals 17β-estradiol (E2) is typically thought of as a female sex hormone. The importance of estrogens in females is unambiguous. However, in males estrogens are also important steroid hormones, which target a variety of reproductive organs, including the prostate. In the female estradiol is primarily produced in the ovaries and acts to stimulate growth and development of the reproductive tract and mammary gland. In the male, estrogen is produced by adipose tissue, the adrenals, testicles, and even the prostate. The role of estrogen/estrogen receptor (ER) signaling in the prostate gland is poorly understood.

Steroid hormones including estrogen are derived from cholesterol. Cholesterol is subsequently converted to pregnenolone, progesterone, and then to testosterone (T) via several different cytochrome P450 enzymes. Testosterone is then converted to E2 by the P450 aromatase/CYP19 gene product. Therefore, aromatase is a key controller of the ratio of androgen to estradiol. This may be important because as men age the ratio of serum E2:T increases [1–4]. Since aromatase is expressed in the prostate, it is likely that local estradiol production plays an important role in prostatic function [5–7].

Circulating estrogens in premenopausal women originate from ovarian steroidogenesis and are in constant flux depending upon the menstrual cycle and pregnancy. However, after menopause, local aromatization of androgens and *de novo* biosynthesis [8] of E2 provide a source of estrogen to responsive tissues despite low circulating levels of estrogens. The adrenals in both men and women produce androgen which can be converted to estrogens via the action of aromatase. In males serum testosterone levels decrease steadily after the age of 39 [9] while estrogen levels remain steady resulting in a change in the androgen:estrogen ratio [10].

20.2 Hormonal Control of Prostate Growth and Development

The prostate develops from the embryonic endodermal urogenital sinus (UGS) in response to androgens, which act via the androgen receptor [11]. During prostatic development androgens mediate their effects via mesenchymal-epithelial interactions [11]. Although the prostate is primarily considered to be an androgen target, it is also a target for estrogen. Estrogens control prostatic development and function both directly and indirectly. Estrogens can elicit their effects directly on the prostate gland which causes squamous metaplasia when unopposed by androgens [12]. Transcriptional regulation by estrogens has been observed in certain genes having putative estrogen response elements (EREs) within their promoters [13–15]. These genes include members of the insulin-like growth factor, fibroblast growth factor, hepatocyte growth factor, nerve growth factor, and transforming growth factor beta families.

Importantly, these potent growth factor pathways have been implicated in human carcinogenesis of many organs including the prostate [16–20].

Organismal physiology of estrogens is extremely complicated because exogenous and endogenous estrogens can indirectly affect target tissues via systemic modulation of other hormones. For example, estrogens can have indirect systemic effects on the prostate gland by acting on the hypothalamus-pituitary-gonadal axis. Estrogens inhibit the release of gonadotropin-releasing hormone from the hypothalamus, which prevents the release of luteinizing hormone (LH) from the pituitary. Interstitial cells of the testicle (Leydig cells) are dependent upon LH for production and secretion of T. Thus, exogenous estrogens affect the prostate by inducing a chemical castration or androgen deprivation, which elicits prostatic epithelial apoptosis and generalized regression of the gland. Additionally, estrogen can cause the pituitary release of prolactin, which is a mitogen for the prostate.

Estrogens can act genomically in classical or nonclassical manners or they can act non-genomically [21–23]. It is thought that estrogens mediate their effects primarily through ER-α and/or ER-β in the prostate [7, 22, 24–26]. The hydrophobic estrogen molecule can diffuse through plasma membranes and bind to ERs found within the cytoplasm or nucleus where cofactors bind to the estrogen-ER complex. The estrogen-ER complex binds to EREs within promoters of genes either via direct protein-DNA interactions or indirectly via interactions with AP1 and SP1 sites within the target DNA (typically promoter regions) of estrogen-regulated genes. Stimulators or corepressors may bind to the estrogen-ER complex to improve or inhibit transcription. Signaling via this genomic route (i.e., estrogen/ER signaling) may take hours to facilitate a response.

ERα and ERβ are widely accepted as estrogen nuclear receptors based on their genomic effects on gene expression. Contrasting genomic ER function, membrane forms of ER exist as ERα and ERβ as well as a truncated form of ER-α termed ERα-36 or ERα-46 [21]. Both are associated with rapid non-genomic signaling. Alternative membrane-bound ERs were investigated when estrogens mediated a rapid (within minutes) induction of signaling. These investigations led to the discovery of intracellular G-protein-coupled ER (GPER) also known as GPR30 [27]. GPER is a member of the G-protein-coupled receptor (GPCR) superfamily whose activation regulates many biological responses of both normal and cancer cells [28]. Estrogen binds GPER, ER-α, and/or ERα-36/46 which stimulates transactivation of epidermal growth factor receptor (EGFR), leading to rapid phosphorylation of mitogen-activated protein kinase (MAPKs), and mobilization of intracellular calcium through synthesis of phosphatidylinostol 3,4,5-triphosphate (PI3K) in the cytoplasm.

In addition to estrogen GPER also binds selective estrogen receptor modulators (SERMS), selective estrogen receptor degraders (SERDS, and environmental ER activators [29]. Cross talk between GPER and growth factor receptors including receptor tyrosine kinases (RTKs), EGF receptor, and IGF receptors have been introduced as a possible signaling mechanism associated with cancer and metastasis [28]. Dimerization of growth factors in the RTK family causes activation of the MAPK cascade, which leads to gene transcription, cell proliferation, and PI3-K/Akt signaling, which promotes cell survival. Additionally deregulated RTK signaling is critical in cancer development and associated acquired resistance to endocrine therapy and reduced cell survival [2]. Overexpression of GPER is associated with tumor progression, increased metastasis, and acquired tamoxifen resistance [28]. The relationship between ERα, ERα-36/46 and GPER signaling is still poorly understood. However current research has focused on the relationship of ERα/variants and GPER using compounds that act as differential antagonists and agonists of the two. Understanding this relationship could provide therapeutic targets for drug therapy in hormone-induced cancers involving estrogen response signaling. Recently, a new mouse model of loss of membrane ERα function was developed [30]. Future studies using new models to decipher estrogen hormone action will lead to a better understanding of how estrogens elicit non-genomic signaling during pathogenesis.

20.3 Estrogens Are Genotoxic Carcinogens

Oxidation of steroidal estrogens and synthetic estrogens [31, 32] are capable of creating toxic agents that react with DNA inducing mutations and mutagenic reactive oxygen species (ROS). The next section will explore how estrogen/estrogen metabolites affect carcinogenesis.

20.3.1 Conversion of Estrogen to Catecholestrogens

Estradiol (E_2) and estrone (E_1) can be converted to catecholestrogens, 2 and 4 hydroxyestrogens [2-OHE1(E2) 4-OHE1(E2)], in both hormone-dependent and -independent cells. P450 1A enzymes are the predominant extrahepatic enzyme that converts steroid hormones to 2-hydroxyestrogens [33–36], but due to their lack of specificity, up to 20% of estrogen is converted to the more potent 4-hydroxyestrogens [37]. Specific estrogen 4-hydroxylase(s) have been identified in various organs including kidney, uterus, and pituitary [37–39]. In humans P450 1B1, an estrogen 4-hydroxylase is present in the breast, ovary, adrenal, and uterus [40, 41]. The tissue specific expression of these P450 isoforms contributes to the differential toxicity of estrogen in different tissues [42].

The hepatic P450s likewise convert estrogen to 4-OHE1 (E2) and may contribute to hepatic tumors in women who used oral contraceptives [43] especially contraceptives that were lacking progesterone.

Not all estrogen metabolites are carcinogenic; indeed some such as 2-methyl-estrogen may be protective prompting the question is estrogen-induced cancer driven by lack of these metabolites, and are their levels dependent upon polymorphisms present within the P450 1A gene [44] that may be specific to susceptible populations.

4-OHE1 (E2) has been shown to be oxidized to a semiquinone or a 3,4-quinone, which can generate reactive oxygen species (ROS) [45]. These molecules can react with the deoxyribonucleotides adenine and guanine within the genomic DNA [46]. Attempts to repair such damage may result in mis-match repair or base pair deletion leading to cancer-promoting mutations and/or cell transformation [8, 47–49]. Evidence that estrogen is indeed a genotoxic carcinogen exerting a mutagenic effect at the level of DNA is rapidly accumulating [45, 50–59].

2-OHE1, another estrogen metabolite, is capable of inhibiting HPV-mediated cellular proliferation by interacting with exons 6 and 7. Interestingly, 16α-OHE1, another estrogen metabolite, promotes proliferation via the same mechanism [60]. HPV and the estrogen metabolite 16α-OHEI may be capable of synergistically interacting to initiate cancers that are known to be HPV related such as cervical cancer [61]. Ratios of 2-OHE1 to 16α-OHE1 are lower in prostate and breast cancer compared to normal [62]. The transforming activities of estrogens and their metabolites were ranked as follows: 4-OHE1 (E2) >16alpha-OHE1 > E2 = 2-OHE1 (E2) [49, 63].

20.3.2 Estrogen DNA Adducts

DNA adducts are formed when chemical carcinogens bind covalently to DNA. There are two types of binding, stable, and depurinating. The differences between the two types depend on where the estrogen binds to the DNA.

20.3.3 Synthesis and Deactivation of Estrogen and Its Metabolites

The estrogens E_1 and E_2 are formed as are all steroids from cholesterol. They are formed by aromatization of 4-androsten-3,17-dione and testosterone, respectively, in an enzymatic reaction catalyzed by aromatase (P450 CYP19). They can be interconverted by 17β-estradiol dehydrogenase. The metabolism of estrogens in the liver and other tissues results in 2-4-hydroxylated estrogens that are then inactivated by conjoining reactions such as glucuronidation and sulfation that prevent excretion into the urine and feces; see Fig. 20.1. Quinines and semiquinones formed by estrogen oxidation are neutralized via conjugation with glutathione or reduced by quinone reductase.

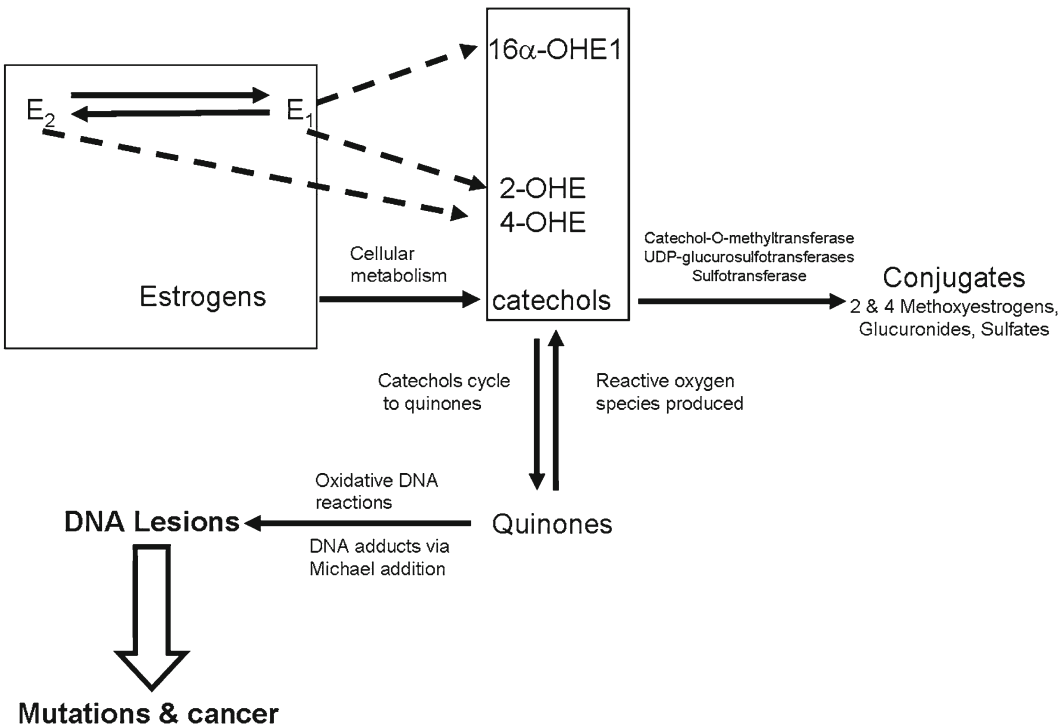

Fig. 20.1 Schematic of the production of estrogen metabolites, conjugates, and DNA adducts.

20.4 Induction of DNA Mutations by Estrogens

20.4.1 Mutations at Level of Chromosome

Chromosome gain and loss (aneuploidy) without gene mutation were observed in Syrian hamster embryo (SHE) cells transformed with E_2 or diethylstilbestrol (DES) suggesting that non-disjunction is responsible [64–66]. E_2, DES, and their quinone metabolites bind microtubules disrupting their polymerization in vitro [67–71] independent of estrogen receptor status [67]. Aneuploidy correlates with estrogen-induced cell transformation of SHE cells and may contribute to hormonal carcinogenesis [72, 73] and appearance of micronuclei [74].

20.4.2 Gene Mutations

Stable binding of DNA adjuncts to the exocyclic N^6 amino group of Adenine (A) or the N2 group of guanine (G) remain in the DNA unless they are detected and restored to normal by the DNA repair machinery. Unless the cell has faulty repair machinery these modifications should not be mutagenic. Depurinating DNA adducts bind N-3 /N-7 of adenine and/or N-7/N-8 of guanine. Depurination leads to apurinic sites that can generate mutations throughout the genome [75]. The formation of DNA adducts is independent of estrogen receptor status as shown by studies in the ERαKO/Wnt-1 mouse which displayed DNA adducts in the mammary gland [76].

20.4.3 Estrogen Receptors

There are two distinct nuclear ERs, ER-α and ER-β, and both have different ligand binding preferences [77, 78] and target genes. The molecular structures of ER-α and ER-β are similar and contain the six domains found in most steroid hormone receptors. The DNA-binding domains are nearly identical between ER-α and ER-β, while the A/B domain and the N-terminal domain share little homology. The N-terminal ligand-binding domains of ER-α and ER-β are approximately 50 % homologous, but the C-terminals are distinct between ER-α and ER-β. The genomic location for ER-α gene is on the q-arm of chromosome 6, whereas ER-β is located on the q-arm of chromosome 14. Both genes have multiple isoforms, ER-α has at least two [79], whereas ER-β has at least 5 [80]. The roles of ER-α and ER-β and their respective isoforms during prostate development, maturation, and carcinogenesis remain to be elucidated. Such structural and regulatory differences confer unique biological responses adding to the complexity of estrogen/ER signaling in estrogen target organs such as the prostate, mammary gland, and bone. Little is known about specific ER target genes and their function during normal growth, development, and carcinogenesis of the prostate and other estrogen target organs. Determining the molecular, cellular, and physiological functions of ER-α and ER-β will most certainly improve our understanding of prostate biology and carcinogenesis.

ER-β is highly expressed within the prostatic epithelium of the adult [81], while ER-α is predominantly expressed within the adult prostatic stroma and to a lesser extent within the adult prostatic epithelium. During prostate pathogenesis, such as benign prostatic hyperplasia (BPH), ER-α-positive cells and protein levels do not change in total numbers; however, stroma ER-α-positive cells significantly decrease in numbers whereas the number of ER α-positive epithelial cells increase. This tissue-specific change in ER-α positivity may play an important role in estrogen signaling and pathogenesis. The tissue distribution of the multiple isoforms of ER-α [80] and ER-β [79] change throughout prostatic development, maturation, and carcinogenesis, and their function is not fully understood.

The use of ER knockout (ERKO) mice null for either ER-α or ER-β has been helpful in elucidating the roles of these receptors in the prostate and other estrogen target organs [82]. In general the prostate develops normally in estrogen receptor-α knockout (αERKO) mice, and prostates of adult αERKO mice are basically normal suggesting that ER-α has a minor role in normal prostatic development and growth [24, 81]. More recently, it has been demonstrated that a subtle, but perhaps important prostatic phenotype exists in αERKO mice. These mice contain a decreased number of ductal branches, and individual ducts appear to be larger in size [81].

In prostate cancer and BPH, ER-α appears to be essential, because αERKO mice do not undergo disease progression [7, 83]. Estrogen receptor-β was initially cloned from the prostate and was subsequently shown to be highly expressed in adult prostatic epithelium. Subsequent studies have focused on determining the function of ER-β in the prostate. Surprisingly, prostates of ER-β knockout mice are also normal. It was reported that aged prostates from βERKO mice exhibited basal epithelial cell hyperplasia and reduced apoptosis [84]. However, these observations could not be verified by other laboratories [85]. It was also proposed that ER-β may act as a tumor suppressor during prostatic carcinogenesis as prostatic carcinomas have decreased levels of ER-β protein during tumor progression. Definitive proof of ER-β acting as a tumor suppressor remains to be established, but is an area of intense investigation.

One area in which use of αERKO and βERKO mice has been informative regarding estrogen action in the prostate concerns the induction of squamous metaplasia of prostate. A well-recognized effect on the prostate of chronic exposure to estrogens is squamous metaplasia of the epithelium [12]. Squamous metaplasia of the prostate is a benign condition and is the consequence of estrogen induction of proliferation

and squamous differentiation in prostatic basal epithelial cells. Studies using wild-type (wt) and αERKO and βERKO mice indicate that estrogen induction of prostatic squamous metaplasia requires estrogen signaling through ER-α but not ER-β [86]. For example, long-term treatment of wt and βERKO mice with diethylstilbestrol (DES) elicited pronounced prostatic squamous metaplasia, while similar treatment of αERKO mice had no such effect.

It is well established that signaling through the androgen receptor is required for prostatic development as mice lacking functional androgen receptors are devoid of a prostate as well as other male reproductive organs. The lack of prostate development in AR-null mice was shown to be associated with the absence androgen signaling in stromal cells [87]. Stromal control of prostatic development may also be important in estrogen-induced dysmorphogenesis, perinatal dysplasia, squamous metaplasia, and carcinogenesis following exposure to exogenous estrogens in various model systems. In this regard, immunohistochemical and steroid autoradiographic methods have superbly demonstrated the presence of ER-α in prostatic stromal cells during prostatic development and in prostatic pathogenesis [88–91].

To determine the respective roles of ER-α in the epithelium versus stroma during estrogen-induced squamous metaplasia of the prostate, tissue recombinants were prepared with prostatic epithelium (PrE) and prostatic stroma (PrS) from wt and α−ERKO mice: wt-PrS + wt-PrE, α−ERKO-PrS + α−ERKO-PrE, wt-PrS + α−ERKO-PrE, and α−ERKO-PrS + wt-PrE. Diethylstilbestrol (DES), a synthetic estrogen, induced squamous metaplasia only in tissue recombinants composed of wt-PrS + wt-PrE (both ER-α-positive). Tissue recombinants having α−ERKO tissues (α−ERKO-PrS+ α−ERKO-PrE, wt-PrS+ α−ERKO-PrE, and α−ERKO-PrS + wt-PrE) did not develop squamous metaplasia. Therefore, estrogen induction of squamous metaplasia of the prostate appears to require the binding of estrogen to stromal ER-α (paracrine mechanism) as well as direct action of estrogen via epithelial ER-α. Similarly, estrogen-induced cornification of vaginal epithelium requires the presence of ER-α in both the epithelium and stroma [92]. The importance of stromal-epithelial interactions mediated via ER-α signaling in the prostate has also been suggested in studies evaluating the effects of estrogenic exposure on neonates [82, 90, 93].

20.5 Role of Estrogens in Breast Cancer

Steroidal estrogens are known to be human carcinogens [94] as reported in The 11th Report on Carcinogens (RoC), a report compiled by both Federal and non-governmental scientific groups. Unlike the majority of human cancers which may present at early and late life the hormonally regulated cancers in women have a different risk pattern with very low risks before 20 years that rise until about 50 years of age when the rate of increase slows but incidence rate rises reflecting the total lifetime risk of breast cancer standing at present at 1:8. These data mirror the rise in hormones particularly E_2 up until 50 years of age when menopause results in changing hormone spectra in the tissue and serum [95–97].

Major risk factors for breast cancer are early age of first menses, late age at menopause [98], null parity [99], lack of exercise, obesity [100, 101], and hormone therapy [102, 103], all of which are estrogen linked [104]. Cancer-preventative trials using tamoxifen have reported favorable outcomes [105–110]; however tamoxifen is a selective estrogen receptor modulator (SERM) and is contraindicated in women who retain their uterus due to increased uterine cancer risks with tamoxifen treatment [105]. Interestingly tamoxifen can protect the rodent (but not human) uterus [110], kidney [107, 111], and breast from E_2-induced cancers [107, 112], but due to conversion into a genotoxic agent tamoxifen can cause liver tumors [105, 113, 114] and transforms SHE cells [115].

20.6 Role of Estrogens in Prostate Cancer

Epidemiologic and experimental studies have shown a pivotal role of steroid hormones in prostate cancer. The evidence emerges from four lines of research. (1) In animals susceptible to prostate cancer (men and dogs), the E2-to-androgen ratio increases during aging when prostate cancer manifests and is diagnosed [116, 117]. Indeed, increase in the E2:T ratio is temporally related with the development of both benign prostatic hyperplasia and prostate cancer [116, 117]. (2) African-American men, who have the highest incidence of prostatic cancer, have elevated levels of both free plasma E2 and T [118]. Caucasian-American, Latino-American, and Asian-Americans (male populations with lower incidences of prostate cancer) have lower levels of serum E2 and T [2]. (3) Testosterone in combination with estrogens induces prostatic hyperplasia in dogs and induces prostate cancer in rats and human tissues [116, 117, 119–122]. (4) The incidence of prostate cancer is highest in elderly men (across all ethnic backgrounds) who have an increased E2:T ratio [123–127]. Systemically, the change in the E2:T ratio is attributed to a decline in testicular function (reduced androgen production) and increased aromatase activity (E2 production). At the cellular level increased prostatic estrogen exposure occurs through high aromatase activity derived primarily from the prostatic stroma [6, 128]. The role of aromatase and hence estrogen/ER signaling in prostate cancer are currently being investigated. Use of aromatase knockout mice (ArKO) and inhibitors of aromatase activity have proven to be useful in understanding the importance of local prostatic E2 production and its relation to carcinogenesis.

20.7 Carcinogenicity of Estrogen in Humans

Estrogen exposure and subsequent cancer risks have been extensively examined in the human female population. Oophorectomy, and subsequent lowering of steroid levels, protects against tumor formation. In utero exposure to exogenous estrogens correlates with future breast cancer risk with low exposure being protective [129]. DES exposure during this time frame is linked to vaginal and cervical clear cell carcinoma, in the so-called DES daughters [130–133].

Testosterone has been both positively [134–137] and negatively [138, 139] associated with breast cancer in a process thought to involve its conversion to estradiol [140, 141]. Androgenic levels are high in postmenopausal women when the incidence of breast cancer is highest [135]. Furthermore treatment of cystic breast disease with androgens increased the risk of breast cancer [142]. The role of aromatase in the conversion of androgens to estrogens is currently being evaluated in breast carcinogenesis.

20.8 Models of Estrogen-Induced Prostate Cancer

Prostate cancer occurs with high frequency in men, and rarely occurs spontaneously in rats, mice, and other laboratory animals. Estrogen-induced tumors are primarily observed in rodent (rat and mouse) reproductive or endocrine tissues including the mammary gland (both male and female), uterus, cervix, vagina, testis, pituitary, and bone [143–148]. However, prostate cancer can be induced experimentally with E2 + T treatment (which mimics the hormonal milieu of men as they age) in rodent, canine, and human models [120–122, 149–151]. Three mechanisms have been proposed to explain estrogen-associated carcinogenesis: (1) Receptor-mediated estrogen receptor alpha (ERα) and estrogen receptor beta (ERβ) are steroid hormone receptors that upon binding steroid initiate transcription due to their transcription factor properties; (2) oxidative metabolism of estrogen, see above; and (3) induction of aneuploidy.

20.8.1 Estrogen and Perinatal Prostate Development

The embryonic and neonatal prostate is particularly susceptible to the pathogenic effects of exogenous estrogens, a phenomenon referred to as estrogen imprinting [152–154]. Estrogen imprinting signifies an irreversible usually deleterious morphogenesis, altered function, biochemical change, and/or pathogenesis elicited by exogenous estrogens administered experimentally during perinatal and early postnatal development. Perinatal exposure of embryos and neonates to exogenous estrogens elicit a multitude of deleterious effects on the prostate, which may lead to carcinogenesis [155]. During gestation the embryo/fetus is naturally exposed to high levels of maternal, placental, and fetal estrogens. In this regard, pregnant African-American females have the highest circulating levels of estrogen [156], and African-American men develop the highest incidence of prostate cancer [157]. Thus, it is possible that African-American men may have an increased incidence of prostate cancer due to their in utero exposure to high levels of estrogen. Neonatal or embryonic rodents (mice or rats) exposed to DES develop increased rates of prostatic carcinoma or premalignant pathologies in adulthood [152, 158–160]. In a similar manner more than one million humans were exposed in utero to the potent estrogen, DES, from the mid-1940s to the early 1970s when massive doses of this synthetic estrogen were prescribed to pregnant women for prevention of miscarriage. These so-called DES sons, men who were exposed to DES in utero, are now approaching an age in which prostate cancer is diagnosed [161]. Therefore, over the next decade more research on this cohort may elucidate the relevance of exogenous estrogen-imprinting in humans and its possible relationship to prostate pathology.

20.8.2 Carcinogenesis Induced by Estrogen Plus Testosterone

Noble was the first to report that chronic exposure to E2- and T-induced prostate cancer in rats [119]. Long-term treatment of Noble rats with E2 and T increased the incidence of epithelial dysplasia, which in turn progressed to adenocarcinoma of the prostate which metastasized [119, 162–165]. Similar studies have subsequently been performed utilizing Sprague-Dawley rats and have verified that E2 plus T induces and promotes prostate cancer [162, 164, 165]. The significance of these observations are underscored by the fact that these hormones are found naturally in men, and the E2:T ratio increases in aging men coincident with the development and diagnosis of prostate cancer. The drawbacks of the Noble rat model are long cancer latency, difficulty in altering genetics (i.e., gain or loss of function), and tumors are of rodent and not human origin. Moreover, it is difficult to study the role of estrogen/ER signaling via stromal-epithelial interactions in the rat models.

The seminal work of Noble has been integral to our current understanding of prostatic carcinogenesis and has led to the development of newer prostate cancer models which take advantage of human cells, mouse genetics, and stroma-epithelial interactions [120–122]. The use of tissue recombination technology, and thus the ability to alter the genetics of the epithelium and stroma, has yielded evidence demonstrating the important role of estrogens in carcinogenesis.

Wang and colleagues developed a model of prostatic carcinogenesis based upon tissue recombinants composed of urogenital sinus mesenchyme (UGM; fetal prostatic stroma) recombined with mouse prostatic epithelium (mPrE) derived from retinoblastoma deficient (Rb−/−) mice [166]. When UGM + mPrE-Rb−/− tissue recombinants were grafted and grown in untreated male athymic mouse hosts, no cancer was observed. However prostatic carcinogenesis rapidly occurred when tissue recombinants were grown in E2 + T-treated hosts. The cancer incidence in this model was 25 % at 2 months of hormone treatment. This finding underscored the importance of both E2 and T in the development of prostate cancer in a mouse model.

Another tissue recombination model utilizing E2 plus T to induce prostate cancer is the UGM + human prostatic epithelia (hPrE) models. Tissue recombinants composed of UGM + BPH-1 or RWPE-1 (BPH-1 and RWPE-1 are both non-tumorigenic human prostate epithelial cell lines) grown in untreated male athymic mouse hosts develop into benign prostate tissue. However, malignant human cells developed when UGM + BPH-1 or UGM + RWPE-1 tissue recombinants were grown in E2 + T-treated hosts. Non-tumorigenic human BPH-1 epithelial cells undergo irreversible malignant transformation in this UGM + BPH-1 E2 + T treatment model, because when BPH-1 cells were purified from UGM + BPH-1 E2 + T-induced tumors, they developed malignant tumors that metastasized when re-grafted into new hosts without stroma or hormones. Moreover, human (BPH-1-derived) malignant cells were found in the circulation and metastases were observed in lymph nodes, lung, and liver [120]. In contrast, UGM + BPH-1 tissue recombinants grown in untreated hosts or with T or E2 separately, rarely formed tumors but instead developed benign and ductal structures (untreated or T) or squamous metaplasia (E2). When BPH-1 cells were re-derived from such UGM + BPH-1 grafts grown in untreated hosts, the re-derived BPH-1 cells did not form tumors when grown in new host animals [120]. Steroid hormone levels in the E2 + T-treated hosts were normal for T and nearly physiologic (2–4 times higher than normal) for E2. Importantly, these hormonal profiles were dynamic and changed over the 4-month period of tumor induction similar to the changes observed in aging men (increasing E2:T ratio with time) [120]. A unique feature of the UGM + BPH-1 or UGM + RWPE-1 hormonal carcinogenesis models is that the epithelia are of human origin, and thus genetic and epigenetic aspects which may be unique to human cells are easily evaluated and should be highly relevant to human disease. Lastly, UGM + hPrE tissue recombination models are able to easily test gain and loss of stromal function through use of UGM derived from mutant mice (e.g., αERKO-stroma or ER-α-expression vectors) which allows for determination of their roles in hormonal carcinogenesis.

A major drawback of rat models is their lack of gene-gain or loss of function abilities. To this end, mouse models (transgenic and knockouts) and cell line (expression vectors and siRNA) models are unmatched for their experimental flexibility. For example, we have extended the hormonal carcinogenesis protocol of Noble and found that wt mice of different strain backgrounds (C57Bl/6 or CD-1 strains), when treated with E2 + T, developed prostaic carcinoma in situ by 4 months of age with high efficiency (40 %). The resultant dysplastic lesions exhibited reduced and diffuse E-cadherin staining and increased cellular proliferation accompanied by loss of prostatic basal cells and loss of smooth muscle in the adjacent stroma. Interestingly, C57Bl/6 mice were more sensitive to E2 + T treatment compared to CD-1 mice as evidenced by an increased incidence of prostatic intraepithelial neoplasia (PIN) in C57Bl/6 mice, which coincides with known differences in responsiveness to estrogen in these two mouse backgrounds [167]. One of the most important aspects of this new mouse model is the ability to use genetically engineered mutant mice to evaluate hormone action and estrogen-regulated downstream pathways involved in carcinogenesis.

In these aforesaid models of hormonal carcinogenesis, molecular and cellular changes induced either directly or indirectly by estrogens lead to increased proliferation, enhanced growth factor signaling pathways, phosphorylation of intracellular signaling molecules, cell survival, oxidative stress, invasion, epigenetic change, malignant transformation, and/or metastatic spread. Importantly, all animal models of prostatic hormonal carcinogenesis require estrogens for carcinogenesis. Androgens acting alone are inefficient inducers of prostatic carcinogenesis [119]. The significance of estrogen in hormonal carcinogenesis of the prostate was further emphasized in our previous report in which E2 and androgen levels were titrated to reveal an estrogen threshold for carcinogenesis below which carcinogenesis dropped abruptly [120].

20.9 Aromatase and Prostatic Pathogenesis

Estrogens produced from various tissues diffuse into the systemic circulation and hence act in an endocrine manner on cells of target tissues. While most cells are exposed to serum levels of estrogens, in the prostate local production of E2 by means of aromatase leads to increased intraprostatic estrogen levels presumably exceeding that in the circulation (systemic E2 plus local E2). Such increased E2 exposure due to local E2 synthesis via aromatase is thought to contribute to progression of breast cancer [168, 169], and such studies on breast cancer may serve as a conceptual model for determining the function of aromatase/ER signaling during carcinogenesis. Interestingly, the aromatizable androgen, T, by itself can

stimulate prostatic carcinogenesis in Noble and Lobound-Wistar rats albeit with low efficiency relative to that of E2+T [119, 170]. Since prostates express aromatase, it is likely that T may act as a substrate for local estrogen production within the prostate. Thus, administration of exogenous T results in exposure of the prostate to both androgen and locally produced E2. This interpretation is supported by studies with dihydrotestosterone (DHT), an androgen which cannot be aromatized to estradiol. In this regard when DHT plus E2 (instead of T+E2) was administered, the incidence of prostatic carcinogenesis was greatly reduced in Noble and Lobound-Wistar rats [150, 157, 164, 170]. One interpretation of these findings is that generation of prostatic carcinogenesis by E2+T only works provided that T can be locally converted into E2 by aromatase. Collectively, these experiments support the pro-oncogenic role of aromatase, and hence estrogen/ER signaling in carcinogenesis.

20.9.1 Perinatal Exposure to Estrogen Induces Prostatic Pathogenesis

To identify the mechanism of hormone action in perinatal estrogen imprinting, Prins and colleagues utilized αERKO and βERKO mice [90]. They demonstrated that adult prostate dysplasia was induced by neonatal estrogenization (estrogen-imprinting) and that estrogen action was a consequence of signaling through ER-α and not through ER-β. This is because when neonatal αERKO mice were treated with exogenous estrogen they did not develop dysplasia later in adulthood, while βERKO and wt mice developed prostatic dysplasia later in life following neonatal estrogen treatment. Since ER-α is expressed predominantly in the stroma of untreated mice, it was concluded that stromal ER-α mediates prostate dysplasia, even though this hypothesis has not been tested through analysis of the appropriate tissue specific loss of function experiments.

Estrogen imprinting elicits permanent alterations in androgen receptor levels, interacinar stroma volume, inflammatory reactions, epithelial hyperplasia, and development of dysplastic lesions in the prostate [89, 153, 159, 171, 172]. Increased expression of ER-α, c-myc, and c-fos as well as decreased expression of AR and ER-β occurred following perinatal exposure to exogenous estrogens and may be part of the downstream mechanisms associated with development of prostatic lesions later in life [89, 171, 173–175].

Another potential source of exogenous estrogens is the environment. Estrogenic compounds are found in numerous products including dental sealants, water treatments, insecticides, and plastics (used to store food and beverages). The effects of environmental estrogens on reproductive status have been known for years. The identification of these estrogens has led to the term endocrine disruptor [176]. One compound currently under scrutiny is bisphenol-A (BPA), a weak estrogen and a component of many plastics. It has been suggested that BPA and other endocrine disrupters may have pathogenic effects in humans, although this is controversial and hotly debated [177]. Recently estrogenic endocrine disrupters, specifically bisphenol A, have been found to induce prostate dysplasia when administered neonatally [155, 178]. A downstream pathway from BPA/ER signaling involved in the process of prostatic dysplasia, appears to be phosphodiesterase type 4 variant 4 (PDE4D4), an enzyme involved in regulating levels of cellular cAMP, which is epigenetically altered via hypomethylation during estrogen imprinting [155]. Constitutive activity of this enzyme is likely a contributing factor to early stages of carcinogenesis. BPA does bind and activate both ER-α and ER-β albeit with lower efficiency than E2 [77, 78]. However, environmental estrogens, such as BPA, are known to elicit their biological activity at much lower concentrations during development than in adulthood [172]. Determining which environmental estrogens are involved in prostatic abnormalities and their mechanisms of action will be important for our understanding of how carcinogenesis is initiated and/or stimulated.

20.9.2 Induction of Carcinogenesis in Adults

Prostates of adult C57Bl/6 mice treated with E2+T implants were significantly enlarged relative to control untreated animals and contained areas of high grade prostatic intraepithelial neoplasia (PIN) after 4 months of E2+T exposure [7]. Prostates from hormone treated mice exhibited biochemical changes consistent with prostate cancer progression. These changes included increased PCNA-positive cells (cellular proliferation), diffuse and reduced expression of E-cadherin, and phosphorylation of AKT. Additionally, areas of high-grade PIN exhibited marked decreases in prostatic basal cells and loss of smooth muscle in the stroma. As with the Noble and Lobound-Wistar rat models, this new mouse model suggests that E2+T induces both initiation and promotion of malignant lesions. Therefore, determination of the role of steroid hormones, especially estrogens, in prostate carcinogenesis may lead to the identification of both initiating factors and those involved in the promotion of cancer.

In prostates from E2+T treated wt mice, ER-α was detected in epithelial as well as stromal cells in areas of PIN, which further adds to the complexity ER-α signaling during carcinogenesis. As seen with human carcinogenesis, ER-α was expressed in the stroma, while epithelial ER-β was reduced or absent in PIN-lesions of wt mice treated with E2+T. Therefore, it is reasonable to assume that increased stromal ER-α signaling mediates the carcinogenic effects of estrogen.

Use of αERKO and βERKO mice have provided additional information on the respective role of these receptors in

normal development and carcinogenesis of the prostate. In αERKO mice, E2 + T failed to induce dysplasia or high grade PIN, suggesting a key role of ER-α in hormonal carcinogenesis [7]. In contrast, ER-β knockout mice (which express ER-α) developed prostatic hyperplasia, dysplasia and high grade PIN comparable to that seen in wild-type mice when treated with E2 + T. This mechanism is also observed for BPH [83]. Several markers indicative of carcinogenesis including E-cadherin, cellular proliferation (PCNA labeling index), and presence of both basal epithelial cells and smooth muscle cells were all within normal parameters in E2 + T-treated αERKO mice. However, in βERKO mice the expression profile of these markers deviated from normal and were consistent with a cancer progression. Together these data highlight the importance of signaling through ER-α in the induction of prostatic carcinogenesis. Future experimentation will determine the specific gain and loss of function of ER-α and ER-β in stromal and/or epithelial tissue compartments and will allow dissection of the mechanism of hormone action and the relevant downstream mediators of hormone-induced prostatic carcinogenesis. See Fig. 20.2 for schematic of estrogen action in the prostate.

The existence of both ER-α and ER-β in the benign and malignant prostate suggests multiple roles for these receptors. It is not known whether ER-α and ER-β interact directly with each other (transcriptional cooperativity) or indirectly (via paracrine factors) during prostate cancer progression. Given the principal expression of ER-β is within the epithelium and the predominant stromal expression of ER-α, this makes the task of determining the role estrogen/ER signaling in pathogenesis very difficult. In this regard, it has been reported that ER-α levels increased with prostate cancer progression [179], even though consensus on this point is still needed [149, 180]. In contrast, ER-β expression decreases during prostate cancer progression, but may reappear in later stages [179–182]. Re-expression of ER-β has been associated with metastases and an increased rate of prostate cancer reoccurrence [180, 183]. These findings suggest that ER-α and ER-β may play separate and pivotal roles in prostatic carcinogenesis. Additionally, the function of ER-α versus ER-β are likely to be different depending on the stage of carcinogenesis.

Estrogen receptor-β has been dubbed a brake for cancer [184] as demonstrated by the ability of ER-β-specific agonists to decrease normal adult prostate cell proliferation [185]. Additionally, βERKO mice have been observed to have increased prostatic basal cell hyperplasia [186]. Finally, ER-β has been shown to increase the expression of detoxifying agents such as glutathione S-transferase-π which acts to prevent oxidative genomic damage and thus stabilizes genomic integrity [187–189]. These data suggest a potential therapeutic/preventative role for ER-β-signaling in prostate cancer progression.

While the significance of decreased ER-β expression during malignancy is unknown, the mechanism of this loss has been attributed to methylation of the ER-β promoter and hence silencing of ER-β transcription [190, 191]. The mechanism for re-expression of ER-β in metastatic cancer may involve demethylation of a unique CpG island residing in the promoter of ER-β, which has been shown to be inversely related to the stage of carcinogenesis [191, 192]. Determination of the precise roles of ER-β as well as their downstream targets will aid in our understanding of this process.

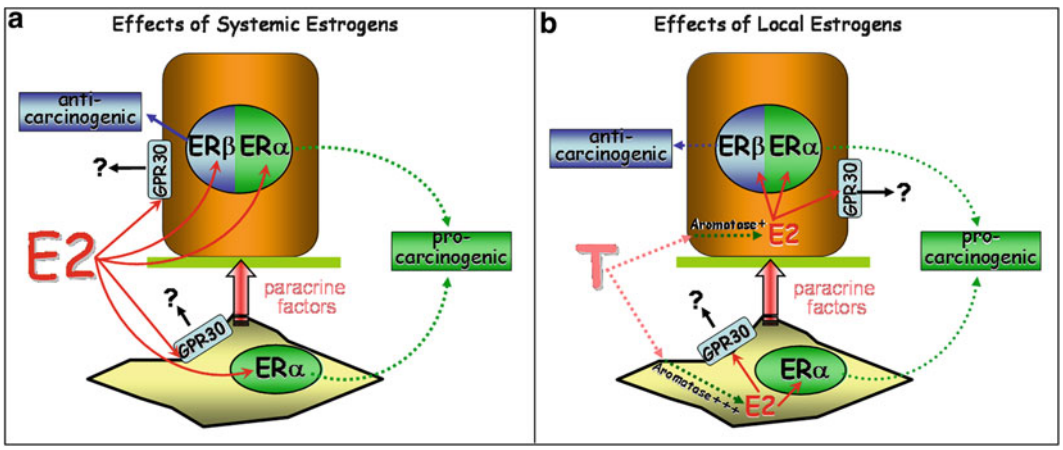

Fig. 20.2 The systemic and local effects of estrogens in stromal-epithelial interactions of the prostate. (**a**) Circulating estradiol (E2) enters the prostate and can bind and activate stromal and/or epithelial estrogen receptors (ER-α or ER-β). E2 binding to stromal and/or epithelial ER-α is likely to be involved in the promotion of carcinogenesis. E2 activation of stromal ER-α stimulates the secretion of putative E2-regulated paracrine factors which stimulate carcinogenesis. Unlike ER-α, ER-β when occupied by ligand slows prostatic epithelial proliferation and hence may be anti-carcinogenic. It is currently unknown if the E2 binding to membrane-bound GPR-30 (or ERα, ERα-36, or ERα-46) is involved in prostate biology or pathogenesis. (**b**) T can be converted to E2 via the P450 enzyme aromatase and thus increase local prostatic concentrations of E2, which may enhance estrogenic effects via ER-mediated events.

Furthermore, understanding the effect of estrogens on ER-β promoter methylation during carcinogenesis may give us additional insights for therapeutic targeting using selective estrogen receptor modulators (SERMs). Ultimately the appropriate timing of therapy as well as use of demethylating agents will aid in our understanding of how these compounds mediate their affects and elucidate of the underlying mechanisms.

20.10 Chemo-Prevention of Carcinogenesis

The involvement of estrogen in prostate cancer suggests that it should be possible to prevent prostate cancer through manipulation of estrogen pathways. The SERM, tamoxifen, has been successfully used in breast cancer studies and is the standard of care in many hospitals. Additionally, there are several models of prostatic carcinogenesis that suggest that anti-estrogens may be chemo-preventative or chemo-therapeutic [193, 194]. Antiestrogens inhibit cell proliferation and induce cell death in breast cancer cells [195, 196]. In regard to the prostate, the SERM, toremifene, decreased the rate of progression of cancer as well as inhibited the presence of high-grade PIN in TRAMP mice [197]. Interestingly these effects were not associated with changes in serum levels of E2 and T, which suggests that the therapeutic effect may have been direct. Toremifene binds and inhibits both ER-α and ER-β. Estrogen receptor-β has been determined to be a suppressor of prostatic growth [84, 91, 183, 185], while prostatic ER-α appears to enhance prostate epithelial growth [86, 90, 198]. Thus, anti-estrogenic activities of tamoxifen/toremifene may exert their actions through ER-α or ER-β or both. However, since estrogen-induced metaplasia, dysplasia, and high grade PIN doesn't occur in αERKO mice [7, 86, 90], it is likely that ER-α mediates the carcinogenic effects of estrogen, and thus chemo-preventative effects of SERMs may also operate via ER-α. Relevance of these studies to human disease is seen within a recent clinical trial of the effects of anti-estrogens in human prostatic carcinogenesis. Men with high grade PIN were treated with toremifene for 1 year, which significantly decreased the rate of prostate cancer progression [199]. In this study men tolerated the SERM well with few side effects. However, these studies have not been resilient [200]. Nonetheless, other SERMs (e.g., raloxifene, tamoxifen) which may recruit different cofactors and thus may lead to more efficacious effects and hence prevent disease progression. Further studies will be needed to establish the efficacy of this therapy and to identify which ER and which tissue layer is affected by the SERM. Moreover, determination of ER-downstream effectors will help dissect the mechanism of estrogen/anti-estrogen action in prostatic carcinogenesis.

Chemoprevention may also be provided through dietary means. Several epidemiological studies linked one's diet to prostate cancer [201–203]. The high fat/low fiber Western diet, as opposed to the low fat high fiber Asian diet, has been inferred to be a risk factor in prostate cancer. In this regard, there is at least one dietary factor related to estrogen/ER signaling: phytoestrogens. High amounts of phytoestrogens in the diet have been determined to be inversely correlated with prostate cancer risk [204]. The isoflavanoid phytoestrogen, genistein, is found in soybeans and soybean products. Genistein binds and activates ER-α and ER-β, although it is a better ligand for ER-β. Thus, genistein selectively promotes ER-β signaling (although ER-α signaling still occurs) in the prostate. If ER-β-signaling is important in preventing cellular proliferation, this may be a mechanism of action for genistein and other phytoestrogens. In support of phytoestrogens as inhibitors of prostatic carcinogenesis, prostatic dysplasia was reduced in DES-treated mice (perinatal model) fed a soybean rich diet [205]. Genistein also reduced rates of prostatic carcinogenesis observed in carcinogen-treated Lobound-Wistar rats [206]. Finally, TRAMP (a transgenic mouse model of prostate cancer) mice had fewer poorly differentiated cancers on a genistein-rich diet [207]. Collectively, these data support the role of phytoestrogens/genistein and ER-β signaling in prevention of prostatic carcinogenesis.

20.11 Chemotherapy

Historically, administration of exogenous estrogens have been used in prostate cancer therapy as chemical castration agents. In this case, the mechanism of estrogen action was indirect, having its' direct effect on the hypothalamus-pituitary-gonadal axis and thus inhibiting androgen secretion, leading to prostatic epithelial apoptosis. However, since estrogens modulate initiation and progression of cancer, anti-estrogens or SERMs have been used experimentally to treat and prevent different stages of prostate cancer. A considerable amount of data has been demonstrated that SERMs may be effective therapies for prostate cancer. The capacity of SERMs to halt cancer cell growth is attributed to a number of different estrogen-regulated pathways and mechanisms including: cytotoxicity [208], microtubule destabilization [209], angiogenesis, anti-metastatic [210], DNA synthesis inhibition [211], cell cycle disruption [212, 213], induction of apoptosis [212–214], and dysregulation or activation of apoptosis machinery [215–217]. These data support the notion that anti-estrogens such as tamoxifen prevent prostate cancer progression, even though SERM therapy in later stages of prostate cancer have not been particularly effective [218–222]. Due to the different ERs/ER-pathways and their tissue specificity and temporal characteristics, each stage of carcinogenesis is expected to respond to SERMS differently. For example, since ER-α (a putative enhancer of carcinogenesis) is present and abundant during the benign/premalignant stage of carcinogenesis, it may be useful to antagonize ER-α in early rather than in later

stages of the disease when it's expression is lower. Likewise, since ER-β (a negative regulator of epithelial growth) is lost during cancer progression, it may be futile to treat prostate cancer using ER-β agonists at this stage. Treatment with ER-β agonists may be most effective in early or late (metastatic) stages of carcinogenesis at times when ER-β is strongly expressed. To emphasize this point, the success of a clinical Phase 2b trial using the anti-estrogen, toremifene, in men with high-grade PIN has provided new insight into the timing of when to treat prostatic carcinogenesis [199].

20.12 Conclusion

Epidemiological and experimental data create a clear link between estrogens and prostatic carcinogenesis. Since estrogens can affect the prostate in many ways and at different times throughout life, it is likely that targeting therapies directed toward ER-α or ER-β selectively and or collectively may be a successful chemo-preventative strategy for prostatic carcinogenesis. Moreover, anti-estrogen treatment directed towards specific tissue compartments (e.g., stromal versus epithelial) and specific ERs at different times of carcinogenesis may also prove beneficial in preventing carcinogenesis. In order to determine mechanisms associated with ER-signaling in the prostate, it is likely that the elucidation of how estrogens mediate their effects temporally and within specific tissue types is needed. The success of anti-estrogens in preventing early stages of carcinogenesis bodes well for the prevention of prostate cancer.

Sporadic Cancers

21

Clemens B. Tempfer and Marc-André Reymond

21.1 General Aspects

Cancer may occur in hereditary and sporadic forms. Clearly, the majority of cancers develop sporadically. For example, in breast cancer, over 90 % of cases are sporadic and only 5–10 % of cases are considered hereditary, with mutations in the tumor suppressor genes BRCA1 and BRCA2 accounting for most of these cases [1]. Among women with synchronous endometrial and ovarian cancer, 7 % meet clinical and/or molecular criteria of hereditary non-polyposis colon cancer (HNPCC) syndrome [2]. Other cancer entities are entirely sporadic and have almost no proportion of hereditary cases, e.g., cervical cancer [3]. In contrast to hereditary cancers with a single genetic factor of high penetrance, the reason why sporadic cancer develops seems to be multifold. In a minority of sporadic cancers, a single etiologic factor can be identified. For example, up to 98 % of cervical cancer cases are caused by malignant transformation of cervical epithelial cells via genomic incorporation of the E5, E6, and E7 proto-oncogenes and subsequent targeting of the p53 and Rb pathways [3]. However, in most sporadic cancers an unknown number of factors, which are alone neither necessary nor sufficient to cause malignant transformation, act together and increase the susceptibility to one or more specific malignancies. This may be achieved by direct interaction such as DNA damage through ionizing radiation or genotoxic compounds or by indirect interaction such as reduced immunocompetence and subsequently limited immunoclearance of malignant cells or cancerogenic viruses such as the Human Papilloma Virus (HPV). In the end, all of these factors influence malignant transformation by genetic and/or epigenetic events and subsequently cause loss of cell proliferation control. In this respect, gatekeeping genes, i.e., those genes that are directly regulating the growth of cells, are frequently mutated in sporadic cancers through somatic mutations, as well as through germline mutations in predisposed individuals [4]. Thus, there seems to be a gradual, but not a principal difference between cancerogenic pathways in sporadic and hereditary cancers.

A wide variety of risk factors for the development of sporadic cancer have been identified, among them physical and chemical agents including radiation and exogenous toxins, and endogenous factors such as hormones and dietary contents. In addition, numerous individual biologic and socioeconomic variables such as age, immune status, viral infections, education, and ethnicity have been associated with cancer risk. Some of these have an obvious and well described etiologic link to cancer such as infection with HPV or exposure to ultraviolet radiation. In other cases, the pathophysiologic reason for the observed association with cancer is less clear, as with oral contraceptive use and cervical cancer or breast feeding and breast cancer. In this chapter we present and discuss an overview of factors found to be associated with the development of sporadic cancer.

21.2 Risk Factors and Associations

21.2.1 Age

The incidence of most cancers increases with age. The reason behind this phenomenon may be the fact that accumulation of mutations is a common driver of both aging and cancer. These mutations may be caused by physical and chemical noxious agents as well as endogenous genetic and epigenetic factors, such as telomere biology, gene silencing, apoptosis, and loss of heterozygosity [5]. Studies conducted in yeast, worms, flies, and mice confirmed substantial changes in gene expression during the natural aging process. Among them, the most important was silencing of tumor

suppressors and other genes involved in the control of cell cycle, apoptosis, detoxification, and the cholesterol metabolism. In addition, age-dependent gene expression of oncogenes typically associated with diseases of advanced age has been documented [6].

Cancer epidemiology shows age-specific distribution patterns. Most cancers have one or more characteristic age-specific incidence peaks. In an overview of 600,000 cases of breast cancer in the US between 1950 and 2003, for example, a bimodal incidence peak at 50 and 70 years was described before the introduction of widespread screening mammography in the early 1980s [7]. Thereafter, age distribution shifted to older ages at diagnosis and later returned to a bimodal distribution similar to patterns before screening within the last decade. These data most likely reflect a complex interaction between age-related biologic factors, risk factors, and interventional phenomena. Specifically, patterns of mammography screening and use of hormone replacement therapy have been shown to parallel breast cancer incidence rates from 1980 to 2006 in a study of a large US health care plan [8]. These two factors are therefore thought to be the major contributors to changes in sporadic breast cancer incidence. Clearly, the association between age and cancer incidence is influenced by many factors and may be more reflective of general characteristics of a given society than of basic cancer biology principles.

Another example of the influence of environmental factors on age-specific incidence peaks is sexual activity and age-specific incidence rates of cervical cancer. Exposure to the DNA damaging effects of the E5, E6, and E7 protein gene sequences of human papilloma virus (HPV) high-risk subtypes such as HPV 16 and 18 is dependent on sexual activity. In addition, a latency period of chronic infection as well as the maturity of the immune system influence the age at onset of cervical intraepithelial neoplasia. Interaction of these factors results in two incidence peaks of cervical intraepithelial neoplasia and invasive cervical cancer at 33 and 51 years of age, respectively [9]. In this case, age is both a surrogate marker for sexual behavior and a biologic factor, because immunological HPV clearance rates are age-dependent.

Also, age may be a risk factor of cancer as a consequence of specific birth cohorts being associated with cancer incidence. This can be due to a known carcinogen exerting its influence in utero or in early childhood. Diethylstilbestrol exposure in utero, for example, has been shown to result in a subsequently increased risk of adenocarcinoma of the vagina in specific birth cohorts [10]. After identification and elimination of the causative agent, this rare form of cancer is no longer seen among other birth cohorts. Associations between cancer incidence and birth cohorts may also be due to the exposure to an unknown risk factor. In a study of testicular cancer incidence patterns in the Netherlands between 1970 and 2004, the incidence rate of testicular cancer remained stable for all age groups at 3/100,000 person years until 1989, but increased annually thereafter by 4 % to 6/100,000 until 2004 [11]. It has been hypothesized that changes in lifestyle factors such as increased maternal age, genetic, and environmental factors, i.e., endocrine disruptors, are responsible for this pattern of testicular cancer incidence.

21.2.2 Obesity

Obesity, defined as a body mass index (body weight in kilograms/body height in meters) of >30, is associated with a significantly increased risk of cancer. Obese individuals have a higher risk of esophageal, colorectal, liver, gallbladder, pancreatic, renal, endometrial, ovarian, prostate, and breast cancer, as well as hematologic malignancies such as non-Hodgkin lymphoma and multiple myeloma. Obesity accounts for 20 % of all cancer deaths [12].

It is believed today that obesity affects several pathophysiologic systems promoting malignant transformation. Obesity is associated with increased sex hormone concentrations due to increased aromatase activity in adipocytes, increased ovarian androgen production, reduced sex hormone binding globulin production, and reduced progesterone production. Other potentially carcinogenic hormones and cytokines such as insulin, insulin-like growth factor-1, leptin, tumor necrosis factor-alpha, plasminogen activator-inhibitor, and angiotensinogen have been found to be increased in the serum and tissue of obese individuals [13]. The contribution of individual hormones and cytokines to malignant transformation is unclear and specific combinations of substances seem to exert a pro-carcinogenic effect, while others do not. For example, evidence from large prospective-randomized intervention trials such as the Women's Health Initiative showed that 5 years of treatment with conjugated equine estrogens and medroxyprogesterone acetate significantly increased breast cancer risk, whereas 8 years of treatment with conjugated equine estrogens alone significantly reduced breast cancer incidence among women with at least 80 % treatment adherence [14].

Obesity also affects sporadic cancer recurrence risk and overall survival. In breast cancer survivors, obesity is an independent predictor of disease-free and overall survival [15]. From a technical perspective, obesity may also adversely affect surgical cancer treatment. Laparoscopic lymph node sampling, for example, is less often successful in obese women with pelvic malignancies compared to nonobese controls. Also, completion of a state-of-the-art surgical staging is achieved significantly less often among obese patients. Erkanli et al. cite a successful surgical staging rate of 93 % in women with a BMI < 30 compared to 81 % in women with a BMI > 40. The technically demanding paraaortic lymph node staging procedure was performed in 74 % of eligible patients

with a BMI < 30 compared to 48 % of eligible patients with a BMI > 40 [16]. Another factor which negatively affects cancer treatment and prognosis of obese individuals is screening compliance. Both cervical cancer screening by cervical PAP smear and breast cancer screening by mammography is underused by obese women. The reason for this is unclear, but socioeconomic status, embarrassment, and lack of mobility due to associated morbidity have been cited [17].

21.2.3 Ethnicity

Ethnic background plays a major role in sporadic cancer incidence, diagnosis, treatment, and prognosis. This is believed to be due to many reasons, among them cultural phenomena, life style patterns, socioeconomic factors such as education level and access to health care as well as genetic factors. Knowledge of ethnicity-specific cancer characteristics has implications for cancer screening programs among ethnic minorities. Tiwari et al. investigated 256 British colorectal cancer patients and found that Afro-Caribbeans, Asians, and Mediterraneans presented at significantly younger ages compared to Caucasians [18]. Also, Afro-Caribbeans had significantly more right-sided and Mediterraneans more left-sided colorectal cancer. Afro-Caribbean and Caucasian patients presented with more advanced stages compared to Mediterraneans. These data indicate that culture-specific dietary patterns, access to health care interventions such as colorectal screening, and genetic factors may influence cancer incidence and cancer biology in different ethnic groups. In another study of ethnic differences in incidence and outcome of 156,570 US women with sporadic breast cancer, all ethnic minority groups including African-American, Hispanic, American Indian/Alaskan Natives, and Asian/Pacific Islanders had significantly lower incidence rates compared to Caucasian women [19]. These differences were explained by a differential distribution of breast cancer risk factors such as mammography screening participation, age, number of first degree relatives with breast cancer, prior breast biopsy, alcohol intake, education, as well as age at menarche, age at first birth, and age at menopause in all investigated ethnic groups. Breast cancer in African-Americans also had significantly more often unfavorable characteristics and a higher mortality compared to Caucasian women, independent of body mass index, hormone therapy use, and socioeconomic characteristics pointing to a strong genetic background for this phenomenon.

In a study of 13 US cancer registries with cervical cancer incidence data collected between 1992 and 2003, significant differences between ethnic groups were identified [20]. Hispanic whites, for example, had the highest cervical cancer incidence rates, whereas non-Hispanic whites had the lowest incidence rates. African-Americans, on the other hand, had the lowest incidence rates of cervical adenocarcinoma. It is of note, that in this study most of the variation among ethnic groups was explained by differences in screening participation and socioeconomic characteristics. Also supporting the importance of socioeconomic factors for cancer incidence, diagnosis, and treatment, a Swedish study analyzed a national cancer database over a period of 14 years and found that University graduates were significantly more likely to be diagnosed with breast cancer compared to women without a University education, but had the highest survival rates after a diagnosis of breast cancer [21]. These data indicate that most variations in cancer incidence among ethnic groups are due to differential distribution of socioeconomic risk factors. However, among selected ethnic groups such as African-Americans genetic factors also seem to play a significant role.

21.2.4 Immunosuppression

Immunologic aspects play an important role in the biology of sporadic cancer. For example, markers of immunologic activity such as local inflammatory reaction at the cancer site and increased production of C-reactive protein are independent prognostic factors for overall and disease-free survival in cervical, ovarian, and endometrial cancer [22]. A state of chronic inflammation has been described as an etiologic factor of cancerogenesis in gastric, pancreatic, and prostate cancer [23, 24]. On the other hand, immunosuppression also seems to increase the risk of malignant transformation.

In individuals with rheumatoid arthritis, treatment with cyclophosphamide, methotrexate, and azathioprine is associated with an increased cancer risk [25–27]. Also, the use of immunomodulatory biologic therapies such as infliximab and adalimumab increased the risk of malignancy threefold in a meta-analysis of randomized trials [28]. In a US study of 13,001 individuals with rheumatoid arthritis, exposure to biologic therapies increased the risk of non-melanoma skin cancer and melanoma, but not solid tumors and lymphoproliferative malignancies [29].

The effect of immunosuppressive antirejection drugs after organ transplantion on the occurrence of cancer was first described in the 1970s. The excess risk of malignancies among immunosuppressed people is accounted for by non-Hodgkin lymphoma, Kaposi's sarcoma, non-melanoma skin cancer, and anogenital cancers. These malignancies are also characteristic of Human Immunodeficiency Virus (HIV)-infected individuals. For example, in a study of 8074 HIV-infected individuals and 2875 transplant recipients undergoing chronic immunosuppressive therapy, the cumulative probability of cancer after 15 years was 13.3 % and 14.7 %, respectively. The increased overall risk of cancer at any site was 2.2-fold increased for transplant recipients and 9.8-fold increased for HIV-infected individuals [30].

The most common entities were Kaposi's sarcoma, non-Hodgkin lymphoma, liver, lung, and cervical cancer. In a long-term study of patients with membraneous nephropathy undergoing chronic cytotoxic and immunosuppressive therapy, a doubling of cancer incidence was observed during 15 years after diagnosis [31]. Clearly, chronic immunosuppression favors the development of virally induced cancers, but cancer types not associated with infectious agents also seem to develop more often among individuals with a compromised immune system.

Altering the immune system after cancer surgery adversely affects prognosis and outcome. For example, in a randomized trial of 847 women with ovarian cancer, the addition of interferon gamma 1-b to standard carboplatin–paclitaxel chemotherapy significantly reduced overall survival [32]. In summary, the available data indicate that deviations in the immunologic control both in the form of increased immunoactivity and immunosuppression may contribute to the process of malignant transformation.

21.3 Exogenous Factors

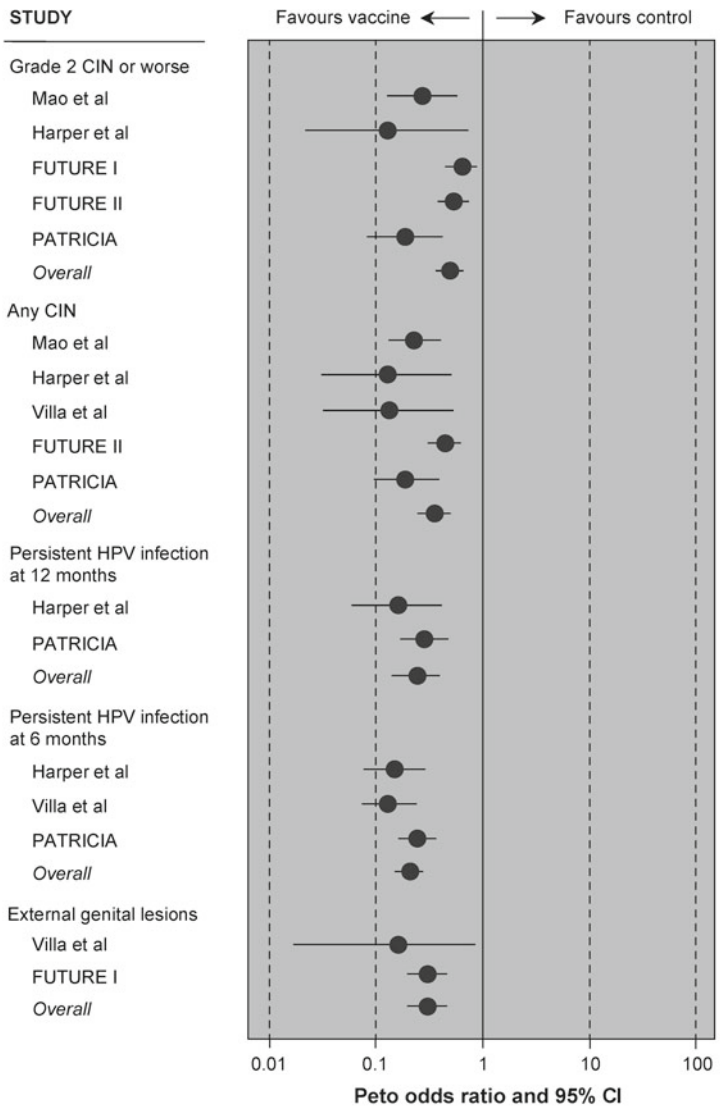
21.3.1 Infectious Agents

Cancer is a disease initiated by genetic events and infectious agents can cause or promote malignant transformation by indirectly or directly damaging DNA. It has been estimated that 15 % of all cancers are etiologically linked to viral infection. Specific cancers with an established viral etiology are T-cell leukemia, hepatocellular carcinoma, and cervical cancer, being associated with human T-cell leukemia virus type-I, hepatitis B virus, and high-risk HPV, respectively [33]. Virally triggered carcinogenesis may be achieved by the integration of proto-oncogenic viral DNA sequences into the host genome. These DNA sequences then function as oncogenes causing expression of oncoproteins such as Tax, HBx, and E6/E7, capable of inducing genome instability. Cervical cancer, for example, is believed to be almost exclusively due to an infection with HPV high-risk subtypes such as HPV 16 and HPV 18. Experimental evidence in neural progenitor cells demonstrates that integration of the HPV E5, E6, and E7 proto-oncogenes leads to the degradation of the tumor suppressor proteins p53 and pRB involving MEK-ERK signalling pathways [34]. Consequently, it has been successfully demonstrated that prophylactic vaccination against specific epitopes of HPV high-risk subtypes such as HPV 16 and HPV 18 efficiently prevents cervical dysplasia. In a meta analysis of six randomized controlled trials and three follow-up reports of non-randomized vaccination trials, HPV vaccination reduced the frequency of high-grade cervical dysplasia by 86 % (Odds Ratio 0.14; 95 % Confidence Interval 0.09–0.21) among HPV naïve women aged 15–25 years [35]. Figure 21.1 shows the clinical outcomes of HPV vaccination trials in an intention-to-treat meta-analysis. Bivalent and quadrivalent HPV vaccines have been proven to effectively prevent the development of cervical cancer and cervical cancer predecessors such as cervical intraepithelial neoplasia (CIN). These vaccines prevent up to 50 % of cervical cancers. Next generation nonavalent HPV vaccines are designed to cover a higher range of the HPV spectrum and may be able to prevent up to 90 % of cervical cancers [36]. In theory, highly effective vaccines may be able to eradicate cervical cancer. Other cancers are HPV-associated, but to a lesser extent then cervical cancer. Anal, vulvar, vaginal, and head-and-neck cancers are associated with HPV high-risk type infections in 10–70 % of cases [37, 38].

Another form of cancer with an infectious etiology is gastric cancer. Helicobacter pylori (H. pylori) infection is the leading cause of gastric cancer worldwide. Infection with this ubiquitous infectious agent is harbored by approximately half of the population worldwide [24]. Malignant transformation is achieved through a multistep cascade including chronic inflammation, atrophy, metaplasia, dysplasia, and invasive cancer. Interestingly, the target cells of malignant transformation in H. pylori caused gastric cancer are bone marrow derived tissue stem cells. These cells are infected in bone marrow and recruited into gastric tissue after local atrophy due to chronic inflammation acting then locally as cancer stem cells. In view of the high prevalence of H. pylori infection and gastric cancer, it is clear that powerful modulatory factors exert their influence. However, the exact nature of these modulatory effects is unknown. Immunologic competence and genetic susceptibility of individuals as well as genetic variation of H. pylori DNA, for example, may play a role in the etiology of both atrophic gastritis and gastric cancer. In a study of 104 affected individuals from Costa Rica, one of the countries with the highest gastric cancer incidence and mortality rates in the world, expression of the H. pylori genes vacA s1b and vacA m1 was associated with gastric cancer and the expression of vacA m1 was associated with atrophic gastritis [39].

21.3.2 Diet

The role of dietary factors in the development of cancer is controversial. While many researchers and lay people instinctively believe that diet—being one of the most basic aspects of life and affecting all organ systems—is very likely to affect cancerogenesis, study data are controversial. For example, a prospective Swedish cohort study of 10,564 men with a mean follow-up of 11 years found no association between dietary intake of total, saturated, or monounsaturated fat, and risk of prostate cancer [40]. A nationwide study from Sweden found no reduced risk of breast cancer in women with regular fish consumption [41]. The prospective National Institutes of Health-AARP Diet and Health Study



Modified intention-to-treat meta-analysis of clinically important outcomes in selected studies of prophylactic vaccination against human papillomavirus (HPV)-related infection and disease. (Modified intention-to-treat analyses included study participants who received at least 1 dose of vaccine and who either were negative for relevant HPV types at enrolment [Harper, Villa, PATRICIA] or were randomly assigned to study group irrespective of their baseline HPV status [Mao, FUTURE I, FUTURE II].) CIN = cervical intraepithelial neoplasia.

Fig. 21.1 Clinical outcomes of HPV vaccination trials in an intention-to-treat meta-analysis. Adapted from [35].

investigated grain and fiber intake of 291,988 men and 197,623 women aged 50–71 years. Total dietary fiber intake was not associated with colorectal cancer. However, whole-grain intake was inversely associated with a moderately reduced colorectal cancer risk (Relative Risk 0.79; 95 % Confidence Interval 0.70–0.89) [42]. Other studies found an association between monounsaturated and polyunsaturated fatty acid intake and breast cancer. A population-based prospective cohort study including 61,471 women reported an inverse association with monounsaturated fat intake and a positive association between polyunsaturated fat intake and breast cancer. The reduction of relative risk for each 10-g increment in the daily intake of monounsaturated fat was 0.45 (95 % Confidence Interval 0.22–0.9) [43]. In accordance, a prospective cohort study of 90,655 premenopausal women, recruited within the Nurses' Health Study, found that the dietary intake of animal fat, mainly from red meat and high-fat dairy foods, during the premenopausal years is associated with an increased risk of breast cancer [44]. Unfortunately, dietary modification aimed at reducing dietary fat has not led to a reduced incidence of breast cancer and colon cancer in a large randomized trial of 48,835 postmenopausal women [45, 46]. In accordance, a controlled dietary modification was also insufficient to significantly

reduce the recurrence risk in a randomized trial of 3088 early breast cancer survivors [47]. Specifically, adoption of a diet that was very high in vegetables, fruit, and fiber, and low in fat did not reduce additional breast cancer events or mortality during a 7.3-year follow-up period. On the other hand, the randomized Women's Intervention Nutrition Study, launched in 1987, found a reduction of breast cancer recurrences among estrogen receptor-negative disease [48]. This randomized trial of 2437 women with early-stage breast cancer determined that low-fat dietary interventions can influence body weight and decrease breast cancer recurrence. Dietary fat intake was lower in the intervention than in the control group and relapse rates were 12.4 % in the control group versus 9.8 % women in the dietary group. However, this effect was restricted to estrogen receptor-negative disease. In summary, no clear and concise dietary strategy has emerged for the primary or secondary prevention of breast cancer.

Other dietary compounds potentially affecting cancer development are phytoestrogens found for example in soy. The sustained consumption of phytoestrogen-rich food correlates with a reduced incidence of breast cancer among Asians. Of note, this association has not been found in European and US populations [49]. Human dietary intervention trials have noted a direct relationship between phytoestrogen intake and a favorable hormonal profile associated with a decreased breast cancer risk. According to a systematic review, 22 case–control and cohort studies examined the incidence of breast cancer among women with and without a diet high in phytoestrogens. A meta-analysis of 21 of these studies among Asian populations found a significantly reduced incidence of breast cancer among past phytoestrogen users. Some, but not all randomized controlled trials document a beneficial effects of phytoestrogens on surrogate parameters such as bone mineral density, vasodilation, platelet aggregation, insulin resistance, and serum concentrations of triglycerides, high-density lipoprotein, and low-density lipoprotein. However, none of the available randomized controlled trials documents a protective effect of phytoestrogens for the clinical end point of site-specific cancer or overall cancer incidence [50]. No consistent evidence of an inverse association between phytoestrogen consumption and breast cancer incidence has been documented among US and European women [49, 50]. Epidemiologic and rodent studies suggest that breast cancer chemoprevention by dietary phytoestrogen compounds may be dependent on the ingestion of large amounts of phytoestrogens before puberty, when the mammary gland is relatively immature [49].

Some dietary components such as polyphenols in tea beverages may affect cancerogenesis, but the evidence supporting this assumption is controversial. Indirect evidence from epidemiologic studies suggests that the incidence of prostate cancer may be lower in populations with regular tea consumption [51].

Adherence to a Mediterranean diet has been associated in observational studies with a reduced incidence and mortality of some cancers. In a meta-analysis of 21 cohort studies including 1,368,736 subjects and 12 case–control studies with 62,725 subjects, adherence to a Mediterranean diet resulted in a significant reduction of overall cancer mortality (10 % reduction) and colorectal cancer (14 % reduction), prostate cancer (4 % reduction), and aerodigestive cancer (56 % reduction) incidence. Nonsignificant changes could be observed for breast cancer, gastric cancer, and pancreatic cancer [52]. However, there is no controlled evidence regarding a cancer-preventing effect of the Mediterranean diet. Thus, it remains unclear, what the exact dietary strategy for cancer prevention should be and whether or not diet is an independent factor or works only within certain cultural, genetic, or climate conditions.

21.3.3 Alcohol

Alcohol features prominently among dietary factors associated with sporadic cancer incidence. However, the biologic effect of alcohol on cancerogenesis is unclear. It has been hypothesized that one mechanism implicated in alcohol-related carcinogenesis may be oxidative stress from alcohol metabolism, inflammation, and increased iron storage. Ethanol-induced cytochrome P-450 2E1 produces various reactive oxygen species, leading to the formation of lipid peroxides such as 4-hydroxy-nonenal. Furthermore, alcohol impairs the antioxidant defense system, resulting in mitochondrial damage and apoptosis. Chronic alcohol exposure elicits tissue hyperregeneration due to the activation of tissue-specific survival factors and interference with the retinoid metabolism. In addition, direct DNA damage may result from acetaldehyde, which can bind to DNA, inhibit DNA repair systems, and lead to the formation of carcinogenic exocyclic DNA adducts. Finally, chronic alcohol abuse interferes with methyl group transfer mechanisms and may thereby alter gene expression [53].

A wide variety of cancers are found at an increased incidence among chronic alcohol users. In case–control studies, the association is dose-dependent, but varies with different cancer sites. Associations between alcohol consumption and an increased risk of cancer have been reported for breast, lung, and ovarian cancer in case–control and prospective cohort studies.

For example, consumption of 20 g or more of alcohol per day increases the risk of breast cancer by 70 % compared to nondrinkers. It is of note that even moderate levels of alcohol intake, i.e., 8 g per day, are sufficient to increase the risk of breast cancer by 50 % [54]. In a large prospective Danish cohort of 13,074 women, an alcohol intake of more than 27 drinks per week increased breast cancer risk more than threefold among premenopausal women irrespective of

alcohol type. In postmenopausal women, an intake of more than six spirits per week increased breast cancer risk over twofold [55]. This effect may be limited to estrogen receptor positive breast cancers and may also be enhanced by the concomitant use of hormone replacement therapy [56]. Carpenter et al. described a statistically significant 1.8-fold increased risk of lung cancer for one or more drinks of hard liquor per day from ages 30 to 40 years after adjusting for other risk factors such as smoking [57]. Serous invasive ovarian cancer has also been associated with alcohol consumption. Interestingly, this effect was restricted to early adult regular drinking suggesting an increased susceptibility of ovarian epithelial tissue to alcohol-induced genetic damage during the early reproductive phase [58].

21.3.4 Radiation

The cancerogenic effect of ionizing radiation based on increased mutagenesis, DNA adducts, and chromosome strand breaks has been established since the early twentieth century. Chronic low-dose exposure, as well as acute high-dose exposure, to ionizing radiation increases the incidence of various forms of malignancies including solid cancers. In a long-term study of 105,448 survivors of the Hiroshima and Nagasaki nuclear bomb explosions, 17,448 first primary cancers were diagnosed between 1958 and 1998 [59]. Solid cancer rates increased by 35 % per Gray for men, and by 58 % per Gray for women at age 70, after exposure at age 30. Significant radiation-associated increases in risk were seen for most sites including oral cavity, esophagus, stomach, colon, liver, lung, non-melanoma skin, breast, ovary, bladder, nervous system, and thyroid, as well as all histologic subgroups of these cancers.

Nuclear power plant accidents such as those in Three Mile Island, Chernobyl, and Fukushima are associated with different cancer risks compared to atomic bomb explosions. In the region around Chernobyl, for example, more than five million people may have been exposed to excess radiation, mainly through contamination by iodine-131 and cesium isotopes. Interestingly, studies evaluating leukemia and non-thyroid solid cancers have not shown consistently elevated risks in the regions around Chernobyl. In the population around Three Mile Island, there was a notable temporary increase in cancer diagnoses in the years immediately after the accident, but this increase may have been the result of intensified cancer screening in the area. Long-term follow-up has shown no increases in cancer mortality [60].

Low-dose long-term exposure also leads to a significant increase in solid cancer risk, as demonstrated by the Techa River cohort study [61]. This investigation of 446,588 person-years of individuals exposed to environmental radiation releases associated with a Soviet nuclear weapons facility in the Southern Urals found a significant dose response with 3 % of solid cancers attributable to radiation exposure.

Another form of electromagnetic waves, i.e., ultraviolet (UV) radiation, has also been associated with sporadic cancer risk. Chronic exposure to solar UV radiation is the most important risk factor of non-melanoma skin cancer [62]. The typical UV-induced DNA damage consists of the generation of dimeric photoproducts between adjacent pyrimidine bases. Both UV-A and UV-B radiation induce pyrimidine dimers and promote the production of oxygen and nitrogen species with subsequent damage to DNA, proteins, and lipids. One of the typical genetic targets of UV radiation-induced mutations is the tumor suppressor gene p53. In addition, UV radiation has an immunosuppressive effect adding to its carcinogenic activity [62]. UV radiation also promotes the development of cutaneous malignant melanoma, but the mechanisms of this effect are less clear.

Surprisingly, UV radiation also has cancer protective effects. Of note, nearly 20 types of cancer have been found to be inversely associated with solar UV-B exposure. In a meta-analysis of second cancers after non-melanoma skin cancer, the risk of subsequent colon, gastric, rectal, cervical, and esophageal cancers was significantly reduced [63]. These data suggest that UV-B exposure may be protective against many internal cancers possibly due to increased vitamin D production.

21.3.5 Chemical Agents and Smoking

Exposure to chemical agents is associated with a wide variety of sporadic cancers. Polycyclic aromatic hydrocarbons and benzopyrenes, for example, induce cancer and sarcoma in murine models [64, 65]. These chemical agents may enter the body directly via environmental exposure or via specific vehicles such as cigarette smoke. Cigarette smoke contains potent carcinogens such as 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, benzopyrene, and 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine [66]. In a case–control study of nine cancer centers from six European countries, smoking cigarettes at any time was associated with a fivefold increase in lung cancer risk and current smoking increased the risk ninefold. The association was dose-dependent and time-dependent. A significant excess risk of 70 % was associated with every ten pack-years smoked. After 10 years of smoking cessation, the relative risk decreased to 20 % compared to current smokers. Adverse characteristics were inhalation of smoke, smoking non-filter cigarettes, smoking dark-type cigarettes, and starting smoking at young age. The typical histologic type of lung cancer associated with cigarette smoke was small-cell lung cancer. In absolute terms, the proportion of lung cancer cases in the population attributable to cigarette smoking varied strongly, ranging from 14 % to 85 % [67].

Active and passive cigarette smoking is associated with a significantly increased risk of lung cancer as well as other forms of cancer, e.g., bladder cancer and head and neck cancer. In a prospective cohort study of 120,852 adult subjects, current cigarette smokers had a threefold higher bladder cancer risk compared to nonsmokers. Ex-smokers also experienced a twofold increased risk. In absolute terms, half of all cases of male bladder cancer and one-fifth of female bladder cancer were attributable to cigarette smoking [68]. In a prospective cohort study of 476,211 individuals, cigarette smoking was a strong risk factor of head and neck cancer with hazard ratios of 12.9 in women and 5.4 in men. Ever-smoking accounted for 45 % of head and neck cancers in men and 75 % in women, suggesting causality [69].

Asbestos is a chemical carcinogen prominent due to its past widespread use in fire protection devices in industry and construction. One of the malignancies associated with asbestos exposure is mesothelioma. In a South East English study of 5753 affected individuals, the highest incidence rates of mesothelioma were found along the Thames river and its estuaries reflecting areas of asbestos use in shipbuilding and industry in the past [70].

Cadmium is a toxic metallic trace element which is capable of blocking oxidative phosphorylation. Exposure to environmental cadmium increases cancer incidence and cancer-specific mortality. In a 20-year longitudinal study of Japanese living in a cadmium-polluted area, cancer-specific mortality was more than doubled (Rate Ratio 2.58; 95 % Confidence Interval 1.25–5.36) [71].

Chemical agents may influence carcinogenesis by inducing chronic inflammation. In an Australian case–control study of 1576 women with invasive and low malignant potential ovarian cancers and 1509 population-based controls, the use of talcum powder in the pelvic region was associated with a small, but statistically significantly increased risk [72].

21.3.6 Hormonal Factors

Hormonal factors play a major role in the development of sporadic cancer. Both cancer-promoting and cancer-preventing effects have been described for a variety of hormones and a variety of cancers. One of the most widely studied cancers with respect to the etiologic role of hormones is breast cancer. Epidemiologic studies link several factors related to estrogen production to an increased risk of breast cancer. These include early menarche, late menopause, obesity, use of postmenopausal hormone therapy, and plasma estradiol levels. Estrogens and estrogen metabolites may mediate breast cancer via estrogen receptor-mediated stimulation of breast cell proliferation with a concomitant enhanced rate of mutations or via genotoxic estradiol metabolites with a resulting increase in DNA mutations. Estradiol metabolites can cause DNA damage by formation of estradiol-adenine-guanine adducts which are released from the DNA backbone leaving depurinated sites which undergo error prone DNA repair. In addition, mutations and oxygen free radicals may be caused by redox cycling of 4-OH estradiol to the 3–4 estradiol quinone and back conversion to 4-OH estradiol. If one or both pathways are operative, sufficient numbers of mutations accumulate over a long period of time to induce neoplastic transformation [73]. From a clinical perspective combined estrogen/progestogen supplementation use has been demonstrated to significantly increase the incidence of breast cancer in a large randomized trial, the WHI study [74]. Of note, this was not the case when estrogen, i.e., conjugated equine estrogens, was used as a monotherapy [14]. Thus, the combination of exogenous estrogens and progestogens is cancerogenic, a fact that has been attributed to interactions between progestogens and the RANKL (receptor activator of NF-κB ligand)/RANK system [75]. It has been demonstrated that the in vivo administration of the progestogen medroxyprogesterone acetate triggers induction of the key osteoclast differentiation factor RANKL in mammary-gland epithelial cells. Genetic inactivation of the RANKL receptor RANK in mammary-gland epithelial cells prevented MPA-induced epithelial proliferation.

Antiestrogens such as tamoxifen and raloxifen have been shown to effectively prevent breast cancer in randomized trials [76]. Estrogens and antiestrogens also appear to play a role in other cancers, for example in lung cancer. In a Canadian case–control study, exposure to antiestrogens was associated with a significantly decreased mortality in those exposed both before and after the diagnosis of non-small-cell lung cancer [77].

Another line of evidence highlights an emerging role of estrogens in the initiation and progression of different malignancies through their interaction with stem cells [78]. Estrogens are involved in increasing hematopoietic stem cell self-renewal in female subjects and more specifically during pregnancy. It is likely that normal and tumor thyroid tissues, which express estrogen receptors, could be subject to the same mechanism of estrogen action [79].

Other hormonal compounds which have been associated with cancer development include growth hormone and endocrine disruptors. Growth hormone treatment has been found to be associated with an increased risk of central nervous system malignomas in some studies [80]. However, the etiologic role of growth hormone with regard to central nervous system malignomas is controversial, since other studies did not confirm an increased cancer risk among recipients of growth hormone therapy. Several epidemiological, cellular, and molecular studies demonstrate a role of environmental chemicals with endocrine disrupting activities in the pathogenesis of numerous diseases including cancer [81], but their exact role has yet to be defined.

Hormones can act as powerful protectors against some cancers and at the same time as promoters of other cancers. This pleiotropic role of hormones is best illustrated by oral contraceptives. These compounds consist of the synthetic estrogen 17-beta-ethinyl-estradiol and a progestogen (e.g., levonorgestrel, dienogest, cyproterone acetate, chlormadinone acetate, etc.). Oral contraceptives are the most widely used hormones among women. Thus, epidemiologic data are available demonstrating clear cancer-promoting and cancer-preventing effects.

In a systematic review to estimate associations between oral contraceptive use and breast, cervical, colorectal, and endometrial cancer incidence, 44 breast, 12 cervical, 11 colorectal, and nine endometrial cancers studies were included [82]. Breast cancer incidence was slightly but significantly increased in users and the risk of cervical cancer was increased with duration of oral contraceptive use in women with human papillomavirus infection. Compared with never-use, ever-use of oral contraceptives was significantly associated with decreases in colorectal and endometrial cancers.

21.4 Genetic Susceptibility

21.4.1 Genetic Susceptibility and Sporadic Cancers

The number of reports investigating sporadic cancer susceptibility based on the carriage of low-penetrance, high-frequency polymorphisms has steadily increased over the last years. Evidence based on meta-analyses of individual case–control studies is accumulating defining specific individual variations in cancer susceptibility. Polymorphisms and mutations leading to functionally relevant biochemical consequences are capable of influencing the development and clinical course of cancer. It has become clear that sporadic cancer as well as many other diseases is the result of a complex interaction between environmental factors and various different genes as well as gene–gene interactions. Consequently, typical phenotypes do not exhibit classic Mendelian inheritance patterns attributable to a single gene locus. Moreover, different genes seem to act in various combinations, thus causing individual degrees of susceptibility in a given person. A polygenetic background has been proposed for many quantitative traits such as hypertension and diabetes, and more generally, for complex traits such as cancer.

21.4.2 Methodological Issues

Besides whole genome searches and gene expression profiling, genetic association studies are used to identify candidate genes with a possible etiologic role in a given disease. Furthermore, genetic association studies can identify specific genetic variations which may be used clinically to describe an increased or decreased risk to develop the condition as well as to describe an altered response to a treatment intervention. In these studies, single nucleotide polymorphisms, i.e., nucleotide deletions, insertions, and substitutions, are used. In addition, microsatellite markers, i.e., replications of specific nucleotide combinations, may be used. Genetic association studies do not prove an etiologic link between the polymorphism and/or the gene in question and the investigated disease. Methodological reasons account for that shortcoming, e.g., low sample size, chance findings, multiple comparisons and subsequent type I error inflation, ethnic background of the study subjects, varying disease definitions and inclusion/exclusion criteria, and ascertainment bias. Therefore, interpretation of studies with positive associations between genetic polymorphisms and endometriosis need to be interpreted with caution.

21.4.3 Polymorphisms and Specific Cancers

The amount of evidence with respect to genotype–phenotype correlations has increased substantially over the last years. These data indicate that a number of polymorphisms in genes associated with estrogen metabolism, cell cycle control, and xenobiotic metabolism are markers of overall cancer risk with the effects of all of these polymorphisms strongly depending on ethnic background. A meta-analysis of seven case–control studies and 4284 individuals established a variant of the Type I Transforming Growth Factor Beta Receptor (TGFBR) gene (TGFBR1*6A) as a risk factor of a variety of cancers [83]. Specifically, the analysis shows that homozygous carriers of this polymorphism have a more than twofold (Odds Ratio 2.53; 95 % Confidence Interval 1.39–4.61) increased risk of cancer. Analysis of specific cancer types showed that TGFBR1*6A carriers are at significantly increased risk of developing breast, ovarian, and colon cancer as well as hematological malignancies. Carriage of specific polymorphisms also modulates response to therapy and survival of cancer patients. A polymorphism of the mannose binding lectin 2 gene (MBL2), for example, is associated with lung cancer survival, dependent on ethnic background and smoking history [84]. Rylander-Rudqvist et al. performed a case–control study of 1521 cases and 1498 controls, and reported that a variant of the CYP1B1 gene (CYP1B1*3) is a genetic risk modifier of long-time hormone replacement therapy. Women who had used menopausal hormone replacement therapy for 4 years or longer and carried the CYP1B1*3/*3 genotype had a twofold increased risk of developing breast cancer [85].

One of the most intensely studies cancer types with respect to polymorphisms is breast cancer. Breast cancer has a strong genetic component, but most cases of breast

cancer are sporadic and do not occur in families with a characteristic pedigree compatible with BRCA-mutations. On the other hand, a first-degree relative of a woman with breast cancer has a twofold increased risk of developing breast cancer herself. Therefore, it is reasonable to speculate that low-penetrance susceptibility genes may play a role in the biological history of sporadic breast cancer. A number of candidate genes have been identified in this respect, most of which are involved in estrogen metabolism and cell growth regulation.

Over 40 association studies investigating polymorphisms of estrogen metabolizing genes and genes involved in cell cycle control and metabolism of xenobiotics have been published. Dunning et al. investigated most of the studies published until 1999 and combined the results of 46 of these individual studies investigating over 10,000 women [86]. They found that statistically significant differences in genotype frequencies were present for a polymorphic marker of the aromatase gene [CYP19 $(TTTA)_{10}$ microsatellite], the GSTP Ile105Val and GSTM1 gene deletion polymorphisms, and the TP53 Arg72Pro polymorphism. In addition, meta-analyses of case–control studies indicate that TGFBR1*6A, HRAS1, GSTP Ile105Val, and GSTM1 SNPs are low-penetrance genetic risk factors of sporadic breast cancer. Nested case–control studies within the prospective Nurses' Health Study found seven polymorphisms—hPRB +331G/A, AR CAG repeat, CYP19 (TTTA)10, CYP1A1 MspI, VDR FOK1, XRCC1 Arg194Trp, and XRCC2 Arg188His—to be small but significant risk factors for sporadic breast cancer [87]. As demonstrated by all of these studies, a wide variety of polymorphisms seems to confer a small, but statistically significant risk of breast cancer. However, common genetic variants associated with breast cancer only modestly improve the performance of traditional risk models for breast cancer. This has been demonstrated in a study using traditional risk factors and ten common genetic variants associated with breast cancer in 5590 case subjects and 5998 control subjects, 50–79 years of age, from four US cohort studies and one case–control study from Poland [88]. Next-generation sequencing has led to a further explosion of discoveries of novel genetic mutations that reveal a promiscuity of genotype–phenotype relationships. Although such discoveries may ultimately revolutionize clinical care in the future, at this time, genetic susceptibility testing based on mutation/polymorphism panels is not recommended [89].

Hereditary Cancer

22

Zoran Gatalica, Anatole Ghazalpour, Stan L. Lilleberg, Jeffrey Swensen, and Henry T. Lynch

22.1 Introduction

The first systematic documentation of a hereditary cancer family was reported over 100 years ago [1] by Aldred Scott Warthin, M.D., Ph.D. Dr. Warthin (Fig. 22.1) was truly a Renaissance man of his time. At age 21, he graduated from the Cincinnati Conservatory of Music. He was a musician, teacher, writer, editor, poet, and linguist. As a pathologist he was a remarkably creative physician-scientist. In 1895, he completed postgraduate work in pathology in Germany, and joined the pathology department at the University of Michigan. While he was setting up his household in Ann Arbor, he wondered why his seamstress was so depressed. She told him that her depression was due to the fact that she knew she would die of cancer of the bowels or female organs, since "… *everyone in my family dies of those cancers* …" Warthin listened carefully and began compiling her family history, in particular recording the pathology, and in 1913, he published [1] the pedigree of what he called Family G (Fig. 22.2). Finally, just as his seamstress had predicted, she died at an early age of metastatic endometrial carcinoma.

Half a century later, Lynch et al. [2] described two Midwestern families with clinical features strikingly similar to Warthin's Family G. Individuals in these families had early-onset colorectal cancers and a litany of other cancer types, particularly gynecologic and gastric. Warthin's successor as chairman of pathology in Ann Arbor, Michigan, invited Lynch to take possession of Warthin's documents, which included detailed scrolls of the pedigree of Family G (Fig. 22.2), slides and cancer tissue blocks. An update of Family G was published in 1971 [3]. The family's mismatch repair (MMR) gene mutation was finally identified in 2000 in a splice site of the *MSH2* gene [4]. In 2005, a description of over a century of work on Family G was published [5]. Importantly, the pattern of cancer has continued relentlessly in Family G in accord with an autosomal dominant mode of genetic transmission.

With the continued efforts of many scientists it was finally accepted that cancer was a genetic disease. In fact, to reflect the recent revolution in cancer research and the discoveries made, it should be stated that cancer is a genomic disease, or a disease of the genome [6]. Over the last 10–15 years, breakthroughs in the identification of many important genes have significantly improved our understanding of cancer pathogenesis. At the foundation of this discovery era was the wealth of information provided by the Human Genome Project.

The intent of this chapter is to review the genes known to be associated with hereditary forms of cancer/cancer syndromes, and highlight examples of pathways in which the products of these genes interact. We also indicate where current knowledge is limited and where further investigation may be warranted.

22.2 Cancer Development

According to current models, tumor development is a continuous process of mutation accumulation that ultimately leads to cellular autonomy, unlimited growth and metastasis [7]. One of the most important events in this process is the initial destabilization of homeostasis that allows mutations to accumulate in genes that regulate cell proliferation, development, and differentiation. The genetic mechanisms involved in the earliest stages are not clear, but certain phenotypic features are notable. The cancer cell phenotype can be described by six hallmark features: self-sufficiency in growth signals, insensitivity to growth-inhibitory signals, avoidance of programmed cell death, limitless replicative

potential, sustained angiogenesis, tissue invasion, and metastasis [7]. Generally it has been thought that three to seven successive mutations are required for the malignant conversion [8–10]. Various sources of spontaneous DNA damage are estimated to alter about 25,000 bases per human genome per cell per day out of the 3×10^9 base pairs in the genome [11]. However, cells are endowed with specific mechanisms for repairing the damage and for maintaining mutations at reasonable levels. Consequently, the mutational load at any given time in both germ-line and somatic cells can be viewed as a dynamic equilibrium between the extent of DNA damage and the efficiency of DNA repair [12]. In principle, the likelihood that a single cell will acquire enough independent mutations necessary for malignant cancer development is quite low and statistically unlikely, given that the normal mutation rate is approximately 1.4×10^{-10} mutations per base pair per cell generation [13]. However, it is now well recognized that this theory is contradicted by the rate of incidence of various cancers. Not surprisingly, cancer biology and genetics have found a way around these statistical predictions. It has been suggested that two major mechanisms could result in higher mutation rates that would make cancer development more probable. First, highly selective mutations could occur that enhance cell proliferation, creating an expanded target cell population for the next mutation [14]. Second, mutations could occur that affect the stability of the entire genome at the DNA and/or the chromosomal level, thereby increasing the overall mutation rate [13, 15].

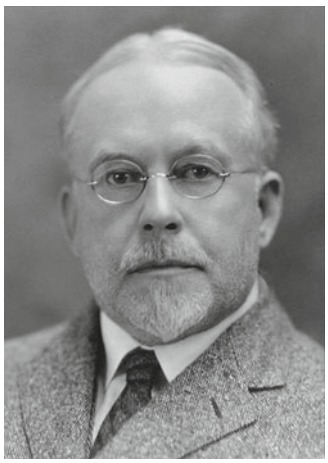

Fig. 22.1 Aldred Scott Warthin, M.D., Ph.D., (1866–1931) pioneer in hereditary cancer research.

Tumorigenesis is associated with alterations (mutations) in two main classes of genes—oncogenes and tumor-suppressor genes—each of which can drive neoplasia by increasing the tumor cell burden through stimulating cell division or inhibiting cell death or cell-cycle arrest.

Less than 10 % of patients with cancer have highly penetrant inherited (germ-line) mutations that predispose to cancer. Germ-line mutations of genes known to be responsible for inherited forms of cancer and their syndromes are summarized in Table 22.1. A mutation within this context is defined as any change in the sequence of the gene, including single base pair substitutions, large or small deletions/insertions and amplifications or translocations of chromosomal segments. In the germ line, the most common mutations are subtle (point mutations or small deletions/insertions), whereas all types of mutation can be found in tumor cells.

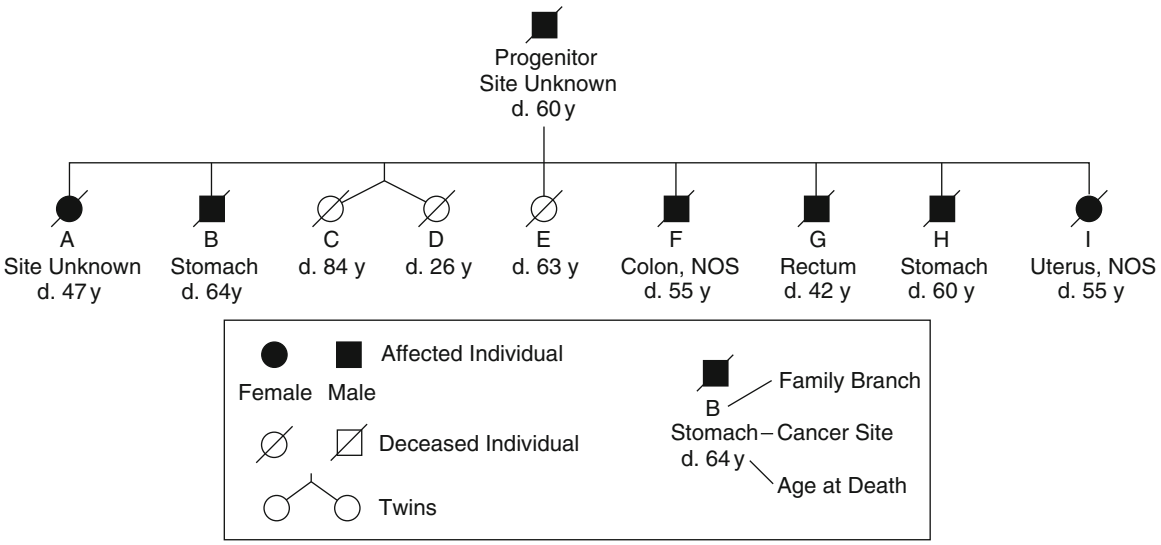

Fig. 22.2 Pedigree family G. This family was described in the first published systematic evaluation of a hereditary cancer syndrome, now known to fit criteria for Lynch syndrome. This is an abridged version of the pedigree since the updated publication contained an extremely large number of individuals. In this figure, each individual (A to I) represents a branch of the family; blackened symbol represents affected branches.

Table 22.1 Overview of inherited cancer syndromes

Cancer gene category	Syndrome	Gene (alias)	Gene location	OMIM ID	Major tumor types
Tumor-suppressor genes (genomic stability and repair genes)					
	Ataxia telangiectasia	*ATM*	11q22.3	208900	Leukemias, non-Hodgkin lymphomas
	Bloom syndrome	*BLM*	15q26.1	210900	Leukemia, lymphoma
	Hereditary breast and ovarian cancer	*BRCA1, BRCA2*	17q21, 13q12.3	113705, 600185	Carcinomas of breast and ovary
	Fanconi anemia	*FANCA, C or G in 90% cases*	16q24.3, 9q22.32, 9p13.3	607139, 613899, 602956	Acute myeloid leukemia, solid cancers
	Lynch syndromes (HNPCC, Lynch I, Lynch II, Lynch III, Turcot and Muir–Torre syndromes)	*MLH1, MSH2, MSH6, PMS2*	3p21.3, 2p22-p21, 2p16, 7p22	120436, 120435, 600678, 600259, 609309, 609310, 614350, 614337	Colon adenocarcinoma, uterus endometrial adenocarcinoma; skin sebaceous tumors (Muir-Torre); biallelic inheritance results in pediatric lymphomas and brain tumors (Lynch III)
	Attenuated polyposis (MAP)	*MUTYH*	1p34.3-p32.1	608456	Colon adenomas and adenocarcinomas
	Nijmegen breakage syndrome	*NBS1*	8q21	251260; 613065, 609135	Lymphoma, leukemia
	Rothmund–Thomson syndrome	*RECQL4*	8q24.3	268400	Bone osteosarcoma
	Werner syndrome	*WRN*	8p12-p11.2	277700	Meningiomas, soft tissue sarcomas
	Xeroderma pigmentosum	*XPA, XPC, ERCC2, ERCC3, ERCC4, ERCC5, DDB2, POLH*	9q22.3, 3p25, 19q13.2-q13.3, 2q21, 16p13.3-p13.13, 13q33, 11p12-p11, 6p21.1	278700, 278720, 126340, 133510, 133520, 133530, 600811, 603968	Non-melanoma skin cancer (basal cell and squamous cell carcinomas) and cutaneous melanoma
Tumor-suppressor genes (other)					
	Familial adenomatous polyposis (FAP), desmoid disease, Turcot syndrome	*APC*	5q21-q22	175100; 135290	Adenomas and adenocarcinomas of colon, small intestine (and CNS for Turcot syndrome)
	Oligodontia–colorectal cancer syndrome	*AXIN2*	17q23-q24	604025;608615	Colon adenomas and adenocarcinomas
	Juvenile polyposis	*BMPR1A, SMAD4*	10q22.3, 18q21.2	174900; 601299, 600993	Juvenile polyps in gastrointestinal tract
	Familial gastric carcinoma	*CDH1 (E-cadherin)*	16q22.1	192090; 137215	Diffuse gastric, and lobular breast carcinoma
	Familial atypical multiple mole melanoma	*CDKN2A (P16/INK4A, p14/ARF)*	9p21.3	600160; 155601	Cutaneous melanoma, pancreatic adenocarcinoma
	Familial cylindromatosis (Brooke–Spiegler syndrome)	*CYLD*	16q12.1	605041; 605018	Cylindromas of skin
	Hereditary multiple exostoses	*EXT1, EXT2, EXT3*	8q24.11-q24.13, 11p12-p11, 19p	133700; 608177; 133701; 608210; 600209	Osteochondromas
	Hereditary leiomyomatosis and renal cell carcinoma (HLRCC)	*FH*	1q43	136850; 150800	Leiomyomas of skin and uterus; renal carcinoma
	Birt–Hogg–Dube syndrome	*FLCN (BHD)*	17p11.2	135150; 607273	Diverse renal tumors, skin fibrofolliculoma

Cancer gene category	Syndrome	Gene (alias)	Gene location	OMIM ID	Major tumor types
	Hereditary papillary renal cell carcinoma (HPRCC)	*MET*	7q31	164860; 605074	Multiple bilateral type I papillary renal cell carcinoma
	Familial gastrointestinal stromal tumors	*PDGFRA*	4q12	173490; 606764	Multiple gastrointestinal stromal tumors (GIST)
	Multiple endocrine neoplasia type II (A and B)	*RET*	10q11.2	164761; 171400; 162300; 142623; 188550	Medullary thyroid carcinoma, parathyroid hyperplasia, adrenal pheochromocytoma

Neoplasia is initiated by a mutation in a cancer gene that results in a clonal expansion, with subsequent mutations in additional genes resulting in further rounds of expansion as part of the process of tumor progression [16, 17]. An individual with a germ-line mutation in a cancer predisposition gene has an early start on tumor development, because a mutation that can contribute to cancer is already present in every cell. As such, these individuals may readily develop multiple tumors that are detectable at an early age. In many dominantly inherited cancer syndromes, the acquired first somatic mutation affects the normal copy of the gene inherited from the unaffected parent [18].

Under normal conditions, proto-oncogenes (the normal, non-mutated form of an oncogene) stimulate cell proliferation and differentiation. These genes mainly encode proteins involved in signal transduction pathways and include growth factors, growth factor receptors, signal transducers, and transcription factors (e.g., the *RET* and *MET* genes). When mutated (activated) these genes become oncogenes and gain the ability to dominantly promote neoplastic processes. In contrast, tumor suppressors are genes whose loss of function promotes malignancy [19, 20]. They are usually negative regulators of growth or other functions that may affect invasive and metastatic potential [21]. Tumor suppressor genes can be divided into two broad functional classes: (1) gatekeepers which directly regulate cell proliferation and are rate limiting for tumorigenesis; (2) caretakers which maintain the integrity of the genome and promote cancer growth indirectly by causing an increased mutation rate [22]. Interestingly, the most common forms of hereditary cancer predisposition are caused by inherited mutations of caretaker genes.

The contribution of tumor suppressors to tumorigenesis was initially proposed by Alfred Knudson in 1971, based upon epidemiological studies of retinoblastoma [23]. According to Knudson's two-hit model, both copies of a tumor suppressor gene need to be inactivated for tumor formation. In the familial form of a disorder associated with a tumor suppressor gene, one mutated allele is inherited from one of the parents and the second allele is somatically inactivated. When the second hit involves a large deletion or mitotic recombination (reduces the mutation to homozygosity), it is referred to as loss of heterozygosity (LOH). Knudson's model has later been applied to other forms of familial cancer as well [18, 24]. However, not all loss-of-function mutations in tumor suppressor genes are truly recessive [25]. Evidence suggests that haploinsufficiency (functional loss of one allele) of some genes might provide a growth advantage [26]. Thus, lower gene-dosage, rather than biallelic inactivation of a tumor suppressor gene may be sufficient to exert a cellular phenotype that leads to tumorigenesis. This may be particularly true for caretaker genes, where haploinsufficiency could result in mildly increased genomic instability [27].

In contrast to classical monogenic Mendelian disorders, such as Duchenne muscular dystrophy or cystic fibrosis, wherein mutations in a single gene cause disease, a single gene defect or alteration does not cause cancer. The vast majority of genetic alterations in cancer are somatic and found only in tumor cells. In an individual with a dominant cancer predisposition syndrome, all cells in the body are *a* priori heterozygous, carrying one mutated and one wild-type allele [19]. The germ-line mutation can be considered as the first hit required for tumorigenesis. The next genetic change in a cell often involves the loss of the remaining wild-type allele (second step in the Knudson's two hit hypothesis) [18]. Even though additional somatic changes are still needed, the presence of a constitutional mutation greatly quickens the process of malignant conversion, and individuals with such mutations are at higher risk of developing cancer. Mutations with strong effects are likely to cause early onset of the disease and development of multiple primary tumors; they are inherited in simple Mendelian fashion, tend to cause familial clustering of disease and show dominant pattern of inheritance [28, 29]. However, the cancers develop only after additional somatic genetic mutations occur. Importantly, clinicians must also consider the pattern of these multiple primary cancers (e.g., breast and ovarian cancers in carriers of *BRCA1* and

BRCA2 mutations; medullary thyroid carcinoma and pheochromocytoma in the carriers of a *RET* mutation, etc.) which could then guide them toward the correct diagnosis.

Most cancer susceptibility syndromes result from inherited mutations in tumor suppressor genes rather than proto-oncogenes [19]. Germ-line mutations in only a limited number of proto-oncogenes (e.g., *RET*, *MET, KIT, PDGFRA,* and *CDK4*) (Table 22.1), have been shown to be involved in hereditary cancer predisposition [30–32]. Although they are rare, these syndromes are of vast biological importance. The study of genes responsible for such disorders, and the cellular pathways disrupted by the mutated proteins, provides significant insights into the molecular origin and pathogenesis of both inherited and sporadic forms of cancer [28].

A subclass of tumor suppressor genes, known as caretakers or stability genes, promotes tumorigenesis in a completely different way when mutated. This group includes the mismatch repair (MMR), nucleotide-excision repair (NER), base-excision repair (BER), and homologous recombination repair genes responsible for correcting subtle errors made during normal DNA replication or induced by mutagenic exposure. In normal cells, genetic alterations are kept to a manageable minimum by stability genes, and mutation rates are much higher when these genes are inactivated [33]. As a result, all genes are potentially at risk for mutations, but only mutations in oncogenes and tumor suppressor genes will provide a selective advantage to the cancer cell.

From this, it is best to picture mutated cancer genes as contributors to cancers, rather than the sole cause. In most cases involving genes associated with hereditary cancer syndromes, the individual with the mutation faces a high probability of developing cancer, but not 100 % certainty. Penetrance is defined as the probability that a person who has the genotype will manifest the expected phenotype. For example, a carrier of a mutation in the *BRCA1* gene (breast and ovarian cancer susceptibility) has an approximate 70–85 % chance of developing breast cancer during their lifetime. Although this is a very high risk, the penetrance is incomplete and not everyone with a mutation will develop the disease. There are some important exceptions to incomplete penetrance; virtually all carriers of a pathogenic mutation in the *TP53* gene (Li–Fraumeni syndrome) or the *APC* gene (familial adenomatous polyposis coli) develop cancer. Differences in penetrance between carriers of a germ-line mutation can be associated with environmental exposures and an individual's genetic makeup (modifier genes).

22.3 Oncogenes

Oncogenes are altered (mutated) in ways that cause the gene product to be constitutively activated or active under conditions in which the normal gene (proto-oncogene) is not active. Activation of an oncogene can result from chromosomal translocation (*BCR-ABL)*, gene amplification (*MYC)*, or intragenic mutations (*RET*) affecting key functional moieties that regulate the activity of the gene product. Activation of an oncogene through the alteration of a single allele is usually sufficient to bestow a cell with a selective growth advantage. Examples of oncogenes associated with inherited cancer syndromes and the associated tumors are included in Table 22.1. Such genes include *RET* and *MET*, which encode receptor tyrosine kinases involved in essential processes such as cell cycle progression, proliferation, differentiation, motility, and survival [34]. Many oncogenic tyrosine kinases are constitutively activated due to specific gain-of-function mutations [34, 35].

22.3.1 RET Oncogene and Multiple Endocrine Neoplasia Type 2 (MEN 2)

One oncogene that has been studied extensively within the context of hereditary cancers is the REarranged during Transfection (*RET*) gene, which encodes a transmembrane receptor tyrosine kinase (RTK) [36, 37]. Normal *RET* is expressed mainly in developing and adult neural ectoderm. *RET* mutations are oncogenic owing to an intrinsic gain-of-function in the receptor tyrosine kinase activity. Germ-line mutations in *RET* are known to cause multiple endocrine neoplasia type II (MEN2), which consists of three distinguishable clinical phenotypes (MEN 2A, MEN 2B, and familial medullary thyroid carcinoma FMTC) [38–42]. MEN 2A is characterized by specific endocrine neoplasms (medullary thyroid carcinoma, pheochromocytoma and parathyroid adenoma); MEN 2B is characterized by neuromas of the lips and tongue, marfanoid habitus, medullary thyroid carcinoma, and pheochromocytoma; FMTC is characterized by medullary thyroid carcinoma in the absence of other tumors.

Almost all of the germ-line *RET* mutations that cause MEN2 are missense, but a small fraction represent small deletions or insertions that preserve the open reading frame. The mutations are concentrated in a fraction of the open reading frame. Most mutations occur in the cysteine-rich portion of the extracellular domain. Specific missense mutations with a highly focused distribution are characteristic of mutations that cause oncogenic gain-of-function, in this case in Ret RTK activity [43–45]. This contrasts with the *RET* mutations that cause familial Hirschsprung disease; such mutations cause loss of protein function and have a much broader distribution across the gene [46, 47]. Hirschsprung disease represents the main genetic cause of functional intestinal obstruction with an incidence of 1/5,000 live births. This developmental disorder is a neurocristopathy and is characterized by the absence of the enteric ganglia along a variable length of the intestine [48, 49]. Occasional MEN2 families with specific mutations express Hirschsprung disease.

22.3.2 RET Activation and Signaling Pathways

One of the two *RET* mutations commonly associated with MEN 2B results in the substitution of threonine for methionine at codon 918 (M918T) in the tyrosine kinase domain [50–52]. *RET* M918T, which also occurs somatically in some sporadic medullary thyroid carcinomas (MTC), leads to a Ret receptor that autophosphorylates in the absence of ligand stimulation [53]. The constitutive activation of the variant Ret RTK results in aberrant cell signaling through a series of cytoplasmic kinases, including JUN kinase, p38 mitogen activated protein kinase, Ras/extracellular signal-regulated kinase, phosphatidylinositol 3-kinase, and Akt [54].

The mechanisms of Ret signaling in tumorigenesis are known in considerable detail, since it is part of a well-studied family of RTKs. The Ret protein is a subunit in a plasma-membrane signaling complex that includes four ligands and four co-receptors [55]. The Ret intracellular domain has at least 12 autophosphorylation sites, and phosphotyrosine 1062 in particular is a binding site for many different docking proteins and is important for the oncogenic activity of Ret [56–59].

22.3.3 Genotype:Phenotype Correlations: RET:MEN 2

Activating mutations in *RET* can be inherited or somatic. Germ-line point mutations are causal for the dominantly inherited disorders MEN 2A, MEN 2B and FMTC [50, 51]. Mutations of cysteine residues in the extracellular domain of RET are frequently associated with MEN 2A (MTC, pheochromocytoma, and parathyroid hyperplasia). MEN 2B (MTC, pheochromocytoma, ganglioneuromas, and marfanoid habitus) is associated almost exclusively with mutations of codons 918 or 883 in the intracellular domain of RET. Genetic testing to identify patients at risk for MEN2 and FMTC has led to clinical screening and prophylactic thyroidectomy in mutation carriers [45, 60, 61].

More than ten somatic rearrangements of *RET* have been identified in papillary thyroid carcinomas [61]. These oncogenic mutations activate the Ret tyrosine kinase domain via different mechanisms, making Ret an excellent candidate for the design of molecular targeted therapy. Recently, various therapeutic approaches, such as tyrosine kinase inhibition, gene therapy with dominant negative *RET* mutants, monoclonal antibodies against oncogene products, and nuclease-resistant aptamers that recognize and inhibit Ret have been developed [62]. Two small molecule kinase inhibitors, vandetanib and cabozantinib, are approved for the treatment of locally advanced and metastatic medullary thyroid carcinoma [59].

22.3.4 MET Oncogene and Hereditary Papillary Renal Cell Carcinoma (HPRCC)

Recent studies have shown that renal cell carcinomas (RCC) are a clinically and genotypically heterogeneous group, consisting of different histologic types with different clinical courses, different responses to therapy, and different associated gene defects [63–65]. Clear cell RCC is the most common type (75 %), papillary RCC is 10 %, chromophobe RCC is 5 %, and the remainder is composed of rare histopathologic and molecular entities. Kidney cancer occurs in both sporadic (non-inherited) and hereditary forms. Most of what is known about the genetic basis of kidney cancer has been learned from study of the hereditary forms [66]. There are four well-defined hereditary syndromes associated with kidney cancer: (1) von Hippel–Lindau (VHL), (2) hereditary papillary renal cell carcinoma (HPRCC), (3) Birt Hogg Dubé (BHD), and (4) hereditary leiomyomatosis and renal cell carcinoma (HLRCC) [66, 67]. This discussion will focus on HPRCC, a cancer syndrome caused by mutations in the *MET* gene that are inherited in an autosomal dominant fashion [68]. HPRCC is highly penetrant and tends to have a late onset of clinical disease. However, an early-onset HPRCC phenotype has also been described. Affected individuals are at-risk of developing bilateral, multifocal, type 1 papillary renal carcinoma [68, 69]. Macroscopically, the tumors contain areas of hemorrhage, necrosis, and cystic degeneration (Fig. 22.3). Histologically, Delahunt and Eble have [70] classified papillary RCCs into type 1 (papillae covered by small cells, single layer) and type 2 (large cells with eosinophilic cytoplasm and pseudostratification). In chromosomal analysis, characteristic gains of chromosomes 7, and 17, and the loss of Y chromosome are frequently found in type 1 papillary RCCs, but the chromosomal aberration of type 2 papillary RCCs seems to be more heterogenous than that of type 1 papillary RCCs. Through genetic linkage analysis on affected families, mutations that activate the *MET* proto-oncogene were found to be the causal for HPRCC [68]. In addition, somatic missense mutations were found in the tyrosine kinase domain of the *MET* gene in the subset of sporadic (non-inherited) papillary renal carcinomas [69]. Three mutations were located in codons homologous to those in which activating mutations occur in the *KIT* and *RET* proto-oncogenes.

22.3.5 MET Activation and Signaling Pathways

Met receptor is activated through gene mutations or by binding of its natural ligand, hepatocyte growth factor/scatter factor (HGF/SF). Activation leads to a plethora of biological and biochemical effects in the cell (cell motility and

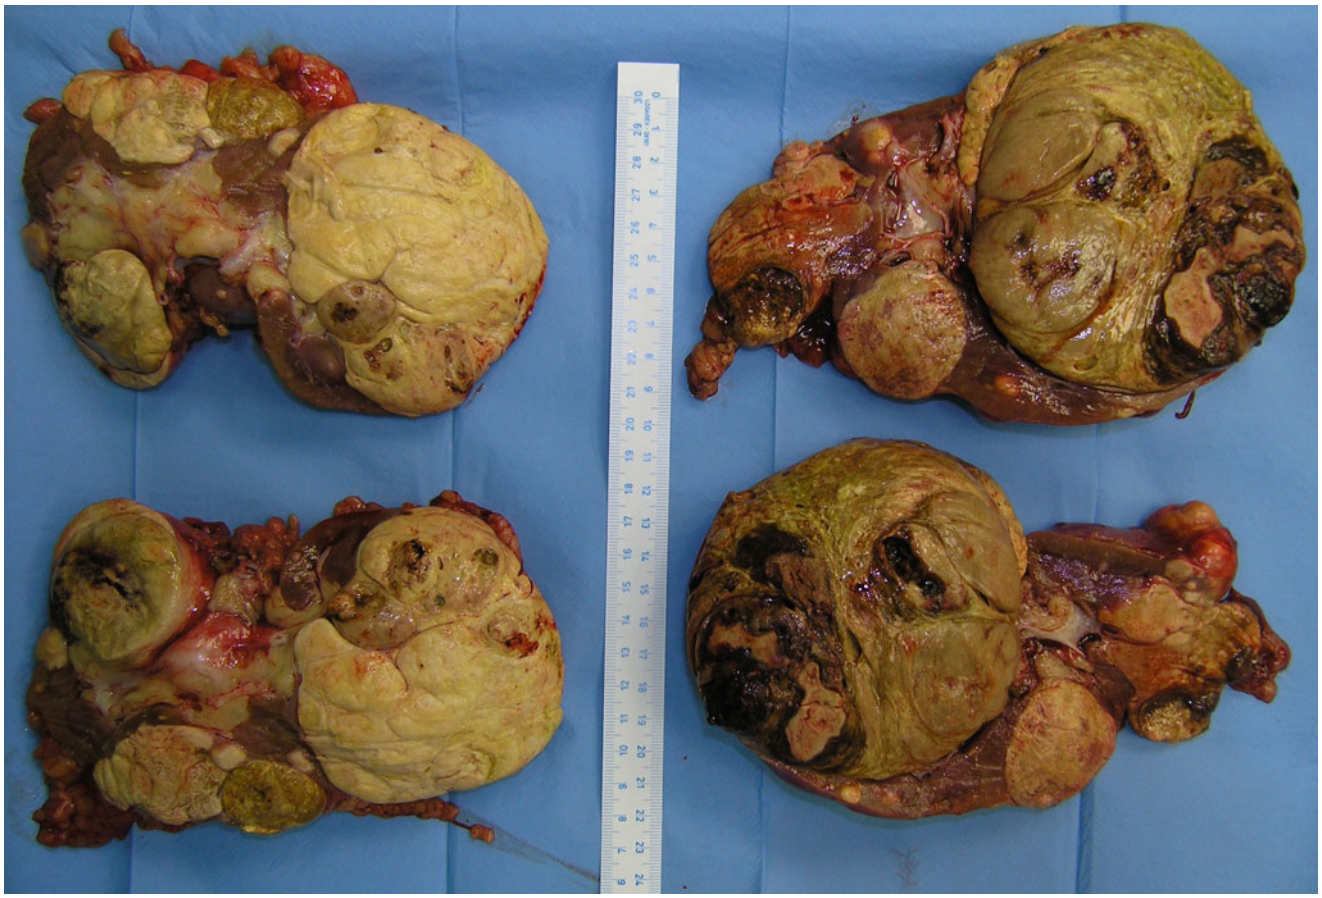

Fig. 22.3 Bilateral renal tumors in a young person with clinicopathologic characteristics of hereditary papillary renal carcinoma. Courtesy of Professor Milan Hora, M.D., Ph.D., (Pilsen, Czech Republic).

scattering, proliferation, branching morphogenesis, angiogenesis, invasion, and eventual metastasis) [71]. The unique biochemical and biological effect of these *MET* mutants has been investigated in several model systems, confirming their suspected oncogenic potential [72–77]. Upon HGF/SF binding, Met autophosphorylation occurs on two tyrosine residues (Y1234 and Y1235) within the activation loop of the tyrosine kinase (TK) domain, which regulates kinase activity. Phosphorylation on two tyrosine residues near the COOH terminus (Y1349 and Y1356) forms a multifunctional docking site that recruits intracellular adapters via Src homology-2 (SH2) domains and other recognition motifs, leading to downstream signaling [78, 79]. An intact multifunctional docking site is required to mediate transformation and induce a metastatic phenotype [80]. Among the many genes up-regulated by pathway activation relevant to cancer are those encoding proteases that regulate HGF/SF and Met processing and extracellular matrix remodeling, as well as *MET* itself, creating the potential for Met overexpression in otherwise normal target cells through persistent ligand stimulation [78].

Inappropriate Met signaling in disease can resemble developmental transitions between epithelial and mesenchymal cell types normally regulated by HGF/SF. While epithelial malignancies (carcinomas) frequently overexpress Met (Fig. 22.4) and paracrine delivery of HGF/SF results in dysregulated signaling, tumors of mesenchymal origin (sarcomas) arising from cells that normally express HGF/SF often acquire Met expression resulting in autocrine Met signaling [79, 80].

Beyond missense mutations, it is important to note that trisomy of chromosome 7, which contains both the *MET* and *HGF/SF* genes, occurs in the majority of sporadic papillary RCC [81]. A detailed study of trisomy 7 in hereditary papillary RCC revealed nonrandom duplication of the mutant *MET* allele in 100 % of tumor samples [82]. Overall, *MET* mutation occurs at a much lower frequency than most other mechanisms of pathway activation in human cancers. Nonetheless, mutations provide strong direct evidence of the pathway's oncogenic potential and a means to identify patient subpopulations that might benefit most from Met-targeted therapy. The current understanding of Met-mediated

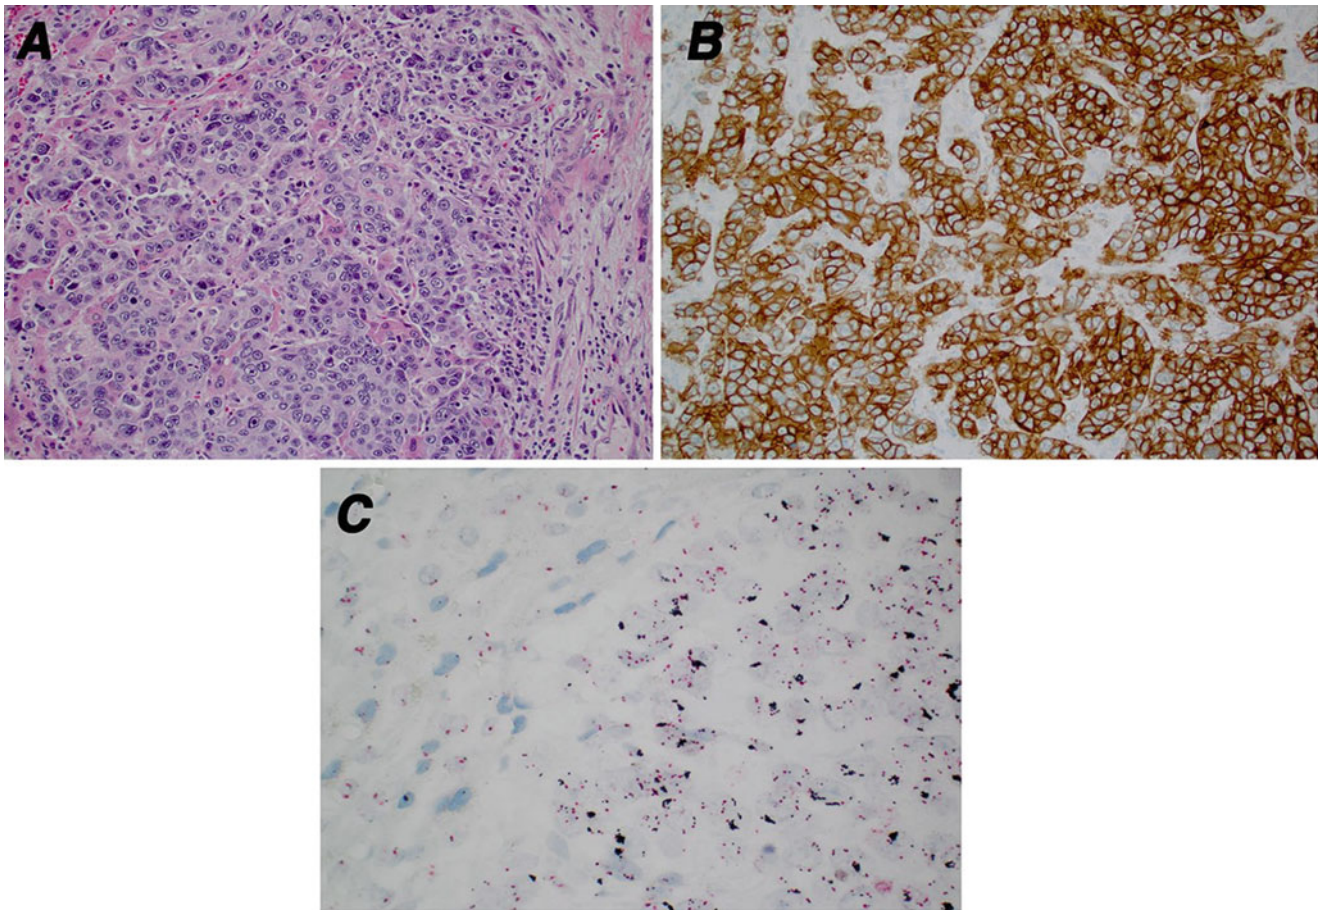

Fig. 22.4 Carcinoma of esophagus. (**a**) Hematoxylin and eosin stained section of the tumor. (**b**) The tumor is overexpressing Met (immunohistochemical stain showing Met expression brown). (**c**) *MET* gene amplification (dual chromogenic DNA in situ hybridization with clusters of black *MET* and variable red chromosome 7 centromeric signals) in the tumor (*right*) but not in the normal tissue (*left*).

oncogenesis supports at least three directions for cancer drug development: (1) antagonism of ligand/receptor interactions, (2) inhibition of TK catalytic activity, and (3) blockade of receptor/effector interactions.

22.4 Tumor Suppressors

In 1971, Alfred George Knudson, Jr., a medical geneticist specializing in cancer genetics, studied 48 cases of bilateral and unilateral retinoblastoma aiming to understand the genetic basis of cancer in these two apparently similar but subtly different subgroups of patients. By utilizing statistical modeling, Knudson was able to show that the presence and the frequency of tumors in retinoblastoma patients were consistent with two mutational events [23]. By fitting the data into this mathematical model, Knudson was also able to demonstrate why a small subset of carriers (i.e., cases in which only one mutation is present) do not develop tumors in the eye. This seminal work provided the basis for further research that collectively has led to the identification of the most common class of hereditary cancer predisposition genes: the tumor suppressor genes.

Classic tumor suppressor genes are autosomal recessive at the cellular level, meaning that within a cell both alleles of the gene have to harbor inactivating mutations for the phenotype to manifest. However, cancer predisposition syndromes caused by germ-line mutations in tumor suppressor genes, are inherited in an autosomal dominant fashion. For cancer to occur, the second allele of the tumor suppressor gene is somatically mutated in a susceptible cell type.

The distinction between tumor suppressor genes and oncogenes is mechanistic by nature. For a gene to be classified as a tumor suppressor, loss of function mutations in that gene must be shown to promote tumorigenesis. This contrasts with oncogenes which require activating mutations to drive tumorigenesis. Based on this broad definition, a wide variety of genes can act as tumor suppressors. As such, these genes are functionally grouped into two main categories: (1) Gatekeepers that directly regulate cell cycle progression, and (2) Caretakers that maintain the integrity of the genetic material in the cell. However, at the molecular and cellular level

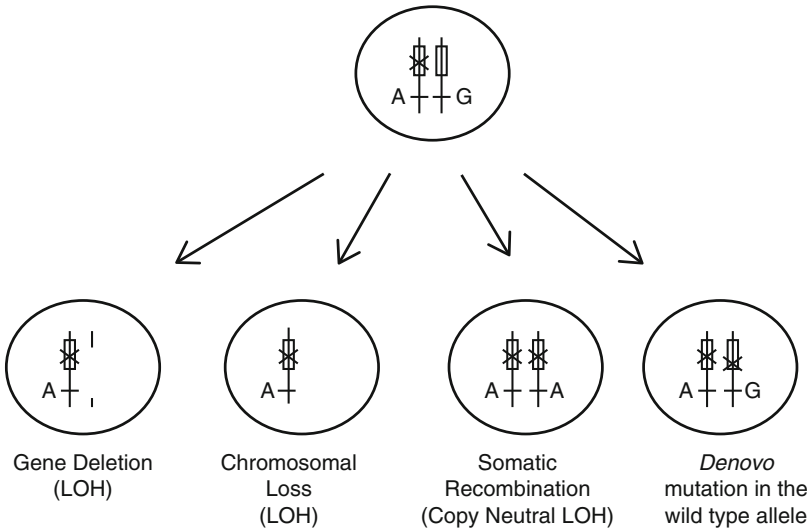

Fig. 22.5 Four alternatives to generate second hit in a cell with a germ-line mutation. From the four mechanisms, three will generate a pattern consistent with loss of heterozygosity. *LOH* loss of heterozygosity. Copy-neutral LOH is a special case of LOH where the wild-type allele is replaced by the mutant allele. This is generally achieved by somatic recombination.

tumor suppressor genes span a wide range of biological functions including transcription factors (*PAX5*), transcription turnover (*DICER1*), protein turnover (*FBXW7*), protein modification (*PTPN12*), and metabolism (*FH*), and their functions cannot always be neatly grouped into gatekeeper and caretaker categories.

22.4.1 Knudson's Hypothesis: The Two-Hit Model

Knudson's mathematical modeling led to what is known as Knudson's two-hit hypothesis. This states that tumors develop as a result of two events that affect separate alleles of the same gene. Consistent with this hypothesis was the observation that familial cases of retinoblastoma had younger age at diagnosis and were more likely to have bilateral tumors than individuals with sporadic retinoblastoma. Accordingly, Knudson proposed that familial cases were born with one mutated allele of the gene (accounting for the first hit) and they only needed to acquire a second mutation (second hit) to develop the cancer. In contrast, three non-mutually exclusive requirements needed to be met in sporadic cases: (1) de novo occurrence of two mutations, (2) occurence of both mutations in the same cell, and (3) occurence of the mutations in different alleles of the same gene. This model accounted for the infrequent nature of sporadic retinoblastoma as the co-occurrence of all three requirements was unlikely given the low rate of spontaneous mutation in a normal cell.

Mechanistically, the second hit described by Knudson could be accounted for via alternative molecular events. One possibility is that an inactivating point mutation (e.g., nucleotide substitution or frameshift) occurs in the remaining wild-type allele. A second possibility is that the wild-type gene is entirely deleted (leaving the cell with no functional copy of *RB1* gene), referred to as loss of heterozygosity (LOH). A third possibility, termed copy-neutral LOH, occurs when the wild-type allele is replaced with the mutant allele via somatic recombination. Figure 22.5 illustrates the various events which could account for a second hit. The term loss of heterozygosity was coined when Cavenee et al. [83] utilized RFLP techniques to look for somatic events that occurred during tumorigenesis. In these experiments, the germ-line cell was shown to be heterozygous for a linked marker residing outside the *RB1* gene. However, when the wild-type allele was lost through a large deletion or somatic recombination, the linked marker appeared homozygous (i.e., heterozygosity was lost). Intragenic mutations (substitutions or small insertions/deletions) did not result in LOH for the linked marker.

22.4.2 Haploinsufficiency

Knudson's two-hit model emphasizes a second hit in a tumor suppressor gene is the requirement for the development of cancer. If true, this hypothesis predicts that the presence of one mutation (the first hit) is benign (without effect) at the cellular level. In fact soon after Knudson proposed the two-hit model, mouse models were created to test this prediction [84]. In these experiments one of the two functional alleles of the tumor suppressor gene was knocked out leaving the animal with single functional allele. One such experiment performed with a gene called *Ptc* (also known as *Ptch1*) confirmed this prediction [85]. However, for some mouse models the results suggested that the first hit was not completely benign and a single mutation increased the chance for the organism to develop a tumor [26]. One such model was for the *TP53* gene which is estimated to be mutated in half of all

human cancers. In these experiments, half of the mice carrying the heterozygous null mutation of *Tp53* developed cancer after 550 days which was in sharp contrast to the 20% frequency of tumor development in the wild-type mice with two functional copies of *Tp53* [86]. Interestingly, when the *Tp53* gene was sequenced in tumors from the heterozygous-null mice, no second hit was detected in the majority of the cases. Additionally, all tumors expressed the wild-type p53 protein (assessed by western blot) and were capable of carrying out normal p53 function in biochemical assays. These observations provided evidence that the first hit was not a completely benign event and put the organism at increased risk of developing tumor. These experiments also showed that tumor development in the *Tp53* heterozygous-null mice was delayed compared to the homozygous-null mice. Similar results in regard to the frequency of tumor and the age of onset were obtained when yet another tumor suppressor gene (*CDKN1B* also known as p27) was tested in similar fashion [87]. In these studies it was shown that mice heterozygous for an inactivating mutation in *CDKN1B* developed cancer more frequently than wild-type mice and less frequently than homozygous mutant mice. In addition these mice were more sensitive to tumor formation when irradiated with X-rays compared to wild-type mice. These and similar observations with other tumor suppressor genes [26] led to the concept of haploinsufficiency in tumor suppressor genes. This term, which was originally coined by Curt Stern while studying gene dosage effects in Drosophila [88], was used to explain the lack of a wild-type phenotype in an organism carrying only one functional (wild-type) allele of a gene. Accordingly, a haploinsufficient tumor suppressor gene is a gene that alters the wild-type phenotype of the organism when it is present in a hemizygous state. The intermediate phenotype of heterozygous *Tp53* null animals suggests there is a gradient dependency on gene function. This contrasts with the more traditional and simplistic threshold model that predicts the presence or absence of a phenotype above or below a certain threshold for either gene expression or gene activity/function [89]. This new paradigm has been demonstrated for the *PTEN* gene where subtle fluctuation of expression was shown to dictate the extent of disease progression in prostate cancer [90] and in breast cancer [91]. In order to both accommodate the concept of haploinsufficiency in Knudson's model and to highlight the significance of tumor suppressor dosage sensitivity, Berger and colleagues [89] proposed a shift to a continuum model for tumor suppression. In this new paradigm, tumor suppressor genes exhibit various degrees of sensitivity to dosage change. Some genes, such as *PTEN* or *TP53* are more sensitive to subtle changes in activity or expression and others, such as *RB1*, are less prone to this dosage sensitivity. Accordingly, the latter group is more likely to conform to the classical two-hit model.

22.4.3 Tumor Suppressor Functional Classification

Motivated by two papers describing the molecular mechanism of *BRCA1* and *BRCA2* function, Kinzler and Vogelstein used the terms Gatekeepers and Caretakers to describe the cellular functions of tumor suppressor genes. Gatekeepers were defined as genes that directly regulated the growth of tumors by inhibiting growth or promoting death. In contrast, the term caretakers was used to describe genes directly involved in maintaining the stability and integrity of the genome [22]. Mutations in gatekeeper genes provide unregulated proliferation opportunities leading to selective expansion of cells carrying mutations. In probabilistic terms, the clonal expansion of mutated cells provides a higher likelihood for subsequent mutations to accumulate, furthering the neoplastic transformation and cancer progression. In contrast, mutations in caretakers result in unrecognized DNA damage and errors in DNA replication leading to accumulation of mutations within the cell. As such, cells with mutations in a caretaker gene will have a higher mutation rate, increasing the likelihood of malignant transformation. Neoplasia is a multistep process that begins by a single driver mutation that allows clonal expansion of a mutated cell. This is followed by subsequent mutations, resulting in further rounds of clonal expansion and cell transformation.

22.4.4 Genotype:Phenotype Correlations: Tumor Suppressor Gene Example: PTEN

PTEN (phosphatase and tensing homolog) is a tumor suppressor gene which encodes a dual-specificity phosphatase that can dephosphorylate both protein and phospholipid substrates. The tumor-suppressor function of Pten is primarily mediated through its lipid phosphatase activity, with its main phospholipid substrate being phosphatidylinositol triphosphate (PIP3) [92].

By regulating intracellular levels of PIP3, Pten is able to function as a negative regulator of the oncogenic Akt pathway [93, 94]. This pathway is closely linked to the new blood vessel development, deregulated cell growth, and resistance to apoptosis that are seen in cancer. When Pten function is lost or aberrant, a major consequence is increased levels of phosphorylated Akt (p-Akt), the activated form of Akt. Thus, p-Akt levels are an important marker of Pten status in terms of its lipid phosphatase function. The protein phosphatase activity of Pten is not as well understood. However, it does appear to mediate arrest of the cell cycle in G1 phase and control spreading and migration of cells through the mitogen activated protein kinase (MAPK) pathway [95], cyclin D1 [96], and focal adhesion kinase (*FAK*) [97]. Recent studies

have demonstrated that the sublocalization or partitioning of Pten between the cytoplasm and the nucleus has a role in the regulation of the Akt and MAPK pathways [98, 99]. Abnormal Pten localization, as a result of *PTEN* gene mutations, is speculated to be a mechanism linked to cancer predisposition.

The clinical spectrum of disorders that are known to be associated with germ-line *PTEN* mutations (known collectively as the *PTEN* hamartoma tumor syndrome or PHTS) encompasses Cowden syndrome (CS), Bannayan-Riley-Ruvalcaba (BRR) syndrome, Proteus-like syndrome, autism spectrum disorder with macrocephaly, and macrocephaly and VATER (vertebral, anal, tracheal, esophageal, and radial/renal anomalies) association [100, 101]. To date, the majority of studies on *PTEN* mutations and clinical phenotypes have focused on defining predictive parameters for patients presenting signs of Cowden syndrome [102]. Clinical manifestations of CS include hamartomatous tumors in multiple organs, notably multifocal and bilateral benign breast lesions, thyroid lesions, and hamartomatous polyps of the stomach and colon.

Cancer-specific phenotypes associated with PHTS have become a very significant area of clinical interest, noting that the lifetime risk of breast cancer in females has been reported to be as high as 50 %, compared to 11 % for the general population [103, 104]. In addition, the gene expression profile of the PHTS breast cancers shows considerable overlap with a characteristic breast cancer subgroup known as molecular apocrine breast carcinoma (Fig. 22.6) [105]. It is now also apparent that endometrial cancer and thyroid carcinomas are frequent [106, 107]. Other cancer types that might occur at a higher frequency include renal cell carcinoma, colorectal cancers, and melanoma.

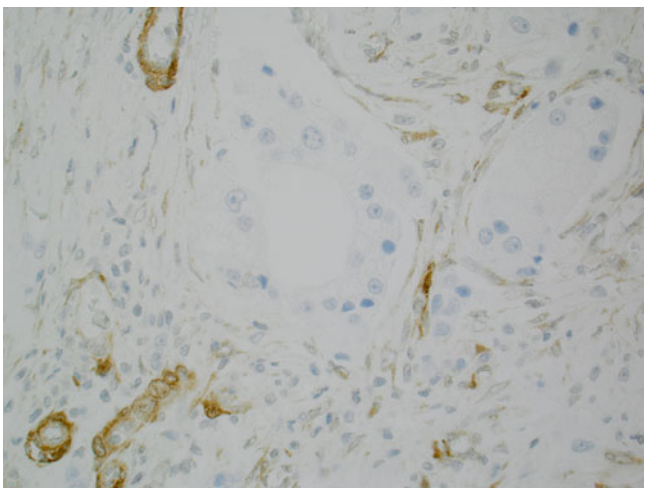

Fig. 22.6 Apocrine breast carcinoma lacking Pten. This section of an apocrine breast carcinoma is stained with antibodies against Pten (Immunohistochemistry). Normal expression of the protein (*brown*) can be seen in the nonneoplastic endothelium and loss of Pten expression in the neoplastic glands (center).

The phenotypic spectrum of germ-line *PTEN* mutations has provided substantial evidence that all patients with *PTEN* mutations should be routinely monitored annually as recommended by the NCCN (The National Comprehensive Cancer Network; http://www.nccn.org/).

22.5 Genomic Stability and Repair Genes (Caretaker Genes)

In contrast to gatekeeper tumor suppressor genes, caretaker genes do not directly regulate proliferation, but act to prevent genomic instability. Thus, mutation of caretaker genes allows for mutations in other genes, leading to accelerated conversion of a normal cell to a neoplastic cell. Many caretaker genes are required for the maintenance of genome integrity. Caretaker genes that play a role, directly or indirectly, in the repair of DNA double-strand breaks through homologous recombination are associated with cancer-predisposition syndromes that include hereditary breast and ovarian cancer, Fanconi anemia, and ataxia telangiectasia [108].

Nucleotide excision repair (NER) is of particular importance for correction of UV-light induced DNA damage (cross linking of pyrimidine residues). Germ-line mutations in any of several NER genes give rise to xeroderma pigmentosum (XP). XP is an autosomal recessive disorder characterized by severe actinic changes leading to early onset of skin cancers, various ocular manifestations, and occasional neurological abnormalities [109].

DNA mismatch repair (MMR) is another important genome maintenance system. MMR ensures genomic stability by correcting mismatches generated during DNA replication and recombination and by triggering apoptosis of cells with large amounts of DNA damage [110, 111].

22.5.1 Genotype-Phenotype Correlations: Lynch Syndrome

Lynch syndrome (OMIM No. 120435–6) is a hereditary cancer syndrome with relatively high incidence (approximately 2–5 % of all newly diagnosed colorectal carcinomas, CRC) caused by a mutation in one of the DNA mismatch repair (MMR) genes. It is a subgroup of hereditary non-polyposis colorectal cancer (HNPCC) which also includes familial colorectal cancer type-X (FCCTX) and familial serrated neoplasia associated with the colorectal cancer somatic BRAF mutation [112]. The molecular genetic *conditio sine qua non* for Lynch syndrome diagnosis is a germ-line mutation in one of the DNA mismatch repair (MMR) genes [111, 113]. The major MMR genes that harbor causal mutations are *MSH2*, *MLH1*, *MSH6*, and *PMS2*. Lynch syndrome is characterized by early age at onset of CRC, excess of synchronous and

Table 22.2 Cardinal features of Lynch syndrome

Mode of inheritance	Autosomal dominant
Average age for the onset of colorectal carcinoma (CRC)	45 (vs. 63 in the general population)
Progression time from adenoma to carcinoma	Approximately 3 years (vs. 8–10 for sporadic adenoma–carcinoma sequence)
Location of CRC	70–85 % proximal to splenic flexure
Risk of additional colorectal carcinoma	25–30 % develop second primary CRC within 10 years since subtotal colectomy
Extracolonic malignancies	Endometrium (40–60 % for female mutation carriers) Ovary (12–15 % lifetime risk for carriers) Stomach, small bowel, hepatobiliary tract, pancreas, upper urinary tract (renal pelvis and ureter) Brain (Turcot syndrome) Skin neoplasms (Muir–Torre syndrome: sebaceous adenomas, carcinoma, and multiple keratoacanthomas)
Pathomorphologic features	Poorly differentiated CRC with excess of mucinous and signet ring type of carcinomas; excess of tumor infiltrating lymphocytes
Survival	Increased in comparison to sporadic CRC
Confirmation of diagnosis	Identification of germ-line mutation in one of the mismatch repair genes

metachronous CRCs, a predilection to the proximal colon, accelerated carcinogenesis, and an excess risk for extracolonic cancers (including endometrium and, to a lesser extent, ovary, stomach, hepatobiliary tract, small bowel, pancreas, brain, transitional cell carcinoma of the ureter and renal pelvis, and sebaceous tumors in the Muir–Torre variant of the Lynch syndrome) (Table 22.2). No significant increase in breast, lung, or prostate cancer has been reported indicating that MMR mutations do not put every organ/cell type at an increased risk for cancer [114, 115]. Penetrance by the age of 70 for colorectal carcinoma in men varies from 22 to 100 %, based on the study population and the affected MMR gene. Similarly, penetrance for endometrial cancer in women varies from 16 to 71 % [116]. The best-known recurrent mutation causing Lynch syndrome is an A → T transversion in the donor splice site of intron 5 of *MSH2* (c.942 + 3A > T). This mutation apparently arises repeatedly because the region is vulnerable to slippage during the DNA replication process. The mutated nucleotide is the first in a tract of 26 adenines. It occurs worldwide and may account for as much as 5–10 % of all Lynch syndrome cases. In contrast, a genomic deletion of exon 16 of *MLH1* accounts for >50 % of all Lynch syndrome in Finns [117]. Molecular genetic heterogeneity must be considered when assessing the Lynch syndrome cancer phenotype. While more evidence will be required to substantiate differences in phenotype, current data suggest that *MLH1* mutations have a higher frequency of CRC than do *MSH2* mutations, which have more extracolonic cancers and Muir–Torre features (variant of Lynch syndrome with sebaceous tumors). Deletions of the last exon of the gene immediately upstream of *MSH2, EPCAM* (also known as *TACSTD1*), lead to epigenetic silencing of *MSH2* and a Lynch syndrome-like phenotype [118]. *MSH6* mutations, when compared with those of *MLH1* and *MSH2*, show a lower frequency of CRC but an excess of endometrial cancer. The phenotypic consequences of *PMS2* mutations are highly variable. Notably, individuals who inherit mutations in both alleles of the same MMR gene present with constitutional mismatch repair deficiency syndrome, characterized by childhood onset of cancers (e.g., glioblastoma, gastrointestinal malignancies, hematologic malignancies) and café-au-lait spots.

Mutations causing functional deficiency in mismatch repair proteins frequently result in microsatellite instability (MSI). Microsatellites are genomic regions in which a short DNA segment or a single nucleotide is repeated. There are hundreds of thousands of microsatellites in the human genome. During DNA replication, mutations occur in some microsatellites owing to frequent misalignment of their repetitive subunits and result in contraction or elongation (instability) of the repeats. These abnormalities are usually repaired by the MMR proteins. However, repair is inefficient in tumors with a deficiency of these proteins. Typically, in cancer cells, half or more of all microsatellites have mutations (contraction or elongation), so MSI testing serves as an excellent marker of MMR deficiency. Although most microsatellites occur in noncoding DNA where contractions or elongations have little or no effect on protein function, there are genes that have repeat tracts in their coding regions where alterations can impact gene function (e.g., *TGFβRII, IGFIIR, MSH3, MSH6, BAX, E2F4*, and *BLM*) [119]. MMR deficiency also results in increased numbers of nucleotide substitution mutations.

A high level of microsatellite instability (MSI-H) is observed in about 15 % of sporadic colorectal carcinomas where it is associated with hypermethylation of the promoter region of *MLH1*. MSI-H underlies a distinctive tumorigenic pathway because cancers with MSI-H exhibit many differences in genotype and phenotype relative to cancers without MSI-H, irrespective of their hereditary or sporadic origins. Genetic, epigenetic, and transcriptomic differences exist between cancers with and without MSI-H. The *BRAF* V600E mutation is associated with sporadic MSI-H colorectal cancers harboring *MLH1* methylation (CpG island methylator phenotype) but not Lynch syndrome-related colorectal cancers. The differences in genotype and phenotype between cancers with and without

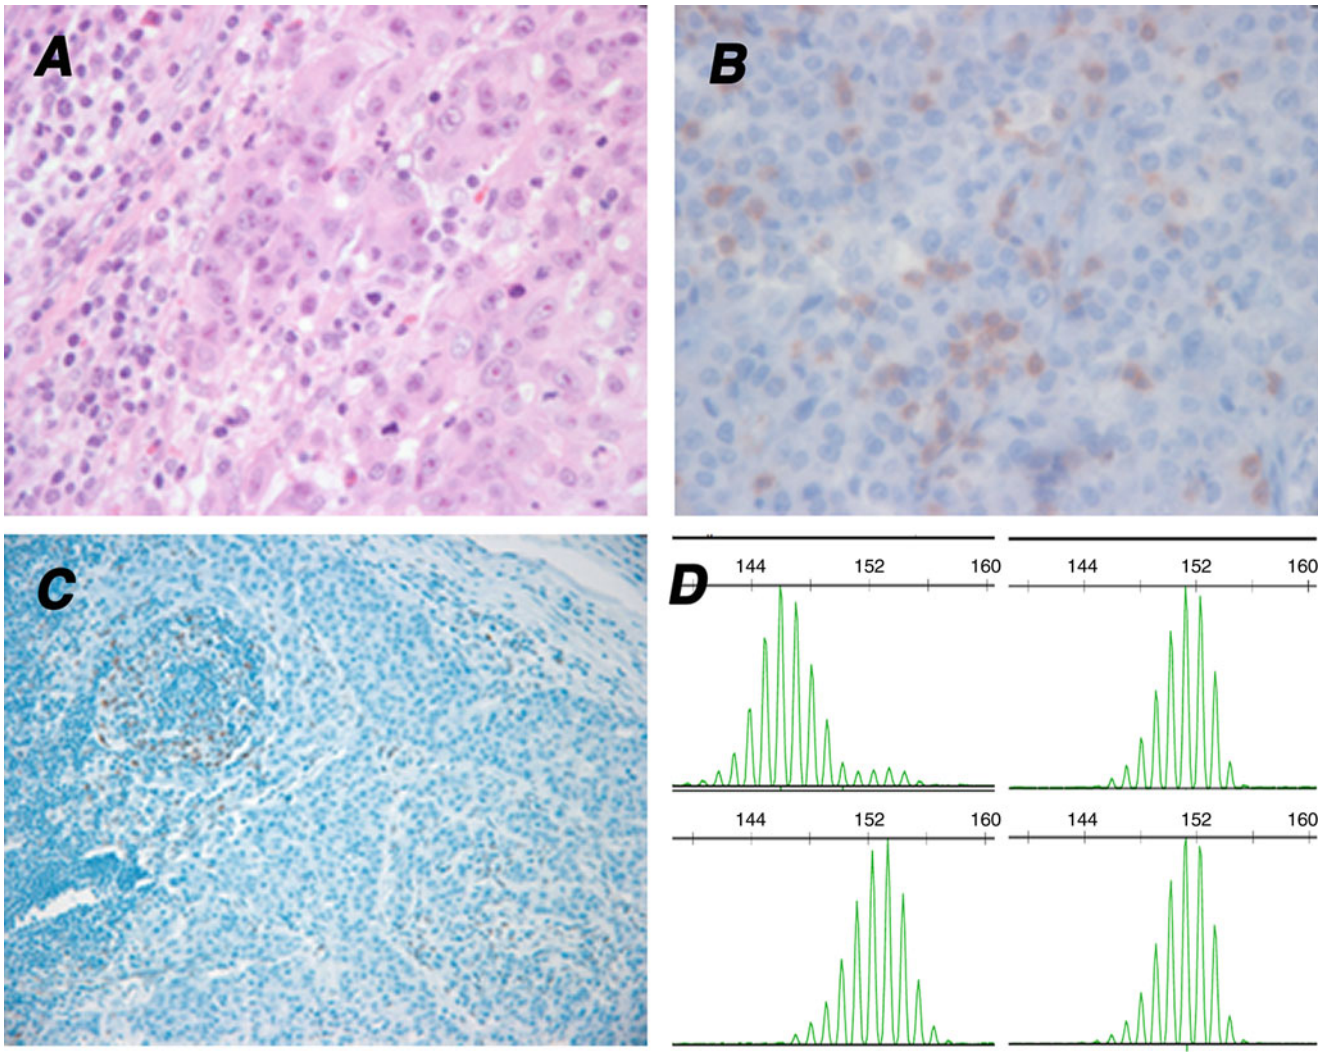

Fig. 22.7 Lynch syndrome, microsatellite instability-high colorectal adenocarcinoma. (**a**) Colorectal carcinomas in Lynch syndrome are characteristically high grade with medullary morphology (high grade carcinoma with malignant cells showing vesicular nuclei, prominent nucleoli, and abundant pink cytoplasm on H&E stain) with prominent intratumoral lymphocytes (small cells with darkly staining nuclei). (**b**) Tumor infiltrating lymphocytes are CD3 positive T-cells (*brown* color, immunohistochemical stain). (**c**) Loss of expression of MSH2 mismatch repair protein in malignant cells of colon carcinoma contrast to the preserved expression (*brown* staining nuclei) of MSH2 in mature lymphocytes (immunohistochemical stain). (**d**) Microsatellite instability: DNA isolated from both normal tissue (*bottom*) and colon cancer tissue (*top half*) from two patients (*left* and *right*). The patient on the left shows changes in the amplification pattern as a consequence of a defect in the mismatch repair. The patient on the *right* shows no change in amplification pattern supporting the absence mismatch repair defect.

MSI-H are likely to be causally linked to their differences in biological and clinical features. Therefore, the diagnosis of MSI-H in cancers is considered to be of increasing relevance. MSI-H is also a useful screening marker for identifying patients with Lynch syndrome, which could affect the efficacy of chemotherapy and allow identification of at-risk unaffected family members [120, 121].

Pathological features of colorectal cancers in Lynch syndrome are shared with MSI-H sporadic CRC and characteristically consist of poor differentiation (medullary carcinoma), mucinous, and signet-ring cell features (Fig. 22.7). Strong lymphoid reaction in the form of a Crohn's-like reaction (lymphoid nodules, including germinal centers, located at the periphery of infiltrating colorectal carcinomas), and particularly the presence of infiltrating lymphocytes within the tumor show strong predictive association with MSI-H CRC [122].

22.6 Mitochondrial Tumor Suppressor Genes

Although mitochondrial dysfunction is a common acquired feature of various cancers, germ-line heterozygous mutations in the autosomally encoded mitochondrial enzymes have only been described recently [123, 124]. There are mul-

tiple familial paraganglioma syndromes associated with germ-line mutations in genes encoding the four subunits of succinate dehydrogenase (*SDHA, SDHB, SDHC,* and *SDHD*) or mitochondrial complex II. Recent discoveries show that these genes are also implicated in the sporadic forms of the disease. A syndrome of multiple cutaneous and uterine leiomyomata (MCUL) is associated with germ-line mutations in fumarate hydratase (*FH*). If there is also a component of renal carcinoma then the syndrome is called hereditary leiomyomatosis and renal cell cancer (HLRCC).

Paragangliomas are tumors of neuroendocrine cells that arise in the parasympathetic and sympathetic nervous systems. Sympathetic paragangliomas arise from the adrenal medulla (where they are called pheochromocytomas) or from the paravertebral sympathetic chain from neck to abdomen, and they commonly secrete catecholamines. Parasympathetic paragangliomas arise from cell nests (paraganglia) adjacent to blood vessels. Symptoms associated with these tumors are related to their sizes and locations. Morbidity and mortality is due to the local and regional spread to adjacent nervous and vascular structures, major cardiovascular complications associated with secretion of catecholamines and the risk of recurrences and metastases. Hereditary paragangliomas are more often multifocal, recurrent, sometimes malignant, have an earlier age of occurrence than sporadic cases. Since early detection of paragangliomas reduces the incidence of morbidity and mortality, genotypic analysis in the search of *SDHB, SDHC,* and *SDHD* (and rarely *SDHA*) mutations in families of affected patients plays a front-line diagnostic role, leading to more efficient patient management. Additional genes (e.g., *SDHAF2*, *MAX*, *TMEM127*) are also associated with hereditary paraganglioma and/or pheochromocytoma syndromes.

Leiomyomas are tumors of the smooth muscle cells arising almost in any organ. In HLRCC both skin and uterine leiomyomas are present. Risk of developing renal carcinoma is estimated at 2–6 %. Renal cell carcinoma is often of papillary type II phenotype. Both sexes can be affected by often painful, clustered skin leiomyomas, and women affected with MCUL present with symptomatic uterine leiomyomas (fibroids) requiring hysterectomy for the control of symptoms.

22.6.1 Mechanisms Linking Loss of SDH and FH to Development of Cancer

SDHs and *FH* are housekeeping genes coding for enzymes in Krebs cycle. Functional losses of SDH and FH lead to a pseudohypoxic state in which succinate and fumarate accumulate and leak from mitochondria into the cytoplasm where they inhibit prolyl hydroxylation of hypoxia inducible factor (HIF1α). HIF1α plays a crucial role in regulation of genes important in cell function under various oxygen tension conditions. Under normal oxygenation HIF1α is hydroxylated and slated for degradation via the VHL-dependent ubiquitination pathway. However, under hypoxic or pseudohypoxic conditions (increased cytosolic succinate and/or fumarate) prolyl hydroxylase enzymes (PHD) are inhibited and HIF1α escapes degradation. Stable HIF1α then translocates to the nucleus where it can heterodimerize with HIFβ to form an active HIF transcription factor leading to expression of genes that can enhance survival in hypoxic conditions or reduce apoptosis (cell death) [125, 126].

22.7 Genetic Polymorphisms and Susceptibility to Cancer

Population data indicate that there are significant differences in individual susceptibility to cancer among humans. Inherited deficiencies in host defense mechanisms against DNA damage can modify cancer susceptibility as well as therapy response. It is believed that these differences arise from inherited genetic predispositions which in turn may be related to the genetic polymorphism (primarily single nucleotide polymorphisms or SNPs) of several enzymes involved in DNA repair, detoxification, and xenobiotic metabolism.

Functional polymorphism in the *MDM2* gene has been extensively studied in association with cancer risks in various populations [127]. The Mdm2 protein is an important part of the p53 tumor suppressor pathway. This pathway is activated upon cellular stress, such as DNA damage, and it elicits cell cycle arrest, senescence, and apoptosis, crucial for prevention of the propagation of DNA damage that could lead to tumor formation. Inactivation of p53 (through acquired mutation) is the most common genetic event in cancer seen in at least 50 % of all cancers. Mdm2 protein plays a crucial role in the p53 pathway where it is the primary E3 ubiquitin ligase for the p53 protein targeting it for proteasome degradation. Hence, Mdm2 provides negative regulation of the most important cellular tumor suppressor. It is known that a subset of human tumors show overexpression of Mdm2 and in experimental models even a modest change in Mdm2 cellular levels can affect cancer formation through the weakening of the p53 pathway.

The G-allele of the single nucleotide polymorphism (SNP309, T/G) in the promoter of *MDM2* increases the binding affinity of the transcriptional activator Sp1 which results in increased cellular concentration of *MDM2* mRNA and protein. Individuals with G/G genotype have up to 2.5-fold higher Mdm2 levels than individuals with T/T genotype. Additionally, carriers of a germ-line mutation in the *TP53* gene (Li–Fraumeni syndrome) who also possess the G-allele of SNP309 (either heterozygous or homozygous state)

develop cancer on average 9 years earlier than those with T/T genotype and also more commonly develop multiple tumors in their lifetime. Similar trends are seen in cancer patients without known germ line mutation in *TP53* (sporadic cancer cases) [128–130].

Genome-wide association studies (GWAS) using high-density SNP genotyping arrays identified common genetic variations contributing to many normal and pathologic traits. The vast majority of GWAS identified SNPs lie in intergenic or intronic regions, and therefore, are likely to influence gene regulation, while only a small fraction of variants affect protein coding regions. There are approximately 4.5 million SNPs in the human genome, which are at the core of inherited genetic variation in humans. However, at this moment no more than weak associations have been found between them and various cancers. These data suggest that the modulation of cancer risk depends not only on a single gene/SNP, but also on a joint effect of multiple polymorphisms (or haplotypes) within different genes or pathways, in close interaction with environmental factors. Virtually all responses to environmental carcinogenesis reflect the contributions of dozens of enzymes, and only simultaneous genotyping and combined analyses of different polymorphisms in larger numbers of patients and controls, as well as stratification of results by ethnicity, gender, and tumor characteristics may uncover the role of these SNPs in sporadic cancer.

22.8 Genetic Counseling

Prior to gene testing, high-risk individuals must receive genetic counseling, so they fully understand the pros and cons of cancer genetic testing, allowing them to provide fully informed written consent. Specifically, the patient must be able to determine whether such DNA testing is acceptable emotionally; he/she must also feel secure regarding issues of confidentiality, which may relate to the patient's perception of insurance or employment discrimination. They must also consider how their close relatives, particularly their children, will react to the presence of the mutation. Will this result in alienation with such questions as "… *Why did you have children, knowing that you'd pass on to us a high cancer risk?* …" Given these concerns, the physician must also carefully appraise, in so far as possible, the individual's emotional state in terms of his or her ability to accept a positive or negative DNA mutation test result. Multiple concerns may arise, such as the perception of insurance discrimination, which in some circumstances may deter mutation testing. When the physician lacks expertise in these matters, the patient should be referred to a medical geneticist and/or a medical genetics center experienced in all facets of hereditary cancer.

In conclusion, recent advances in our knowledge of cancer genetics are beginning to pay translational dividends in the management of this common clinical problem. Individuals with inherited cancer syndromes are at significant risk of developing both benign and malignant tumors as a result of a germ-line mutation in a specific tumor suppressor gene or proto-oncogene. We are now able to accurately screen and counsel individuals at risk for rare inherited cancer syndromes. Some neoplasia risk can be reduced by various preventive surgery measures, e.g., prophylactic bilateral mastectomy and/or bilateral salpingo-oophorectomy in *BRCA1* or *BRCA2* mutation carriers. Finally, our advancing knowledge has led to significant inroads into understanding what genetic alterations define prognosis and predict response to specific chemotherapeutic agents, and we are beginning to explore the utility of this knowledge in mass genetic-based clinical screening efforts. Enthusiasm must be tempered, however, by the extraordinary cost that often accompanies relatively modest gains. Finally, although genetic-based therapy often receives the greatest attention, molecular genetics, will likely have the greatest cost-effective impact in primary prevention and early diagnosis.

Retinoblastoma: Clinical and Molecular Perspectives

23

J. William Harbour

23.1 Introduction

Retinoblastoma is the most common childhood eye cancer, affecting approximately 1 in 250,000 children in the USA [1], and it is one of the clinical success stories in pediatric oncology. A century ago, retinoblastoma was uniformly fatal, but today the survival rates are greater than 95 % in developed countries. This dramatic improvement in clinical outcomes is the result of advances in diagnostic techniques and treatment modalities [2, 3]. In addition, retinoblastoma has had a far-reaching impact that on cancer research that far exceeds its clinical prevalence. The retinoblastoma (RB) gene encodes a protein that is central to cell cycle regulation and is the namesake of a tumor suppressor pathway that is disrupted in virtually all human cancers.

23.2 Clinical Perspectives

23.2.1 Epidemiology and Clinical Genetics

Retinoblastoma is the most common intraocular malignancy in the pediatric population. There are no significant gender or race predilections. No specific environmental risk factors have been identified. Retinoblastoma accounts for approximately 3 % of all registered cancers in children [4].

About 93 % of new cases of retinoblastoma are sporadic with no family history. Among sporadic cases, about 60 % will have the nonheritable form and 40 % will have the heritable form of retinoblastoma. In patients with nonheritable disease, the eye cancer is unilateral and typically diagnosed between 1 and 2 years of age, although it can be diagnosed in older individuals. There is no increased risk of other cancers, and if the primary cancer is treated effectively, these patients have a normal life expectancy [5].

Patients with the heritable disease are usually diagnosed at an earlier age, typically within the first year of life. About 85 % of these patients will have multiple, bilateral eye tumors, and about 10 % will develop a midline intracranial tumor similar in embryonic origin and histologic appearance to retinoblastoma [6, 7]. Patients with heritable retinoblastoma are also at risk of many other types of second primary cancers throughout life. The risk of all of second primary cancer is particularly elevated if the patient has received radiation therapy [8–10].

The inheritance pattern of retinoblastoma was instrumental in the discovery of the RB tumor suppressor gene [11]. From a clinical standpoint, retinoblastoma is inherited in an autosomal dominant fashion, and for many years it was assumed that the gene causing retinoblastoma would operate in a dominant fashion [12]. In 1971, Alfred Knudson proposed the landmark two-hit hypothesis suggesting that the RB gene is, in fact, recessive at the molecular level [13]. The hypothesis suggested that a germ line mutation was present in most or all cells of the body in heritable cases, and that a second somatic mutation was rate-limiting in cancer formation. In the nonheritable cases, both mutations occurred as somatic events, thereby explaining why the disease was always unilateral and did not predispose to second primary cancers.

23.2.2 Clinical Features

Since most patients are young children at initial diagnosis, it is rare for them to complain of ocular symptoms. The most common presenting signs are leukocoria (white pupil reflex) and strabismus (misaligned eyes). Family history is important, but is usually negative. On clinical examination, retinoblastoma typically involves the posterior segment of the eye

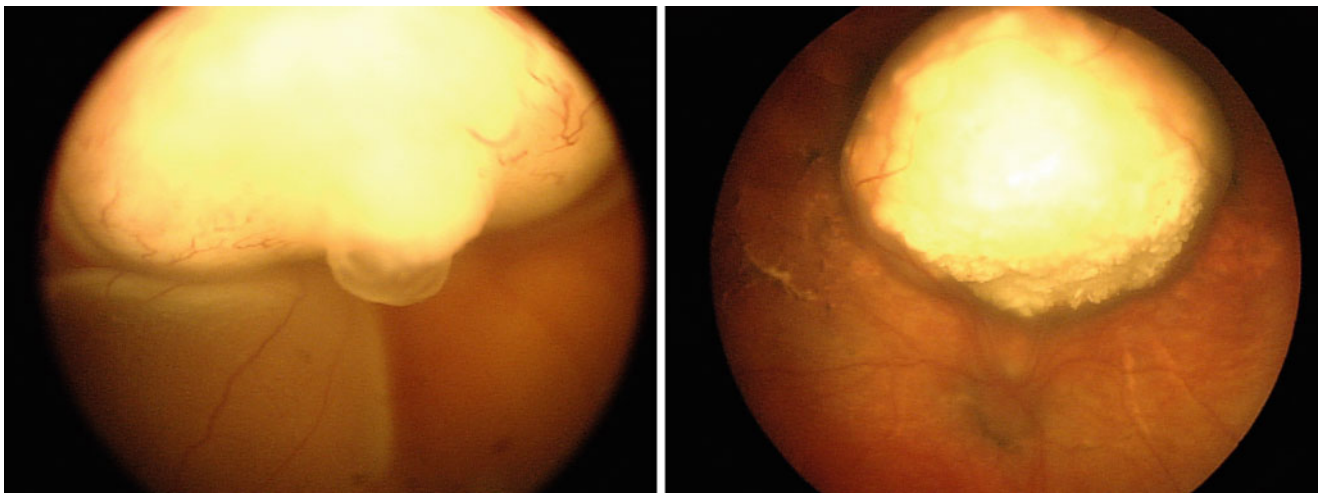

Fig. 23.1 Clinical appearance of retinoblastoma. A large retinoblastoma before (*left*) and after (*right*) chemotherapy. Note the marked reduction in tumor size after chemotherapy. This view was obtained with a fundus camera that simulates the view with indirect ophthalmoscopy.

and is best visualized with indirect ophthalmoscopy (Fig. 23.1). Retinoblastomas usually appear grey to white in color and may grow beneath the retina (exophytic pattern) or into the vitreous cavity (endophytic pattern). Accompanying findings can include retinal detachment, vitreous seeding, iris neovascularization, glaucoma, and invasion of the choroidal, optic nerve, and anterior segment. Ultrasonography and computed tomography are useful in confirming intratumoral calcifications, which are almost pathognomonic for retinoblastoma in children under 5 years old.

The differential diagnosis of retinoblastoma includes persistent hyperplastic primary vitreous, Coats' disease (congenital retinal telangiectasis), ocular toxocariasis, endophthalmitis, retinopathy of prematurity and other conditions that can result in the appearance of a white pupil reflex.

The benign variant of retinoblastoma is referred to as retinoma or retinocytoma [14, 15]. These benign retinal tumors can be distinguished from retinoblastoma clinically by features such as calcification and surrounding chorioretinal atrophy, and histopathologically by the presence of well-differentiated retinal-like cells forming fleurettes and rosettes. The molecular pathogenesis of these lesions remains uncertain, but they can be found in the parents of children with sporadic heritable retinoblastoma and in patients with low-penetrance forms of retinoblastoma.

23.2.3 Histopathology

The cell of origin for retinoblastoma remains unclear but is most likely a retinal progenitor cell that has the capacity to differentiate along the lineage of photoreceptors and Mueller cells [16–18]. Retinoblastomas are composed of small round cells with large nuclei and minimal cytoplasm (Fig. 23.2). Tumor cells vary in the degree of differentiation, with Homer-Wright rosettes, Flexner-Wintersteiner rosettes, and fleurettes representing attempts at photoreceptor differentiation. However, unlike most cancers the degree of differentiation in retinoblastoma has no prognostic significance. Histopathologic features with indisputable prognostic significance include optic nerve and choroidal invasion [19].

23.2.4 Second Primary Tumors

Patients with heritable retinoblastoma have a systemic predisposition to cancer resulting from the germ line RB gene mutation present in most or all cells in the body. Multiple types of second primary cancers can be seen, including osteosarcomas, soft tissue sarcomas, melanomas, and epithelial cancers [8, 20]. The incidence of second primary tumors is roughly 25 % at 40 years after diagnosis of retinoblastoma [9]. If a patient receives radiation therapy, the risk of second malignancies increases significantly [21]. The finding of biallelic RB gene mutations in osteosarcomas and other second primary cancers lends support to the idea that the two-hit hypothesis of tumorigenesis also applies to these tumors [22].

23.2.5 Treatment and Prognosis

Over the past century there have been steady advances in the treatment of retinoblastoma [2]. Enucleation (eye removal) remains an important treatment option in certain cases (e.g., unilateral cases, very large tumors and invasion of the optic nerve or anterior segment). External beam radiotherapy (EBRT) was a mainstay of treatment for many years. However, the increased risk of second primary tumors and facial bone deformities

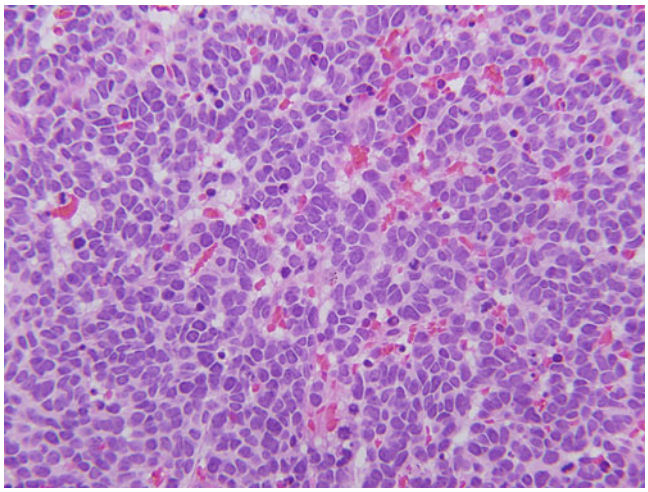

Fig. 23.2 Histopathologic appearance of retinoblastoma. Hematoxylin and eosin staining reveals small round blue cells with large nuclei and scant cytoplasm. This example is poorly differentiated.

associated with radiation has tempered enthusiasm for this treatment, particularly in patients younger than 12 months of age, who are at highest risk for these complications [23].

As an alternative to EBRT, several groups pioneered the use of chemotherapy in the 1990s [24, 25]. It was known from previous work several decades before that retinoblastoma responds to chemotherapy but frequently recurs due to the emergence of multidrug resistance. Therefore, the new approach combined chemotherapy with local consolidative techniques, such as laser and cryotherapy, to ablate the residual tumor masses after they had first been reduced in size by chemotherapy [24, 25]. Currently, the most frequently used agents are carboplatin, vincristine, and etoposide, given in 6–9 cycles. The survival rate in most developed countries is now greater than 95 %, but there are still many deficiencies that need to be addressed in the management of retinoblastoma. The risk of second primary tumors with current chemotherapy regimens remains unclear. Eyes with significant vitreous seeding generally do not do well with chemotherapy and often require radiation to salvage the eye. Intensive research efforts continue to identify new therapeutic options.

23.3 Molecular Perspectives

23.3.1 Molecular Genetics and Background

Retinoblastoma has played a pivotal role in cancer research that far outweighs its epidemiologic significance. Despite its rarity, retinoblastoma has provided unique and far-reaching insights into the genetics and molecular biology of cancer. The autosomal dominant inheritance of retinoblastoma has attracted the attention of cancer researchers for many years. The pivotal breakthrough occurred in 1971, when Alfred Knudson proposed his two-hit hypothesis that proposed that retinoblastoma results from the mutational inactivation of both alleles of a putative recessive oncogene [13]. The retinoblastoma locus was mapped to chromosome 13q through its linkage to esterase D, an enzyme that had previously been mapped to this region and which could be assayed for its enzymatic activity [26]. Esterase D activity was found to be about half the normal level in retinoblastoma patients with karyotypically visible deletions on chromosome 13q [27]. In another study, esterase D activity was 50 % of normal in healthy tissues of retinoblastoma patients but was undetectable in tumor tissue [28], providing further support for Knudson's hypothesis. The recessive nature of the retinoblastoma locus was conclusively demonstrated by loss of heterozygosity in tumor tissue [29], a technique that subsequently has become a standard for studying tumor suppressor genes. Based on the proximity to the esterase D gene, several groups independently identified and characterized a nearby gene that proved to be the retinoblastoma gene [22, 30, 31]. Reintroduction of this gene into retinoblastoma cells suppressed the tumor phenotype, providing functional evidence for its role as a tumor suppressor [32].

23.3.2 The RB Gene

The retinoblastoma gene (RB) spans over 200 kilobases of DNA and contains 27 exons [33, 34]. Germ line mutations tend to cluster at CpG areas but are also spread throughout the gene with no mutational hot-spot [35, 36]. Germ line mutations can include deletions, frameshift and nonsense mutations, splicing mutations, and mutations in introns resulting in a truncated protein product [35]. The second hit is usually a nondisjunction or recombination event during mitosis, resulting in reduction to hemizygosity of the mutant allele [37]. Most RB mutations result in >90 % penetrance, but some mutations have been associated with low penetrance retinoblastoma. These low penetrance mutations can be divided into those that cause a reduction in the amount of normal Rb protein (usually promoter mutations) and those that result in a partially functional Rb protein (usually missense mutations) [38].

23.3.3 The Rb Protein

The retinoblastoma protein (Rb) is composed of 928 amino acids and has three functional domains: the N-terminus, the central pocket domain, and the C-terminus. The pocket, which is formed by the highly conserved A and B boxes, is required for binding to E2F, viral oncoproteins and chromatin remodeling proteins, and it is required for tumor suppression [39, 40]. Most RB mutations affect the pocket [35]. The C-terminus is also required for efficient binding to

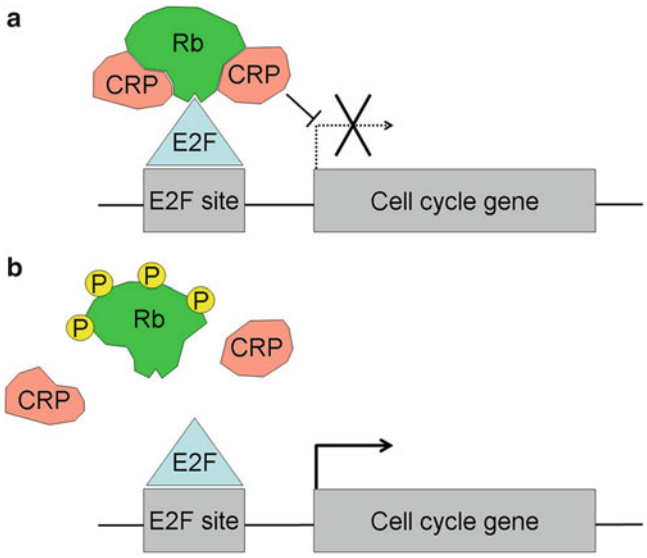

Fig. 23.3 The molecular mechanism of action of Rb. (**a**) When Rb is hypophosphorylated and active, it binds to E2F transcription factors that bind to E2F sites in the promoter regions of genes involved in cell cycle progression and apoptosis. Rb directly inhibits E2Fs by binding and masking the transactivation domain, and it also recruits chromatin remodeling proteins (CRPs) that alter local chromatin structure into a conformation that is not permissive for transcription. (**b**) When Rb is hyperphosphorylated, it does not bind efficiently to chromatin remodeling proteins or E2Fs, which allows E2Fs to transactivate cell cycle genes.

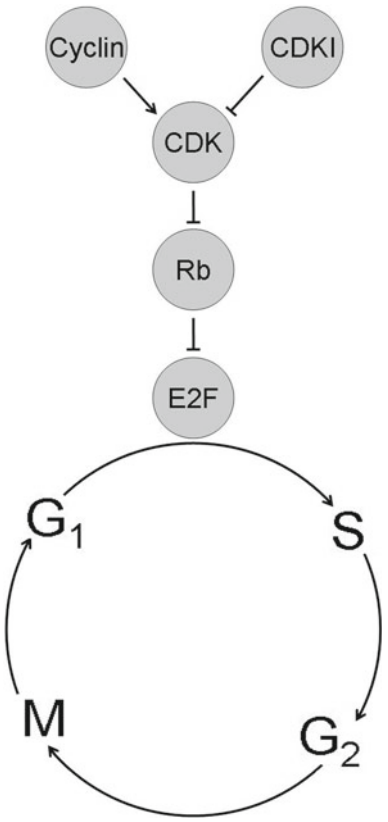

Fig. 23.4 The retinoblastoma tumor suppressor pathway.)E2F transcription factors promote cell cycle progression in part by transactivating genes involved in DNA synthesis (S) phase of the cell cycle. Hypophosphorylated, active Rb inhibits cell cycle progression from G_1 phase into S phase by directly inhibiting E2Fs and by actively repressing transcription of cell cycle genes. Rb can be inhibited by hyperphosphorylation catalyzed by cyclin dependent kinases (CDK). CDKs, in turn, require activation by cyclins, and they can be inhibited by CDK inhibitors (CDKIs) such as p16. Cancers tend to upregulate cyclins and CDKs and to downregulate CDKIs through genetic mutation or functional perturbation.

E2Fs, and it has binding sites for the oncoproteins MDM2 and c-abl [41–44]. The function of the N-terminus is less clear, and it does not appear to be required for tumor suppression [45].

A major function of Rb is to inhibit the G_1–S phase transition of the cell cycle [46]. Protein activity is modulated during the cell cycle by phosphorylation, which can occur on 16 cyclin-dependent kinase Ser/Thr-Pro phosphoacceptor sites. Rb phosphorylation varies throughout the cell cycle, with hypophosphorylated Rb predominating in G_0 and G_1, and hyperphosphorylated Rb in S-phase and G_2/M [47–49]. Rb usually becomes hypophosphorylated during differentiation and senescence, and it becomes hyperphosphorylated in cells reentering the cell cycle [50–52]. The Rb protein can also be modulated by viral oncoproteins, such as SV40 large T antigen, adenovirus E1a protein and herpes virus E7 protein, which bind and inhibit Rb, thereby stimulating cell cycle progression [53–55] (Fig. 23.4).

A major binding partner of Rb is the E2F family of transcription factors (E2Fs) [56]. Rb does not have a DNA binding domain but is brought to specific promoters through its interaction with E2Fs. E2F-responsive genes contain one or more E2F binding sites in their promoters, and these genes play an important role in cell cycle, apoptosis and other cellular functions [57]. In addition to a DNA binding domain, E2Fs 1–5 also have a transactivation domain by which they promote the transcription of specific genes. Rb inhibits transcription in part by binding and masking the E2F transactivation domain [58, 59]. In addition, Rb actively represses promoter and enhancer elements independently of its effect on the E2F transactivation domain [60, 61]. This so-called active repression is now thought to result from the recruitment by Rb of chromatin remodeling proteins that reconfigure local chromatin into a nonpermissive state for transcription [62]. These proteins include histone deacetylases, DNA methyltransferases, and polycomb complexes [63–68]. The functional significance of these two independent mechanisms of transcriptional repression by Rb remains controversial (Fig. 23.3). However, it seems clear that active repression by Rb is required for the full tumor suppressor activity of Rb, including its inhibition of the G_1–S phase transition [69] (Fig. 23.4).

In addition to its role as a cell cycle inhibitor, Rb also inhibits apoptosis [46]. These seemingly opposing roles of Rb have not been satisfactorily reconciled. The widely accepted view of Rb as an on-off regulator of the G1–S transition that is completely inactivated every cell cycle does not explain why cells do not undergo apoptosis with every attempt at cell division. The most straightforward explanation is that Rb is not completely inactivated every cell cycle but that the degree of Rb phosphorylation and inactivation can be graded, depending on the cellular context. In support for this idea, Rb is phosphorylated in several hierarchical steps, and the phosphorylation events regulating the cell cycle can be differentiated from those regulating apoptosis [70, 71]. It seems likely that Rb is only partially phosphorylated and inhibited during normal cell division, and that this incomplete inactivation is sufficient to block its cell cycle inhibitory function and to allow cell cycle progression without triggering apoptosis [72]. This residual anti-apoptotic activity may persist unless Rb is more completely phosphorylated (or unless the RB gene is mutated), suggesting that Rb may serve as a buffer against apoptosis during normal cell division and a checkpoint for triggering apoptosis under abnormal stress conditions such as excessive mitogenic stimulation, DNA damage, and hypoxia in which apoptosis may be favored for survival of the organism.

23.3.4 The Rb Pathway

Although RB gene mutations are common in only a few types of cancer, such as retinoblastoma and small cell lung cancer, the RB pathway is functionally disrupted in virtually all human cancers [73, 74]. The RB pathway is composed of proteins that modulate Rb phosphorylation state. Rb is phosphorylated by cyclin-dependent kinases (CDKs), which are activated by interaction with cyclins [74, 75]. Therefore, overactivity of cyclins or CDKs can lead to functional inactivation of Rb. For example, cyclin D1 is a bona fide oncogene that is overexpressed and functionally inhibits Rb in many cancer types [76, 77]. A constitutively active CDK4 mutant that maintains Rb in a phosphorylated state has been identified in some cancers [78]. On the other hand, CDKs are inhibited by proteins such as $p16^{INK4a}$, which is a tumor suppressor that is mutationally inactivated in some cancers [79]. Interestingly, the cancers associated with complete Rb inactivation by genetic deletion (e.g., retinoblastoma and small cell lung cancer) have a different phenotype than those associated with partial Rb inhibition by loss of p16Ink4a or overexpression of cyclin D (e.g., melanoma, most solid tumors). The former tend to exhibit rapid proliferation, high apoptotic rates and sensitivity to chemotherapy, whereas the latter tend to have slow rates of proliferation and apoptosis and tend to be resistant to chemotherapy [80].

23.4 Conclusions

Retinoblastoma continues to provide important new insights into cancer biology and treatment. New discoveries will continue to emerge from the study of retinoblastoma and the RB pathway, and these will likely play an important role in the continued search for better cancer therapies.

Xeroderma Pigmentosum and the DNA Damage Response to Ultraviolet Light

24

James E. Cleaver

24.1 Xeroderma Pigmentosum: Clinical and Genetic Aspects of Disease

Xeroderma pigmentosum (XP) is a rare autosomal recessive disease with sun sensitivity and progressive degenerative changes of sun-exposed portions of the skin and the anterior portion of the eyes. Patients develop non-melanoma skin cancer and melanoma; about 20 % of patients show additional developmental disorders and progressive neurological degeneration [1, 2]. XP occurs at a frequency of about 1 per million in the USA and Europe, but is considerably more common in Japan (1 in 100,000) and North Africa. The frequency of heterozygotes in Japan is as high as about 1 % [3]. The median age of onset of symptoms is between 1 and 2 years and can include severe sunburn with blistering and persistent erythema after short sun exposure, and development of freckling within a few years of life. The skin symptoms are directly related to the failure of nucleotide excision repair (NER) of damage to DNA of the cells of the skin and eyes caused by solar exposure in the UVB range of the sun's spectrum (280–310 nm) [4–6]. Defective DNA repair leads to cancer development with a median age of onset of 8 years, nearly 50 years younger than that in the general population of the United States [7]. Heterozygotes (parents) are generally without symptoms of solar sensitivity, but in several mouse knockouts of XP genes heterozygous abnormalities have been observed [8–11].

Several other recessively inherited diseases are associated with XP and involve related pathways of DNA repair or rare mutations that present distinctive symptoms. Cockayne syndrome (CS) is a wasting disease with progressive neurological deficits including demyelination, ataxia, cerebellar atrophy, and calcification in the brain, particularly in the basal ganglia, but with no increased risk of cancer [12, 13]. Symptoms may be present at birth or during childhood and the average lifespan is 12 years [12, 13]. CS encompasses a wide range of clinical symptoms from the very mild UV^{s} syndrome that shows virtually no neurological symptoms and only mild skin sensitivity to solar exposure [14–18], through varying degrees of severity of CS symptoms [12, 13], to the extremely severe neonatal lethal disorder cranial oculo-facio-skeletal syndrome (COFS) that has been associated with CSB and other repair genes [19–21]. CS individuals are deficient in a sub-pathway of NER known as transcription-coupled repair (TCR) [22–24]. Trichothiodystrophy (TTD) is a developmental disorder in which patients have sulfur-deficient brittle hair with characteristic tiger tail banding when examined in polarized light, skin photosensitivity without increased pigmentation or cancer, and immune deficiency caused by mutations in components of the transcription factor TFIIH that contains NER gene products [2, 25]. Although CS and TTD do not exhibit cancer in humans, the corresponding mouse knockout strains all show increased skin cancer incidence when exposed to UVB or skin carcinogens [8, 26, 27].

The molecular basis of XP, CS, and TTD is a series of defects in components of the DNA damage response (DDR) to UV damage involving the NER system that removes and replaces DNA damage in DNA or the low fidelity polymerase Pol eta (η) that replicates past DNA damage. Genetic analysis of XP showed that there are 8 different groups: XP-A through XP-G, that represent different steps in damage recognition and excision and XP-V that corresponds to the bypass polymerase Pol eta. Other repair deficient disease genes include *CSA*, *CSB*, and *TTDA*. Many components of the NER system, estimated to be about 30 [22], have not been identified among human patients either because mutations would be lethal or have not been clinically recognized due to extreme rarity. Mouse knockouts have revealed the essential nature of some of these genes and can present with symptoms significantly different from the corresponding

human patients, either more severe or less. XP-A patients for example have severe progressive neurodegeneration, but the mouse knockout is without neurological disorder [28, 29]. XP-B and XP-D patients have severe neurodegenerative symptoms, but the mouse knockouts are lethal in very early embryo [30]. XP-E and XP-F patients are generally only mildly affected, but the mouse knockouts have severe disorders [9, 31]. One patient was identified with a severe COFS-like disorder due to mutations in *ERCC1*, a cofactor for the XP-F gene [21]. These differences between human and mouse have several explanations, in addition to those associated with broad mouse and human differences. Differences arise because mutations may cause different phenotypes from complete gene loss, as well as because of the selective screen by which only a subset of mutations give rise to viable patients.

24.2 The DNA Damage Response: Oncogenes, Tumor Suppressors, Recombination, and Signal Transduction

In recent years there has been a convergence in understanding that many endogenous and exogenous factors, including oncogenes, tumor suppressors, radiation, chemical carcinogens, and viral infections can all impact a common, but complex, set of pathways that regulate cellular survival, apoptosis, and genomic stability: the DNA damage response (DDR) and cell cycle checkpoints (Fig. 24.1) [32, 33]. The DDR involves a cascade of damage recognition, repair, and signal transduction that coordinates the response of the cell cycle to DNA damage. The DDR activates checkpoints that delay the cell cycle, provides time for repair, and directs damaged cells into senescent or apoptotic pathways. The DDR is significantly different in primary normal cells (fibroblasts, keratinocytes) as compared to immortalized (telomerase-expressing) or transformed cells, due to significant changes in p53 expression, kinase activities, and signal transduction. Associated with these changes in the DDR, the spontaneous mutation rate is low in primary cells but increases by orders of magnitude in transformed, malignant cells [34]. Consequently tumors contain large numbers of mutations and other genomic changes [35, 36]. The emerging complete picture of the interacting signal transduction pathways remains unclear, but is increasingly recognized as an important part of the overall process of carcinogenesis [32, 33].

The DDR has been most extensively studied as a response to DNA double strand breaks (DSBs), usually caused directly by X-rays [37]. Common assumptions assert that DNA double strand breaks activate the kinases ATM and Chk2, and replication stress (e.g., hydroxyurea, UV light) activates

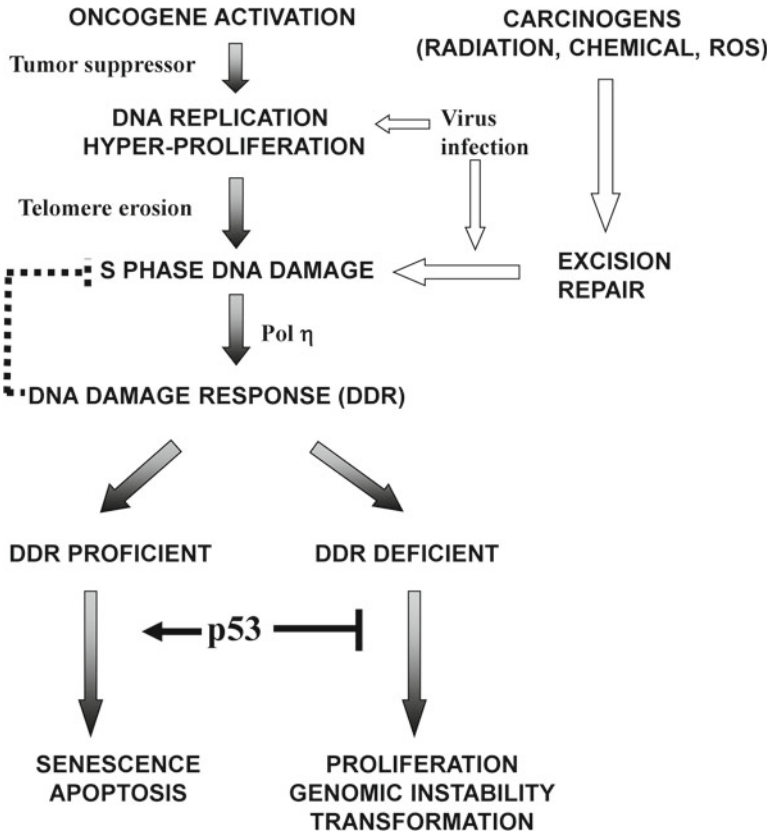

Fig. 24.1 Nucleotide excision repair and the DNA damage response from radiation and chemicals, oncogene driven replication and virus infections. Adapted with modifications from ref. [33].

ATR and Chk1 [37–46]. ATM can also be activated by oxidative stress without necessarily involving DSBs [47]. The Chk1 and Chk2 kinases phosphorylate p53, cause nuclear translocation of the Cdc25 phosphatases, and increase expression of p21. Increased p21 results in G1/S, S, and G2/M cell cycle arrest, during which DNA repair can occur. Both ATM and ATR kinases are involved in the DSB and replication stress responses with considerable variation according to the damage and cell type [48]. At least 700 different protein substrates have been identified as targets for phosphorylation by these kinases [49]. There will be substantial differences in the structure of DNA and chromatin adjacent to DSBs compared with that resulting from replication arrest which lead to different signaling cascades and checkpoint activation [50–52]. The ATR pathway is essential for viability, ATR and Chk1 knockout strains are lethal [53]. ATM and Chk2 mutants are viable even though cells lacking these kinases display genomic instability and a predisposition to cancer [54]. The long history of sensitization of cells to UV damage by growth in caffeine [55] now appears to be explained at least in part by the sensitivity of the ATR-CHK1 pathway to caffeine [56, 57].

A major early signal of DNA damage and repair is the phosphorylation of the minor histone H2AX which occurs within minutes of DSB induction. H2AX is one of several nonallelic isoforms of histone H2A [58]. H2AX is ubiquitously distributed throughout the genome and has phosphorylation sites within the conserved C-terminal region at serine 139 and tyrosine 142 [59, 60]. Induction of DNA DSBs triggers H2AX phosphorylation (γH2AX) over megabases adjacent to DNA DSBs [60, 61]. After exposure to ionizing radiation, H2AX phosphorylation promotes chromatin condensation, which is detectable by immunofluorescence microscopy as nuclear γH2AX foci [60]. Initial recruitment of DNA repair and checkpoint factors, e.g., Mre11, Rad50, Nbs1, Brca1, and 53BP1, to DNA DSBs is not affected in H2AX knockout mice but repair and checkpoint factors subsequently fail to form foci, indicating that γH2AX functions to concentrate repair and checkpoint proteins in the vicinity of DNA lesions [62, 63].

The DDR from UV-induced photoproducts is more complex, and has distinct G1 and S phase responses. NER in G1, for example, excises UV photoproducts before onset of DNA replication and thereby eliminates mutagenic lesions completely [64]. NER is required during this phase for activation of the ATR-Chk1-p53 signal pathway [65]. Cells defective in the global branch of NER (XP-A through XP-G), but not the TCR branch (CSA, CSB), show reduced ATR-dependent signaling in G1 [65] and less γH2AX formation [66]. H2AX-knockout mice are cancer-prone and the knockout cells are sensitive to X-rays and etoposide that make DSBs [67], but show little sensitivity to UV light or cisplatin that do not produce direct DNA DSBs (Cleaver, unpublished observations). Therefore despite extensive H2AX phosphorylation after most forms of DNA damage, γH2Ax is only functionally important for DSBs but is only a biomarker for other forms of damage.

Damage that persists in S elicits a stronger ATR-Chk1-p53 response than in G1 [65], and contributes to recovery of DNA replication [68]. Stalled replication forks form long (kilobase) stretches of single-stranded DNA [44, 69–73]. These become coated with RPA that activates ATR through ATRIP [44]. The bypass polymerase Pol η is recruited through reversible ubiquitylation of PCNA [74–77]. A small fraction of arrested replication forks degrade to DSBs [78] or are resolved by nonhomologous or homologous recombination [79]. Replication fork breakage may be an active enzymatic process, and by analogy with DNA cross-links could involve either MUS81 or the NER nuclease XPF/ERCC1 [80]. UV-induced replication arrest results in large increases in γH2AX formation associated with coordination of the numerous replication and recombination factors associated with the arrested forks [66, 81, 82], but the absence of H2AX does not confer any increased UV sensitivity (Cleaver, unpublished observations). Resolution of the arrested replication forks also depends on p53, and cells lacking both p53 and Pol η are extremely sensitive to cell killing by UV light [83].

Resolution of arrested forks can result either in complete restoration of normal DNA replication, or large changes in genomic stability leading to mutagenesis or malignant transformation (Fig. 24.1).

24.3 Two Branches to Damage Removal

The main substrates for NER relevant to XP are the UV photoproducts between adjacent pyrimidines: the cyclobutane pyrimidine dimers and the [6-4] pyrimidinone dimers [84]. These are produced in DNA in skin over the whole UV wavelength range (UVA–UVB–UVC), although the most important wavelengths from solar exposure, from a practical standpoint, are UVB, approximately 280 to 320 nm [85]. The precise proportions of these photoproducts, and their pyrimidine constitution (T=T, C=C, T=C, and C=T) vary with wavelength, but in general they are the archetype large DNA adduct that is the main class of substrates for NER [86–89].

NER can remove DNA damage before DNA replication begins (Fig. 24.2), and consequently plays a major role in reducing the amount of damage that becomes fixed as mutations during replication [64, 90], but there is also evidence for a direct role in the UV damage response during the S phase, especially the ATR/Chk1 pathway [91]. The NER process has two main branches distinguished by the mechanisms used for initial recognition of DNA damage [92]:

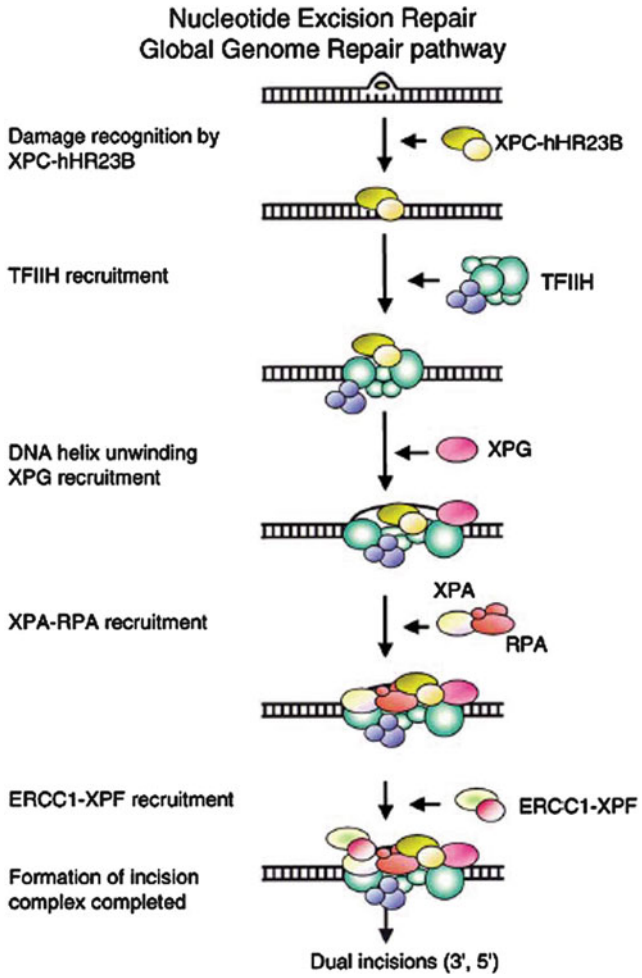

Fig. 24.2 Sequence of action of nucleotide excision repair (global genomic repair) on untranscribed DNA. Transcription coupled repair employs the arrest of RNA Pol II at DNA photoproducts as the damage recognition step, bypassing XPE and XPC, and entering the excision process at the TFIIH step. Reproduced from ref. [107] with permission from Elsevier.

transcription coupled repair (TCR) by which actively transcribed genes are repaired more rapidly than the rest of the genome [93–97], and global genomic repair (GGR), by which non-transcribed regions of the genome are repaired [6]. Damage in transcribed genes is recognized through the arrest of RNA Pol II that is relieved through the action of two proteins, CSA and CSB. Damage in the non-transcribed or global regions of the genome is recognized by the binding of two heterodimeric XP proteins, XPE (DDB1/DDB2) and XPC/HR23B, which may act in concert to bind to damaged DNA [6]. TCR and GGR converge on a common pathway through which the damage is verified (XPA/RPA), the DNA is unwound by the XPB and XPD helicase components of the transcription factor TFIIH, cleaved by structure-specific nucleases (XPG, XPF/ERCC1), and the damage excised and replaced.

The complete excision process on metabolically inactive DNA can be carried out in vitro with a minimal set of recombinant proteins: RPA, XPA, TFIIH (6 subunit core of XPB, XPD, p44, p34, p52, p62, and 3 subunit kinase CAK), XPC, hHR23B, XPG, ERCC1, and XPF [98–101]. Both TCR [102, 103] and GGR [104–106] are regulated by p53.

The sequence of action of the damage recognition, unwinding, and excision steps are interwoven rather than proceeding in a strictly sequential process [107]. The individual factors of NER associate independently on UV photoproducts without a necessary preassembly of a repairosome complex, although many of the components exist as heterodimers or within the larger 10-member TFIIH complex [100, 107–109]. The individual damage-binding proteins have relatively low affinity for damage as separate factors, but cooperatively XPA, XPC, and RPA, with cooperation from TFIIH, form a high specificity complex [110].

24.4 Global Genomic Repair

The initial damage recognition factors uniquely required for GGR are the XPC and XPE (DDB2) DNA binding proteins (Figs. 24.2 and 24.3), both of which function as heterodimers: DDB1/DDB2 and XPC/HR23B. Naturally occurring mutations in XPE (DDB2) have only a small effect on the levels of NER [111], whereas mutations in XPC cause a large reduction in NER and increased UV sensitivity. For this reason, XPC appears to be the major DNA damage recognition protein and XPE may play a lesser role, but this conclusion may be misleading. Mouse knockouts in *Ddb2* [9] and virally induced downregulation of DDB1 [112] have a large influence on the excision process.

The XPE group includes patients who are mildly to moderately affected and whose cells carry out near normal levels of NER [113]. The XPE gene product is the smaller partner of a dimeric protein with subunits of 127 kDa (DDB1) and 48 kDa (DDB2) [104, 113–118]. Mutations that are diagnostic for XPE are located in the DDB2 subunit (see http://www.xpmutations.org for a summary of XP and CS mutations). DDB2 and p53 regulate each others' expression [119, 120], with the consequence that XPE cells and those from mouse knockouts are resistant to p53-dependent UV induced apoptosis [9].

The DDB1/2 heterodimer is involved in the recognition of damaged DNA and has the capacity to bind to UV-damaged DNA with a chemically defined footprint [114, 121–124]. Binding appears specific for most cyclobutane and [6-4] photoproducts, except for the T[cis,syn]T photoproduct which is marginally discriminated from normal undamaged DNA [121]. DDB1 (p127) is present in excess over its partner, and is predominantly cytoplasmic but translocates to the nucleus after UV irradiation [125], a function that requires

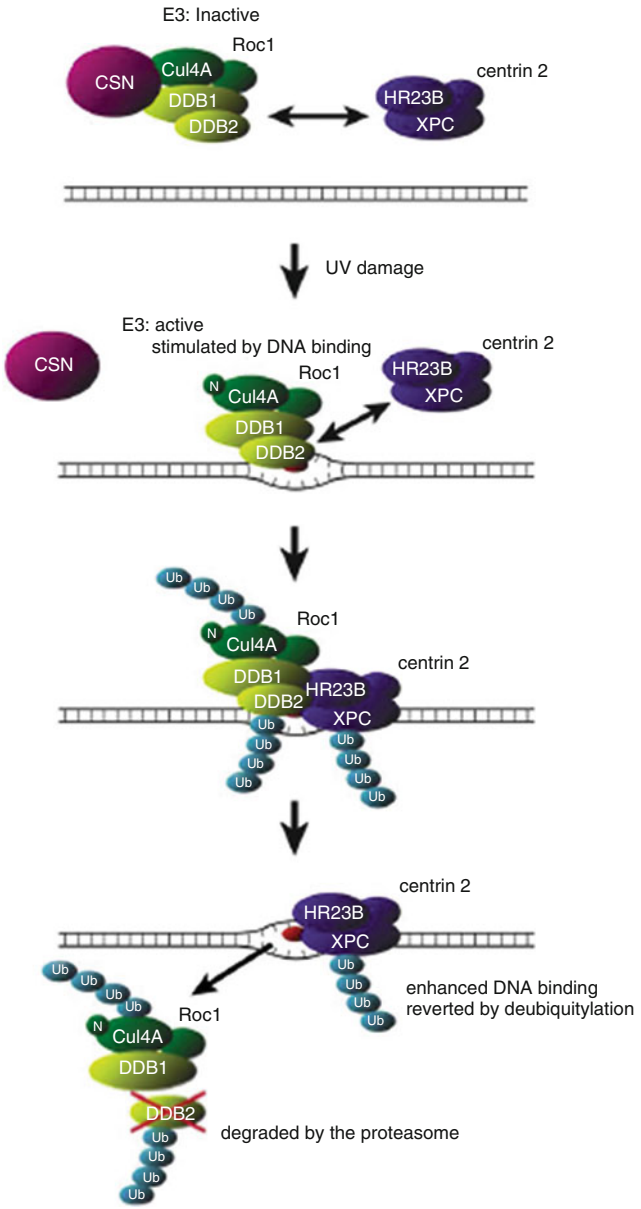

Fig. 24.3 Model for UV-Induced DDB1/2 dependent ubiquitylation of XPC. In unirradiated cells, DDB1/2-associated E3 is inactivated by its interaction with the COP9 signalosome (CSN). Thus, XPC is not ubiquitylated, despite its interaction with DDB1/2. Upon UV irradiation, UV-DDB translocates onto the damaged chromatin by binding to lesions, particularly [6-4] photoproducts. Its dissociation from the CSN and the neddylation of cullin 4A (indicated by "N") activate E3. The binding of UV-DDB to the lesion further stimulates E3 activity. The activated DDB1/2-E3 then recruits XPC via protein–protein interaction, and XPC, DDB2, and cullin 4A are ubiquitylated at the lesion site. Polyubiquitylated UV-DDB1/2 loses its damaged DNA binding activity, whereas the DNA binding of XPC is potentiated by its ubiquitylation. This results in the displacement of UV-DDB by XPC on the lesion. The ubiquitylated DDB2 is degraded by the proteasome. The ubiquitylated form of XPC reverts to the unmodified form through deubiquitylation. Reproduced from ref. [285] with permission from Elsevier.

DDB2 [126], and has a large number of other functions apparently unrelated to NER.

XPC is the major damage binding protein that initiates NER [127]. XPC binds tightly with a cofactor HR23B, one of the two human homologs of the yeast Rad23 gene product, and both are located on chromosome 3p25, a region deleted frequently in human squamous cell carcinomas [128]. The XPC/HR23B complex [129, 130] binds to damage in non-transcribed DNA, acting to stabilize subsequent XPA/RPA binding to the damaged site, with a high affinity [92, 127]. XPC is displaced through ubiquitylation by the E3 ligase activity of DDB1/DDB2. XPC has sequence similarity to single strand binding proteins and DNA binding appears to be critically dependent on one tryptophan residue (Tryp690) [131]. The mechanism appears to involve binding to the undamaged strand depending on the relaxation of base-pairing in the damaged region, giving the recognition process great versatility and independence from the actual chemistry of the damaged site [131].

Residual repair in XP-C cells is confined to small transcriptionally active islands of the genome, where repair occurs at normal rates, surrounded by oceans of unrepaired transcriptionally silent DNA [132–135]. The XPC/HR23B complex is associated with CEN2, a protein that stabilizes XPC and which is also involved in centrosome duplication, suggesting a direct link between GGR and cell division [136]. The constitutive level of expression of XPC is controlled by p53, and expression can be induced by UV and ionizing radiation [137, 138].

Several of the UV repair components, including XPC are also involved in repair of base damage or double strand breaks from ionizing radiation [139–141], which may represent a minor function of the ability of XPC to bind to small distortions with single strand properties [131].

24.5 Transcription-Coupled Repair

Pyrimidine dimers are excised more rapidly from actively transcribed genes, especially from the DNA strand used as the template for transcription [93–97]. A detailed base by base analysis of excision in the promoter and early region of the *PGKI* gene, using ligation-mediated PCR, revealed that excision is slow where binding proteins interact with the promoter but increases immediately after the ATG start site for transcription [142]. The initial damage recognition mechanism for TCR may be the stalled RNA Pol II, itself, although a potentially large number of gene products play a role in mediating the increased rate of repair in transcriptionally active genes [96, 97]. During transcription on a damaged template the pyrimidine dimer causes mis-incorporation of

uridine into the messenger RNA, which blocks further transcription [143].

The arrest of RNA Pol II at sites of DNA damage during transcription elongation plays a central role for damage recognition in TCR [144]. The blocked RNA Pol II masks damaged sites and must be removed, or backed off, to alleviate the arrested transcription and provide access for repair enzymes. Recent evidence suggests that the CSB protein prevents Pol II back-tracking induced by TFIIS, to produce a stable stalled complex [143]. This complex provides time for the assembly of the NER excision complex and expansion of the transcription bubble by TFIIH. Excision then removes the damaged strand, the Pol II enzyme and the nascent transcript.

Cells from patients suffering from the neurodegenerative and sun-sensitive disease Cockayne syndrome are specifically defective in TCR [12, 145]. The excision of DNA photoproducts from total genomic DNA of CS cells is normal, but repair of transcriptionally active genes is reduced [145], and DNA and RNA synthesis fail to recover to normal levels after UV irradiation [146]. The neurodegenerative symptoms of CS could be a direct result of neuronal loss through apoptosis of non-dividing cells that experience natural oxidative damage in the brain. Two CS genes, *CSA* and *CSB*, are involved specifically in TCR. CSA contains WD-repeat motifs that are important for protein–protein interactions [147]. CSB contains an ATPase, helicase motifs, and a nucleotide binding domain, but only the latter is essential for TCR and CSB does not function as a helicase [148, 149] The CSB protein is associated in the RNA Pol II elongation complex with DNA and nascent RNA [150–152] and can actively wrap DNA [153]. The CSA protein is neither part of this complex, nor forms a stable complex with CSB [150], but is still required for TCR during transcription elongation [151, 154]. Cells lacking either CSA or CSB are unable to ubiquitinate the CTD of RNA pol II [155].

24.6 Damage Verification and Unwinding

After damage recognition through the specific GGR or TCR proteins, a process of damage verification appears to occur in which the region containing the damage is expanded into a single stranded bubble by the 3′-5′ (XPB) and 5′-3′ (XPD) helicases contained in the transcription factor TFIIH [109, 156]. The initial DNA binding proteins are replaced by another damage binding complex, XPA and RPA, that stabilizes the region and has a larger binding affinity [157, 158]. XPA binds to both the damaged and the undamaged strand, but RPA binds mainly to the undamaged strand [157]. XPA binds to the p34 subunit of RPA through its N-terminal region and to the p70 subunit through a central portion in exon IV; to ERCC1 through a small region in exon II; to DNA through its central region covering approximately exons III to V and a Zn finger in exon III; and TFIIH through its N-terminal region [159].

The transcription factor TFIIH plays a central role in unwinding the damaged region and downloading several of the other NER components. TFIIH can interact with all of the components of the core excision complex, individually, but its strongest binding under physiological conditions is with XPC and XPG [109]. Mutations in the XPB and XPD components can also affect the promoter opening function of TFIIH [160, 161]. The phenotypes of mutations in *XPD* are associated with three different clinical disorders: XP group D, TTD, or a rare combination of XP and CS. XP-B is similarly associated with a combined XP and CS disorder.

The XPB protein is required for both repair and basal transcription, whereas XPD is dispensable for basal transcription, which may explain why fewer surviving patients with mutations in XPB are reported than XPD [65]. Most TTD patients exhibiting UV sensitivity fall into the XP-D complementation group [30]. Human mutations that are relevant to the disease phenotype in the *XPB* and *XPD* genes are all mis-sense because loss-of-function mutations are lethal, although the severity can be influenced by gene dosage [30]. XPD is an essential protein for transcription and cell viability, and no patient can have two null alleles [30]. Several cases of XP-D and TTD patients have an allele in common, suggesting that the second alleles determine the clinical presentation, which is supported by studies in *S. pombe* showing the shared alleles behave as null mutations [162] and would play no direct role in the disease. The distribution of mutations within the XPD protein reveals that essentially all XP-D mutations fall within one of the conserved helicase domains [163]. This pattern indicates that these mutations can be expected to reduce the helicase activity of the protein [160]. In contrast, the TTD mutations usually fall outside of the helicase domains and show significant clustering at the C-terminus of the protein. The structure of the *Archeal* homolog of XPD has elucidated the functional consequences of many mutations by placing them within the structure of the protein [164, 165]. A mouse strain with a mutation that copies a human *TTD* mutation in *XPD* has similar symptoms to those seen in human TTD patients, together with an aging and cancer-prone phenotype [26].

TTD-specific mutations may subtly interfere with the ability of XPD to interact with its partner proteins within the TFIIH complex and thereby destabilize the complex [160, 166]. Evidence in support of this idea comes from the identification of a component of the transcription factor TFIIH corresponding to TTD-A patients that have no mutations in *XPB* or *XPD* but have low levels of TFIIH [167]. This component has a small size, only 8 kDa [168, 169] and is mutated in three patients with TTD, and appears to be required for maintenance of normal levels of TFIIH.

24.7 Excision Nucleases

The final stable complex that binds and remains at the site of DNA damage acts as an assembly point for the XPG and ERCC1/XPF nucleases that cut the damaged strand 3′ and 5′ to the damaged site. The excision process removes a 27–29 nucleotide oligonucleotide containing the photoproduct by cleavages 5 nucleotides on the 3′ side of the photoproduct, and 24 nucleotides on the 5′ side [170]. The structure-specific cleavage pattern is determined by binding of RPA to the unwound damaged site, and the excised fragment is close in size to the footprint of RPA on the DNA [171]. Slight variations in the precise sites of cleavage result in the removal of variable fragments between 27 and 29 nucleotides in size. The nucleases also function in the repair of DNA-DNA crosslinks [172], recombinational repair [173], chromatid exchange aberrations [174], and telomere maintenance [175, 176]. These nucleases a have sequence similarities to the FEN-1 class of nucleases and interact with PCNA and hence play a role in DNA replication [177, 178].

The 5′ cleavage occurs first and is carried out by a heterodimer of XPF and ERCC1 that incises DNA on the 5′ side of the damaged site [108, 123, 179, 180]. The *XPF* and *ERCC1* genes may represent an ancient duplication and are unstable unless in a heterodimer complex [181]. The enzymatic activity resides in the XPF partner of the complex [182]. XPA serves as an anchor for the 5′ nuclease through binding to ERCC1 [183]. Patients with mutations in XPF are rare and most cases have been found in Japan with relatively mild symptoms [184]. Only one patient has been identified with mutations in ERCC1, which is associated with extremely severe symptoms [21]. In contrast knockout mice for both the *XPF* and *ERCC1* genes are very severely affected and are neonatal lethal [31, 185, 186].

The XPG nuclease cleaves on the 3′ side of the damage and interacts with the XPC-hHR23B complex and TFIIH [109, 187]. The XPG nuclease has a complex range of activities, and mutations in XPG are associated with both XP and CS diseases [12, 188, 189]. XPG is an endonuclease in the FEN-1 family that is capable of strand-specific cleavage of a range of DNA substrates that may arise during DNA replication, repair, and recombination [173]. The enzyme binds to the single strand/double strand junction at the NER bubble but remains inactive until unwinding by TFIIH from the XPF/ERCC1 cleavage causes its activation. The protein not only cleaves the 3′ side of photoproducts during NER [190, 191], but it also resolves recombination intermediates by strand specific cleavage at double strand-single strand junctions [173, 192]. XPG is also a cofactor for thymine glycosylase through which it stimulates repair of oxidative DNA damage (thymine glycols, 8-oxoguanine, etc.) that may also be important in maintaining neural functions that fail in CS patients [191, 193, 194].

The XPG gene product interacts with RNA Pol II by interaction with the elongation factor TFIIS, independently of CSB and facilitates efficient transcription elongation [195], which provides an explanation for the complex symptoms of some XPG patients that show both XP and CS symptoms. The excised region is replaced by the action of a complex similar to that involved in normal DNA replication [101]. PCNA is loaded onto the DNA by the 5 subunit RFC complex, which then anchors the replicative polymerases Pol delta or Pol epsilon [196]. The cell cycle regulator p21 is upregulated after damage and slows S phase progression through binding to PCNA, but it appears to be specifically degraded during the repair polymerization. The final closure of the repaired site occurs with DNA ligase, most probably ligase I [196].

24.8 Nucleotide Excision Repair: Polymorphisms and Heterozygote Risk

The disease alleles of the NER genes represented in the human diseases XP, CS, TTD, and COFS represent high penetrance mutations that cause disease when homozygous [197]. There are in addition susceptibility alleles that may give rise to disease at lower penetrance according to lifestyle, diet, hormonal balance, and exposure to environmental chemicals, radiation, and infectious agents. A large number of alleles present at low frequency individually could combine to create variation in disease frequency in the overall population. Heterozygosity in XP genes has also been of concern, especially in parents of affected children.

Polymorphisms have been found in most of the XP genes and many disease associations have been claimed [198–202]. Many of these polymorphisms result in nonconservative amino acid changes that could have an impact on NER function and disease [203]. The reported associations between repair gene polymorphisms and disease suffer in many cases from problems of statistical power. A detailed reexamination suggests that as yet few of the reported associations are on sufficiently large data sets to be firmly established [199].

Heterozygosity in NER genes has not been clearly associated with significant disease among XP parents, although the evidence is largely anecdotal. Detection of small increases in skin cancer among XP parents is likely compromised by the small numbers of subjects, and low solar dose rate, especially if they share their children's restricted sun exposure. In contrast several mouse strains with NER genes knocked out have shown increased cancer in the heterozygotes. These include the XPE (Ddb2) mouse [9], the Xpc mouse [10], and

the Xpv (Pol eta) mouse [11]. These may represent increased ease of detection of an heterozygous UV sensitivity by the high UVB dose rates used in mouse cancer studies, as well as potential unique properties of the repair genes on mouse backgrounds as compared to human.

24.9 Replication of Large DNA Adducts: Class Y Bypass Polymerases

DNA photoproducts are blocks to the replicative DNA polymerases, alpha, delta, and epsilon that cannot accommodate large distortions such as DNA photoproducts or adducts in their active sites [204, 205]. Replicative bypass of these photoproducts is achieved instead by damage-specific polymerases with relaxed substrate specificity, now defined as class Y polymerases [206, 207]. Class Y polymerases have larger active sites that allow them to read through noninformative sequence information resulting from DNA damage [208]. As a consequence these polymerases have high error rates on the order of 1 % when assayed in vitro, and this property must be restricted in vivo to prevent catastrophic levels of mutation [209, 210].

Three class Y polymerases have been identified in the mammalian genome, Pol eta, iota, and kappa. The genes *Pol eta* and *Pol iota* are close homologs, unique to mammalian cells, and only a single *Pol eta* (*yRad30*) gene is found in yeast [206]. Pol iota has a poorer capacity for replication of UV damage and Pol kappa seems completely unable to replicate UV damage. Pol eta has a greater capacity for replicating T-containing photoproducts and Pol iota a preference for C-containing photoproducts. Pol eta can therefore insert adenines across from thymine-containing photoproducts accurately replicating a T=T pyrimidine dimer. Pol iota can insert guanines across from cytosine-containing photoproducts, resulting in accurate replication of a T=C pyrimidine dimer or [6-4] photoproduct.

Pol eta is regulated by several mechanisms that prevent extensive replication and restricts its subcellular location. Pol eta acts distributively, and extends nascent DNA chains by one or two bases across from the photoproducts, after which replication switches to Pol zeta or kappa [211]. Pol eta is uniformly distributed in the nucleus, and excluded from the replication fork until replication is stalled by UV damage, whereupon it relocates with other proteins in microscopically visible foci coincident with PCNA at the replication fork [74, 212]. Relocation requires specific sequence motifs at the C-terminal end of the protein for translocation and for binding to ubiquitylated PCNA [212, 213].

The error-free DNA damage replication pathway involving Pol eta and other polymerases is part of an overall DNA replication pathway for UV damage defined in yeast as the RAD 6 epistasis group [214]. Several of the components of this pathway are ubiquitinating enzymes that target PCNA, which functions as a major control point for the overall process [215]. PCNA is modified by UBC9 that is a small ubiquitin-related modifying enzyme (SUMO), and by Rad6 and the MMS2-UBC13 heterodimer that are ubiquitin-conjugating enzymes [215]. Multiple modifications compete for the same lysine (K164) residue on PCNA and redirect subsequent pathways through SUMO, monoubiquitination, and multiubiquitination [215]. Recruitment of Pol eta is regulated by reversible ubiquitylation of PCNA by the Rad6/Rad18 ligase and the USP1 deubiquitylating protease [77]. The monoubiquitylation favors recruitment of Pol eta, whereas Ub(K63) favors error-free bypass or recombination, and sumoylation favors normal DNA synthesis [76]. Delays in replication fork progression leads to autodegradation of USP1 and increased PCNA ubiquitylation which recruits Pol eta [77], as well as Pol iota and Pol kappa [216]. Pol eta is consequently recruited to the replication fork in response to more general cellular stresses than just its specific role in bypass of bulky UV DNA lesions.

Pol eta plays a large number of roles in situations where replication presents significant obstacles to normal replication polymerases as well as during important physiological processes. Pol eta is important, for example, during immunoglobulin hypermutation and contributes to generating the strand bias of A–T base pair substitution errors [217–225], and in homologous recombination during immunoglobulin conversion [226]. Pol eta also plays a role in the extension of invading strands in D-loops during homologous recombination to prevent replication fork degradation [227], although in contrast Pol eta deficiency in vivo increases homologous recombination [79]. Immunoglobulin hypermutation is also enhanced by other polymerases such as Pol iota [228] and Pol theta [229]. Deficiencies in nucleotide pools, such as caused by the inhibitor hydroxyurea, are also sufficient to recruit Pol eta to replication forks [82]. Pol eta activity is enhanced by interaction with other components of the damage response that accumulate at replication forks, such as the mismatch proteins MSH2-MSH6 [230], although mismatch repair generates a different mutation spectrum than Pol eta [223].

In the absence of the low fidelity polymerases, a complex set of overlapping intra-S phase checkpoints are activated that prevent gross chromosome rearrangements [81, 231, 232]. The extended regions of single stranded DNA remaining after the fork progresses without Pol eta increase signaling by the ATRIP-ATR kinase pathway and enhance S phase arrest [44]. Blocked replication forks are further stabilized in UV damaged cells by p53, and its inactivation by viral transformation allows fork breakage and DNA rearrangements to occur [74, 81, 83, 231, 233]. The actual frequency of fork breakage is low [78] and most arrested forks are resolved without breaks [68]. Central players in these rearrangements

are the protein complex hMre11/hRad50/Nbs1 and Rad51 that are involved in nonhomologous and homologous recombination, DNA replication arrest, and telomere maintenance [81, 231, 232, 234].

24.10 Systemic Impacts of Nucleotide Excision Repair

24.10.1 Disorders of the Central Nervous System

Patients with mutations in the NER genes associated with TCR, both XP and CS, often exhibit progressive neurological abnormalities in addition to skin photosensitivity [235] and this is presumed to be caused by endogenous sources of DNA damage. Consistent with this attribution, mouse embryo fibroblasts derived from *Csb−/−* mice are sensitive to X-rays and oxidative damage [236–238], but in both species the sensitivity to oxidative damage is greater for mutations in CSB than CSA [236, 239].

The neurological symptoms include progressive mental deterioration, diminished deep tendon reflexes, and deafness sometimes beginning early in life [12]. Patients may have microcephaly, intellectual deterioration with loss of the ability to talk, and increasing spasticity with loss of ability to walk, leading to quadriparesis, in addition to dwarfism, and immature sexual development. The major histological feature is primary neuronal degeneration with dysmyelination, particularly in the cerebral cortex and cerebellum. CS patients show extensive cerebellar atrophy including a marked reduction of granule cells and the loss of Purkinje cells [13, 240].

The neurological symptoms of XP and CS patients have been ascribed to defective repair in the brain of endogenous oxidative damage that blocks transcription [191, 193, 237, 241–243]. The precise origin of oxidative damage is not known, but presumed to be mitochondrial leakage. Cerebellar granule cells are vulnerable to a variety of toxins that decrease glutathione levels and make the cells more vulnerable to cellular damage from reactive oxygen species [244, 245]. Purkinje cells are susceptible to ischemic death due to their reduced capacity to sequester glutamate and reduced ability to generate energy during anoxia [246]. Tissues that degenerate in XP and CS appear to be sensitive to oxygen levels, including the Purkinje cells, retina, and oligodendrocytes [247–250]. TUNEL staining and oxidative stress has been observed in cerebellar granule cells from clinical samples of CS and XP-A patients [251–254].

No consistent correlation has yet been established between sites of mutation and the severity of the clinical symptoms. Null mutations in the early region of the CSB gene have been found in a mildly UV sensitive patient with minimal neurodegenerative symptoms [14], and in quite severe patients [255, 256]. The presence of the PiggyBac transposon in intron 5 is flanked by *CSB* mutations and its contribution to the symptoms remains to be established [255, 257].

Mouse knockouts of XP and CS genes generally present a weaker neurological phenotype than the corresponding human disorder but greater cancer predisposition [8, 258, 259]. *Xpa−/−* mice, for example, have no neurological deficit, and only a slight reduction in lifespan [28, 29], in comparison to human XP-A patients who are usually severely affected. Cs-a and Cs-b mice, unlike the corresponding human CS disorder, are predisposed to UVB-induced and chemically induced skin cancer [259–262].

The severity of the neurological symptoms in mice has been increased by crossing strains of Cs-b or Xp-g knockouts with Xp-a or Xp-c knockouts to increase the extent of NER deficiency. These include *Csb−/−* mice crossed with *Xpa−/−* mice [28], Ttd mice crossed with *Xpa−/−* [263], and *Xpg−/−* crossed with *Xpa−/−* [264]. Loss of both Purkinje cells and granule cells occurred in *Csb−/−/Xpc−/−* mice [265]. The compound knockout *Csb−/−/Xpa−/−* mice had stunted dendritic trees of Purkinje cells, along with decreased thickness of the molecular layer and internal granule layer [28]. These observations suggest that the cerebellum is particularly susceptible to DNA repair deficiencies. A dramatic increase in p53 accumulation and apoptosis was identified in the external granule cells of the cerebella of *Csb−/−/Xpc−/−* mice, suggesting that the loss of both Csb and Xpc rendered these cells vulnerable to cell death. Other NER deficient mouse strains exhibit increased cell death and/or increased p53 staining in the brain. *Ercc1−/−* mice show increased p53 levels in the brain and liver [185]. In *Xpg−/−* mice, pyknotic figures and reduced calbindin staining were observed in the Purkinje layer, while TUNEL staining was strongest in the granule layer, and rare in the Purkinje layer [266]. In *Csb−/−/Xpa−/−* mice, TUNEL staining was increased in the external granule layer at day 8 [28].

The most obvious source of endogenous DNA damage would be the high level of oxidative metabolism in the brain [267], combined with its relative deficiency of antioxidative protective mechanisms [268–270]. DNA lesions are repaired more slowly in neurons relative to dividing cells suggesting that lesions are likely to accumulate in neurons over time [270]. The relevant DNA damage must be of the kind that is a significant substrate for the NER system, rather than the commonly oxidized bases such as 8-OH-dG because neurodegeneration is greater when strains are crossed to reduce overall NER capacity, but not when crossed with strains specifically defective in repair of oxidative damage such as *Ogg1* [265]. Even though loss of *Ogg1* increases the mutation rate in vivo for the oxidative lesion 8-OH-dG [271], the neurological status of *Ogg1*-knockout mice seem normal,

indicating that the major classes of oxidative damage are not the proximal cause of neurodegeneration.

Xpc and Csb are both components of the endogenous proteolytic system: Xpc through the proteasome [272], and Csb and Csa as cofactors of an E3 ubiquitylation ligase [273]. Consequently XP and CS could, like many other neurodegenerative disorders, be caused by defective clearance of denatured proteins [274].

24.10.2 The Somatotroph Axis (GH/IGF-1)

Interactions between DNA repair deficiencies and hormone-dependent pathways contribute to the complexity of many of the DNA repair deficient human disorders [2]. Developmental disorders involving reduced stature and weight gain and liver abnormalities were seen in the first mouse knockout targeting the *Ercc1* gene [185], and in subsequent knockouts of *Xpg, Xpf*, and combined strains [26, 28, 263, 264, 275, 276]. This pathology has been identified as the result of accumulation of DNA damage, increased levels of p53, and cellular apoptosis in the liver [31, 276]. The damage affects major hormonal pathways of growth regulation and aging: the growth hormone (GH) and insulin-like growth factor-1 (IGF-1) [31, 276].

Mutations in the XPD component of the transcription factor TFIIH, with which CS proteins interact, also result in many transcriptional defects including: reduced responses to nuclear receptors [277, 278], dysregulation of peroxisome proliferator-activated target genes [279], vitamin D receptor-responsive genes [280], and thyroid hormone-responsive genes leading to hypomyelination [281]. Nuclear receptors that mediate hormone-dependent gene activation require phosphorylation by the cdk7 component of TFIIH, and the *XPD* repair gene influences signal transduction by retinoids (RAR and RXR), vitamin D, steroids (ER, AR, and GR), and thyroid hormone [278].

24.10.3 DDB1 and DDB2: Essential Functions and Viral Infection

The XPE complementation group of XP represents a mildly affected group of patients whose cells carry out near normal levels of NER [111, 113], and for this reason XPE was thought to have a relatively minor role in NER. The discovery that DDB1 is a cofactor in a DDB1-Cul4A-ROC1 E3 ubiquitin ligase [273] indicated that the heterodimer DDB1/DDB2 could play a wider role in many cellular functions depending on the interacting substrates for ubiquitylation. At least 30 target proteins of the E3 ubiquitin ligase have been identified including DDB2, CSA, CSB, XPC, histone H1, histone 2a, and histone 4, PCNA, and transcriptional activation through E2F1 [126, 282, 283]. DDB2 exists in at least four forms: (1) free DDB2, (2) the DDB1/DDB2 heterodimer, and two complexes associated with protein degradation, (3) the CUL4, and (4) the COP9 signalosome [284]. The ubiquitylation of XPC plays an important part of the sequential loading of XPC onto damaged sites and its subsequent displacement by the XPA/RPA binding complex (Fig. 24.3) [285].

The role of DDB1/2 in DNA repair in vivo is still unclear because, despite its affinity for damaged DNA [121], it is dispensable for in vitro excision experiments where the damage is in pure DNA [284]; the repair deficiency is more explicit when the substrate is chromatin bound. Suggested functions [286] include: DDB1/2 binds to damaged DNA, ubiquitylates DDB2 to release it and download XPC/HR23B, which in turn is ubiquitylated to increase it binding affinity [285]; DDB1/2 ubiquitylates histones to make regions of DNA more accessible to repair; DDB1/2 plays accessory roles in the cell cycle, signal transduction, and mutation.

DDB2 expression is induced by UV light through p53 transactivation in human cells, but not mouse or hamster cells [104–106], and is anti-apoptotic [9]. A consensus DNA-binding site for p53 is present in the human p48 promoter region but has either diverged or is absent from the mouse homolog [287]. These observations provide a partial explanation for early observations that excision repair can be low in some mouse cell strains, especially for cyclobutane dimers but not [6-4] photoproducts [288–290].

Targeted knockdown of DDB1 efficiently reduces excision repair of pyrimidine dimers, but not [6-4] photoproducts [291]. UV irradiation converts DDB1 from cytoplasmic into a tightly bound chromatin form that recruits DDB2 and CUL 4A to chromatin-bound functions [284]. The cytoplasmic DDB1 protein also interacts with a range of viral proteins [112, 292, 293] and the amyloid precursor protein involved with Alzheimer's [294]. The Vpr protein of HIV downregulates NER through interaction with DDB1, stimulating an ATM/ATR damage response, indicating common pathways for cellular attack by DNA damaging agents and viral infection (Fig. 24.1) [112].

Elimination of *Ddb1* in mouse knockouts is lethal in the early embryo, being essential for normal development of the epidermis and neuronal precursor cells which are eliminated by p53-dependent apoptosis [295, 296]. This resembles the neuronal loss in TCR defective Cockayne mice and humans [265].

Acknowledgements We are grateful to the Luke O'Brien Foundation and the XP Society whose continued support and encouragement have been instrumental in furthering our work on XP and Cockayne Syndrome. The work described here was supported in part by grants from the National Institutes of Neurological Disorders and Stroke grant 1R01NS052781 (JEC), P01 AR050440-01 (PI: E. Epstein). This chapter draws upon and updates several previous reviews [84, 235, 297].

Hereditary Colorectal Cancer

25

Sonia S. Kupfer and Nathan A. Ellis

25.1 Introduction

Colorectal cancer (CRC) is one of the most significant causes of cancer morbidity and mortality in the United States. It is estimated that approximately 142,500 men and women will have been diagnosed with CRC and 51,370 persons will have died of this disease in 2010 [1]. CRC incidence rates increase with age with greater than 90 % of cases occurring in persons over the age of 50. The age-adjusted standardized incidence and mortality rates are higher in males than in females, and incidence and mortality also vary between different populations (Table 25.1).

Twin [2] and family [3–5] studies have shown that genetic risk factors influence CRC incidence in up to 35 % of cases, but within that 35 % the level of risk conferred by genetic factors that predispose to CRC varies enormously. In comparison to the risk for a person with no relatives with CRC (Fig. 25.1), the risk for a person who has a single first-degree relative with CRC is threefold greater (6 % lifetime risk), and it is eightfold greater for a person who has two first-degree relatives with CRC (17 % lifetime risk). Moreover, risk is increased fivefold if the affected first-degree relative was diagnosed before age 45 [6, 7]. There is also increased risk of developing CRC in the first-degree relative of a person who has been diagnosed with one or more adenomatous colonic polyps [8, 9]. These correlations between family history and CRC susceptibility are propelled by a range of genetic mechanisms, from high-risk, disease-causing mutations that ablate gene function to low-risk genetic variants that perturb gene function in subtler ways. In addition, genetic risk factors can interact with each other and with nongenetic factors to increase or decrease CRC risk. However, the impact of interaction on risk is poorly understood.

The correlations between family history and CRC risk are also reflected in the types of family histories in which CRC occurs and the proportions of these types. Approximately 70 % of CRCs occur in persons with no known family history of CRC, so-called sporadic CRC (Fig. 25.2). In ~25 % of CRC cases, the person with CRC has up to two first-degree or second-degree relatives with CRC, which is often termed familial CRC [10, 11]. In ~5 % of cases, there is a dramatic family history (three or more CRCs in multiple generations in the family). Cases with strong family histories are often associated with a disease-causing mutation in a known hereditary CRC gene. For example, in ~3 % of all CRC cases, a mutation in one of the mismatch repair (MMR) genes is present. When a disease-causing MMR gene mutation is present, the CRC predisposition syndrome is referred to as Lynch syndrome or hereditary non-polyposis colorectal cancer (HNPCC). In ~1 % of CRC cases, a mutation in the adenomatous polyposis coli (*APC*) gene is present, which is strongly associated with colonic polyposis. When a mutation in *APC* is present, the syndrome is referred to as familial adenomatous polyposis (FAP). In <1 % of CRC cases, a mutation is present in a gene that is associated with a hamartomatous syndrome, including familial juvenile polyposis, Cowden's disease, and Peutz-Jeghers syndrome (PJS).

Given the range of risks associated with known genetic risk factors and the distribution of family histories of CRC, what do we mean by hereditary CRC? Certainly, syndromes such as Lynch syndrome and FAP, which are associated with single-gene mutations and found in multiple family members, are hereditary in the classical Mendelian sense. When a disease-causing mutation is known to be present in a person, the quantitative information regarding cancer risk is available. However, family history is an imprecise tool for predicting the presence of a disease-causing mutation. In the

following examples, we present some of the reasons for this lack of predictive power. These examples show how family history can be a poor predictor of CRC risk, and they underline the importance of developing more precise and reliable genetic tools to identify persons at high risk of CRC.

25.1.1 Variable Penetrance

One and the same MMR gene mutation can be found in families with a range of family histories of CRC from very strong to relatively weak. One reason for this range of family histories is that penetrance is variable (penetrance is defined as the probability of developing the disease given the presence of the mutation). On average, penetrance of MMR mutations is less than 50 %. The reasons for variable penetrance are not well understood. Probabilistic events (family size, ascertainment bias, etc.) may explain some of the variation in family history. Deterministic factors also probably play an important role, including genetic factors that modify the risk conferred by the cancer-causing mutation (these genetic factors are called modifiers), exposure to environmental factors, or both.

25.1.2 New Mutations

Up to 30 % of *APC* mutations are new mutations that are not associated with previous family history of CRC, but which

are every bit as dangerous to the present and subsequent generations. Clearly, in these cases, there is no family history to help predict disease occurrence.

25.1.3 Recessive Inheritance

Late-onset Mendelian syndromes associated with increased susceptibility that are caused by recessive genes are difficult to identify and characterize because family sizes are generally small and penetrance is dependent on age. Neither parent is likely to have been diagnosed with CRC and the probability for each son or daughter of having both disease alleles is 25 %. A perfect example of this scenario is the recently described CRC syndrome *MYH*-associated polyposis (MAP), which is associated with biallelic recessively inherited mutations in *MUTYH* (also referred to as *MYH*). Many more recessive CRC syndromes may explain CRC incidence in persons with no previous family history or in familial CRC.

25.1.4 Polygenic Inheritance

Strong family histories of CRC may not be associated with classical single-gene, Mendelian mutations, but rather with the presence of multiple genetic risk factors that combine to create high risk. This scenario can resemble recessive inheritance in that each parent may be at low risk of CRC because he or she carries one or two low-risk or moderate-risk genetic factors. Segregation of genetic factors to a son or daughter from both parents is thus a relatively low-frequency event.

25.1.5 Hereditary Colorectal Cancer

For the purposes of this chapter, we define hereditary CRC as a syndrome caused by one or more genetic risk factors that are associated with a strong family history of CRC, which can be established statistically through tests of genetic segregation in families. Consequently, the main focus here is on the syndromes defined by disease-causing mutations in single-gene Mendelian disorders. There is a general consensus now that the known single-gene disorders do not account for all the genetic variation that influences CRC susceptibility and that many low-risk or moderate-risk genetic variants need to be identified in order to explain the remaining heritability of CRC. We note that numerous reports describing low-risk CRC susceptibility factors have recently been published and elucidation of the role and impact of the major low-penetrance risk alleles is an active area of current genetic investigation [12]. These low-risk genetic factors explain but a small fraction of the yet-to-be-determined CRC susceptibility factors. Consequently, the search goes on to identify genetic risk factors that explain the heritability of CRC with the hope that these factors will some day allow a more precise and reliable prediction of CRC risk.

25.2 Lynch Syndrome

The non-polyposis disorders are so called to distinguish them from those syndromes that lead to the formation of numerous polyps of the lower gastrointestinal tract. Foremost among the non-polyposis disorders is Lynch syndrome (hereditary non-polyposis colorectal cancer). This syndrome arises from mutations in the MMR pathway and results, to varying degrees, in a phenotype of early-onset CRC and extracolonic malignancies. The MMR genes function in a specific type of DNA repair that ensures high fidelity of DNA replication. When MMR function is deficient in a cell, it is associated with a high mutation rate, which drives carcinogenesis. The high mutation rate can be detected using a simple polymerase chain reaction (PCR) assay that tests for microsatellite instability (MSI). Tumors that exhibit MSI have the hypermutation phenotype that is associated with loss of MMR gene function.

Historically, the earliest descriptions of Lynch syndrome came from the pathologist Aldred S. Warthin at the University of Michigan who, in 1913, published a review of several cancer-prone families [13]. Approximately 50 years later, Henry T. Lynch and colleagues collected data from these same families and recognized that CRC was the most prominent cancer in this syndrome. Initially, this familial syndrome was given the name hereditary non-polyposis colorectal cancer (HNPCC) to distinguish it from hereditary conditions in which cancers arise in a milieu of carpeting colonic polyps. In 1984, the name Lynch syndrome was proposed in honor of Dr. H.T. Lynch's seminal observations. Moreover, HNPCC was thought to be a misleading name because polyps are still encountered albeit not to the degree seen in polyposis conditions. Arguably, the definition of polyposis is somewhat arbitrary. In 1993, the field of Lynch syndrome genetics was energized by the identification of *MSH2* and, shortly thereafter, *MLH1* as genes the mutation of which results in Lynch syndrome. In the 1990s, clinical criteria and guidelines were established including the Amsterdam criteria and Bethesda guidelines that are used to guide molecular genetic testing in individuals who might be affected by the syndrome (Table 25.2). The Amsterdam criteria were devised to enrich for families with mutations to help in the identification of the culprit genes; the Bethesda guidelines were an attempt to devise a more inclusive set of rules to identify mutation carriers. These guidelines nonetheless cannot be used to identify all persons with disease-causing mutations or families in which MMR gene mutations are segregating,

Table 25.2 Amsterdam II criteria and revised Bethesda criteria

Amsterdam II	Revised Bethesda Patient who meets Amsterdam II criteria
Three or more relatives with a Lynch syndrome- associated cancer	CRC diagnosed in a patient less than 50 years old
Two or more successive generations affected	presence of synchronous or metachronous CRC or other LS-associated tumor regardless of age
One or more relatives diagnosed before age 50	CRC with microsatellite instability in patient less than 60 years old
One should be a first-degree relative of the other two	CRC diagnosed in one or more first-degree relative with a LS-associated tumor, with one of the cancer diagnosed less than 50 years old
Exclude familial adenomatous polyposis	CRC diagnosed in two or more first- or second-degree relatives with LS-associated tumors, regardless of age

CRC colorectal cancer, *LS* Lynch syndrome

because age of disease onset is variable, penetrance is variable, and family sizes are often small. Universal screening—MSI testing, immunohistochemistry (IHC) for MLH1, MSH2, MSH6, and PMS2, or both—on all CRCs has been recommended, which obviates the need for guidelines, and it has slowly gained widespread acceptance. As whole-genome DNA sequencing becomes more efficient and lower cost, we can foresee a day in which genetic screening using whole-genome sequencing would help overcome the limitations of clinical guidelines.

25.2.1 Natural History of Lynch Syndrome

Lynch syndrome is the most common type of hereditary CRC and is estimated, depending on the study, to represent 1–6 % of all CRC cases. It is inherited in an autosomal dominant fashion. It is highly penetrant with approximately 50 % of mutation carriers developing CRC and approximately 80 % developing CRC or a malignancy associated with Lynch syndrome [14].

The clinical features of Lynch syndrome include CRC in multiple family members in several generations. The mean age of cancer diagnosis is 45 years. Approximately 70 % of colon cancers are proximal to the splenic flexure, though it should not be overlooked that up to 30 % of Lynch syndrome-associated tumors are found in the distal colon. The histologic features of these tumors include tumor-infiltrating lymphocytes, mucinous and signet-ring features, and medullary growth patterns. In addition, progression of colonic adenomas to carcinomas is accelerated compared to the rate in sporadic CRC. Compared to an 8–10 year progression interval, in Lynch syndrome, adenomas become carcinomas in 2–3 years [15].

Table 25.3 Lifetime risk of extracolonic tumors reported in families with a mismatch repair mutation

Endometrial cancer	27–71 %
Ovarian cancer	3–13 %
Gastric cancer	2–13 %
Urinary tract cancer	1–12 %
Brain tumor	1–4 %
Biliary cancer	2 %
Small bowel cancer	4–7 %

From Vasen HF et al. J Med Gen 2007;44:353–362 [22]

Although CRC is the predominant tumor, extracolonic tumors also can develop. Lynch-associated tumors are listed in Table 25.3. Endometrial cancer is the second most frequent malignancy in Lynch syndrome. Additional tumors include ovary, stomach, small bowel, pancreas, hepatobiliary, brain, and urothelial tract [16]. A subset of patients with MMR gene mutations develop cutaneous lesions, a syndrome known as Muir-Torre (see Sect. 25.6). Given the number and diversity of related tumors, clinicians need to be especially astute and query patients' family histories carefully in order to facilitate diagnosis.

25.2.2 Genetics of Lynch Syndrome

25.2.2.1 Inheritance

Lynch syndrome is inherited as an autosomal dominant disorder. Carriers inherit one mutated MMR gene from one parent and one un-mutated gene from the other parent. The heterozygous cell has sufficient MMR function to carry out normal DNA repair and protect the cell from excessive mutation. However, when, in a somatic precursor cell, the un-mutated gene is lost by normal mutagenic processes, which inevitably happens in the many cell divisions that occur during human development and adult life, then this cell loses all MMR function and excessive mutation ensues in the subsequent generations of this cell's lineage. A striking hypermutability develops and increases the probability that transforming mutations will accumulate in oncogenes or tumor suppressor genes. The second hit that leads to loss of the un-mutated MMR gene results from random mutational processes, including large gene deletion, chromosome loss and re-duplication, homologous recombination proximal on the chromosome to the mutated MMR gene followed by segregation of the two chromosomes carrying the same mutated allele, nucleotide substitution, or small insertion or deletion. There are rare reports of children with biallelic *MLH1* and *MSH2* mutations who are prone to develop cancers at a young age. These cancers include leukemia, lymphoma, brain tumors,

and gastrointestinal malignancies. There are also café au lait spots reminiscent of neurofibromatosis. This syndrome is referred to as the Childhood Cancer Syndrome (CCS) [17, 18].

25.2.2.2 MSH2, MLH1, and MSH6

In 1993, *MSH2* was identified as the first Lynch syndrome-associated gene. Linkage analysis performed in two large Lynch syndrome families mapped a susceptibility locus to chromosome 2p16. Subsequent work identified the *MSH2* gene in this region as a candidate locus [19]. Germline mutations of *MSH2* were subsequently identified in Lynch syndrome patients. *MSH2* mutations constitute the largest percentage of mutations found in Lynch syndrome. Linkage methods were also utilized to identify the *MLH1* gene in Scandinavian Lynch syndrome families [20]. The gene was localized to chromosome 3p21 and subsequent work revealed germline *MLH1* mutations in Lynch syndrome patients. Mutations in *MSH2* and *MLH1* account for the majority (over 85 %) of MMR gene mutations in patients with Lynch syndrome. In 1997, disease-causing mutations were identified in Lynch syndrome families in the *MSH6* gene, which is localized within 500 kb of *MSH2* on chromosome 2p21 [21]. *MSH6* mutations account for approximately 10 % of all mutations in Lynch syndrome.

A multi-national database maintained by the International Collaborative Group on HNPCC (ICG-HNPCC now called InSight) was established to catalog Lynch syndrome-associated mutations. The group's website (http://www.insight-group.org/) provides regular updates on mutations reported worldwide in MMR genes. To date, there are over 500 reported mutations primarily involving *MLH1, MSH2,* and *MSH6*. Most of the mutations cause loss of MSH2 function. The majority of these null mutations result in premature translation-termination of the protein through large multi-exon deletions or small insertions or deletions that cause reading frame shifts, nucleotide substitutions that cause stop codons or aberrations in RNA splicing. In addition, a significant proportion of the putatively disease-causing mutations cause amino acid substitutions that produce a mutant protein that has no catalytic activity. These missense mutations can pose a serious challenge in the clinical interpretation of the mutation because (1) biochemical information of the amino acid change is usually unavailable, (2) it is difficult to distinguish rare disease-causing variants from rare benign variants, and (3), if the affected is in a small family, segregation analysis lacks power.

The most common recurrent mutation in *MSH2* is an A→T transversion at c.942+3 in the donor splice site of intron 5. The substitution disrupts normal splicing so that the mutant gene produces an abnormal mature mRNA in which exon 4 is joined to exon 6. The abnormal mRNA encodes a functionally inactive, mutant protein with an in-frame deletion of amino acids 265–314. *MSH2c.942+3* is a hot spot for mutation. The adenine at this site is the first in a run of 26 adenines, which presumably causes the hypermutability. However, the mechanism is not understood. It is estimated that this mutation accounts for 5–10 % of all Lynch syndrome mutations and it has arisen independently multiple times on different chromosomal backgrounds. *MSH2c.942+3A>T* is the most common mutation in Newfoundland, and it occurs on one and the same chromosomal background, indicating that in this population the mutation is inherited identical by descent from a founder individual who introduced the mutation into the population many generations ago. Numerous other MMR gene mutations are known to be shared by unrelated individuals due to founder mutation in an ancestral individual, as the mutation is found on the same chromosomal background [22].

25.2.2.3 PMS2

The *PMS2* gene is localized to chromosome 7p22, originally identified based on its homology with bacterial and yeast MMR genes [23]. Early work on *PMS2* was complicated by the existence of a family of *PMS2* related genes and a partial *PMS2* pseudogene, confounding investigators who thereby missed disease-causing variants in PMS2. Mutations in *PMS2* appear to predispose to Turcot syndrome and early-onset CRC (see Sect. 25.6). However, this finding is controversial as a large European group could not replicate the findings [24]. Similar to the situation for *MLH1* and *MSH2*, biallelic *PMS2* mutations cause a childhood cancer syndrome [25].

25.2.2.4 EPCAM

In 2009, two groups studied cancers that were deficient for MSH2 and MSH6 protein by immunohistochemistry or that exhibited MSI but in which no germline mutation had been identified in *MSH2, MSH6,* or *MLH1* [26, 27]. Diagnostic multiplex ligation-dependent probe amplification (MLPA) analysis (a method that allows detection of large genomic deletions) showed a decreased signal for exon 9 of the *EPCAM* gene (also referred to as *TACSTD1*), which is the last exon in the gene that is located 16 kb upstream of *MSH2*, but the deletion did not extend into the *MSH2* gene. Further analysis of Dutch and Chinese families showed that deletions of the 3′ end of *EPCAM*, which includes the polyadenylation-signal, abolish transcription termination. Failure to appropriately terminate *EPCAM* transcription, in turn, leads to transcription read-through into the *MSH2* promoter across its CpG-rich promoter region. Inappropriate transcription of the *MSH2* promoter results in induction of methylation of the *MSH2* promoter and transcriptional silencing of *MSH2* in cells expressing *EPCAM*. This unusual mechanism explains both the *MSH2* methylation mosaicism (cells that express *EPCAM* exhibit the methylation, whereas cells that do not express *EPCAM* do not exhibit methylation) and the allele-specific methylation of the *MSH2* promoter (*MSH2* methylation occurs

in *cis* on the chromosome that carries the *MSH2* deletion and not on the intact chromosome). Moreover, this mechanism also explains why the abnormal pattern of mosaic somatic methylation segregated with the mutation in families.

A subsequent clinical study of 194 carriers of 3′ *EPCAM* polyadenylation-signal deletions was noted to have similar ages of colorectal cancer onset as *MLH1* and *MSH2* carriers [28]. In contrast, only three women with *EPCAM* deletions were found to have endometrial cancer leading to a lower cumulative lifetime risk compared to other MMR gene mutation carriers. *EPCAM* is expressed at lower levels in uterine tissue. Consequently, *MSH2* silencing as result of *EPCAM* polyadenylation-signal deletion may occur less frequently in the uterus. Higher rates of duodenal and pancreatic cancers were noted in *EPCAM* polyadenylation-signal deletion carriers compared to other Lynch syndrome families. Whether screening recommendations should be different for *EPCAM* polyadenylation-signal deletion carriers remains to be determined. Molecular genetic testing for *EPCAM* deletions is recommended for the subset of families in whom germline mutations in MMR genes are suspected but have not been identified.

25.2.2.5 Genotype-Phenotype Correlations

Clinically, Lynch syndrome cancer phenotypes vary as a function of the mutated MMR gene involved. Mutations in *MLH1* have been associated with higher incidence of CRC, whereas *MSH2* mutations have been associated with higher rates of extracolonic tumors. *MSH6* mutations have been associated with lower rates of CRC with higher rates of endometrial cancer [29], while the phenotypic pattern associated with *PMS2* mutations is still unclear. Furthermore, while the mean age of colorectal cancer diagnosis in *MSH2* and *MLH1* mutation carriers is 43–46 years, in *MSH6* mutation carriers, the mean age of cancer diagnosis is 10 years older [29]. *EPCAM* deletion carriers appear to have lower rates of endometrial cancer but possibly higher rates of duodenal and pancreatic tumors [28].

The reasons for these gene-specific clinical phenotypes are poorly understood and may be due to different functions of MMR proteins, modifier genes and/or environmental risk factors. Data on modifier genes in Lynch syndrome are conflicting. Candidate genes such as *TP53* [30], *NAT2* [31–33], and *CCND1* (the gene that encodes cyclin D1) [34, 35] have been tested for modifier effects but the data are not conclusive. Environmental risk factors have also not been extensively examined, though a multicenter American study found tobacco use to be associated with higher risk of CRC development [36]. More recent data has suggested that higher body mass indices (BMIs) greatly increase the risk of colorectal adenomas, a finding that was noted only in men [37]. Further studies with large, collaborative study design are needed to elucidate the role of modifier genes and environmental factors in Lynch syndrome.

25.2.3 Management of Lynch Syndrome

25.2.3.1 Diagnosis

Diagnosis is defined by the presence of a mutation in one of the MMR genes. The diagnosis can be supported by the presence of MSI in the cancer, absence of MMR protein by immunohistochemistry (IHC), or a variety of other laboratory tests (biochemical or mRNA analysis, methylation testing, etc). Statistical models that take into account all available cancer family history and laboratory testing have been developed to estimate the probability that a person carries a mutation [38, 39] and universal testing of all incident CRC cases helps to identify mutation carriers, who are then referred to the genetics clinic. Unaffected relatives can then learn their mutation status and take preventive measures [38, 39].

There are two approaches to molecular testing for Lynch syndrome. The first is to test for a mutation in an MMR gene directly by PCR-based direct DNA sequencing and some form of analysis for large deletions (MLPA or hybridization-based assays). The sensitivity of PCR-based direct sequence analysis is 80–90 %. However, the high frequency of amino acid substitutions of unknown clinical significance reduces the specificity of this testing and additional testing (e.g., MSI testing) would be required in these cases. The other approach is to test the tumor for MSI, MMR protein staining by IHC, or both, and then perform mutational analysis on cases in which MSI is found and/or an MMR protein is absent. MSI is more sensitive than IHC because as noted above missense mutations constitute a substantial proportion of Lynch syndrome mutations. The sensitivity of MSI testing is ~90 %. Consequently, in families with compelling family history, both approaches may be used. If no germline MMR mutation is identified, a missed mutation (e.g., methylation aberration transmitted through the germline) or mutation in one of the less-often-sequenced MMR genes (e.g., *PMS2*) is possible. Testing of additional tumors in the family for MSI or loss of expression of MMR protein or linkage analysis can help rule out missed mutation. Since MSI or loss of expression of MMR protein can result from non-hereditary causes, namely, by somatic mutation or somatic gene silencing by methylation of the *MLH1* promoter, methylation studies and/or *BRAF* mutation assessment can be performed to help identify such tumors [40]. Finally, advances in DNA sequencing technologies have led to the development of methods to sequence many culprit genes at one time, which provides a simplified approach to mutation identification in presumptive carriers. Indeed, it is now feasible to sequence the entire genome on a clinical basis, and the day is coming when people will have their whole genome sequenced in order to learn their genetic risks and take appropriate medical precautions.

25.2.3.2 CRC Treatment and Survival

There has been conflicting evidence about response to chemotherapy and survival in tumors with MSI (including Lynch syndrome and non-hereditary cases) compared to tumors without MSI. Survival studies do not suggest major differences in Lynch syndrome patients with CRC compared with sporadic CRC [41, 42]. In contrast, a systematic meta-analysis of MSI status and prognosis in CRC (including both Lynch syndrome-associated and non-hereditary tumors) suggested that patients with tumors that exhibit MSI had a 15 % better outcome compared with those with tumors that did not exhibit MSI [43]. As result of these studies, most oncologists withhold chemotherapy for Stage II CRCs with MSI, because the outcomes are the same if not better without treatment.

Regarding responsiveness to chemotherapeutic agents, in vitro studies have suggested that MMR deficiency reduces the cytotoxicity of 5-fluorouracil (5-FU), which is a commonly used chemotherapeutic agent for CRC [44, 45]. To date, studies on response to chemotherapy stratified by MSI status have yielded mixed results and, therefore, MSI status is not yet recommended as a predictive marker of response to chemotherapy.

Finally, immune checkpoint inhibitor therapy is now being used now for metastatic MSI-H colon cancer.

25.2.3.3 Screening

Colonoscopy remains the preferred method for screening in established or suspected Lynch mutation carriers. The current recommended screening regimen is colonoscopy every 1–2 years starting at age 20–25 years or 10 years younger than the youngest age at diagnosis in the family [46]. The recommendation for short intervals between colonoscopies is based on evidence of accelerated adenoma-to-carcinoma progression in MMR mutation carriers [47]. The relative risk reduction with colonoscopic screening was 62 % in two Finnish studies [48, 49]. This translates into a 72 % reduction in mortality attributed to colonoscopic screening with polypectomy [50, 51].

Data on screening for extracolonic cancer is less clear. Endometrial sampling for endometrial cancer, transvaginal ultrasound for endometrial and ovarian cancer, and urinalysis with cytology for urothelial malignancies are often recommended. Similarly, prophylactic colectomy, hysterectomy, or oophorectomy may be pursued but solid prospective data on the effectiveness of these surgical options is not currently available [46].

25.2.3.4 Prevention

The effect of nonsteroidal anti-inflammatory drugs (NSAIDs) as a chemopreventive agent in CRC development in MMR mutation carriers is unknown. A recent study investigating the effect of sulindac on surrogate endpoints for cancer showed increased epithelial proliferation in the proximal colon of Lynch syndrome patients taking the NSAID, which does not support a chemopreventive role for this NSAID [52]. The first large-scale, randomized control trial of aspirin and starch in MMR mutation carriers did not show differences in CRC incidence between the treatment and standard-care arms at 5 years [53]. However, subsequent follow-up data suggested a delayed benefit in aspirin users compared to placebo (Burn, unpublished data). Further studies would need to be done to elucidate the potential role of NSAIDs, aspirin, and other chemopreventive agents in Lynch syndrome.

25.3 Mismatch Repair

The MMR system recognizes and corrects incorporation errors that occur during DNA replication, some chemically induced or spontaneous DNA lesions, and mismatches produced during homologous recombination. Components of the system are also utilized during somatic hypermutation in the maturation of B-cells. MMR repairs both base-base mismatches and insertion/deletion loops (IDLs). Base-base mismatches can be generated by DNA polymerase incorporation errors that escape the proofreading activity of the DNA polymerases. IDLs occur when primer and template strands dissociate and re-anneal incorrectly. Slipped strand mispairings, as these are called, occur preferentially in repetitive DNA sequences of one-nucleotide to five-nucleotide repeats, referred to as microsatellites. Slipped strand mispairings in microsatellite regions can be of varying lengths depending on where loops form in the double helix. The high frequency of unrepaired IDLs plays an important role in development of MSI. MSI is one part of the mutator phenotype associated with MMR gene mutations, in which somatic mutations accumulate at a higher rate as a result of loss of MMR function.

MMR pathways are conserved across all domains of life. Initially, investigation of prokaryotic MMR provided major insights into the existence and functions of genes involved in MMR. The genes *mutH*, *mutL,* and *mutS* were identified in *E. coli,* and subsequently homologues for *mutL* and *mutS* were found in yeasts, mammals, and other species. In Fig. 25.3, we depict MMR mechanisms in eukaryotes schematically. MMR involves four stages: (1) mismatch recognition, (2) incision of the strand that contains the erroneous base(s), (3) strand excision to remove the base(s), and (4) restoration of the correct base by DNA replication using the undamaged DNA template. While MMR mechanisms have been more precisely defined in prokaryotes, the focus in this chapter is on eukaryotic MMR mechanisms. Recent review articles provide in-depth discussions of MMR biochemistry in both prokaryotes and eukaryotes [54–56].

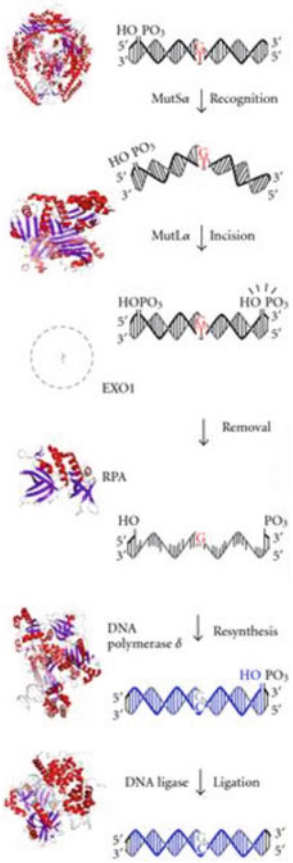

Fig. 25.3 Mismatch repair (MMR) mechanisms in eukaryotes. MMR is a mechanism to repair mismatched bases and small insertion/deletion loops. MMR involves four stages: (1) mismatch recognition, (2) incision of the strand that contains the erroneous base(s), (3) strand excision to remove the base(s), and (4) resynthesis by DNA replication to restore the correct base using the undamaged DNA template followed by ligation. The figure depicts the main steps of MMR along with structural models of the human proteins based on crystallography data. In the first stage, a DNA substrate with a mismatch is shown along with a nick 5′ of the mismatch that represents a discontinuity in the duplex that is usually associated with RNA replication; the discontinuity is required for recognition of the nascent strand on which the mismatch arose through replication error. MutSα (depicted to the left of the substrate) recognizes the mismatch. In the second stage, MutSα binds to the mismatched bases and recruits MutLα (left of the substrate) to the repair site. In the third stage, MutLα nicks 3′ of site of the mismatched base; MutLα can also nick 5′ of the site. In the fourth stage, EXO1, for which a crystal structure is not available, excises the mismatched DNA segment by its 3′ to 5′ exonuclease activity, and single-stranded DNA-binding protein RPA (depicted to the left of the substrate) binds the single-stranded DNA as it is exposed by EXO1. In the fifth stage, DNA polymerase δ (depicted at *left*) resynthesize DNA across the gap, and in the sixth stage DNA ligase I (depicted at *left*) seals the remaining nick by ligation to complete mismatch repair. Adapted from [56] and used by permission.

25.3.1 Eukaryotic MMR

Eukaryotic MMR involves homologues of bacterial components MutS and MutL but not MutH. MutS homologues include MSH2 (*M*ut*S* *H*omologue), MSH3, and MSH6. MutL homologues include MLH1, MLH3, PMS1 (*p*ost-*m*eiotic *s*egregation-1), and PMS2. In contrast to MutS and MutL, which are homodimers in prokaryotes, eukaryotes have evolved heterodimers composed of subunits that are homologous but that have different structures and functions. One such heterodimer is MutSα, which is composed of MSH2 and MSH6. MutSα recognizes mismatched bases and initiates repair of base-base mismatches and small IDLs. 80–90 % of the cellular MSH2 is found in the MutSα complex. MutSβ, composed of MSH2 and MSH3, repairs larger IDLs. MutLα is a heterodimer composed of MLH1 and PMS2; approximately 90 % of MLH1 in humans is found in the MutLα complex. The MutLβ complex is composed of MLH1 and PMS1 and the MutLγ is composed of MLH1 and MLH3. MutL homologues are responsible for strand incision.

25.3.2 MutS Homologue Function

Studies in *E. coli* have elucidated the molecular mechanisms of MutS and provide insight into function of MutS homologues in eukaryotes. Crystallography has revealed that eukaryotic MutS complexes bind double-stranded DNA as heterodimers [56]. Mismatch recognition appears to occur via non-specific DNA binding and bending to search for mismatched bases in an ATP-dependent manner.

MutS mismatch recognition occurs by stacking the mismatched base with a phenylalanine and adjacent glutamate residue intercalated from the minor groove side. These phenylalanine and glutamate residues are highly conserved among bacterial and eukaryotic MutS homologues (specifically MSH6 in humans). In the *E. coli* MutS-DNA complex, the DNA is kinked and unbent at a mismatched site forming a stable recognition complex. Upon mismatch recognition, MutS exchanges ADP to ATP and undergoes a conformational change forming a sliding clamp. This sliding clamp has also been confirmed in eukaryotic MutS complexes [56].

Subsequent activation of downstream reactions of the MutS sliding clamp remains controversial. The moving or cis model postulates that the sliding clamp diffuses along the DNA to activate downstream reactions. The stationary or trans model proposes that MutS remains bound to the mismatched base after initial recognition and the ATPase activity is required for verification of mismatch recognition [56].

25.3.3 MutL Homologue Function

Of the eukaryotic MutL complexes (MutLα, MutLβ, and MutLγ), the majority of MMR appears to be performed by MutLα (composed of MLH1 and PMS2 in humans). MutL and MutLα complexes have an N-terminal ATPase/DNA-binding domain and a C-terminal endonuclease/DNA-

binding domain. MutL proteins are ATPases of the gyrase/Hsp90/histidine-kinase/MutL family (GHKL family) which undergo conformational changes with ATP binding and hydrolysis required for MutL endonuclease activity.

In *E. coli,* MutL interacts with the MutS-DNA complex that activates MutH restriction endonuclease activity and strand incision. MutH is an endonuclease found in Gram-negative bacteria that is bound to hemimethylated GATC sites to the left or right of the mismatch. Activated MutH carries out incision of the newly synthesized DNA strand by recognizing the hemimethylated GATC site. MutH nicks the unmethylated strand at this site, which serves as a point of entry for the subsequent excision reaction. Hence, MMR in *E. coli* is known as methyl-directed MMR.

Eukaryotes, however, do not have MutH homologues, raising the question of how strand discrimination takes place in 5′ and 3′-directed MMR. Recent work has indicated that human and yeast MutLα have latent endonuclease activity that nicks the nascent DNA strand (as opposed to the template strand) proximal to the mismatched base duplex. MutLα nicks 5′ or 3′ of a mismatch, which serves as an entry for exonucleases. MutLα may recognize the nascent DNA strand through interactions with proliferating cell nuclear antigen (PCNA).

25.3.4 Additional Factors in Eukaryotic MMR

Excision events are catalyzed by factors with exonucleolytic activities from strand nicks either 5′ or 3′ of the mismatch lesion. EXO1, which has a 5′ to 3′ exonuclease activity, plays a central role in the excision reaction in eukaryotic MMR; however, a factor(s) with 3′ to 5′ exonuclease activity must also come into play. Moreover, genetic evidence indicates additional exonucleases are involved because *exo1* null alleles have a less severe phenotype than *msh2* null alleles in yeast and in mice [57, 58]. Single-stranded DNA-binding protein replication protein A (RPA) functions to stabilize the gap left by exonuclease degradation of the site of the base-base mismatch, and it inhibits EXO1 activity. The gap is filled by DNA Polymerase δ and the nick is sealed by DNA ligase 1 [55].

25.4 Tumorigenesis

25.4.1 MSI

The discovery of MSI as a marker in Lynch syndrome proved important in defining the mechanism of tumorigenesis in Lynch-related cancers as well as in some non-hereditary cancers. In general, microsatellites, repeats of one to five nucleotides, have a higher mutation rate than other DNA sequences, because DNA polymerases tends to stall or slip on these sequences, the nascent replicated strand loops out, and, if the loop is not corrected to the normal state, the loop can be processed to a gain or loss of repeat units. The DNA repair mechanism that repairs loops to their normal state is the MMR pathway [59].

In contrast to Lynch syndrome, in which a germline mutation in an MMR gene is present and MMR function is lost by somatic mutation of the un-mutated gene copy, in about 15 % of non-hereditary CRC cases, MMR gene function is lost by biallelic methylation of the *MLH1* promoter, resulting in MSI and tumorigenesis. Methylation of the *MLH1* promoter results in reduced gene expression without changing the nucleotide sequence, a phenomenon known as an epigenetic change. In mammals, DNA methylation only occurs in the dinucleotide sequence CpG. Certain gene promoters, predominantly the promoters of housekeeping genes, contain a high proportion of CpG dinucleotides [60]. In general, promoter methylation down-regulates gene transcription, effectively silencing the gene. In 1998, two groups independently reported hypermethylation of the *MLH1* promoter and MSI in sporadic colorectal tumors. In these studies, 84–100 % of tumors with MSI had a hypermethylated *MLH1* promoter and protein expression was absent by immunohistochemistry [61, 62]. These tumors appear to have similar clinicopathological features as the tumors associated with Lynch syndrome, which nearly always exhibit MSI.

Colorectal tumors (cancers and adenomas, as well as other Lynch-related tumors such as endometrial cancers) can be tested by PCR amplification of microsatellites or by immunohistochemistry (IHC). In the PCR-based MSI assay, DNA from microdissected tumor and normal tissue is prepared and five to ten microsatellite loci are amplified by PCR. By fragment analysis with DNA electrophoresis, the lengths of DNA fragments at each locus are determined; the appearances of novel fragments in the tumor in contrast to the normal tissue are indicators of the hypermutation phenotype. Currently, there are several commercially available panels of microsatellite repeat loci that are routinely used in clinical testing. A panel of markers that consist of long mononucleotide runs in the adenine base are most reliable efficient in distinguishing MSI from non-MSI tumors [63]. In the IHC-based test, a tumor specimen is stained with antibodies to the major MMR proteins, MLH1, MSH2, MSH6, and PMS2. Normally, these proteins can be found in the nucleus of dividing cells. If the tumor specimen fails to stain with one of these antibodies, then the tumor is scored MMR protein absent (a positive result), and this is an indication that MMR function is deficient. False-negative IHC results can arise when protein expression is present but the MMR protein is catalytically dysfunctional due to missense mutations; hence, in the hereditary situation, as noted above the MSI test is more sensitive than the IHC test.

25.4.2 Mutator Carcinogenic Pathway

Analysis of tumors with MSI has revealed different mechanisms of CRC carcinogenesis, referred to as the mutator pathway, which is partially distinct from the dominant mechanisms that operate in the classic adenoma-to-carcinoma sequence referred to as the chromosomal instability pathway [64]. Genes targeted in the mutator pathway have mononucleotide runs that are susceptible to mutation when MMR is not functional. *TGFBR2* (also referred to as *TGFβ-RII*) is one of the most commonly targeted genes in the mutator pathway. Loss of responsiveness of the inhibitory effects of TGFβ contributes to the development of many cancers but is particularly prominent in CRC. TGFβ sends an inhibitory signal for cell proliferation that is mediated through two receptors: TGF*β*-RI and TGF*β*-RII. TGF*β*-RII is susceptible to replication errors because of a run of ten adenines in the part of the gene that encodes the signal sequence. Mutations in TGF*β*-RII cause failure of binding and response to TGFβ. Moreover, experimental introduction of a normal TGF*β*-RII gene into receptor-negative colon cancer cell lines restores TGF*β*-RII function and suppresses cancer-cell tumorigenicity [65].

Other genes that are mutated in the mutator pathway include those involved in signal transduction (IGFII, PTEN), apoptosis and inflammation (BAX, caspase-5), transcription regulation (E2F4, TCF-4), and DNA repair (MSH6, MSH3, MLH3, MED-1, RAD50, DNA-PKcs, BLM). Functional studies are ongoing to determine which genes play a role in major tumor initiation and progression and to distinguish them from alterations that are merely bystanders in the milieu of increased mutagenesis.

25.5 Familial Adenomatous Polyposis (FAP)

In contrast to Lynch syndrome, patients with polyposis syndromes are less challenging to identify clinically because of the presence of many adenomatous polyps in the colon and rectum. Adenomatous polyps are precursor lesions of CRC. The prototypical polyposis syndrome is FAP, and it is caused by either inherited or *de novo* germline mutations in the *APC* gene. There is marked heterogeneity in expression of *APC* mutations leading to a spectrum of disease rather than a single phenotype. This spectrum includes typical FAP, attenuated FAP (AFAP), profuse polyposis, and Gardner's syndrome. In the last 10 years, a distinct polyposis syndrome MAP was identified due to mutations in the *MUTYH* gene.

Histologic confirmation of a condition of multiple colonic polyps was recognized over 120 years ago when Sklifasowski published a case of polyadenoma tractus intestinalis. An inherited version of this condition was reported a year later by Cripps who described two siblings each with multiple adenomas. In the 1920s, a polyposis registry was begun at St. Mark's Hospital in England from which Lockhart-Mummery and Dukes published the first series of ten families with familial intestinal polyposis. In 1951, Gardner recognized a polyposis condition which was associated with desmoids, bone and cyst-like surface tumors. In 1987, the *APC* gene was localized to 5q21-22. The last decade has seen advances in understanding of genetics, pathophysiology, and management of polyposis syndromes ranging from recognition of attenuated FAP and MAP, genotype-phenotype correlation, surgical colectomy techniques, chemoprophylaxis, and improved screening strategies [66].

25.5.1 Clinical Aspects of FAP

25.5.1.1 Natural History

FAP accounts for less than 1 % of all CRC [67]. The incidence is thought to be 1 in 13,000 to 1 in 18,000 in Northern European populations [68, 69]. It is inherited in an autosomal dominant fashion. *De novo* germline mutations account for up to 25 % of cases [70]. The penetrance of polyposis approaches 100 % in individuals with *APC* mutations, although there is substantial variation in disease presentation as will be discussed. Without intervention, malignant transformation of one or more polyps is highly likely to occur on average by the fourth decade of life.

Patients present with hundreds of adenomatous polyps that carpet the colon and rectum starting in adolescence. Cancer develops by age 35–40 with 70–80 % of the tumors being localized distally [69, 71]. Additional clinical features include desmoids tumors, upper intestinal (gastric and duodenal) polyps and cancer, thyroid cancer, hepatoblastoma, and congenital hypertrophy of the retinal pigment epithelium (CHRPE). Although a minor part of the syndrome and still relatively infrequent, an increased frequency of pancreatic adenocarcinomas is associated with FAP. Relative and absolute lifetime risk of extracolonic cancers associated with FAP is presented in Table 25.4.

Table 25.4 Risks of extracolonic tumors in familial adenomatous polyposis (FAP)

Tumor	Relative risk (%)	Absolute lifetime risk (%)
Desmoids	852	15
Duodenal cancer	330.8	3.0–5.0
Thyroid	7.6	2
Brain	7	2
Ampullary	123.7	1.7
Pancreatic	4.5	1.7
Hepatoblastoma	847	1.6
Gastric		0.6

From Galiatsatos *Am J Gastroenterol* 2006 [72]

The clinical spectrum of FAP includes Gardner syndrome, AFAP, profuse polyposis, and Turcot syndrome. All of these clinical variants result from *APC* mutations and are associated with mutations at different regions of *APC* (the allelic series). Gardner syndrome is a condition of gastrointestinal polyposis associated with osteomas as well as epidermal cysts, desmoids, and thyroid tumors. In these patients, the extraintestinal manifestations are particularly prominent compared to typical FAP. Dental abnormalities including supernumerary and impacted teeth are seen in one quarter to one third of patients with this variant of the syndrome. In AFAP, there are between 10 and 100 colorectal adenomas. These polyps are more proximally located and the age of CRC onset is 15 years later than individuals with FAP. AFAP patients may not have a family history and often do not exhibit extracolonic tumors. In contrast, profuse polyposis describes individuals with more than 5000 colonic adenomas.

25.5.1.2 Diagnosis

FAP is usually diagnosed when patients present with carpeting adenomatous colonic polyps or when a relative is diagnosed with FAP. Algorithms have been developed to aid in the clinical diagnosis and management of FAP in affected individuals and their first-degree family members [72]. For an individual in whom FAP is suspected, full DNA sequencing of the *APC* gene is recommended. For first-degree relatives, the recommendation is to test for the mutation found in the proband beginning at age 10–12. Embryonic testing is also available.

25.5.1.3 Prophylaxis

If an *APC* mutation is identified, patients should be referred for proctocolectomy. In addition, patients should have upper endoscopy every 1–3 years, annual thyroid examination, and periodic abdominal ultrasound for pancreatic cancer and desmoids tumor screening. If a mutation is identified in a family member, colonoscopy should be performed yearly from age until the onset of polyps at which time prophylactic colectomy is recommended. If genetic testing is not desired or possible in a first-degree relative or no mutation is identified in the proband, flexible sigmoidoscopy is recommended annually starting at age 10–12. If polyps are found, individuals should consider colectomy. If no polyps are found by age 50, general screening guidelines can be followed [72].

As a result of screening and appropriate therapy, there has been a 55 % reduction in incidence of CRC at time of FAP diagnosis (that is, diagnosis of FAP prior to CRC diagnosis) as well as an improvement in survival for all FAP patients [73, 74]. Colectomy dramatically reduces the risk of CRC development. Surgical options are either subtotal colectomy with ileorectal anastomosis (IRA) and sigmoidoscopy every 6 months or total colectomy with ileal-pouch anal anastomosis (IPAA) with periodic sigmoidoscopy of the pouch. Presently, IPAA, which removes all colorectal mucosa, has become the preferred surgical approach. There is still a small, but not negligible risk of polyps and cancer in both the remnant rectum (with IRA) and the pouch (with IPAA). The option of IRA is most appropriate in young patients with few rectal adenomas and a family history of a mild phenotype as well as in AFAP [75].

25.5.1.4 Chemoprevention

Over the past decade, chemoprevention in FAP has gained attention. Clinically investigated agents include NSAIDs (predominantly sulindac), COX-2 inhibitors (both celecoxib and rofecoxib) as well as nutritional, micronutrient, and combination therapies. The prophylactic role of COX-2 inhibitors has been questioned due to important cardiovascular risks. Presently, these preventive medical therapies are not considered alternatives to surgical colectomy. Most studies have been performed for polyp prevention post-colectomy. Chemoprevention is most appropriate in young patients with adenomas before surgery, post-IRA patients for prevention of rectal adenomas, individuals with duodenal adenomas, and those with abdominal wall or intra-abdominal desmoids [76].

25.5.2 Genetics of FAP

25.5.2.1 APC Gene

APC was localized to chromosome 5q by the identification of a deletion of chromosome 5q in an individual with Gardner syndrome [77]. In 1991, linkage analysis and conventional positional cloning strategies were used to identify mutations in the *APC* gene in families with FAP, confirming this gene's causative role in the syndrome [78]. The gene has an 8538 bp open reading frame with 15 transcribed exons (Fig. 25.4). Exon 15 is the largest exon and accounts for 75 % of the coding sequence and is the location of most germline and somatic *APC* mutations [79]. Most germline and somatic *APC* mutations result in premature chain-termination. Truncated protein products can be detected by a molecular genetic assay referred to as in vitro synthesized protein (IVSP), and this analysis can be carried out on exon 15 directly from genomic DNA or on *APC* cDNA preparations from cellular RNA.

More than 800 different germline and somatic *APC* mutations have been reported. The region located at the 5′ end of exon 15 roughly between codons for amino acid residues 1286 and 1513 comprises the mutation cluster region (MCR). The most common germline mutations are 5-bp deletions that occur between codons 1061 and 1309; these mutations

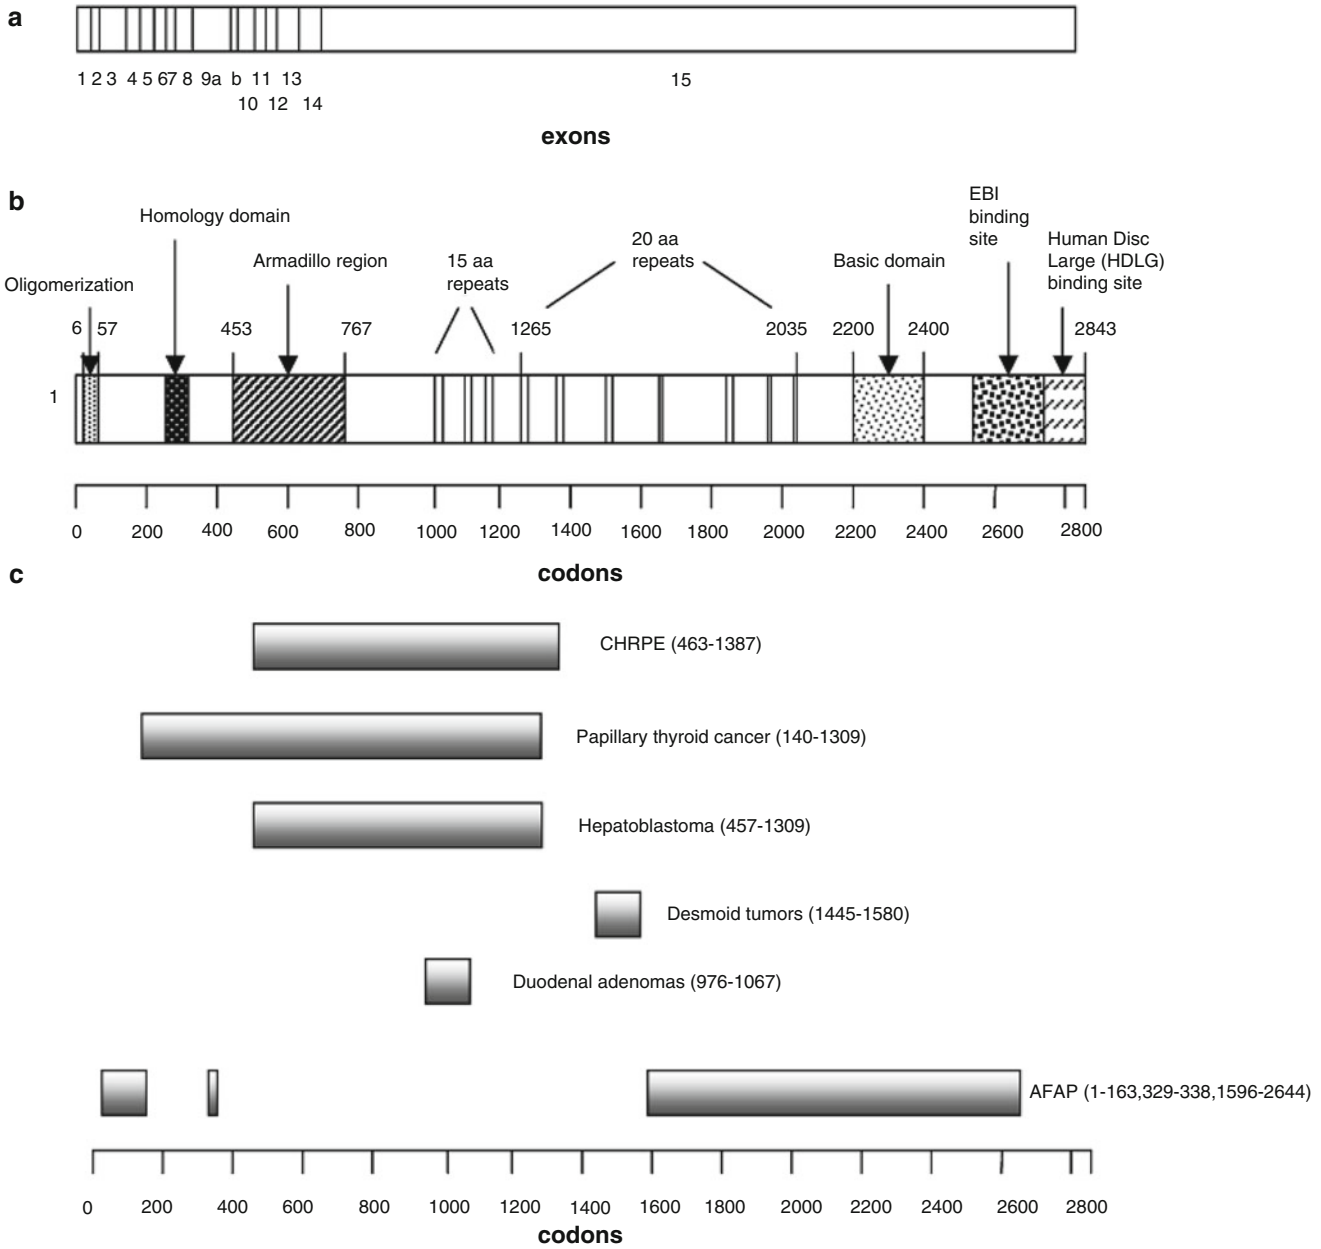

Fig. 25.4 APC gene and protein. (**a**) The *APC* gene encodes 15 exons. The drawing shows the relative sizes of each coding segment in the genome. (**b**) The APC protein contains numerous structural motifs and binding domains. See text for more details on selected regions of the protein. (**c**) *APC* mutations in different regions of the gene, as depicted by the shaded rectangles, are associated with different clinical susceptibilities. CHRPE, congenital hypertrophy of the retinal pigmented epithelium; AFAP, attenuated familial adenomatous polyposis. Adapted from Galiatsatos [72] and used by permission.

account for 1/3 of all germline mutations [80]. Somatic *APC* mutations occur most frequently between codons 1286 and 1513 with hotspots at codons 1309 and 1450 [79].

Inactivating somatic mutation of *APC* is the predominant first step in mutational pathway of colorectal carcinogenesis occurring in over 85 % of all CRCs, consistent with its role as a tumor suppressor. In order for *APC*-associated disease to develop, two hits are required. Loss of *APC* function in a precursor colonocyte leads to increased proliferation of the mutant cell. In FAP, the first hit is usually inherited from a parent, but the somatic mutation that constitutes the second hit may not be entirely random. More advantageous mutations are selected for during tumor initiation. These advantageous somatic mutations are not functionally null, instead they retain some APC activity in down-regulating Wnt signaling rather than allowing for excessive β-catenin accumu-

lation that would induce apoptosis. This is known as the just-right signaling model [81].

25.5.2.2 Genotype-Phenotype Correlations

Location of germline mutations in *APC* partially predicts the varying polyposis phenotypes, although the underlying mechanisms for these genotype-phenotype correlations have not been fully elucidated. Mutations between codons 1250 and 1464 in the MCR have been associated with profuse polyposis [82]. Age of CRC onset in this sub-type is about 8 years earlier compared to typical FAP. In contrast, the milder phenotype of AFAP is associated with mutations at the very 3′ end of the *APC* gene, nonsense mutations at exon 9, as well as nonsense and frameshift mutations at exons 3, 4, and 5 [83–87].

Certain extracolonic manifestations of FAP also appear to have specific genotype-phenotype correlations. First, CHRPE can be seen in families with a mutation anywhere between codons 311 and 1465. Desmoid tumors have been associated with mutations at the 3′ end of the gene downstream of codon 1400. While no large study has been done to confirm the association between upper intestinal polyps and *APC* mutations, it has been suggested that mutations from codons 976 to 1067 increase risk of duodenal adenomas. The evidence for associations with desmoid and upper gastrointestinal tumors is weaker than it is for CHRPE. Additional correlations are shown in Fig. 25.4c.

25.5.2.3 Min Mouse Model

The *m*ultiple *i*ntestinal *n*eoplasia (*Min*) ($Apc^{Min/+}$) mouse is the best-characterized model of FAP. The *ApcMin/+* mouse has a mutation at codon 850 and develops multiple adenomas of the small intestine as well as a more limited number of colonic lesions [88]. This mouse model has been used to characterize genetic and epigenetic modifiers of FAP. It has also been useful for testing putative chemotherapeutic regimens including NSAIDs.

25.5.2.4 Modifier Genes

Modifier genes have been implicated in the variable expression of FAP phenotypes [89]. In 1993, Dietrich reported a modifier gene on chromosome 4 in the Min mouse model [90]. The *m*odifier *o*f *M*in 1 (Mom1) strongly influences tumor number in the animal model. A candidate gene in this region is secretory phospholipase A2 (Pla2s) or its human equivalent locus *PLA2G2A* [91]. Variants in *PLA2G2A* have been associated with severity of duodenal polyposis in FAP patients [92]. In the last decade, two further modifiers (Mom2 and Mom7) [93, 94] have been described in the Min model, but investigators have yet to study these loci in humans. Another candidate modifier gene is N-acetyltransferase (both NAT1 and NAT2), which has been associated with a twofold increase in the number of polyps in FAP patients [95].

25.5.3 APC Protein and Wnt Signaling Pathway

25.5.3.1 Canonical Wnt Signaling

Wnts (the name is derived from the homologous genes identified by the *Drosophila melanogaster* mutant *wingless* and the mouse mutant *int1*) are a family of conserved signaling proteins that allow cells to converse with one another in order to coordinate a variety of cellular processes in development, homeostasis, and wound healing. There are several Wnt signaling pathways (referred to as canonical and non-canonical). While the canonical pathway is the best-characterized, non-canonical pathways include the planar cell polarity pathway, the Wnt/Ca pathway, and the protein kinase A pathway.

The *canonical* pathway refers to Wnt signaling that ultimately leads to β-catenin translocation to the nucleus (Fig. 25.5). Normally, in the off state of Wnt signaling, β-catenin is maintained in the cytoplasm by a protein complex known as the destruction complex composed of AXIN1, APC, and glycogen synthase kinase-3β (GSK-3β). In the on state, Wnt proteins bind to a receptor complex made up of Frizzleds and low-density lipoprotein receptor-related protein (Fz/LRP) leading to phosphorylation of a downstream protein Disheveled (Dvl). Phosphorylated Dvl inhibits GSK-3β leading to cytoplasmic accumulation of β-catenin which is not degraded and which translocates to the nucleus. Nuclear β-catenin complexes with T-cell transcription factor (TCF) and lymphoid enhancer-binding factor (LEF), which, upon recruitment of coactivators, leads to transcription of target genes. A recent review provides additional detail on APC and Wnt signaling in CRC [96].

25.5.3.2 APC Protein

APC is expressed in most cell types. In the colon, APC is a regulatory protein of colonic epithelial cell homeostasis. The protein is comprised of 2843 amino acids with several functional domains (Fig. 25.4). These domains have been implicated primarily in Wnt signal transduction but also in cell migration, adhesion, and chromosomal segregation. In the N-terminus, there is an oligomerization domain and a region consisting of armadillo repeats. The central portion consists of several 15- and 20-amino acid repeats. The C-terminus contains a basic domain as well as binding sites for EB1, microtubules, actin, human disc large (HDLG) protein, and scribble. β-catenin binding occurs at three of the 15 amino acid repeats and seven of the 20 amino acid repeats in APC, with the latter being essential for β-catenin downregulation. Three so-called serine-alanine-methionine-proline (SAMP) repeats also are crucial to regulate β-catenin degradation via binding to AXIN1. Inactivating *APC* mutations generally result in truncation of the C-terminus of APC thereby eliminating the SAMP repeats and all but one of the
