Handbook of Engineering Statistics

Pham
Editor

Springer

Springer Handbook of Engineering Statistics

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physics and engineering. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of physical and technical information.

The volumes will be designed to be useful as readable desk reference books to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

for Michelle, Hoang Jr., and David

Preface

The Springer Handbook of Engineering Statistics, altogether 54 chapters, aims to provide a comprehensive state-of-the-art reference volume that covers both fundamental and theoretical work in the areas of engineering statistics including failure time models, accelerated life testing, incomplete data analysis, stochastic processes, Bayesian inferences, data collection, Bootstrap models, burn-in and screening, competing risk models, correlated data analysis, counting processes, proportional hazards regression, design of experiments, DNA sequence analysis, empirical Bayes, genetic algorithms, evolutionary model, generalized linear model, geometric process, life data analysis, logistic regression models, longitudinal data analysis, maintenance, data mining, six sigma, Martingale model, missing data, influential observations, multivariate analysis, multivariate failure model, nonparametric regression, DNA sequence evolution, system designs, optimization, random walks, partitioning methods, resampling method, financial engineering and risks, scan statistics, semiparametric model, smoothing and splines, step-stress life testing, statistical process control, statistical inferences, statistical design and diagnostics, process control and improvement, biological statistical models, sampling technique, survival model, time-series model, uniform experimental designs, among others.

The chapters in this handbook have outlined into six parts, each contains nine chapters except Part E and F, as follows:

Part A Fundamental Statistics and Its Applications
Part B Process Monitoring and Improvement
Part C Reliability Models and Survival Analysis
Part D Regression Methods and Data Mining
Part E Statistical Methods and Modeling
Part F Applications in Engineering Statistics

Prof. Hoang Pham

All the chapters are written by over 100 outstanding scholars in their fields of expertise. I am deeply indebted and wish to thank all of them for their contributions and cooperation. Thanks are also due to the Springer staff for their patience and editorial work. I hope that practitioners will find this Handbook useful when looking for solutions to practical problems; researchers, statisticians, scientists and engineers, teachers and students can use it for quick access to the background, recent research and trends, and most important references regarding certain topics, if not all, in the engineering statistics.

January 2006 Hoang Pham

List of Abbreviations

A

ABC	approximated bootstrap confidence
ACK	acknowledgment
ADDT	accelerated destructive degradation tests
ADI	average inter-demand interval
ADT	accelerated degradation test
AF	acceleration factor
AGP	arithmetico-geometric process
ALM	accelerated life model
ALT	accelerated life testing
AMA	arithmetic moving-average
ANN	artificial neural networks
ANOVA	analysis of variations
AP	arithmetic process
APC	automatic process control
AQL	acceptable quality level
AQM	active queue management
AR	autoregressive process
ARI	adjusted Rand index
ARL	average run length
ARMA	autoregressive and moving average
ARMDT	accelerated repeated measures degradation tests
ARRSES	adaptive response rate single-exponential smoothing
ART	accelerated reliability
ASN	average sample number
ASQ	American Society for Quality
ATI	average total inspection
AUC	area under the receiver operating characteristics curve
AW	additive Winter

B

BIB	burn-in board
BIR	built-in reliability
BLAST	Berkeley lazy abstraction software verification tool
BLUP	best linear unbiased predictor
BM	binomial model
BVE	bivariate exponential

C

CART	classification and regression tree
CBFQ	credit-based fair queueing
CBQ	class-based queues
CCD	central composite design
CDF	cumulative distribution function
CE	classification error
CF	characteristic function
CFE	Cauchy functional equation
CFF	call for fire
CHAID	chi-square automatic interaction detection
CID	collision-induced dissociation
CIM	cluster-image map
CLT	central limit theorem
CM	corrective maintenance
CML	canonical maximum likelihood
CMW	combination warranty
CNM	customer needs mapping
COPQ	cost of poor quality
COT	cumulative sum of T
cPLP	capacitated plant location problem
CRC	cumulative results criterion
CRUISE	classification rule with unbiased interaction selection and estimation
CS-CQ	cycle stealing with central queue
CS-ID	cycle stealing with immediate dispatch
CSALT	constant-stress accelerated life test
CSS	conditional single-sampling
CTQ	critical-to-quality
CUSUM	cumulative sum
CV	coefficient of variance
CV	cross-validation
CVP	critical value pruning
CX	cycle crossover
Cdf	cumulative distribution function
Cuscore	cumulative score
Cusum	cumulative sum

D

DBI	dynamic burn-in
DBSCAN	Density-based clustering
DCCDI	define, customer concept, design, and implement
DES	double-exponential smoothing
df	degrees of freedom
DFM	design for manufacturability
DFR	decreasing failure rate
DFR	design for reliability
DFSS	design for Six Sigma
DFY	design for yield
DLBI	die-level burn-in
DLBT	die-level burn-in and testing
DM	Data mining
DMADV	define, measure, analyze, design and verify
DMAIC	define, measure, analyze, improve, and control

DMAICT	define, measure, analyze, improve, control and technology transfer
DOE	design of experiments
DP	dynamic programming
DP	design parameters
DPMO	defects per million opportunities
DQ	dual-queue
DQLT	dual queue length threshold
DRD	dynamic robust design
DRR	deficit round-robin
DSSP	dependent stage sampling plan
DUT	device under test
DWC	discounted warranty cost
DoD	Department of Defense

E

EBD	equivalent business days
EBP	error-based pruning
EDWC	expected discounted warranty cost
EF	estimating function
EM	expectation maximization
EOQ	economic order quantity
EOS	electrical-over-stress
EQL	expected quality loss
ES	exponential smoothing
ESC	expected scrap cost
ESD	electrostatic discharge
ETC	expected total cost
EWC	expected warranty cost
EWMA	exponentially weighted moving average
EWMAST	exponentially weighted moving average chart for stationary processes

Part A Fundamen

Part A Fundamental Statistics and Its Applications

Part A provides the concepts of fundamental statistics and its applications. The first group of five chapters exposes the readers, including researchers, practitioners and students, to the elements of probability, statistical distributions and inference and their properties. This comprehensive text can be considered as a foundation for engineering statistics. The first chapter provides basic statistics-related concepts, including a review of the most common distribution functions and their properties, parameter-estimation methods and stochastic processes, including the Markov process, the renewal process, the quasi-renewal process, and the nonhomogeneous Poisson process. Chapter 2 discusses the basic concepts of engineering statistics and statistical inference, including the properties of lifetime distributions, maximum-likelihood estimation, the likelihood ratio test, data modeling and analysis, and system reliability analysis, followed by variations of the Weibull and other related distributions, parameter estimations and hypothesis testing, and their applications in engineering. Chapter 4 describes the basic concept of characterizing functions based on random samples from common univariate discrete and continuous distributions such as the normal, exponential, Poisson, and multivariate distributions, including the Marshall–Olkin bivariate exponential and multivariate normal distributions. Chapter 5 discusses two-dimensional approaches to failure modeling, with applications in reliability and maintenance such as minimal repair and imperfect repair, and compares this through applications with the one-dimensional case.

The following four chapters cover the basic concepts in engineering statistics in specific topics such as reliability growth, warranty, marked point processes and burn-in. Chapter 6 presents the derivation of the prediction intervals for the time to detect the next fault for a small sample size by combining the Bayesian and frequentist approaches. It also provides examples to explain the predictions of the models, as well as their strengths and weaknesses. Chapter 7 gives an overview of various existing warranty models and policies and a summary of the issues in quantitative warranty modeling such as warranty cost factors, warranty policies, the warranty cost of multicomponent systems, the benefits of warranties, and optimal warranty policy analysis. Chapter 8 discusses the concept of a random market point process and its properties, including two-sided market point processes, counting processes, conditional intensity, the Palm distribution, renewal processes, stationary sequences, and time-homogeneous Poisson processes, while Chapt. 9 focuses on the yield, multilevel burn-in and reliability modeling aspects for applications in semiconductor manufacturing, considering various infant-mortality issues with the increased complexity of integrated circuits during manufacturing processes.

1. Basic Statistical Concepts

This brief chapter presents some fundamental elements of engineering probability and statistics with which some readers are probably already familiar, but others may not be. Statistics is the study of how best one can describe and analyze the data and then draw conclusions or inferences based on the data available. The first section of this chapter begins with some basic definitions, including probability axioms, basic statistics and reliability measures.

The second section describes the most common distribution functions such as the binomial, Poisson, geometric, exponential, normal, log normal, Student's t, gamma, Pareto, Beta, Rayleigh, Cauchy, Weibull and Vtub-shaped hazard rate distributions, their applications and their use in engineering and applied statistics.

The third section describes statistical inference, including parameter estimation and confidence intervals. Statistical inference is the process by which information from sample data is used to draw conclusions about the population from which the sample was selected that hopefully represents the whole population. This discussion also introduces the maximum likelihood estimation (MLE) method, the method of moments, MLE with censored data, the statistical change-point estimation method, nonparametic tolerance limits, sequential sampling and Bayesian methods.

The fourth section briefly discusses stochastic processes, including Markov processes, Poisson processes, renewal processes, quasi-renewal processes, and nonhomogeneous Poisson processes.

Finally, the last section provides a short list of books for readers who are interested in advanced engineering and applied statistics.

1.1 Basic Probability Measures

We start off this chapter by defining several useful terms:

1. Outcome: A result or observation from an experiment, which cannot be predicted with certainty.
2. Event: Subset of a set of all possible outcomes.
3. Probability: The relative frequency at which an event occurs in a large number of identical experiments.
4. Random variable: A function which assigns real numbers to the outcomes of an experiment.

5. Statistics: A function (itself a random variable) of one or more random variables, that does not depend upon any unknown parameters.

1.1.1 Probability Axioms

Now let C be a subset of the sample space ($C \subset \mathbb{Z}$). A probability set function, denoted by P(C), has the following properties:

1. $P(\mathbb{Z}) = 1, \quad P(C) \geq 0$
2. $P(C_1 \cup C_2 \cup \dots) = P(C_1) + P(C_2) + \dots$

where the subsets C_i have no elements in common (i. e., they are mutually exclusive).

Let C_1 and C_2 be two subsets of the sample space $\mathbb{Z}$. The conditional probability of getting an outcome in C_2 given that an outcome from C_1 is given by

$$P(C_2/C_1) = \frac{P(C_2 \cap C_1)}{P(C_1)}.$$

Let $C_1, C_2, \dots, C_n$ be n mutually disjoint subsets of the sample space $\mathbb{Z}$. Let C be a subset of the union of the C_is; that is

$$C \subset \bigcup_{i=1}^{n} C_i.$$

Then

$$P(C) = \sum_{i=1}^{n} P(C/C_i)P(C_i) \tag{1.1}$$

and

$$P(C_i/C) = \frac{P(C/C_i)P(C_i)}{\sum_{i=1}^{n} P(C/C_i)P(C_i)}.$$

Equation (1.1) is known as the law of total probability.

1.1.2 Basic Statistics

The cumulative distribution function (cdf) F is a unique function which gives the probability that a random variable X takes on values less than or equal to some value x. In other word, $F(x) = P(X \leq x)$.

The probability density function (pdf) f is the probability that X takes on the value x; that is, $f(x) = P(X = x)$.

The pdf satisfies the following two relations for discrete and continuous random variables, respectively,

$$\sum_{\text{all } x} f(x) = 1$$

and

$$\int_{-\infty}^{\infty} f(x)\,\mathrm{d}x = 1.$$

In the continuous case, the pdf is the derivative of the cdf:

$$f(x) = \frac{\partial F(x)}{\partial x}.$$

The expected value of a random variable X is given by

$$E(X) = \sum_{\text{all } x} x f(x)$$

in the discrete case, and by

$$E(X) = \int_{-\infty}^{\infty} x f(x)\,\mathrm{d}x$$

in the continuous case. Similarly, the variance of a random variable X, denoted by σ^2, is a measure of how the values of X are spread about the mean value. It is defined as

$$\sigma^2 = E\,(X - \mu)^2\,.$$

It is calculated for discrete and continuous random variables, respectively, by

$$\sigma^2 = \sum_{\text{all } x} (x - \mu)^2 f(x)$$

and

$$\sigma^2 = \int_{-\infty}^{\infty} (x - \mu)^2 f(x)\,\mathrm{d}x.$$

The standard deviation of X, denoted by σ, is the square root of the variance.

The skewness coefficient of a random variable X is a measure of the symmetry of the distribution of X about its mean value μ, and is defined as

$$S_\mathrm{c} = \frac{E(X - \mu)^3}{\sigma^3}.$$

The skewness is zero for a symmetric distribution, negative for a left-tailed distribution, and positive for a right-tailed distribution.

Similarly, the kurtosis coefficient of a random variable X is a measure of how much of the mass of the distribution is contained in the tails, and is defined as

$$K_\mathrm{c} = \frac{E(X - \mu)^4}{\sigma^4}.$$

Obviously, kurtosis is always positive; however, larger values represent distributions with heavier tails.

Assume there are n random variables $X_1, X_2, \ldots, X_n$ which may or may not be mutually independent. The joint cdf, if it exists, is given by

$$P(X_1 \le x_1, X_2 \le x_2, \ldots X_n \le x_n) = \int_{-\infty}^{x_n} \int_{-\infty}^{x_{n-1}} .. \int_{-\infty}^{x_1} f(t_1, t_2, .., t_n)\,\mathrm{d}t_1\,\mathrm{d}t_2..\mathrm{d}t_n$$

If the n random variables are mutually statistically independent, then the joint pdf can be rewritten as

$$f(x_1, x_2, \ldots, x_n) = \prod_{i=1}^{n} f(x_i).$$

The conditional distribution of a random variable Y given that another random variable X takes on a value x is given by:

$$f(y/X = x) = \frac{f(x, y)}{f_1(x)},$$

where

$$f_1(x) = \int_{-\infty}^{\infty} f(x, y)\,\mathrm{d}y.$$

Given a random sample of size n from a distribution, the sample mean and sample variance are defined as, respectively,

$$\bar{X} = \frac{1}{n}\sum_{i=1}^{n} X_i$$

and

$$S^2 = \frac{1}{n-1}\sum_{i=1}^{n} (X_i - \bar{X})^2.$$

1.1.3 Reliability Measures

Definitions of reliability given in the literature vary according to the practitioner or researcher. The generally accepted definition is as follows.

Definition 1.1

Reliability is the probability of success or the probability that the system will perform its intended function under specified design limits.

More specifically, reliability is the probability that a product or system will operate properly for a specified period of time (design life) under the design operating conditions (such as temperature, voltage, etc.) without failure. In other words, reliability can be used as a measure of the system's success at providing its function properly. Reliability is one of the quality characteristics that consumers require from manufacturers.

Mathematically, reliability $R(t)$ is the probability that a system will be successful in the interval from time 0 to time t:

$$R(t) = P(T > t), \quad t \ge 0, \tag{1.2}$$

where T is a random variable denoting the time-to-failure or failure time.

Unreliability, or the cdf $F(t)$, a measure of failure, is defined as the probability that the system will fail by time t.

$$F(t) = P(T \le t), \quad t \ge 0.$$

In other words, $F(t)$ is the failure distribution function. If the time-to-failure random variable T has a density function $f(t)$, then

$$R(t) = \int_{t}^{\infty} f(s)\,\mathrm{d}s$$

or, equivalently,

$$f(t) = -\frac{\mathrm{d}}{\mathrm{d}t}[R(t)].$$

The density function can be mathematically described in terms of T:

$$\lim_{\Delta t \to 0} P(t < T \le t + \Delta t).$$

This can be interpreted as the probability that the failure time T will occur between the operating time t and the next interval of operation $t + \Delta t$.

Consider a new and successfully tested system that operates well when put into service at time $t = 0$. The system becomes less likely to remain successful as the time interval increases. The probability of success for an infinite time interval is, of course, zero. Thus, the system starts to function at a probability of one and eventually decreases to a probability of zero. Clearly, reliability is a function of mission time. For example, one can say that the reliability of the system is 0.995 for a mission time of 24 h.

Example 1.1: A computer system has an exponential failure time density function

$$f(t) = \frac{1}{9000}\,\mathrm{e}^{-\frac{t}{9000}}, \quad t \geq 0.$$

The probability that the system will fail after the warranty (six months or 4380 h) and before the end of the first year (one year or 8760 h) is given by

$$P(4380 < T \leq 8760) = \int_{4380}^{8760} \frac{1}{9000}\,\mathrm{e}^{-\frac{t}{9000}}\,\mathrm{d}t = 0.237.$$

This indicates that the probability of failure during the interval from six months to one year is 23.7%.

Consider the Weibull distribution, where the failure time density function is given by

$$f(t) = \frac{\beta t^{\beta-1}}{\theta^{\beta}}\,\mathrm{e}^{-(\frac{t}{\theta})^{\beta}}, \quad t \geq 0,\ \theta > 0,\ \beta > 0.$$

Then the reliability function is

$$R(t) = \mathrm{e}^{-(\frac{t}{\theta})^{\beta}}, \quad t \geq 0.$$

Thus, given a particular failure time density function or failure time distribution function, the reliability function can be obtained directly. Section 1.2 provides further insight for specific distributions.

System Mean Time to Failure

Suppose that the reliability function for a system is given by $R(t)$. The expected failure time during which a component is expected to perform successfully, or the system mean time to failure (MTTF), is given by

$$\mathrm{MTTF} = \int_0^{\infty} t f(t)\,\mathrm{d}t \tag{1.3}$$

or, equivalently, that

$$\mathrm{MTTF} = \int_0^{\infty} R(t)\,\mathrm{d}t. \tag{1.4}$$

Thus, MTTF is the definite integral evaluation of the reliability function. In general, if $\lambda(t)$ is defined as the failure rate function, then, by definition, MTTF is not equal to $1/\lambda(t)$.

The MTTF should be used when the failure time distribution function is specified because the reliability level implied by the MTTF depends on the underlying failure time distribution. Although the MTTF measure is one of the most widely used reliability calculations, it is also one of the most misused calculations. It has been misinterpreted as a "guaranteed minimum lifetime". Consider the results given in Table 1.1 for a twelve-component life duration test.

A component MTTF of 3660 h was estimated using a basic averaging technique. However, one of the components failed after 920 h. Therefore, it is important to note that the system MTTF denotes the average time to failure. It is neither the failure time that could be expected 50% of the time nor is it the guaranteed minimum time of system failure, but mostly depends on the failure distribution.

A careful examination of (1.4) will show that two failure distributions can have the same MTTF and yet produce different reliability levels.

Table 1.1 Results from a twelve-component life duration test

Component	Time to failure (h)
1	4510
2	3690
3	3550
4	5280
5	2595
6	3690
7	920
8	3890
9	4320
10	4770
11	3955
12	2750

Failure Rate Function

The probability of a system failure in a given time interval $[t_1, t_2]$ can be expressed in terms of the reliability function as

$$\int_{t_1}^{t_2} f(t)\,\mathrm{d}t = \int_{t_1}^{\infty} f(t)\,\mathrm{d}t - \int_{t_2}^{\infty} f(t)\,\mathrm{d}t = R(t_1) - R(t_2)$$

or in terms of the failure distribution function (or the unreliability function) as

$$\int_{t_1}^{t_2} f(t)\,\mathrm{d}t = \int_{-\infty}^{t_2} f(t)\,\mathrm{d}t - \int_{-\infty}^{t_1} f(t)\,\mathrm{d}t = F(t_2) - F(t_1).$$

The rate at which failures occur in a certain time interval $[t_1, t_2]$ is called the *failure rate*. It is defined as the probability that a failure per unit time occurs in the interval, given that a failure has not occurred prior to t_1, the beginning of the interval. Thus, the failure rate is

$$\frac{R(t_1) - R(t_2)}{(t_2 - t_1)R(t_1)}.$$

Note that the failure rate is a function of time. If we redefine the interval as $[t, t + \Delta t]$, the above expression becomes

$$\frac{R(t) - R(t + \Delta t)}{\Delta t R(t)}.$$

The rate in the above definition is expressed in failures per unit time, but in reality the time units might instead correspond to miles, hours, trials, etc. The *hazard function* is defined as the limit of the failure rate as the interval approaches zero. Thus, the hazard function $h(t)$ is the instantaneous failure rate, and is defined by

$$\begin{aligned} h(t) &= \lim_{\Delta t \to 0} \frac{R(t) - R(t + \Delta t)}{\Delta t R(t)} \\ &= \frac{1}{R(t)} \left[-\frac{\mathrm{d}}{\mathrm{d}t} R(t) \right] \\ &= \frac{f(t)}{R(t)}. \end{aligned} \tag{1.5}$$

The quantity $h(t)\,\mathrm{d}t$ represents the probability that a device of age t will fail in the small interval of time t to $(t + \mathrm{d}t)$. The importance of the hazard function is that it indicates the change in the failure rate over the life of a population of components by plotting their hazard functions on a single axis. For example, two designs may provide the same reliability at a specific point in time, but the failure rates up to this point in time can differ.

The death rate, in statistical theory, is analogous to the failure rate, as the nature of mortality is analogous to the hazard function. Therefore, the hazard function, hazard rate or failure rate function is the ratio of the pdf to the reliability function.

1.2 Common Probability Distribution Functions

This section presents some of the most common distribution functions and several hazard models that are applied in engineering statistics [1.1].

1.2.1 Discrete Random Variable Distributions

Binomial Distribution

The binomial distribution is one of the most widely used discrete random variable distributions in reliability and quality inspection. It has applications in reliability engineering, for example when one is dealing with a situation in which an event is either a success or a failure.

The binomial distribution can be used to model a random variable X which represents the number of successes (or failures) in n independent trials (these are referred to as Bernoulli trials), with the probability of success (or failure) being p in each trial. The pdf of the distribution is given by

$$P(X = x) = \binom{n}{x} p^x (1 - p)^{n-x}, \; x = 0, 1, 2, \ldots, n,$$

$$\binom{n}{x} = \frac{n!}{x!(n - x)!},$$

where $n =$ number of trials, $x =$ number of successes, $p =$ single trial probability of success.

The mean of the binomial distribution is np and the variance is $np(1 - p)$. The coefficient of skewness is given by

$$S_c = \frac{1 - 2p}{\sqrt{np(1 - p)}}$$

and the coefficient of kurtosis is

$$K_c = 3 - \frac{6}{n} + \frac{1}{np(1 - p)}.$$

The reliability function $R(k)$ (i. e., at least k out of n items are good) is given by

$$R(k) = \sum_{x=k}^{n} \binom{n}{x} p^x (1 - p)^{n-x}.$$

Example 1.2: Suppose that, during the production of lightbulbs, 90% are found to be good. In a random sample of 20 lightbulbs, the probability of obtaining at least 18 good lightbulbs is given by

$$\begin{aligned} R(18) &= \sum_{x=18}^{20} \binom{20}{18} (0.9)^x (0.1)^{20-x} \\ &= 0.667. \end{aligned}$$

Poisson Distribution

Although the Poisson distribution can be used in a manner similar to the binomial distribution, it is used to deal with events in which the sample size is unknown. A Poisson random variable is a discrete random variable distribution with a probability density function given by

$$P(X = x) = \frac{\lambda^x \mathrm{e}^{-\lambda}}{x!} \quad \text{for } x = 0, 1, 2, \ldots \tag{1.6}$$

where λ = constant failure rate; x = is the number of events. In other words, $P(X = x)$ is the probability that exactly x failures occur.

A Poisson distribution is used to model a Poisson process. A Poisson random variable has a mean and a variance both equal to λ where λ is called the parameter of the distribution. The skewness coefficient is

$$S_\mathrm{c} = \frac{1}{\sqrt{\lambda}}$$

and the kurtosis coefficient is

$$K_\mathrm{c} = 3 + \frac{1}{\lambda}.$$

The Poisson distribution reliability up to time t, $R(k)$ (the probability of k or fewer failures), can be defined as follows

$$R(k) = \sum_{x=0}^{k} \frac{(\lambda t)^x \mathrm{e}^{-\lambda t}}{x!}.$$

This distribution can be used to determine the number of spares required for a system during a given mission.

Example 1.3: A nuclear plant is located in an area susceptible to both high winds and earthquakes. From historical data, the mean frequency of large earthquakes capable of damaging important plant structures is one every 50 y. The corresponding frequency of damaging high winds is once in 25 y. During a strong earthquake, the probability of structure damage is 0.1. During high winds, the damage probability is 0.05. Assume that earthquakes and high winds can be described by independent Poisson random variables and that the damage caused by these events are independent. Let us answer the following questions:

1. What is the probability of having strong winds but not large earthquakes during a 10y period?
2. What is the probability of having strong winds and large earthquakes in the 10y period?
3. What is the probability of building damage during the 10y period?

Considering the first question, let the random variables X and Y represent the number of earthquakes and the number of occurrences of high winds, respectively. We assume that the two random variables are statistically independent. The means of X and Y are, respectively, given by

$$\lambda_X = \frac{1}{50\,\mathrm{y}}\,(10\,\mathrm{y}) = 0.2$$

and

$$\lambda_Y = \frac{1}{25\,\mathrm{y}}\,(10\,\mathrm{y}) = 0.4\,.$$

The conditional damage probabilities are given as follows:

$$P(\text{damage/earthquake}) = 0.1$$

and

$$P(\text{damage/wind}) = 0.05.$$

Let event

A = {strong winds and no earthquakes},
B = {strong winds and large earthquakes},
C = {building damage}.

Assuming that the winds and earthquakes are independent of each other, the probability of having strong winds but not earthquakes during the 10 y period can be written as

$$\begin{aligned} P(A) &= P(\text{winds})P(\text{no earthquakes}) \\ &= [1 - P(\text{no winds})]P(\text{no earthquakes}) \end{aligned}$$

Therefore, we obtain

$$P(A) = (1 - \mathrm{e}^{-0.4})(\mathrm{e}^{-0.2}) = 0.27$$

For the second question, the probability of having strong winds and earthquakes during the 10 y period can be obtained from

$$\begin{aligned} P(B) &= P(\text{winds})P(\text{earthquakes}) \\ &= [1 - P(\text{no winds})][1 - P(\text{no earthquakes})] \\ &= (1 - \mathrm{e}^{-0.4})(1 - \mathrm{e}^{-0.2}) = 0.06\,. \end{aligned}$$

Finally, for the third question, we assume that multiple occurrences of earthquakes and high winds do not occur during the 10 y period. Therefore, the probability of

building damage can be written as

$$\begin{aligned} P(C) &= P(\text{damage/earthquakes})P(\text{earthquakes}) \\ &\quad + P(\text{damage/wind})P(\text{wind}) \\ &\quad - P(\text{damage/earthquakes and wind}) \\ &\quad P(\text{earthquake and wind}) \\ &= P(\text{damage/earthquakes})P(\text{earthquakes}) \\ &\quad + P(\text{damage/wind})P(\text{wind}) \\ &\quad - P(\text{damage/earthquakes})P(\text{damage/wind}) \\ &\quad P(\text{earthquake and wind}) \\ &= (1-\mathrm{e}^{-0.2})(0.1)+(1-\mathrm{e}^{-0.4})(0.05) \\ &\quad -(0.05)(0.1)(0.06) \\ &= 0.0343\,. \end{aligned}$$

Geometric Distribution

Consider a sequence of independent trials where each trial has the same probability of success, p. Let N be a random variable representing the number of trials until the first success. This distribution is called the geometric distribution. It has a pdf given by

$$P(N=n) = p\,(1-p)^{n-1}\,, \quad n = 1, 2, \ldots\,.$$

The corresponding cdf is

$$F(n) = 1-(1-p)^{n}\,, \quad n = 1, 2, \ldots\,.$$

The expected value and the variance are, respectively,

$$E(N) = \frac{1}{p}$$

and

$$V(N) = \frac{1-p}{p^2}.$$

Hypergeometric Distribution

The hypergeometric distribution is a discrete distribution that arises in sampling, for example. It has a pdf given by

$$f(x) = \frac{\binom{k}{x}\binom{N-k}{n-x}}{\binom{N}{n}} \quad x = 0, 1, 2, \ldots, n. \tag{1.7}$$

Typically, N will be the number of units in a finite population; n will be the number of samples drawn without replacement from N; k will be the number of failures in the population; and x will be the number of failures in the sample.

The expected value and variance of the hypergeometric random variable X are, respectively

$$E(X) = \frac{nk}{N}$$

and

$$V(X) = \frac{k(N-k)n(N-n)}{N^2(N-1)}.$$

1.2.2 Continuous Distributions

Exponential Distribution

The exponential distribution plays an essential role in reliability engineering because it has a constant failure rate. It has been used to model the lifetimes of electronic and electrical components and systems. This distribution is applicable to the case where a used component that has not failed is as good as a new component – a rather restrictive assumption. It should therefore be used carefully, since there are numerous situations where this assumption (known as the "memoryless property" of the distribution) is not valid.

If the time to failure is described by an exponential failure time density function, then

$$f(t) = \frac{1}{\theta}\,\mathrm{e}^{-\frac{t}{\theta}}, \quad t \geq 0,\ \theta > 0 \tag{1.8}$$

and this will lead to the reliability function

$$R(t) = \int_t^\infty \frac{1}{\theta}\,\mathrm{e}^{-\frac{s}{\theta}}\,\mathrm{d}s = \mathrm{e}^{-\frac{t}{\theta}}, \quad t \geq 0,$$

where $\theta = 1/\lambda > 0$ is an MTTF's parameter and $\lambda \geq 0$ is a constant failure rate.

The hazard function or failure rate for the exponential density function is constant, i. e.,

$$h(t) = \frac{f(t)}{R(t)} = \frac{\frac{1}{\theta}\,\mathrm{e}^{-\frac{1}{\theta}}}{\mathrm{e}^{-\frac{1}{\theta}}} = \frac{1}{\theta} = \lambda.$$

The failure rate for this distribution is λ, a constant, which is the main reason for this widely used distribution. Because of its constant failure rate, the exponential is an excellent model for the long flat "intrinsic failure" portion of the bathtub curve. Since most parts and systems spend most of their lifetimes in this portion of the bathtub curve, this justifies frequent use of the exponential distribution (when early failures or wearout is not a concern). The exponential model works well for interarrival times. When these events trigger failures, the exponential lifetime model can be used.

We will now discuss some properties of the exponential distribution that can be used to understand its characteristics and when and where it can be applied.

Property 1.1

(*Memoryless property*) The exponential distribution is the only continuous distribution that satisfies

$$P\{T \geq t\} = P\{T \geq t+s | T \geq s\} \quad \text{for } t > 0,\ s > 0. \tag{1.9}$$

This result indicates that the conditional reliability function for the lifetime of a component that has survived to time s is identical to that of a new component. This term is the so-called "used as good as new" assumption.

Property 1.2

If $T_1, T_2, \ldots, T_n$, are independently and identically distributed exponential random variables (r.v.'s) with a constant failure rate λ, then

$$2\lambda \sum_{i=1}^{n} T_i \sim \chi^2(2n), \tag{1.10}$$

where $\chi^2(2n)$ is a chi-squared distribution with $2n$ degrees of freedom. This result is useful for establishing a confidence interval for λ.

Uniform Distribution

Let X be a random variable with a uniform distribution over the interval (a, b) where $a < b$. The pdf is given by

$$f(x) = \begin{cases} \frac{1}{b-a} & a \leq x \leq b \\ 0 & \text{otherwise} \end{cases}.$$

The expected value and variance are, respectively,

$$E(X) = \frac{a+b}{2}$$

and

$$V(X) = \frac{(b-a)^2}{12}.$$

Normal Distribution

The normal distribution plays an important role in classical statistics due to the *Central Limit Theorem*. In production engineering, the normal distribution primarily applies to measurements of product susceptibility and external stress. This two-parameter distribution is used to describe mechanical systems in which a failure results from some wearout effect. The normal distribution takes the well-known bell shape. This distribution is symmetrical about the mean and the spread is measured by the variance. The larger the value, the flatter the distribution. The pdf is given by

$$f(t) = \frac{1}{\sigma\sqrt{2\pi}} \mathrm{e}^{-\frac{1}{2}\left(\frac{t-\mu}{\sigma}\right)^2}, \quad -\infty < t < \infty,$$

where μ is the mean value and σ is the standard deviation. The cumulative distribution function (cdf) is

$$F(t) = \int_{-\infty}^{t} \frac{1}{\sigma\sqrt{2\pi}} \mathrm{e}^{-\frac{1}{2}\left(\frac{s-\mu}{\sigma}\right)^2} \mathrm{d}s.$$

The reliability function is

$$R(t) = \int_{t}^{\infty} \frac{1}{\sigma\sqrt{2\pi}} \mathrm{e}^{-\frac{1}{2}\left(\frac{s-\mu}{\sigma}\right)^2} \mathrm{d}s.$$

There is no closed-form solution for the above equation. However, tables for the standard normal density function are readily available (see Table 1.6 in Sect. 1.A) and can be used to find probabilities for any normal distribution. If

$$Z = \frac{T-\mu}{\sigma}$$

is substituted into the normal pdf, we obtain

$$f(z) = \frac{1}{\sqrt{2\pi}} \mathrm{e}^{-\frac{z^2}{2}}, \quad -\infty < Z < \infty.$$

This is a so-called standard normal pdf, with a mean value of 0 and a standard deviation of 1. The standardized cdf is given by

$$\Phi(t) = \int_{-\infty}^{t} \frac{1}{\sqrt{2\pi}} \mathrm{e}^{-\frac{1}{2}s^2} \mathrm{d}s, \tag{1.11}$$

where Φ is a standard normal distribution function. Thus, for a normal random variable T, with mean μ and standard deviation σ,

$$P(T \leq t) = P\left(Z \leq \frac{t-\mu}{\sigma}\right) = \Phi\left(\frac{t-\mu}{\sigma}\right),$$

where Φ yields the relationship required if standard normal tables are to be used.

It should be noted that the coefficent of kurtosis in the normal distribution is 3. The hazard function for a normal distribution is a monotonically increasing function

of t. This is easily shown by proving that $h'(t) \geq 0$ for all t. Since

$$h(t) = \frac{f(t)}{R(t)}$$

then

$$h'(t) = \frac{R(t)f'(t) + f^2(t)}{R^2(t)} \geq 0.$$

One can attempt this proof by using the basic definition of a normal density function f.

Example 1.4: A component has a normal distribution of failure times with $\mu = 2000\,\text{h}$ and $\sigma = 100\,\text{h}$. The reliability of the component at 1900 h is required.

Note that the reliability function is related to the standard normal deviate z by

$$R(t) = P\left(Z > \frac{t-\mu}{\sigma}\right),$$

where the distribution function for Z is given by (1.11). For this particular application,

$$\begin{aligned} R(1900) &= P\left(Z > \frac{1900-2000}{100}\right) \\ &= P(z > -1). \end{aligned}$$

From the standard normal table in Table 1.6 in Sect. 1.A, we obtain

$$R(1,900) = 1 - \Phi(-1) = 0.8413.$$

The value of the hazard function is found from the relationship

$$h(t) = \frac{f(t)}{R(t)} = \frac{\Phi\left(\frac{t-\mu}{\sigma}\right)}{\sigma R(t)},$$

where Φ is the pdf of the standard normal density. Here

$$\begin{aligned} h(1900) &= \frac{\Phi(-1.0)}{\sigma R(t)} = \frac{0.1587}{100(0.8413)} \\ &= 0.0019 \text{ failures/cycle}. \end{aligned}$$

The normal distribution is flexible enough to make it a very useful empirical model. It can be theoretical derived under assumptions matching many failure mechanisms. Some of these are: corrosion, migration, crack growth, and failures resulting from chemical reactions or processes in general. That does not mean that the normal distribution is always the correct model for these mechanisms, but it does perhaps explain why it has been empirically successful in so many of these cases.

Log Normal Distribution

The log normal lifetime distribution is a very flexible model that can empirically fit many types of failure data. This distribution, when applied in mechanical reliability engineering, is able to model failure probabilities of repairable systems, the compressive strength of concrete cubes, the tensile strength of fibers, and the uncertainty in failure rate information. The log normal density function is given by

$$f(t) = \frac{1}{\sigma t\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\ln t-\mu}{\sigma}\right)^2}, \quad t \geq 0, \tag{1.12}$$

where μ and σ are parameters such that $-\infty < \mu < \infty$, and $\sigma > 0$. Note that μ and σ are not the mean and standard deviations of the distribution.

Its relationship to the normal (just take natural logarithms of all of the data and time points and you have "normal" data) makes it easy to work with many good software analysis programs used to treat normal data.

Mathematically, if a random variable X is defined as $X = \ln T$, then X is normally distributed with a mean of μ and a variance of σ^2. That is,

$$E(X) = E(\ln T) = \mu$$

and

$$V(X) = V(\ln T) = \sigma^2.$$

Since $T = e^X$, the mean of the log normal distribution can be found via the normal distribution. Consider that

$$E(T) = E(e^X) = \int_{-\infty}^{\infty} \frac{1}{\sigma\sqrt{2\pi}} e^{\left[x - \frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2\right]} dx.$$

By rearranging the exponent, this integral becomes

$$E(T) = e^{\mu+\frac{\sigma^2}{2}} \int_{-\infty}^{\infty} \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2\sigma^2}\left[x-(\mu+\sigma^2)\right]^2} dx.$$

Thus, the mean of the log normal distribution is

$$E(T) = e^{\mu+\frac{\sigma^2}{2}}.$$

Proceeding in a similar manner,

$$E(T^2) = E(e^{2X}) = e^{2(\mu+\sigma^2)}$$

so the variance for the log normal is

$$V(T) = e^{2\mu+\sigma^2}(e^{\sigma^2} - 1).$$

The coefficient of skewness of this distribution is

$$S_c = \frac{e^{3\sigma^2} - 3e^{\sigma^2} + 2}{\left(e^{\sigma^2} - 1\right)^{\frac{3}{2}}}.$$

It is interesting that the skewness coefficient does not depend on μ and grows rapidly as the variance σ^2 increases.

The cumulative distribution function for the log normal is

$$F(t) = \int_0^t \frac{1}{\sigma s\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\ln s - \mu}{\sigma}\right)^2} ds$$

and this can be related to the standard normal deviate Z by

$$F(t) = P(T \le t) = P(\ln T \le \ln t) = P\left(Z \le \frac{\ln t - \mu}{\sigma}\right).$$

Therefore, the reliability function is given by

$$R(t) = P\left(Z > \frac{\ln t - \mu}{\sigma}\right) \tag{1.13}$$

and the hazard function would be

$$h(t) = \frac{f(t)}{R(t)} = \frac{\Phi\left(\frac{\ln t - \mu}{\sigma}\right)}{\sigma t R(t)}$$

where Φ is the cdf of standard normal density.

The log normal lifetime model, like the normal, is flexible enough to make it a very useful empirical model. It can be theoretically derived under assumptions matching many failure mechanisms, including corrosion, migration, crack growth and failures resulting from chemical reactions or processes in general. As with the normal distribution, this does not mean that the log normal is always the correct model for these mechanisms, but it suggests why it has been empirically successful in so many of these cases.

Student's *t* Distribution

Student's t probability density function of a random variable T is given by:

$$f(t) = \frac{\Gamma\left(\frac{r+1}{2}\right)}{\sqrt{\pi}\Gamma\left(\frac{r}{2}\right)\left(1 + \frac{t^2}{r}\right)^{\frac{r+1}{2}}} \quad \text{for } -\infty < t < \infty. \tag{1.14}$$

In other words, if a random variable T is defined as

$$T = \frac{W}{\sqrt{\frac{V}{r}}},$$

where W is a standard normal random variable and V has a chi-square distribution with r degrees of freedom, and W and V are statistically independent, then T is Student's t-distributed, and parameter r is referred to as the degrees of freedom (see Table 1.7 in Sect. 1.A).

The *F* Distribution

Let us define the random variable F is as follows

$$F = \frac{U/r_1}{V/r_2},$$

where U has a chi-square distribution with r_1 degrees of freedom, V is also chi-square-distributed, with r_2 degrees of freedom, and U and V are statistically independent, then the probability density function of F is given by

$$f(t) = \frac{\Gamma\left(\frac{r_1+r_2}{2}\right)\left(\frac{r_1}{r_2}\right)^{\frac{r_1}{2}}(t)^{\frac{r_1}{2}-1}}{\Gamma\left(\frac{r_1}{2}\right)\Gamma\left(\frac{r_2}{2}\right)\left(1 + \frac{r_1 t}{r_2}\right)^{\frac{r_1+r_2}{2}}} \quad \text{for } t > 0. \tag{1.15}$$

The F distribution is a two-parameter – r_1 and r_2 – distribution where the parameters are the degrees of freedom of the underlying chi-square random variables (see Table 1.8 in Sect. 1.A).

It is worth noting that if T is a random variable with a t distribution and r degrees of freedom, then the random variable T^2 has an F distribution with parameters $r_1 = 1$ and $r_2 = r$. Similarly, if F is F-distributed with r_1 and r_2 degrees of freedom, then the random variable Y, defined as

$$Y = \frac{r_1 F}{r_2 + r_1 F}$$

has a beta distribution with parameters $r_1/2$ and $r_2/2$.

Weibull Distribution

The exponential distribution is often limited in applicability owing to its memoryless property. The Weibull distribution [1.2] is a generalization of the exponential distribution and is commonly used to represent fatigue life, ball-bearing life and vacuum tube life. The Weibull distribution is extremely flexible and appropriate for modeling component lifetimes with fluctuating hazard rate functions and is used to represent various

types of engineering applications. The three-parameter probability density function is

$$f(t) = \frac{\beta(t-\gamma)^{\beta-1}}{\theta^{\beta}} \, \mathrm{e}^{-\left(\frac{t-\gamma}{\theta}\right)^{\beta}}, \quad t \geq \gamma \geq 0, \tag{1.16}$$

where θ and β are known as the scale and shape parameters, respectively, and γ is known as the location parameter. These parameters are always positive. By using different parameters, this distribution can follow the exponential distribution, the normal distribution, etc. It is clear that, for $t \geq \gamma$, the reliability function $R(t)$ is

$$R(t) = \mathrm{e}^{-\left(\frac{t-\gamma}{\theta}\right)^{\beta}} \quad \text{for } t > \gamma > 0,\ \beta > 0,\ \theta > 0 \tag{1.17}$$

hence,

$$h(t) = \frac{\beta(t-\gamma)^{\beta-1}}{\theta^{\beta}}, \quad t > \gamma > 0,\ \beta > 0,\ \theta > 0. \tag{1.18}$$

It can be shown that the hazard function decreases for $\beta < 1$, increases for $\beta > 1$, and is constant when $\beta = 1$.

Note that the Rayleigh and exponential distributions are special cases of the Weibull distribution at $\beta = 2$, $\gamma = 0$, and $\beta = 1$, $\gamma = 0$, respectively. For example, when $\beta = 1$ and $\gamma = 0$, the reliability of the Weibull distribution function in (1.17) reduces to

$$R(t) = \mathrm{e}^{-\frac{t}{\theta}}$$

and the hazard function given in (1.18) reduces to $1/\theta$, a constant. Thus, the exponential is a special case of the Weibull distribution. Similarly, when $\gamma = 0$ and $\beta = 2$, the Weibull probability density function becomes the Rayleigh density function. That is,

$$f(t) = \frac{2}{\theta} t \, \mathrm{e}^{-\frac{t^2}{\theta}} \quad \text{for } \theta > 0,\ t \geq 0.$$

Other Forms of Weibull Distributions

The Weibull distribution is widely used in engineering applications. It was originally proposed in order to represent breaking strength distributions of materials. The Weibull model is very flexible and has also been applied in many applications as a purely empirical model, with theoretical justification. Other forms of Weibull probability density function include, for example,

$$f(x) = \lambda\gamma x^{\gamma-1} \, \mathrm{e}^{-\lambda t^{\gamma}}. \tag{1.19}$$

When $\gamma = 2$, the density function becomes a Rayleigh distribution.

It is easy to show that the mean, variance and reliability of the above Weibull distribution are, respectively:

$$\begin{aligned} \text{Mean} &= \lambda^{\frac{1}{\gamma}} \Gamma\left(1 + \frac{1}{\gamma}\right); \\ \text{Variance} &= \lambda^{\frac{2}{\gamma}} \left\{ \Gamma\left(1 + \frac{2}{\gamma}\right) - \left[\Gamma\left(1 + \frac{1}{\gamma}\right)\right]^2 \right\}; \\ \text{Reliability} &= \mathrm{e}^{-\lambda t^{\gamma}}. \end{aligned} \tag{1.20}$$

Example 1.5: The time to failure of a part has a Weibull distribution with $\frac{1}{\lambda} = 250$ (measured in 10^5 cycles) and $\gamma = 2$. The part reliability at 10^6 cycles is given by:

$$R(10^6) = \mathrm{e}^{-(10)^2/250} = 0.6703.$$

The resulting reliability function is shown in Fig. 1.1.

Gamma Distribution

The gamma distribution can be used as a failure probability function for components whose distribution is skewed. The failure density function for a gamma distribution is

$$f(t) = \frac{t^{\alpha-1}}{\beta^{\alpha}\Gamma(\alpha)} \mathrm{e}^{-\frac{t}{\beta}}, \quad t \geq 0,\ \alpha,\ \beta > 0, \tag{1.21}$$

where α is the shape parameter and β is the scale parameter. In this expression, $\Gamma(\alpha)$ is the gamma function, which is defined as

$$\Gamma(\alpha) = \int_0^{\infty} t^{\alpha-1} \mathrm{e}^{-t} \, \mathrm{d}t \quad \text{for } \alpha > 0.$$

Hence,

$$R(t) = \int_t^{\infty} \frac{1}{\beta^{\alpha}\Gamma(\alpha)} s^{\alpha-1} \mathrm{e}^{-\frac{s}{\beta}} \, \mathrm{d}s.$$

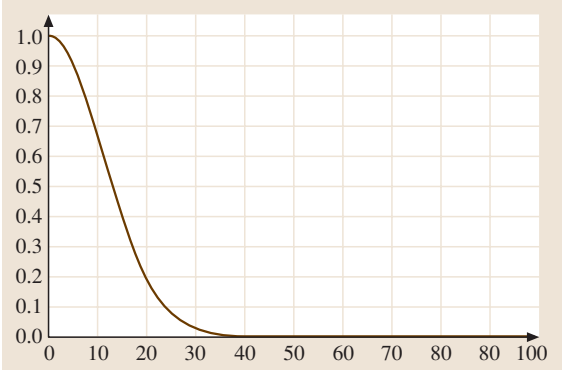

Fig. 1.1 Weibull reliability function versus time

If α is an integer, it can be shown by successive integration by parts that

$$R(t) = \mathrm{e}^{-\frac{t}{\beta}} \sum_{i=0}^{\alpha-1} \frac{\left(\frac{t}{\beta}\right)^i}{i!} \tag{1.22}$$

and

$$h(t) = \frac{f(t)}{R(t)} = \frac{\frac{1}{\beta^\alpha \Gamma(\alpha)} t^{\alpha-1} \mathrm{e}^{-\frac{t}{\beta}}}{\mathrm{e}^{-\frac{t}{\beta}} \sum_{i=0}^{\alpha-1} \frac{\left(\frac{t}{\beta}\right)^i}{i!}}. \tag{1.23}$$

The gamma density function has shapes that are very similar to the Weibull distribution. At $\alpha = 1$, the gamma distribution becomes the exponential distribution with a constant failure rate $1/\beta$. The gamma distribution can also be used to model the time to the nth failure of a system if the underlying failure distribution is exponential. Thus, if X_i is exponentially distributed with parameter $\theta = 1/\beta$, then $T = X_1 + X_2 + \cdots + X_n$ is gamma-distributed with parameters β and n.

Example 1.6: The time to failure of a component has a gamma distribution with $\alpha = 3$ and $\beta = 5$. Obtain the reliability of the component and the hazard rate at 10 time units.

Using (1.22), we compute

$$R(10) = \mathrm{e}^{-\frac{10}{5}} \sum_{i=0}^{2} \frac{\left(\frac{10}{5}\right)^i}{i!} = 0.6767\,.$$

The hazard rate is given by

$$h(10) = \frac{f(10)}{R(10)} = \frac{0.054}{0.6767} = 0.798 \text{ failures/unit time.}$$

The other form of the gamma probability density function can be written as follows:

$$f(x) = \frac{\beta^\alpha t^{\alpha-1}}{\Gamma(\alpha)} \mathrm{e}^{-t\beta}, \quad t > 0. \tag{1.24}$$

This pdf is characterized by two parameters: the shape parameter α and the scale parameter β. When $0 < \alpha < 1$, the failure rate monotonically decreases; when $\alpha > 1$, the failure rate monotonically increases; when $\alpha = 1$ the failure rate is constant.

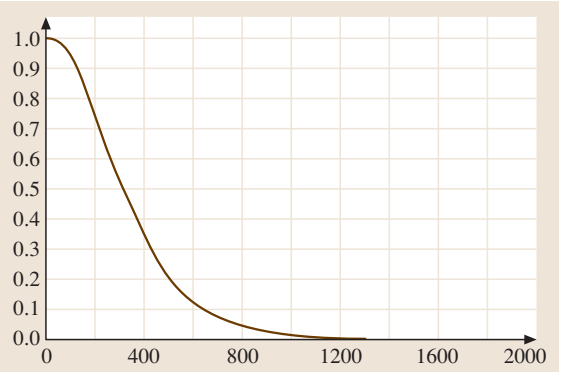

Fig. 1.2 Gamma reliability function versus time

The mean, variance and reliability of the gamma random variable are:

$$\text{Mean (MTTF)} = \frac{\alpha}{\beta};$$

$$\text{Variance} = \frac{\alpha}{\beta^2};$$

$$\text{Reliability} = \int_t^\infty \frac{\beta^\alpha x^{\alpha-1}}{\Gamma(\alpha)} \mathrm{e}^{-x\beta}\,\mathrm{d}x.$$

Example 1.7: A mechanical system time to failure is gamma-distributed with $\alpha = 3$ and $1/\beta = 120$. The system reliability at 280 h is given by

$$R(280) = \mathrm{e}^{\frac{-280}{120}} \sum_{k=0}^{2} \frac{\left(\frac{280}{120}\right)^2}{k!} = 0.851\,19$$

and the resulting reliability plot is shown in Fig. 1.2.

The gamma model is a flexible lifetime model that may offer a good fit to some sets of failure data. Although it is not widely used as a lifetime distribution model for common failure mechanisms, the gamma lifetime model is commonly used in Bayesian reliability applications.

Beta Distribution

The two-parameter beta density function $f(t)$ is given by

$$f(t) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)} t^{\alpha-1}(1-t)^{\beta-1}\,,$$
$$0 < t < 1,\ \alpha > 0,\ \beta > 0\,, \tag{1.25}$$

where α and β are the distribution parameters. This two-parameter beta distribution is commonly used in many reliability engineering applications and also

plays an important role in the theory of statistics. Note that the beta-distributed random variable takes on values in the interval (0, 1), so the beta distribution is a natural model when the random variable represents a probability. Likewise, when $\alpha = \beta = 1$, the beta distribution reduces to a uniform distribution.

The mean and variance of the beta random variable are, respectively,

$$E(T) = \frac{\alpha}{\alpha + \beta}$$

and

$$V(T) = \frac{\alpha\beta}{(\alpha + \beta + 1)(\alpha + \beta)^2}.$$

Pareto Distribution

The Pareto distribution was originally developed to model income in a population. Phenomena such as city population size, stock price fluctuations and personal incomes have distributions with very long right tails. The probability density function of the Pareto distribution is given by

$$f(t) = \frac{\alpha k^\alpha}{t^{\alpha+1}}, \quad k \le t \le \infty. \tag{1.26}$$

The mean, variance and reliability of the Pareto distribution are:

$$\text{Mean} = k/(\alpha - 1) \quad \text{for } > 1;$$
$$\text{Variance} = \alpha k^2/[(\alpha - 1)^2(\alpha - 2)] \quad \text{for } \alpha > 2;$$
$$\text{Reliability} = \left(\frac{k}{t}\right)^\alpha.$$

The Pareto and log normal distributions are commonly used to model population size and economical incomes. The Pareto is used to fit the tail of the distribution, and the log normal is used to fit the rest of the distribution.

Rayleigh Distribution

The Rayleigh model is a flexible lifetime model that can apply to many degradation process failure modes. The Rayleigh probability density function is

$$f(t) = \frac{t}{\sigma^2} \exp\left(\frac{-t^2}{2\sigma^2}\right). \tag{1.27}$$

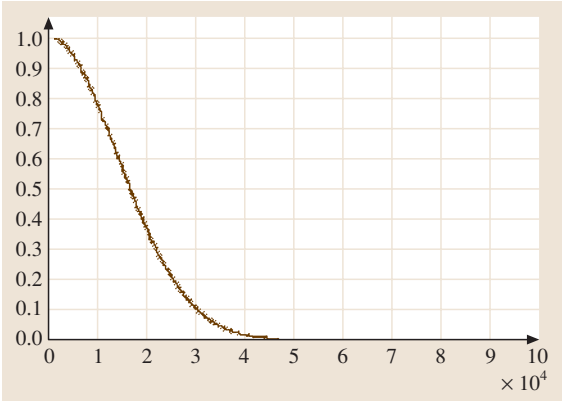

Fig. 1.3 Rayleigh reliability function versus time

The mean, variance and reliability of the Rayleigh function are:

$$\text{Mean} = \sigma\left(\frac{\pi}{2}\right)^{\frac{1}{2}};$$
$$\text{Variance} = \left(2 - \frac{\pi}{2}\right)\sigma^2;$$
$$\text{Reliability} = \mathrm{e}^{\frac{-\sigma t^2}{2}}.$$

Example 1.8: Rolling resistance is a measure of the energy lost by a tire under load when it resists the force opposing its direction of travel. In a typical car traveling at sixty miles per hour, about 20% of the engine power is used to overcome the rolling resistance of the tires. A tire manufacturer introduces a new material that, when added to the tire rubber compound, significantly improves the tire rolling resistance but increases the wear rate of the tire tread. Analysis of a laboratory test of 150 tires shows that the failure rate of the new tire increases linearly with time (h). This is expressed as

$$h(t) = 0.5 \times 10^{-8} t.$$

The reliability of the tire after one year (8760 h) of use is

$$R(1\text{ y}) = \mathrm{e}^{-\frac{0.5}{2} \times 10^{-8} \times (8760)^2} = 0.8254.$$

Figure 1.3 shows the resulting reliability function.

Vtub-Shaped Hazard Rate Distribution

Pham recently developed a two-parameter lifetime distribution with a Vtub-shaped hazard rate, known as

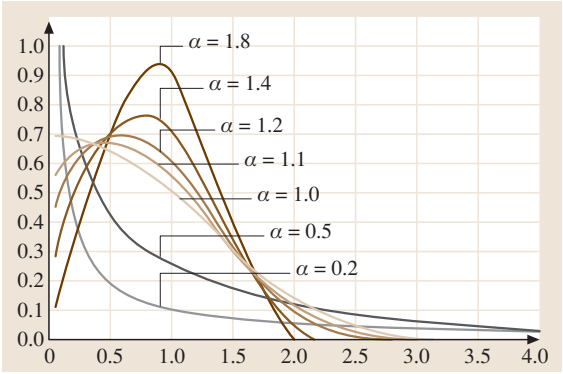

Fig. 1.4 Probability density function for various values of α with $a = 2$

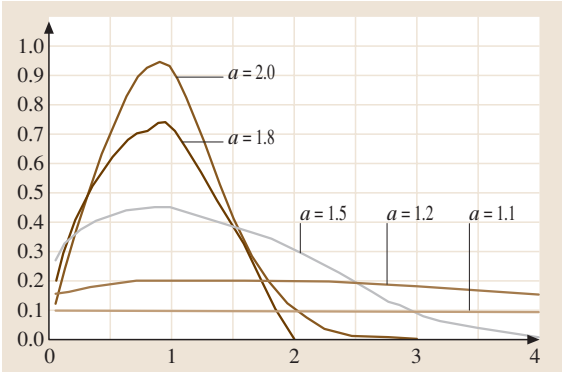

Fig. 1.5 Probability density function for various values of a with $\alpha = 1.5$

a *loglog distribution with a Vtub-shaped hazard rate* or a *Pham distribution* for short [1.3].

Note that the loglog distribution with a Vtub-shaped hazard rate and the Weibull distribution with bathtub-shaped failure rates are not the same. For the bathtub-shaped failure rate, after an initial "infant mortality period", the useful life of the system begins. During its useful life, the system fails at a constant rate. This period is then followed by a wearout period during which the system failure rate slowly increases with the onset of wearout. For the Vtub-shaped, after the infant mortality period, the system experiences a relatively low but increasing failure rate. The failure rate increases due to aging.

The Pham probability density function is given as follows [1.3]:

$$f(t) = \alpha \ln a t^{\alpha-1} a^{t^\alpha} \mathrm{e}^{1-a^{t^\alpha}}$$
$$\text{for } t > 0,\ a > 0,\ \alpha > 0. \tag{1.28}$$

The Pham distribution and reliability functions are

$$F(t) = \int_0^t f(x)\,\mathrm{d}x = 1 - \mathrm{e}^{1-a^{t^\alpha}}$$

and

$$R(t) = \mathrm{e}^{1-a^{t^\alpha}}, \tag{1.29}$$

respectively. The corresponding failure rate of the Pham distribution is given by

$$h(t) = \alpha \ln a t^{\alpha-1} a^{t^\alpha}. \tag{1.30}$$

Figures 1.4 and 1.5 describe the density functions and failure rate functions for various values of a and α.

Two-Parameter Hazard Rate Function

This is a two-parameter function that can have increasing and decreasing hazard rates. The hazard rate $h(t)$, the reliability function $R(t)$ and the pdf are, respectively, given as follows

$$h(t) = \frac{n\lambda t^{n-1}}{\lambda t^n + 1} \quad \text{for } n \geq 1,\ \lambda > 0,\ t \geq 0, \tag{1.31}$$
$$R(t) = \mathrm{e}^{-\ln(\lambda t^N + 1)}$$

and

$$f(t) = \frac{n\lambda t^{n-1}}{\lambda t^n + 1} \mathrm{e}^{-\ln(\lambda t^n + 1)}, \quad n \geq 1,\ \lambda > 0,\ t \geq 0,$$

where n = shape parameter; λ = scale parameter.

Three-Parameter Hazard Rate Function

This is a three-parameter distribution that can have increasing and decreasing hazard rates. The hazard rate $h(t)$ is given as

$$h(t) = \frac{\lambda(b+1)[\ln(\lambda t + \alpha)]^b}{(\lambda t + \alpha)},$$
$$b \geq 0,\ \lambda > 0,\ \alpha \geq 0,\ t \geq 0. \tag{1.32}$$

The reliability function $R(t)$ for $\alpha = 1$ is

$$R(t) = \mathrm{e}^{-[\ln(\lambda t + \alpha)]^{b+1}}.$$

The probability density function $f(t)$ is

$$f(t) = \mathrm{e}^{-[\ln(\lambda t + \alpha)]^{b+1}} \frac{\lambda(b+1)[\ln(\lambda t + \alpha)]^b}{(\lambda t + \alpha)},$$

where $b =$ shape parameter; $\lambda =$ scale parameter, and $\alpha =$ location parameter.

Extreme-Value Distribution

The extreme-value distribution can be used to model external events such as floods, tornadoes, hurricanes and high winds in risk applications. The cdf of this distribution is given by

$$F(t) = \mathrm{e}^{-\mathrm{e}^{y}} \quad \text{for } -\infty < t < \infty. \tag{1.33}$$

Cauchy Distribution

The Cauchy distribution can be applied when analyzing communication systems where two signals are received and one is interested in modeling the ratio of the two signals. The Cauchy probability density function is given by

$$f(t) = \frac{1}{\pi(1+t^2)} \quad \text{for } -\infty < t < \infty. \tag{1.34}$$

It is worth noting that the ratio of two standard normal random variables is a random variable with a Cauchy distribution.

1.3 Statistical Inference and Estimation

The problem of "point estimation" is that of estimating the parameters of a population, such as λ or θ from an exponential, μ and σ^2 from a normal, etc. It is assumed that the type of population distribution involved is known, but the distribution parameters are unknown and they must be estimated using collected failure data. This section is devoted to the theory of estimation and discusses several common estimation techniques, such as maximum likelihood, method of moments, least squared estimation, and Bayesian methods. We also discuss confidence interval and tolerance limit estimation. For example, assume that n independent samples are drawn from the exponential density function $f(x;\lambda) = \lambda\,\mathrm{e}^{-\lambda x}$ for $x > 0$ and $\lambda > 0$. Then the joint probability density function (pdf) or sample density (for short) is given by

$$f(x_1,\lambda)\cdot f(x_1,\lambda)\cdots f(x_1,\lambda) = \lambda^n\,\mathrm{e}^{-\lambda\sum_{i-1}^{n} x_i}. \tag{1.35}$$

The problem here is to find a "good" point estimate of λ, which is denoted by $\hat{\lambda}$. In other words, we want to find a function $h(X_1, X_2, \ldots, X_n)$ such that, if $x_1, x_2, \ldots, x_n$ are the observed experimental values of $X_1, X_2, \ldots, X_n$, the value $h(x_1, x_2, \ldots, x_n)$ will be a good point estimate of λ. By "good", we mean that it possesses the following properties:

- unbiasedness,
- consistency,
- efficiency (minimum variance),
- sufficiency.

In other words, if $\hat{\lambda}$ is a good point estimate of λ, then one can select a function $h(X_1, X_2, \ldots, X_n)$ where $h(X_1, X_2, \ldots, X_n)$ is an unbiased estimator of λ and the variance of $h(X_1, X_2, \ldots, X_n)$ is a minimum. We will now present the following definitions.

Unbiasedness. For a given positive integer n, the statistic $Y = h(X_1, X_2, \ldots, X_n)$ is called an unbiased estimator of the parameter θ if the expectation of Y is equal to a parameter θ; that is,

$$E(Y) = \theta.$$

Consistency. The statistic Y is called a consistent estimator of the parameter θ if Y converges stochastically to a parameter θ as n approaches infinity. If ε is an arbitrarily small positive number when Y is consistent, then

$$\lim_{n\to\infty} P(|Y-\theta| \le \varepsilon) = 1.$$

Minimum Variance. The statistic Y is called the minimum variance unbiased estimator of the parameter θ if Y is unbiased and the variance of Y is less than or equal to the variance of every other unbiased estimator of θ. An estimator that has the property of minimum variance in large samples is said to be efficient.

Sufficiency. The statistic Y is said to be sufficient for θ if the conditional distribution of X, given that $Y = y$, is independent of θ.

This is useful when determining a lower bound on the variance of all unbiased estimators. We now establish a lower bound inequality known as the *Cramér–Rao inequality*.

Cramér–Rao Inequality. Let $X_1, X_2, \ldots, X_n$ denote a random sample from a distribution with pdf $f(x;\theta)$ for $\theta_1 < \theta < \theta_2$, where θ_1 and θ_2 are known. Let $Y =$

$h(X_1, X_2, \ldots, X_n)$ be an unbiased estimator of θ. The lower bound inequality on the variance of Y, $\mathrm{Var}(Y)$, is given by

$$\mathrm{Var}(Y) \geq \frac{1}{nE\left[\left(\frac{\partial \ln f(x;\theta)}{\partial\theta}\right)^2\right]} = \frac{1}{-nE\left(\frac{\partial^2 \ln f(x;\theta)}{\partial\theta^2}\right)}. \tag{1.36}$$

Theorem 1.1

An estimator $\hat{\theta}$ is said to be asymptotically efficient if $\sqrt{n}\hat{\theta}$ has a variance that approaches the Cramér–Rao lower bound for large n; that is,

$$\lim_{n\to\infty} \mathrm{Var}(\sqrt{n}\hat{\theta}) = \frac{1}{-nE\left(\frac{\partial^2 \ln f(x;\theta)}{\partial\theta^2}\right)}. \tag{1.37}$$

1.3.1 Parameter Estimation

We now discuss some basic methods of parameter estimation, including the method of maximum likelihood estimation (MLE) and the method of moments. The assumption that the sample is representative of the population will be made both in the example and in later discussions.

Maximum Likelihood Estimation Method

In general, one deals with a sample density

$$f(x_1, x_2, \ldots, x_n) = f(x_1;\theta) f(x_2;\theta) \ldots f(x_n;\theta),$$

where $x_1, x_2, \ldots, x_n$ are random, independent observations of a population with density function $f(x)$.

For the general case, we would like to find an estimate or estimates, $\hat{\theta}_1, \hat{\theta}_2, \ldots, \hat{\theta}_m$ (if such exist), where

$$f(x_1, x_2, \ldots, x_n; \theta_1, \theta_2, \ldots, \theta_m) >$$
$$f(x_1, x_2, \ldots, x_n; \theta_1', \theta_2', \ldots, \theta_m').$$

The notation $\theta_1', \theta_2', \ldots, \theta_n'$ refers to any other estimates different to $\hat{\theta}_1, \hat{\theta}_2, \ldots, \hat{\theta}_m$.

Consider a random sample $X_1, X_2, \ldots, X_n$ from a distribution with a pdf $f(x;\theta)$. This distribution has a vector $\theta = (\theta_1, \theta_2, \ldots, \theta_m)'$ of unknown parameters associated with it, where m is the number of unknown parameters. Assuming that the random variables are independent, then the likelihood function, $L(X;\theta)$, is the product of the probability density function evaluated at each sample point

$$L(X,\theta) = \prod_{i=1}^{n} f(X_i;\theta), \tag{1.38}$$

where $\boldsymbol{X} = (X_1, X_2, \ldots, X_n)$. The maximum likelihood estimator $\hat{\theta}$ is found by maximizing $L(\boldsymbol{X};\theta)$ with respect to θ. In practice, it is often easier to maximize $\ln[L(\boldsymbol{X};\theta)]$ in order to find the vector of MLEs, which is valid because the logarithmic function is monotonic. The log likelihood function is given by

$$\ln L(X,\theta) = \sum_{i=1}^{n} \ln f(X_i;\theta) \tag{1.39}$$

and is asymptotically normally distributed since it consists of the sum of n independent variables and the central limit theorem is implied. Since $L(X;\theta)$ is a joint probability density function for $X_1, X_2, \ldots, X_n$, its integral must be 1; that is,

$$\int_0^\infty \int_0^\infty \cdots \int_0^\infty L(X;\theta)\,\mathrm{d}X = 1.$$

Assuming that the likelihood is continuous, the partial derivative of the left-hand side with respect to one of the parameters, θ_i, yields

$$\begin{aligned}
&\frac{\partial}{\partial\theta_i}\int_0^\infty \int_0^\infty \cdots \int_0^\infty L(X;\theta)\,\mathrm{d}X \\
&= \int_0^\infty \int_0^\infty \cdots \int_0^\infty \frac{\partial}{\partial\theta_i} L(X;\theta)\,\mathrm{d}X \\
&= \int_0^\infty \int_0^\infty \cdots \int_0^\infty \frac{\partial \log L\,(X;\theta)}{\partial\theta_i} L(X;\theta)\,\mathrm{d}X \\
&= E\left(\frac{\partial \log L\,(X;\theta)}{\partial\theta_i}\right) \\
&= E[U_i(\theta)] \quad \text{for } i = 1, 2, \ldots, m,
\end{aligned}$$

where $\boldsymbol{U}(\theta) = [U_1(\theta), U_2(\theta), \ldots U_n(\theta)]'$ is often called the score vector, and the vector $\boldsymbol{U}(\theta)$ has components

$$U_i(\theta) = \frac{\partial[\log L\,(X;\theta)]}{\partial\theta_i} \quad \text{for } i = 1, 2, \ldots, m \tag{1.40}$$

which, when equated to zero and solved, yields the MLE vector $\boldsymbol{\theta}$.

Suppose that we can obtain a nontrivial function of $X_1, X_2, \ldots, X_n$, say $h(X_1, X_2, \ldots, X_n)$, such that, when θ is replaced by $h(X_1, X_2, \ldots, X_n)$, the likelihood function L will achieve a maximum. In other words,

$$L[X, h(X)] \geq L(X,\theta)$$

for every θ. The statistic $h(X_1, X_2, \ldots, X_n)$ is called a maximum likelihood estimator of θ and will be denoted as

$$\hat{\theta} = h(x_1, x_2, \ldots, x_n). \tag{1.41}$$

The observed value of $\hat{\theta}$ is called the MLE of θ. In general, the mechanics for obtaining the MLE can be obtained as follows:

Step 1. Find the joint density function $L(X, \theta)$
Step 2. Take the natural log of the density $\ln L$
Step 3. Find the partial derivatives of $\ln L$ with respect to each parameter
Step 4. Set these partial derivatives to "zero"
Step 5. Solve for parameter(s).

Example 1.9: Let $X_1, X_2, \ldots, X_n$, denote a random sample from the normal distribution $N(\mu, \sigma^2)$. Then the likelihood function is given by

$$L(X, \mu, \sigma^2) = \left(\frac{1}{2\pi}\right)^{\frac{n}{2}} \frac{1}{\sigma^n} \mathrm{e}^{-\frac{1}{2\sigma^2}\sum_{i=1}^{n}(x_i-\mu)^2}$$

and

$$\ln L = -\frac{n}{2}\log(2\pi) - \frac{n}{2}\log\sigma^2 - \frac{1}{2\sigma^2}\sum_{i=1}^{n}(x_i-\mu)^2.$$

Thus, we have

$$\frac{\partial \ln L}{\partial \mu} = \frac{1}{\sigma^2}\sum_{i=1}^{n}(x_i-\mu) = 0,$$
$$\frac{\partial \ln L}{\partial \sigma^2} = -\frac{n}{2\sigma^2} - \frac{1}{2\sigma^4}\sum_{i=1}^{n}(x_i-\mu)^2 = 0.$$

Solving the two equations simultaneously, we obtain

$$\hat{\mu} = \frac{\sum_{i=1}^{n} x_i}{n},$$
$$\hat{\sigma}^2 = \frac{1}{n}\sum_{i=1}^{n}(x_i-\bar{x})^2.$$

Note that the MLEs, if they exist, are both sufficient and efficient estimates. They also have an additional property called invariance – in other words, for an MLE of θ, $\mu(\theta)$ is the MLE of $\mu(\theta)$. However, they are not necessarily unbiased (i. e., $E(\hat{\theta}) = \theta$). In fact, the point is that

$$E(\hat{\sigma}^2) = \left(\frac{n-1}{n}\right)\sigma^2 \neq \sigma^2.$$

Therefore, for small n, σ^2 is usually adjusted to account for this bias, and the best estimate of σ^2 is

$$\hat{\sigma}^2 = \left(\frac{1}{n-1}\right)\sum_{i=1}^{n}(x_i-\bar{x})^2.$$

Sometimes it is difficult, if not impossible, to obtain maximum likelihood estimators in a closed form, and therefore numerical methods must be used to maximize the likelihood function.

Example 1.10: Suppose that $X_1, X_2, \ldots, X_n$ is a random sample from the Weibull distribution with pdf

$$f(x, \alpha, \lambda) = \alpha\lambda x^{\alpha-1}\mathrm{e}^{-\lambda x^{\alpha}}. \tag{1.42}$$

The likelihood function is

$$L(X, \alpha, \lambda) = \alpha^n \lambda^n \prod_{i=1}^{n} x_i^{\alpha-1} \mathrm{e}^{-\lambda\sum_{i=1}^{n} x_i^{\alpha}}.$$

Then

$$\ln L = n\log\alpha + n\log\lambda + (\alpha-1)\sum_{i=1}^{n}\log x_i - \lambda\sum_{i=1}^{n} x_i^{\alpha},$$
$$\frac{\partial \ln L}{\partial \alpha} = \frac{n}{\alpha} + \sum_{i=1}^{n}\log x_i - \lambda\sum_{i=1}^{n} x_i^{\alpha}\log x_i = 0,$$
$$\frac{\partial \ln L}{\partial \lambda} = \frac{n}{\lambda} - \sum_{i=1}^{n} x_i^{\alpha} = 0.$$

As noted, solutions of the above two equations for α and λ are extremely difficult to obtain and require the application of either graphical or numerical methods. It is sometimes desirable to use a quick method of estimation, which leads to a discussion of the method of moments.

Method of Moments

Here one simply sets the sample moments equal to the corresponding population moments. For example, for the gamma distribution, the mean and the variance of

the distribution are, respectively, $\frac{\alpha}{\beta}$ and $\frac{\alpha}{\beta^2}$. Therefore, one has the following two equations in two unknowns:

$$\bar{X} = \frac{\alpha}{\beta},$$
$$S^2 = \frac{\alpha}{\beta^2}.$$

Solving these two equations simultaneously, we obtain

$$\alpha = \frac{\bar{X}^2}{S^2},$$
$$\beta = \frac{\bar{X}}{S^2}.$$

1.3.2 Maximum Likelihood Estimation with Censored Data

Censored data arises when we monitor for a random variable of interest – unit failure, for example – but the monitoring is stopped before measurements are complete (i. e. before the unit fails). In other words, censored observation contains only partial information about the random variable of interest. In this section, we consider two types of censoring. The first type of censoring is called Type I censoring, where the event is only observed if it occurs prior to some prespecified time. The second type of censoring is Type II censoring, in which the study continues until the failure of the first r units (or components), where r is some predetermined integer ($r < n$).

Examples of Type II censoring are often used when testing equipment life. Here our items are tested at the same time, and the test is terminated when r of the n items have failed. These approaches may save time and resources because it may take a very long time for all of the items to fail. Both Type I and Type II censoring arise in many reliability applications.

For example, let's say that we have a batch of transistors or tubes. We begin to test them all at $t = 0$, and record their times to failure. Some transistors may take a long time to burn out, and we will not want to wait that long to end the experiment. We might stop the experiment at a prespecified time t_c, in which case we have Type I censoring. On the other hand, we might not know what fixed value to use for the censoring time beforehand, so we decide to wait until a prespecified number of units have failed, r, in which case we have Type II censoring.

Censoring times may vary from individual to individual or from application to application. We now discuss a general case known as multiple-censored data.

Parameter Estimate with Multiple-Censored Data

The likelihood function for multiple-censored data is given by

$$\begin{aligned} L &= f(t_{1,\mathrm{f}}, \ldots, t_{r,\mathrm{f}}, t_{1,\mathrm{s}}, \ldots, t_{m,\mathrm{s}}) \\ &= C \prod_{i=1}^{r} f(t_{i,\mathrm{f}}) \prod_{j=1}^{m} [1 - F(t_{j,\mathrm{s}})], \end{aligned} \tag{1.43}$$

where C is a constant, $f(.)$ is the density function and $F(.)$ is the distribution function. There are r failures at times $t_{1,\mathrm{f}}, \ldots, t_{r,\mathrm{f}}$ and m units with censoring times $t_{1,\mathrm{s}}, \ldots, t_{m,\mathrm{s}}$.

Note that we obtain Type-I censoring by simply setting $t_{i,\mathrm{f}} = t_{i,n}$ and $t_{j,\mathrm{s}} = t_0$ in the likelihood function in (1.43). The likelihood function for Type II censoring is similar to Type I censoring except $t_{j,\mathrm{s}} = t_r$ in (1.43). In other words, the likelihood function for the first r observations from a sample of size n drawn from the model in both Type I and Type II censoring is given by

$$L = f(t_{1,n}, \ldots, t_{r,n}) = C \prod_{i=1}^{r} f(t_{i,n}) [1 - F(t_*)]^{n-r}, \tag{1.44}$$

where $t_* = t_0$, the time of cessation of the test for Type I censoring and $t_* = t_r$, the time of the rth failure for Type II censoring.

Example 1.11: Consider a two-parameter probability density distribution with multiple-censored data and a distribution function with bathtub shaped failure rate, as given by [1.4]:

$$f(t) = \lambda\beta t^{\beta-1} \exp[t^{\beta} + \lambda(1 - \mathrm{e}^{t^{\beta}})], \; t, \lambda, \beta > 0 \tag{1.45}$$

and

$$F(t) = 1 - \exp[\lambda(1 - \mathrm{e}^{t^{\beta}})], \; t, \lambda, \beta > 0, \tag{1.46}$$

respectively.

Substituting the functions $f(t)$ and $F(t)$ into (1.45) and (1.46) into (1.44), we obtain the logarithm of the likelihood function:

$$\begin{aligned} \ln L = {} & \ln C + r \ln \lambda + r \ln \beta + \sum_{i=1}^{r} (\beta - 1) \ln t_i \\ & + (m + r)\lambda + \sum_{i=1}^{r} t_i^{\beta} - \left[\sum_{i=1}^{r} \lambda \mathrm{e}^{t_i^{\beta}} + \sum_{j=1}^{m} \lambda \mathrm{e}^{t_j^{\beta}} \right]. \end{aligned}$$

The function $\ln L$ can be maximized by setting the partial derivative of $\ln L$ with respect to λ and β equal to zero,

and solving the resulting equations simultaneously for λ and β. Therefore, we obtain

$$\frac{\partial \ln L}{\partial \lambda} = \frac{r}{\lambda} + (m+r) - \sum_{i=1}^{r} e^{t_i^{\beta}} - \sum_{j=1}^{m} e^{t_j^{\beta}} \equiv 0,$$

$$\frac{\partial \ln L}{\partial \beta} = \frac{r}{\beta} + \sum_{i=1}^{r} \ln t_i + \sum_{i=1}^{r} t_i^{\beta} \ln t_i - \lambda \left(\sum_{i=1}^{r} e^{t_i^{\beta}} t_i^{\beta} \ln t_i + \sum_{j=1}^{m} e^{t_j^{\beta}} t_j^{\beta} \ln t_j \right) \equiv 0.$$

This implies that

$$\hat{\lambda} = \frac{r}{\left(\sum_{i=1}^{r} e^{t_i^{\hat{\beta}}} + \sum_{j=1}^{m} e^{t_j^{\hat{\beta}}} \right) - m - r} \tag{1.47}$$

and that $\hat{\beta}$ is the solution of

$$\frac{r}{\hat{\beta}} + \sum_{i=1}^{r} \ln t_i + \sum_{i=1}^{r} t_i^{\hat{\beta}} \ln t_i = \frac{r}{\left(\sum_{i=1}^{r} e^{t_i^{\hat{\beta}}} + \sum_{j=1}^{m} e^{t_j^{\hat{\beta}}} \right) - m - r} \left(\sum_{i=1}^{r} e^{t_i^{\hat{\beta}}} t_i^{\hat{\beta}} \ln t_i + \sum_{j=1}^{m} e^{t_j^{\hat{\beta}}} t_j^{\hat{\beta}} \ln t_j \right). \tag{1.48}$$

We now discuss two special cases.

Case 1: Type I or Type II censored data

From (1.44), the likelihood function for the first r observations from a sample of size n drawn from the model in both Type I and Type II censoring is

$$L = f(t_{1,n}, \ldots, t_{r,n}) = C \prod_{i=1}^{r} f(t_{i,n}) [1 - F(t_*)]^{n-r},$$

where $t_* = t_0$, the test cessation time for Type I censoring, and $t_* = t_r$, the time of the rth failure for Type II censoring. Equations (1.47) and (1.48) become

$$\hat{\lambda} = \frac{r}{\sum_{i=1}^{r} e^{t_i^{\hat{\beta}}} + (n-r) e^{t_*^{\hat{\beta}}} - n},$$

$$\frac{r}{\hat{\beta}} + \sum_{i=1}^{r} \ln t_i + \sum_{i=1}^{r} t_i^{\hat{\beta}} \ln t_i = \frac{r}{\sum_{i=1}^{r} e^{t_i^{\hat{\beta}}} + (n-r) e^{t_*^{\hat{\beta}}} - n} \times \left(\sum_{i=1}^{r} e^{t_i^{\hat{\beta}}} t_i^{\hat{\beta}} \ln t_i + \sum_{j=1}^{m} e^{t_j^{\hat{\beta}}} t_j^{\hat{\beta}} \ln t_j \right)$$

Case 2: Complete censored data

Simply replace r with n in (1.47) and (1.48) and ignore the t_j portions. The maximum likelihood equations for the λ and β are given by

$$\hat{\lambda} = \frac{n}{\sum_{i=1}^{n} e^{t_i^{\hat{\beta}}} - n},$$

$$\frac{n}{\hat{\beta}} + \sum_{i=1}^{n} \ln t_i + \sum_{i=1}^{n} t_i^{\hat{\beta}} \ln t_i = \frac{n}{\sum_{i=1}^{n} e^{t_i^{\hat{\beta}}} - n} \times \sum_{i=1}^{n} e^{t_i^{\hat{\beta}}} t_i^{\hat{\beta}} \ln t_i .$$

Confidence Intervals of Estimates

The asymptotic variance–covariance matrix for the parameters (λ and β) is obtained by inverting the Fisher information matrix

$$I_{ij} = E\left(-\frac{\partial^2 L}{\partial \theta_i \partial \theta_j} \right), \quad i, j = 1, 2, \tag{1.49}$$

where $\theta_1, \theta_2 = \lambda$ or β [1.5]. This leads to

$$\begin{pmatrix} \mathrm{Var}(\hat{\lambda}) & \mathrm{Cov}(\hat{\lambda}, \hat{\beta}) \\ \mathrm{Cov}(\hat{\lambda}, \hat{\beta}) & \mathrm{Var}(\hat{\beta}) \end{pmatrix} = \begin{pmatrix} E\left(-\frac{\partial^2 \ln L}{\partial \lambda^2} |_{\hat{\lambda}, \hat{\beta}} \right) & E\left(-\frac{\partial^2 \ln L}{\partial \lambda \partial \beta} |_{\hat{\lambda}, \hat{\beta}} \right) \\ E\left(-\frac{\partial^2 \ln L}{\partial \beta \partial \lambda} |_{\hat{\lambda}, \hat{\beta}} \right) & E\left(-\frac{\partial^2 \ln L}{\partial^2 \beta} |_{\hat{\lambda}, \hat{\beta}} \right) \end{pmatrix}^{-1}. \tag{1.50}$$

We can obtain approximate $(1-\alpha)100\%$ confidence intervals for the parameters λ and β based on the asymptotic normality of the MLEs [1.5] as:

$$\hat{\lambda} \pm Z_{\alpha/2} \sqrt{\mathrm{Var}(\hat{\lambda})} \quad \text{and} \quad \hat{\beta} \pm Z_{\alpha/2} \sqrt{\mathrm{Var}(\hat{\beta})}, \tag{1.51}$$

where $Z_{\alpha/2}$ is the upper percentile of the standard normal distribution.

Application 1. Consider the lifetime of a part from a helicopter's main rotor blade. Data on lifetime of the part taken a system database collected from October 1995 to September 1999 [1.3] are shown in Table 1.2. In this application, we consider several distribution functions for this data, including Weibull, log normal, normal, and loglog distribution functions.

The Pham pdf with parameters a and α is

$$f(t) = \alpha(\ln a)t^{\alpha-1}a^{t^\alpha}\,\mathrm{e}^{1-a^{t^\alpha}} \quad \text{for } t>0,\ \alpha>0,\ a>1$$

and its corresponding log likelihood function (1.39) is

$$\begin{aligned}\log L(a,\alpha) &= n\log\alpha + n\ln(\ln a)\\ &\quad + (\alpha-1)\left(\sum_{i=1}^{n}\ln t_i\right)\\ &\quad + \ln a\cdot\sum_{i=1}^{n}t_i^{\alpha} + n - \sum_{i=1}^{n}a^{t_i^{\alpha}}\,.\end{aligned}$$

We then determine the confidence intervals for parameter estimates a and α. From the above log likelihood function, we can obtain the Fisher information matrix $\mathbf{H}$ as $\mathbf{H} = \begin{pmatrix} h_{11} & h_{12} \\ h_{21} & h_{22}\end{pmatrix}$, where

$$h_{11} = E\left(-\frac{\partial^2 \log L}{\partial a^2}\right),$$

$$h_{12} = h_{21} = E\left(-\frac{\partial^2 \log L}{\partial a\partial\alpha}\right),$$

$$h_{22} = E\left(-\frac{\partial^2 \log L}{\partial \alpha^2}\right).$$

The variance matrix $\mathbf{V}$ can be obtained as follows:

$$\mathbf{V} = (\mathbf{H})^{-1} = \begin{pmatrix} v_{11} & v_{12} \\ v_{21} & v_{22}\end{pmatrix}. \tag{1.52}$$

The variances of a and α are

$$\mathrm{Var}(a) = v_{11} \quad \mathrm{Var}(\alpha) = v_{22}.$$

One can approximately obtain the $(1-\beta)100\%$ confidence intervals for a and α based on the normal distribution as $\left[\hat{a}-z_{\frac{\beta}{2}}\sqrt{v_{11}}, \hat{a}+z_{\frac{\beta}{2}}\sqrt{v_{11}}\right]$ and $\left[\hat{\alpha}-z_{\frac{\beta}{2}}\sqrt{v_{22}}, \hat{\alpha}+z_{\frac{\beta}{2}}\sqrt{v_{22}}\right]$, respectively, where v_{ij} is given in (1.52) and z_β is $(1-\frac{\beta}{2})100\%$ of the standard normal distribution. Having obtained $\hat{a}$ and $\hat{\alpha}$, the MLE of the reliability function can be computed as

$$\hat{R}(t) = \mathrm{e}^{1-\hat{a}t^{\hat{\alpha}}}. \tag{1.53}$$

Let us define a partial derivative vector for reliability $R(t)$ as:

$$v[R(t)] = \left(\frac{\partial R(t)}{\partial a}\ \frac{\partial R(t)}{\partial \alpha}\right)$$

Then the variance of $R(t)$ can be obtained as

$$\mathrm{Var}\left[R(t)\right] = v[R(t)]\mathrm{V}\left(v[R(t)]\right)^{\mathrm{T}},$$

where V is given in (1.52).

One can approximately obtain the $(1-\beta)100\%$ confidence interval for $R(t)$ is

$$\left[\hat{R}(t) - z\beta\sqrt{\mathrm{Var}\left[R(t)\right]},\ \hat{R}(t) + z\beta\sqrt{\mathrm{Var}\left[R(t)\right]}\right].$$

The MLE parameter estimations for the loglog distribution and its corresponding parameters, based on the data set shown in Table 1.2, are:

$$\hat{\alpha} = 1.1075, \quad \mathrm{Var}(\hat{\alpha}) = 0.0162,$$
$$95\%\ \text{CI for}\ \hat{\alpha}: [0.8577, 1.3573];$$
$$\hat{a} = 1.0002, \quad \mathrm{Var}(\hat{a}) = 2.782\,\mathrm{e}^{-08},$$
$$95\%\ \text{CI for}\ a: [0.9998, 1.0005].$$

Similarly, the C.I. for $R(t)$ can be obtained directly using (1.53).

1.3.3 Statistical Change-Point Estimation Methods

The change-point problem has been widely studied in reliability applications in areas such as biological sciences, survival analysis and environmental statistics.

Assume that there is a sequence of random variables $X_1, X_2, \ldots, X_n$, that represents the inter-failure times, and that an index change-point τ exists, such that $X_1, X_2, \ldots, X_\tau$ have a common distribution F with a density function $f(t)$ and $X_{\tau+1}, X_{\tau+2}, \ldots, X_n$ have a distribution G with a density function $g(t)$, where $F \neq G$. Consider the following assumptions:

1. There is a finite but unknown number of units N to be tested.
2. At the beginning, all of the units have the same lifetime distribution F. After τ failures are observed, the remaining $(N-\tau)$ items have the distribution G. The change-point τ is assumed unknown.
3. The sequence $\{X_1, X_2, \ldots, X_\tau\}$ is statistically independent of the sequence $\{X_{\tau+1}, X_{\tau+2}, \ldots, X_n\}$.
4. The lifetime test is performed according to the Type II censoring approach, in which the number of failures n is predetermined.

Note that the total number of units to put up for testing N can be determined in advance in hardware reliability testing. However, in software reliability testing, the parameter N can be defined as the initial number of faults in the software, and it can be considered to be an unknown parameter. Let $T_1, T_2, \ldots, T_n$ be the arrival times for sequential failures. Then

$$\begin{aligned} T_1 &= X_1, \\ T_2 &= X_1 + X_2, \\ &\vdots \\ T_n &= X_1 + X_2 + \cdots X_n. \end{aligned} \tag{1.54}$$

The failure times $T_1, T_2, \ldots, T_\tau$ are the first τ order statistics of a sample of size N from the distribution F. The failure times $T_{\tau+1}, T_{\tau+2}, \ldots, T_n$ are the first $(n-\tau)$ order statistics of a sample of size $(N-\tau)$ from the distribution G.

Example 1.12: The Weibull change-point model of the lifetime distributions F and G with parameters (λ_1, β_1) and (λ_2, β_2), respectively, can be expressed as

$$F(t) = 1 - \exp\left(-\lambda_1 t^{\beta_1}\right), \tag{1.55}$$

$$G(t) = 1 - \exp\left(-\lambda_2 t^{\beta_2}\right). \tag{1.56}$$

Assume that the distributions belong to parametric families $\{F(t \mid \theta_1), \theta_1 \in \Theta_1\}$ and $\{G(t \mid \theta_2), \theta_2 \in \Theta_2\}$. Assume that $T_1, T_2, \ldots, T_\tau$ are the first τ order statistics of a sample of size N from the distribution $\{F(t \mid \theta_1), \theta_1 \in \Theta_1\}$ and that $T_{\tau+1}, T_{\tau+2}, \ldots, T_n$ are the first $(n-\tau)$ order statistics of a sample of size $(N-\tau)$ from the distribution $\{G(t \mid \theta_2), \theta_2 \in \Theta_2\}$, where N is unknown. The log likelihood function can be expressed

as follows [1.6]:

$$L(\tau, N, \theta_1, \theta_2 \mid T_1, T_2, \ldots, T_n) = \sum_{i=1}^{n}(N-i+1) + \sum_{i=1}^{\tau} f(T_i \mid \theta_1) + \sum_{i=\tau+1}^{n} g(T_i \mid \theta_2) + (N-\tau)\log[1-F(T_\tau \mid \theta_1)] + (N-n)\log[1-G(T_n \mid \theta_2)]. \quad (1.57)$$

If the parameter N is known in which where hardware reliability is commonly considered for example, then the likelihood function is given by

$$L(\tau, \theta_1, \theta_2 \mid T_1, T_2, \ldots, T_n) = \sum_{i=1}^{\tau} f(T_i \mid \theta_1) + \sum_{i=\tau+1}^{n} g(T_i \mid \theta_2) + (N-\tau)\log[1-F(T_\tau \mid \theta_1)] + (N-n)\log[1-G(T_n \mid \theta_2)].$$

The maximum likelihood estimator (MLE) of the change-point value $\hat{\tau}$ and $(\hat{N}, \hat{\theta}_1, \hat{\theta}_2)$ can be obtained by taking partial derivatives of the log likelihood function in (1.57) with respect to the unknown parameters that maximize the function. It should be noted that there is no closed form for $\hat{\tau}$, but it can be obtained by calculating the log likelihood for each possible value of τ, $1 \le \tau \le (n-1)$, and selecting the value that maximizes the log likelihood function.

Application 2: A Software Model with a Change Point

In this application, we examine the case where the sample size N is unknown. Consider a software reliability model developed by *Jelinski* and *Moranda* in 1972, often called the Jelinski–Moranda model. The assumptions of the model are as follows:

1. There are N initial faults in the program.
2. A detected fault is removed instantaneously and no new fault is introduced.
3. Each failure caused by a fault occurs independently and randomly in time according to an exponential distribution.
4. The functions F and G are exponential distributions with failure rate parameters λ_1 and λ_2, respectively.

Based on these assumptions, the inter-failure times $X_1, X_2, \ldots, X_n$ are independently exponentially distributed. Specifically, $X_i = T_i - T_{i-1}$, $i = 1, 2, \ldots \tau$, are exponentially distributed with parameter $\lambda_1 (N-i+1)$, where λ_1 is the initial fault detection rate of the first τ failures, and $X_j = T_j - T_{j-1}$, $j = \tau+1, \tau+2, \ldots n$ are exponentially distributed with parameter $\lambda_2 (N-\tau-j+1)$, where λ_2 is the fault detection rate of the first $n-\tau$ failures. If $\lambda_1 = \lambda_2$, it means that each fault removal is the same and that the change-point model becomes the Jelinski–Moranda software reliability model [1.7].

The MLEs of the parameters $(\tau, N, \lambda_1, \lambda_2)$ can be obtained by solving the following equations simultaneously:

$$\hat{\lambda}_1 = \frac{\tau}{\sum_{i=1}^{\tau}(\hat{N}-i+1)x_i}, \quad (1.58)$$

$$\hat{\lambda}_2 = \frac{(n-\tau)}{\sum_{i=\tau+1}^{n}(\hat{N}-i+1)x_i}, \quad (1.59)$$

$$\sum_{i=1}^{n}\frac{1}{(\hat{N}-i+1)} = \hat{\lambda}_1\sum_{i=1}^{\tau}x_i + \hat{\lambda}_2\sum_{i=\tau+1}^{n}x_i. \quad (1.60)$$

To illustrate the model, we use the data set shown in Table 1.3 to obtain the unknown parameters $(\tau, N, \lambda_1, \lambda_2)$ using (1.58)–(1.60). The data in Table 1.3 [1.8] shows the successive inter-failure times for a real-time command and control system. The table reads from left to right in rows, and the recorded times are execution times, in seconds. There are 136 failures in total. Figure 1.6 plots the log-likelihood function versus the number of failures. The MLEs of the parameters $(\tau, N, \lambda_1, \lambda_2)$ with one change point are given by

$$\hat{\tau} = 16,\ \hat{N} = 145,\ \hat{\lambda}_1 = 1.1\times10^{-4},\ \hat{\lambda}_2 = 0.31\times10^{-4}.$$

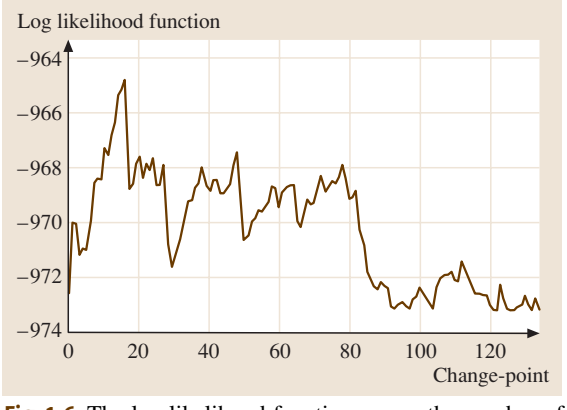

Fig. 1.6 The log likelihood function versus the number of failures

Table 1.3 Successive inter-failure times (in s) for a real-time command system

3	30	113	81	115	9	2	91	112	15
138	50	77	24	108	88	670	120	26	114
325	55	242	68	422	180	10	1146	600	15
36	4	0	8	227	65	176	58	457	300
97	263	452	255	197	193	6	79	816	1351
148	21	233	134	357	193	236	31	369	748
0	232	330	365	1222	543	10	16	529	379
44	129	810	290	300	529	281	160	828	1011
445	296	1755	1064	1783	860	983	707	33	868
724	2323	2930	1461	843	12	261	1800	865	1435
30	143	108	0	3110	1247	943	700	875	245
729	1897	447	386	446	122	990	948	1082	22
75	482	5509	100	10	1071	371	790	6150	3321
1045		648	5485	1160	1864	4116			

If we do not consider a change point in the model, the MLEs of the parameters N and λ, can be given as

$$\hat{N} = 142,\ \hat{\lambda} = 0.35 \times 10^{-4}.$$

From Fig. 1.6,

it is clear that it is worth considering change points in reliability functions.

1.3.4 Goodness of Fit Techniques

The problem discussed here is one of comparing an observed sample distribution with a theoretical distribution. Two common techniques that will be discussed are the χ^2 goodness-of-fit test and the Kolmogorov–Smirnov "d" test.

Chi-Squared Test

The following statistic

$$\chi^2 = \sum_{i=1}^{k} \left(\frac{x_i - \mu_i}{\sigma_i} \right)^2 \tag{1.61}$$

has a chi-squared (χ^2) distribution with k degrees of freedom. The procedure used for the chi-squared test is:

1. Divide the sample data into mutually exclusive cells (normally 8–12) such that the range of the random variable is covered.
2. Determine the frequency, f_i, of sample observations in each cell.
3. Determine the theoretical frequency, F_i, for each cell (the area under density function between cell boundaries X_n – total sample size). Note that the theoretical frequency for each cell should be greater than 1. This step normally requires estimates for the population parameters, which can be obtained from the sample data.
4. Form the statistic

$$A = \sum_{i=1}^{k} \frac{(f_i - F_i)^2}{F_i}. \tag{1.62}$$

5. From the χ^2 tables, choose a value of χ^2 with the desired significance level and degrees of freedom ($= k - 1 - r$, where r is the number of population parameters estimated).
6. Reject the hypothesis that the sample distribution is the same as the theoretical distribution if

$$A > \chi^2_{1-\alpha,k-1-r},$$

where α is called the significance level.

Example 1.13: Given the data in Table 1.4, can the data be represented by the exponential distribution with a significance level of α?

From the above calculation, $\hat{\lambda} = 0.002\,63$, $R_i = \mathrm{e}^{-\lambda t_i}$ and $Q_i = 1 - R_i$. Given that the significance level α is 0.1, from (1.62), we obtain

$$A = \sum_{i=1}^{11} \frac{(f_i - F_i)^2}{F_i} = 6.165\,.$$

From Table 1.9 in Sect. 1.A, the value of χ^2 with nine degrees of freedom and $\alpha = 0.1$ is 14.68; that is,

$$\chi^2_{9,0.1} = 14.68\,.$$

Since $S = 6.165 < 14.68$, we would not reject the hypothesis of an exponential with $\lambda = 0.002\,63$.

Table 1.4 Sample observations for each cell boundary

Cell boundaries	f_i	$Q_i = (1 - R_i)\,60$	$F_i = Q_i - Q_{i-1}$
0 – 100	10	13.86	13.86
100 – 200	9	24.52	10.66
200 – 300	8	32.71	8.19
300 – 400	8	39.01	6.30
400 – 500	7	43.86	4.85
500 – 600	6	47.59	3.73
600 – 700	4	50.45	2.86
700 – 800	4	52.66	2.21
800 – 900	2	54.35	1.69
900 – 1000	1	55.66	1.31
> 1000	1	58.83	2.17

If in the statistic

$$A = \sum_{i=1}^{k} \left(\frac{f_i - F_i}{\sqrt{F_i}} \right)^2, \quad \left(\frac{f_i - F_i}{\sqrt{F_i}} \right)$$

is approximately normal for large samples, then A also has a χ^2 distribution. This is the basis for the goodness of fit test.

Kolmogorov–Smirnov d Test

Both the χ^2 and "d" tests are nonparametric tests. However, the χ^2 test largely assumes sample normality of the observed frequency about its mean, while "d" assumes only a continuous distribution. Let $X1 \le X_2 \le X_3 \le \ldots \le X_n$ denote the ordered sample values. Define the observed distribution function, $F_n(x)$, as:

$$F_n(X) = \begin{cases} 0 & \text{for } x \le x_1 \\ \frac{i}{n} & \text{for } x_i < x \le x_{i+1} \\ 1 & \text{for } x > x_n \end{cases} .$$

Assume the testing hypothesis

$$H_0 : F(x) = F_0(x),$$

where $F_0(x)$ is a given continuous distribution and $F(x)$ is an unknown distribution. Let

$$d_n = \sup_{-\infty < x < \infty} |F_n(x) - F_0(x)|.$$

Since $F_0(x)$ is a continuous increasing function, we can evaluate $|F_n(x) - F_0(x)|$ for each n. If $d_n \le d_{n,\alpha}$, then we will not reject the hypothesis H_0; otherwise, we will reject it when $d_n > d_{n,\alpha}$. The value of $d_{n,\alpha}$ can be found in Table 1.10 in Sect. 1.A, where n is the sample size and a is the level of significance.

1.3.5 Least Squared Estimation

One common approach to curve fitting, which is unrelated to normal regression theory and MLE estimates of coefficients but uses identical formulae, is called the method of least squares. This method is based on minimizing the sum of the squared distances from the best fit line to the actual data points. It just so happens that finding the MLEs for the coefficients of the regression line also involves this sum of squared distances.

Normal Linear Regression

Regression considers the distribution of one variable as a function of another when the other variable is fixed at each of several levels. In the normal bivariate case, consider the distribution of X as a function of given values of Z where $X = \alpha + \beta Z$. Consider a sample of n observations (x_i, z_i). We can obtain the likelihood and its natural log for the normal distribution as follows:

$$\begin{aligned} & f(x_1, x_2, \ldots, x_n) \\ & \quad = \frac{1}{2\pi^{\frac{n}{2}}} \left(\frac{1}{\sigma^2} \right)^{\frac{n}{2}} \mathrm{e}^{-\frac{1}{2\sigma^2} \sum_{i=1}^{n} (x_i - \alpha - \beta z_i)^2}, \\ & \ln L = -\frac{n}{2} \log 2\pi - \frac{n}{2} \log \sigma^2 \\ & \quad - \frac{1}{2\sigma^2} \sum_{i=1}^{n} (x_i - \alpha - \beta z_i)^2. \end{aligned}$$

Taking the partial derivatives of $\ln L$ with respect to α and β, we have

$$\begin{aligned} \frac{\partial \ln L}{\partial \alpha} &= \sum_{i=1}^{n} (x_i - \alpha - \beta z_i)^2 = 0, \\ \frac{\partial \ln L}{\partial \beta} &= \sum_{i=1}^{n} z_i (x_i - \alpha - \beta z_i) = 0. \end{aligned}$$

The solutions to the simultaneous equations are

$$\begin{aligned} \hat{\alpha} &= \bar{X} - \beta \bar{Z}, \\ \hat{\beta} &= \frac{\sum_{i=1}^{n} (X_i - \bar{X})(Z_i - \bar{Z})}{\sum_{i=1}^{n} (Z_i - \bar{Z})^2}. \end{aligned} \tag{1.63}$$

Least Squared Straight Line Fit

Assume that there is a linear relationship between X and $E(Y|x)$; that is, that $E(Y|x) = a + bx$. Given a set of data, we want to estimate the coefficients a and b

that minimize the sum of the squares. Suppose that the desired polynomial, $p(x)$, is written as

$$\sum_{i=0}^{m} a_i x^i,$$

where $a_0, a_1, \ldots, a_m$ are to be determined. The method of least squares chooses as "solutions" those coefficients that minimize the sum of the squares of the vertical (y) distances from the data points to the presumed polynomial. This means that the "best" polynomial is the one whose coefficients minimize the function L, where

$$L = \sum_{i=1}^{n} [y_i - p(x_i)]^2.$$

Here, we will only treat the linear case, where $X = \alpha + \beta Z$. The procedure for higher order polynomials is identical, although the computations become much more tedious. Assume a straight line of the form $X = \alpha + \beta Z$. For each observation (x_i, z_i) : $X_i = \alpha + \beta Z_i$, let

$$Q = \sum_{i=1}^{n} (x_i - \alpha - \beta z_i)^2.$$

We wish to find estimates for α and β that minimize Q. Taking partial differentials, we obtain

$$\frac{\partial Q}{\partial \alpha} = -2 \sum_{i=1}^{n} (x_i - \alpha - \beta z_i) = 0,$$

$$\frac{\partial Q}{\partial \beta} = -2 \sum_{i=1}^{n} z_i (x_i - \alpha - \beta z_i) = 0.$$

Note that the above are the same as the MLE equations for normal linear regression. Therefore, we obtain the following results:

$$\hat{\alpha} = \bar{x} - \beta \bar{z},$$

$$\hat{\beta} = \frac{\sum_{i=1}^{n} (x_i - \bar{x})(z_i - \bar{z})}{\sum_{i=1}^{n} (z_i - \bar{z})^2}. \tag{1.64}$$

The above gives an example of least squares applied to a linear case. The same pattern applies for higher-order curves with 3, 4 and so on solutions.

1.3.6 Interval Estimation

A point estimate is sometimes inadequate at providing an estimate for an unknown parameter, since it rarely coincides with the true value of the parameter. An alternative way is to obtain a confidence interval estimation of the form $[\theta_L, \theta_U]$ where θ_L is the lower bound and θ_U is the upper bound.

Point estimates can become more useful if some measure of their error is given; in other words, if some kind of tolerance for their high and low values is given. Thus, if an interval estimator is $[\theta_L, \theta_U]$ with a given probability $(1-\alpha)$, then θ_L and θ_U are called the $100\,(1-\alpha)\,\%$ confidence limits for the given parameter θ, and the interval between them is a $100\,(1-\alpha)\,\%$ confidence interval, while $(1-\alpha)$ is called the confidence coefficient.

Confidence Intervals for Normal Parameters

The one-dimensional normal distribution has two parameters: mean μ and variance σ^2. The simultaneous employment of both parameters in a confidence statement concerning percentages of the population will be discussed in the next section on tolerance limits. Hence, individual confidence statements about μ and σ^2 will be discussed here.

Confidence Limits for a Mean μ with a Known σ^2. It is easy to show that the statistic

$$Z = \frac{\bar{X} - \mu}{\sigma/\sqrt{n}}$$

is a standard normal distribution, where

$$\bar{X} = \frac{1}{n} \sum_{i=1}^{n} X_i.$$

Hence, a $100\,(1-\alpha)\,\%$ confidence interval for the mean μ is given by

$$P\left[\bar{X} - Z_{\frac{\alpha}{2}} \frac{\sigma}{\sqrt{n}} < \mu < \bar{X} + Z_{\frac{\alpha}{2}} \frac{\sigma}{\sqrt{n}}\right] = 1 - \alpha. \tag{1.65}$$

In other words,

$$\mu_L = \bar{X} - Z_{\frac{\alpha}{2}} \frac{\sigma}{\sqrt{n}} \quad \text{and} \quad \mu_U = \bar{X} + Z_{\frac{\alpha}{2}} \frac{\sigma}{\sqrt{n}}.$$

Example 1.14: Draw a sample of size 4 from a normal distribution with a known variance = 9, say $x_1 = 2$, $x_2 = 3$, $x_3 = 5$, $x_4 = 2$. Determine the location of the true mean (μ). The sample mean can be calculated as

$$\bar{x} = \frac{\sum_{i=1}^{n} x_i}{n} = \frac{2+3+5+2}{4} = 3.$$

Assuming that $\alpha = 0.05$ and, from the standard normal distribution (Table 1.6 in Sect. 1.A), $Z_{0.025} = 1.96$, then we obtain

$$P\left[3 - 1.96\frac{3}{\sqrt{4}} < \mu < 3 + 1.96\frac{3}{\sqrt{4}}\right] = 0.95,$$
$$P[0.06 < \mu < 5.94] = 0.95.$$

This example shows that there is a 95% probability that the true mean is somewhere between 0.06 and 5.94. Now, μ is a fixed parameter and does not vary, so how do we interpret the probability? If samples of size 4 were to be repeatedly drawn, a different set of limits would be constructed each time. If this is the case, the interval becomes the random variable and the interpretation is that, for 95% of the time, the interval constructed in this way will contain the true (fixed) parameter.

Confidence Limits for a Mean μ with an Unknown σ^2. Let

$$S = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(X_i - \bar{X})^2}. \tag{1.66}$$

It can be shown that the statistic

$$T = \frac{\bar{X} - \mu}{\frac{S}{\sqrt{n}}}$$

has a t distribution with $(n-1)$ degrees of freedom (see Table 1.7 in Appendix A). Thus, for a given sample mean and sample standard deviation, we obtain

$$P\left[|T| < t_{\frac{\alpha}{2},n-1}\right] = 1 - \alpha.$$

Hence, a $100\,(1-\alpha)\,\%$ confidence interval for the mean μ is given by

$$p\left[\bar{X} - t_{\frac{\alpha}{2},n-1}\frac{S}{\sqrt{n}} < \mu < \bar{X} + t_{\frac{\alpha}{2},n-1}\frac{S}{\sqrt{n}}\right]$$
$$= 1 - \alpha. \tag{1.67}$$

Example 1.15: The variability of a new product was investigated. An experiment was run using a sample of size $n = 25$; the sample mean was found to be $\bar{X} = 50$ and the variance $\sigma^2 = 16$. From Table 1.7 in Appendix A, $t_{\frac{\alpha}{2},n-1} = t_{0.025,24} = 2.064$. The 95% confidence limit for μ is given by

$$P\left[50 - 2.064\sqrt{\frac{16}{25}} < \mu\right.$$
$$\left. < 50 + 2.064\sqrt{\frac{16}{25}}\right] = 0.95\,,$$
$$P[48.349 < \mu < 51.651]x = 0.95\,.$$

Note that, for one-sided limits, one should choose t_α, or $t_{1-\alpha}$.

Confidence Limits on σ^2. Note that $n\hat{\sigma}^2/\sigma^2$ has a χ^2 distribution with $(n-1)$ degrees of freedom. Correcting for the bias in $\hat{\sigma}^2$, it is clear that $(n-1)\hat{\sigma}^2/\sigma^2$ has this same distribution. Hence,

$$P\left[\chi^2_{\frac{\alpha}{2},n-1} < \frac{(n-1)S^2}{\sigma^2} < \chi^2_{1-\frac{\alpha}{2},n-1}\right] = 1 - \alpha$$

or

$$P\left[\frac{\sum(x_i - \bar{x})^2}{\chi^2_{1-\frac{\alpha}{2},n-1}} < \sigma^2 < \frac{\sum(x_i - \bar{x})^2}{\chi^2_{\frac{\alpha}{2},n-1}}\right] = 1 - \alpha. \tag{1.68}$$

Again, for one-sided limits, one should choose $\chi^2(\alpha)$ or $\chi^2(1-\alpha)$.

Confidence Intervals for Exponential Parameters

The pdf and cdf for the exponential distribution are

$$f(x) = \lambda\,\mathrm{e}^{-\lambda x}, \quad x > 0, \lambda > 0$$

and

$$F(x) = 1 - \mathrm{e}^{-\lambda x},$$

respectively. It was shown that the distribution of a function of the estimate

$$\hat{\lambda} = \frac{r}{\sum_{i=1}^{n} x_i + (n-r)x_r} \tag{1.69}$$

derived from a test of n identical components with common exponential failure density (failure rate λ), whose testing was stopped after the rth failure, was chi-squared (χ^2), i. e.,

$$2r\frac{\lambda}{\hat{\lambda}} = 2\lambda T$$
(χ^2 distribution with $2r$ degrees of freedom),

where T is the total time accrued by all units. Knowing the distribution of $2\lambda T$ allows us to obtain the confidence limits on the parameter as:

$$P\left[\chi^2_{1-\frac{\alpha}{2},2r} < 2\lambda T < \chi^2_{\frac{\alpha}{2},2r}\right] = 1 - \alpha$$

or, equivalently, that

$$P\left[\frac{\chi^2_{1-\frac{\alpha}{2},2r}}{2T} < \lambda < \frac{\chi^2_{\frac{\alpha}{2},2r}}{2T}\right] = 1 - \alpha.$$

Table 1.5 Confidence limits for θ

Confidence limits	Fixed number of failures	Fixed time
One-sided lower limit	$\frac{2T}{\chi^2_{\alpha,2r}}$	$\frac{2T}{\chi^2_{\alpha,2r+2}}$
One-sided upper limit	$\frac{2T}{\chi^2_{1-\alpha,2r}}$	$\frac{2T}{\chi^2_{1-\alpha,2r}}$
Two-sided limits	$\frac{2T}{\chi^2_{\alpha/2,2r}}, \frac{2T}{\chi^2_{1-\alpha/2,2r}}$	$\frac{2T}{\chi^2_{\alpha/2,2r+2}}, \frac{2T}{\chi^2_{1-\alpha/2,2r}}$

This means that in $(1-\alpha)\%$ of the samples of a given size n, the random interval

$$\left(\frac{\chi^2_{1-\frac{\alpha}{2},2r}}{2T}, \frac{\chi^2_{\frac{\alpha}{2},2r}}{2T}\right)$$

will contain a population of constant failure rate. For $\theta = 1/\lambda$ or the MTBF, the above confidence limits change to

$$P\left[\frac{2T}{\chi^2_{\frac{\alpha}{2},2r}} < \theta < \frac{2T}{\chi^2_{1-\frac{\alpha}{2},2r}}\right] = 1-\alpha.$$

If testing is stopped at a fixed time rather than a fixed number of failures, the number of degrees of freedom in the lower limit increases by two. Table 1.5 shows the confidence limits for θ, the mean of the exponential density.

Confidence Intervals for Binomial Parameters

Consider a sequence of n Bernoulli trials with k successes and $(n-k)$ failures. We now determine one-sided upper and lower and two-sided limits on the parameter p, the probability of success. For the lower limit, the binomial sum is set up such that the probability of k or more successes with a true p as low as p_L is only $\alpha/2$. This means that the probability of k or more successes with a true p higher than p_L is $\left(1-\frac{\alpha}{2}\right)$.

$$\sum_{i=k}^{n}\binom{n}{i}p_L^i(1-p_L)^{n-i} = \frac{\alpha}{2}.$$

Similarly, the binomial sum for the upper limit is

$$\sum_{i=k}^{n}\binom{n}{i}p_U^i(1-p_U)^{n-i} = 1-\frac{\alpha}{2}$$

or, equivalently,

$$\sum_{i=0}^{k-1}\binom{n}{i}p_U^i(1-p_U)^{n-i} = \frac{\alpha}{2}.$$

Solving for p_L and p_U in the above equations,

$$P[p_L < p < p_U] = 1-\alpha.$$

For one-sided limits, merely change $\alpha/2$ to α.

Example 1.16: Given $n = 100$ with 25 successes, and 75 failures, an 80% two-sided confidence limit on p can be obtained as follows:

$$\sum_{i=25}^{100}\binom{100}{i}p_L^i(1-p_L)^{100-i} = 0.10,$$

$$\sum_{i=0}^{24}\binom{100}{i}p_U^i(1-p_U)^{100-i} = 0.10.$$

Solving the above two equations simultaneously, we obtain

$$p_L \approx 0.194 \quad \text{and} \quad p_U \approx 0.313,$$
$$P[0.194 < p < 0.313] = 0.80.$$

Continuing with Example 1.16 above, we now find an 80% one-sided confidence limit on p.

We start by setting the top equation to 0.20 and solving for p_L. It is then easy to obtain $p_L = 0.211$ and $P[p > 0.211] = 0.80$.

Let us now define $\bar{p} = k/n$, the number of successes divided by the number of trials. For large values of n and if $np > 5$ and $n(1-p) > 5$, and from the central limit theorem [1.9], the statistic

$$Z = \frac{(\bar{p}-p)}{\sqrt{\frac{\bar{p}(1-\bar{p})}{n}}}$$

approximates to the standard normal distribution. Hence

$$P[-z_{\frac{\alpha}{2}} < Z < z_{\frac{\alpha}{2}}] = 1-\alpha.$$

Then

$$P\left[\bar{p} - z_{\frac{\alpha}{2}}\sqrt{\frac{\bar{p}(1-\bar{p})}{n}} < p < \bar{p} + z_{\frac{\alpha}{2}}\sqrt{\frac{\bar{p}(1-\bar{p})}{n}}\right] = 1-\alpha.$$

Example 1.17: Find the two-sided confidence limit for $n = 900$, $k = 180$, and $\alpha = 0.05$. Then we obtain $p = 180/900 = 0.2$ and

$$P\left[0.2 - 1.96\sqrt{\frac{0.2(0.8)}{900}} < p < 0.2 + 1.96\sqrt{\frac{0.2(0.8)}{900}}\right] = 0.95,$$

$$P[0.174 < p < 0.226] = 0.95.$$

Confidence Intervals for Poisson Parameters

Limits for the Poisson parameters are completely analogous to those for the binomial distribution except that the sample space is denumerable instead of finite. The lower and upper limits can be solved simultaneously in the following equations:

$$\sum_{i=k}^{\infty} \frac{\lambda_{\mathrm{L}}^{i} \mathrm{e}^{-\lambda_{\mathrm{L}}}}{i!} = \frac{\alpha}{2},$$

$$\sum_{i=k}^{\infty} \frac{\lambda_{\mathrm{U}}^{i} \mathrm{e}^{-\lambda_{\mathrm{U}}}}{i!} = 1 - \frac{\alpha}{2},$$

or, equivalently,

$$\sum_{i=k}^{\infty} \frac{\lambda_{\mathrm{L}}^{i} \mathrm{e}^{-\lambda_{\mathrm{L}}}}{i!} = \frac{\alpha}{2},$$

$$\sum_{i=0}^{k-1} \frac{\lambda_{\mathrm{U}}^{i} \mathrm{e}^{-\lambda_{\mathrm{U}}}}{i!} = \frac{\alpha}{2}.$$

The one-sided limits are constructed in the same way as for binomial limits.

1.3.7 Nonparametric Tolerance Limits

Nonparametric tolerance limits are based on the smallest and largest observation in the sample, designated X_{S} and X_{L}, respectively. Due to their nonparametric nature, these limits are quite insensitive, and obtaining precisions similar to the parametric methods necessitates much larger samples. An interesting question here is to determine the sample size required to include at least $100\,(1-\alpha)\,\%$ of the population between X_{S} and X_{L} with a given probability y.

For two-sided tolerance limits, if $(1-\alpha)$ is the minimum proportion of the population contained between the largest observation X_{L} and the smallest observation X_{S} with a confidence $(1-\gamma)$, then it can be shown that

$$n(1-\alpha)^{n-1} - (n-1)(1-\alpha)^{n} = \gamma.$$

Therefore, the number of observations required is given by

$$n = \left(\frac{(2-\alpha)}{4\alpha} \chi^2_{1-\gamma,4} + \frac{1}{2} \right) + 1,$$

where a value of $\chi^2_{1-\gamma,4}$ is given in Table 1.8 of Sect. 1.A.

Example 1.18: Determine the tolerance limits that include at least 90% of the population with probability 0.95. Here,

$$\alpha = 0.1,\ \gamma = 0.95 \quad \text{and} \quad \chi^2_{0.05,4} = 9.488.$$

Therefore, a sample of size

$$n = \left[\frac{(2-0.1)}{4(0.1)} (9.488) + \frac{1}{2} \right] + 1 = 46$$

is required. For a one-sided tolerance limit, the number of observations required is given by

$$n = \left(\frac{\log(1-\gamma)}{\log(1-\alpha)} \right) + 1.$$

Example 1.19: As in Example 1.18, we wish to find a lower tolerance limit; that is, the number of observations required such that the probability is 0.95 that at least 90% of the population will exceed X_{S}. This is given by

$$n = \left(\frac{\log(1-0.95)}{\log(1-0.1)} \right) + 1 = 30.$$

One can easily generate a table containing the sample size required to include a given percentage of the population between X_{S} and X_{L} with a given confidence, or the sample size required to include a given percentage of the population above or below X_{S} or X_{L}, respectively.

1.3.8 Sequential Sampling

A sequential sampling scheme is one in which items are drawn one at a time and the results at any stage determine whether sampling or testing should stop. Thus, any sampling procedure for which the number of observations is a random variable can be regarded as sequential sampling. Sequential tests derive their name from the fact that the sample size is not determined in advance, but allowed to "float" with a decision (accept, reject, or continue test) after each trial or data point.

In general, let us consider the hypothesis

$$H_0 : f(x) = f_0(x) \text{ versus } H_1 : f(x) = f_1(x).$$

For an observational test, say X_1, if $X_1 \le A$, then we will accept the testing hypothesis $[H_0 : f(x) = f_0(x)]$; if $X_1 \ge A$ we will reject H_0 and accept $H_I : f(x) = f_1(x)$. Otherwise, we will continue to perform at least one more test. The interval $X_1 \le A$ is called the acceptance region. The interval $X_1 \ge A$ is called the rejection or critical region.

A "good" test is one that makes the α and β errors as small as possible. However, there is not much freedom to do this without increasing the sample size. A common procedure is to fix the β error and then choose a critical region to minimize the error or to maximize the "power"

(power $= 1-\beta$) of the test, or to choose the critical region so as to equalize the α and β errors to reasonable levels.

One criterion (similar to the MLE) used to construct tests is called the "probability ratio", which is the ratio of the sample densities under H_1/H_0. Consider the ratio of probabilities

$$\lambda_m = \frac{\prod_{i=1}^{n} f_1(x_i)}{\prod_{i=1}^{n} f_0(x_i)} > k.$$

Here, $x_1, x_2, \ldots, x_n$ are n independent random observations and k is chosen to give the desired a error.

Recall from the MLE discussion in Sect. 1.3.1 that $f_1(x_1), f_1(x_2), \ldots, f_1(x_n)$ are maximized under H_1 when the parameter(s), e.g. $\theta = \theta_1$ and similarly $f_0(x_1), f_0(x_2), \ldots, f_0(x_n)$, are maximized when $\theta = \theta_0$. Thus, the ratio will become large if the the sample favors H_1 and will become small if the sample favors H_0. Therefore, the test will be called a sequential probability ratio test if we

1. stop sampling and reject H_0 as soon as $\lambda_m \geq A$;
2. stop sampling and accept H_0 as soon as $\lambda_m \leq B$;
3. continue sampling as long as $B < \lambda_m < A$, where $A > B$.

The selection of A and B using the above test, as suggested by *Wald* (see [1.9]), can be determined as follows:

$$B = \frac{\beta}{1-\alpha} \quad \text{and} \quad A = \frac{1-\beta}{\alpha}$$

The bases for α and β are therefore:

$$P[\lambda_m > A|H_0] = \alpha$$
$$P[\lambda_m < A|H_1] = \beta$$

1.3.9 Bayesian Methods

The Bayesian approach to statistical inference is based on a theorem first presented by Thomas Bayes. To demonstrate the approach, let X have a pdf $f(x)$, which is dependent on θ. In the traditional statistical inference approach, θ is an unknown parameter, and hence is a constant. We now describe our prior supposition for the value of θ by a pdf of $h(\theta)$. This amounts to quantitatively assessing subjective judgment and should not be confused with the so-called objective probability assessment derived from the long-term frequency approach. Thus, θ will now essentially be treated as a random variable θ with a pdf of $h(\theta)$.

Consider a random sample $X_1, X_2, \ldots, X_n$ from $f(x)$ and define a statistic Y as a function of this random sample. Then there exists a conditional pdf $g(y|\theta)$ of Y for a given θ. The joint pdf for y and θ is

$$f(\theta, y) = h(\theta)g(y|\theta).$$

If θ is continuous, then

$$f_1(y) = \int_{\theta} h(\theta)g(y|\theta)\,\mathrm{d}\theta$$

is the marginal pdf for the statistic y. Given the information y, the conditional pdf for θ is

$$k(\theta|y) = \frac{h(\theta)g(y|\theta)}{f_1(y)} \quad \text{for } f_1(y) > 0$$
$$= \frac{h(\theta)g(y|\theta)}{\int_{\theta} h(\theta)g(y|\theta)\,\mathrm{d}\theta}$$

If θ is discrete, then

$$f_1(y) = \sum_k P(\theta_k)P(y|\theta_k)$$

and

$$P(\theta_i|y_i) = \frac{P(\theta_k)P(y_i|\theta_i)}{\sum_k P(\theta_k)P(y_j|\theta_k)}$$

where $P(\theta_j)$ is the prior probability of event θ_i and $P(\theta_j|y_j)$ is the posterior probability of event y_j given θ_i. This is simply a form of Bayes' theorem. Here, $h(\theta)$ is the prior pdf that expresses our belief about the value of θ before the data $(Y = y)$ became available. Then $k(\theta|y)$ is the posterior pdf, given the data $(Y = y)$.

Note that the difference in the shape of the prior pdf $h(\theta)$ compared to the posterior pdf $k(\theta|y)$ due to the information is a result of the product of $g(y|\theta)$ and $h(\theta)$, because $f_l(y)$ is simply a normalization constant for a fixed y. The idea of reliability is to take "prior" data and combine it with current data to gain a better estimate or confidence interval or test than would be possible with either on their own. As more current data is acquired, the prior data is "washed out" [1.1].

1.4 Stochastic Processes

Stochastic processes are used to describe the operation of a system over time. There are two main types of stochastic processes: continuous and discrete. A complex continuous process is a process describing a system transition from state to state. The simplest process that will be discussed here is a Markov process. In this case, the future behavior of the process does not depend on its past or present behavior. In many systems that arise in practice, however, past and present states of the system influence the future states, even if they do not uniquely determine them.

1.4.1 Markov Processes

In this section, we will discuss discrete stochastic processes. As an introduction to the Markov process, let us examine the following example.

Example 1.20: Consider a parallel system consisting of two components. From a reliability point of view, the states of the system can be described by

State 1: Full operation (both components operating);
State 2: One component is operating and one component has failed;
State 3: Both components have failed.

Define

$$P_i(t) = P[X(t) = i] = P[\text{system is in state } i \text{ at time } t]$$

and

$$P_i(t + \mathrm{d}t) = P[X(t + \mathrm{d}t) = i] = P[\text{system is in state } i \text{ at time } t + \mathrm{d}t].$$

Define a random variable $X(t)$ which can assume the values 1, 2, or 3 corresponding to the states mentioned above. Since $X(t)$ is a random variable, one can discuss $P[X(t) = 1]$, $P[X(t) = 2]$ or the conditional probability $P[X(t_1) = 2|X(t_0) = 1]$. Again, $X(t)$ is defined as a function of time t, while the conditional probability $P[X(t_1) = 2|X(t_0) = 1]$ can be interpreted as the probability of being in state 2 at time t_1, given that the system was in state 1 at time t_0. In this example, the "stage space" is discrete, i. e., 1, 2, 3, etc., and the parameter space (time) is continuous. The simple process described above is called a stochastic process: a process that develops over time (or space) in accordance with some probabilistic (stochastic) laws. There are many types of stochastic processes.

Here we emphasize the Markov process, which is a special type of stochastic process. Let the system be observed at discrete moments of time t_n, where $n = 0, 1, 2, \ldots$, and let $X(t_n)$ denote the state of the system at time t_n.

Definition 1.2
Let $t_0 < t_1 < \ldots < t_n$. If

$$P[X(t_n) = x_n|X(t_{n-1}) = x_{n-1}, X(t_{n-2}) = x_{n-2}, \ldots, X(t_0) = x_0] = P[X(t_n) = x_n|X(t_{n-1}) = x_{n-1}]$$

then the process is called a *Markov process*.

From the definition of a Markov process, given the present state of the process, its behavior in the future does not depend on its behavior in the past. Many systems have this property, which is called the *Markov property*, and systems that have this property are called *Markov chains*. The Markov property is precisely defined by the following requirement:

$$P[X(t_n) = x_n|X(t_{n-1}) = x_{n-1}, X(t_{n-2}) = x_{n-2}, \ldots, X(t_0) = x_0] = P[X(t_n) = x_n|X(t_{n-1}) = x_{n-1}].$$

The essential characteristic of a Markov process is that it is a process that has no memory; its future is determined by the present and not the past. If, in addition to having no memory, the process is such that it depends only on the difference $(t + \mathrm{d}t) - t = \mathrm{d}t$ and not the value of t – in other words $P[X(t + \mathrm{d}t) = j|X(t) = i]$ is independent of t – then the process is Markov with stationary transition probabilities or is homogeneous in time. This is the same property noted in exponential event times; in fact, referring back to the graphical representation of $X(t)$, the times between state changes are exponential if the process has stationary transition probabilities.

Thus, a Markov process which is homogeneous in time can describe processes with exponential event occurrence times. The random variable of the process is $X(t)$, the state variable rather than the time to failure used in the exponential failure density. To illustrate the types of processes that can be described, we now review the exponential distribution and its properties. Recall that, if $X_1, X_2, \ldots, X_n$, are independent random variables, each with exponential density and a mean of $1/\lambda_i$, then $\min\{X_1, X_2, \ldots, X_n\}$ has an exponential density with a mean of $\left(\sum \lambda_i\right)^{-1}$.

The significance of this property is as follows:

1. The failure behavior of components operated simultaneously can be characterized by an exponential density with a mean equal to the reciprocal of the sum of the failure rates.
2. The joint failure/repair behavior of a system where components are operating and/or undergoing repair can be characterized by an exponential density with a mean equal to the reciprocal of the sum of the failure and repair rates.
3. The failure/repair behavior of a system similar to that described in (2) above but further complicated by active and dormant operating states and sensing and switching can be characterized by an exponential density.

The above property means that almost all reliability and availability models can be characterized by a time-homogeneous Markov process if the various failure times and repair times are exponential. The notation for the Markov process is $\{X(t), t > 0\}$, where $X(t)$ is discrete (state space) and t is continuous (parameter space). By convention, this type of Markov process is called a continuous-parameter Markov chain.

From a reliability/availability viewpoint, there are two types of Markov processes. These are defined as follows:

1. *Absorbing process:* Contains an "absorbing state", which is a state that, once entered, the system can never leave (e.g. a failure which aborts a flight or a mission).
2. *Ergodic process:* Contains no absorbing states, meaning that $X(t)$ can move around indefinitely (e.g. the operation of a ground power plant where failure only temporarily disrupts the operation).

Pham ([1.1], p. 265) presents a summary of Markov processes broken down into absorbing and ergodic categories. Both the reliability and the availability can be described in terms of the probability of the process or system being in defined "up" states, e.g. states 1 and 2 in the initial example. Likewise, the MTBF can be described as the total time spent in the "up" states before proceeding to the absorbing state or failure state.

Define the incremental transition probability as

$$P_{ij}(\mathrm{d}t) = P[X(t+\mathrm{d}t) = j | X(t) = i].$$

This is the probability that the process [random variable $X(t)$] will move to state j during the increment t to $(t+\mathrm{d}t)$, given that it was in state i at time t. Since we are dealing with time-homogeneous Markov processes (exponential failure and repair times), the incremental transition probabilities can be derived from an analysis of the exponential hazard function. It was shown that the hazard function for an exponential with a mean of $1/\lambda$ was just λ. This means that the limiting (as $\mathrm{d}t \to 0$) conditional probability of an event occurring between t and $t+\mathrm{d}t$, given that an event had not occurred at time t, is simply λ, in other words:

$$h(t) = \lim_{\mathrm{d}t \to 0} \frac{P[t < X < t+\mathrm{d}t | X > t]}{\mathrm{d}t} = \lambda.$$

The equivalent statement for the random variable $X(t)$ is

$$h(t)\,\mathrm{d}t = P[X(t+\mathrm{d}t) = j | X(t) = i] = \lambda\,\mathrm{d}t.$$

Now, $h(t)\,\mathrm{d}t$ is in fact the incremental transition probability, so $P_{ij}(\mathrm{d}t)$ can be stated in terms of the basic failure and/or repair rates.

Returning to Example 1.20, it is easy to construct a state transition showing the incremental transition probabilities between all possible states for the process:

State 1: Both components operating;
State 2: One component up and one component down;
State 3: Both components down (absorbing state).

The loops in *Pham* ([1.1], p. 265) indicate the probability of remaining in the present state during the $\mathrm{d}t$ increment

$$P_{11}(\mathrm{d}t) = 1 - 2\lambda\,\mathrm{d}t \qquad P_{12}(\mathrm{d}t) = 2\lambda\,\mathrm{d}t$$
$$P_{21}(\mathrm{d}t) = 0 \qquad P_{22}(\mathrm{d}t) = 1 - \lambda\,\mathrm{d}t$$
$$P_{31}(\mathrm{d}t) = 0 \qquad P_{32}(\mathrm{d}t) = 0$$

$$P_{13}(\mathrm{d}t) = 0$$
$$P_{23}(\mathrm{d}t) = \lambda\,\mathrm{d}t$$
$$P_{33}(\mathrm{d}t) = 1$$

The zeros for P_{ij}, $i > j$ show that the process cannot go backwards: this is not a repair process. The zero on P_{13} shows that, for a process of this type, the probability of more than one event (e.g. failure, repair, etc.) occurring in the incremental time period $\mathrm{d}t$ approaches zero as $\mathrm{d}t$ approaches zero.

Except for the initial conditions of the process (the state in which the process starts), the process is completely specified by incremental transition probabilities. The reason that this is useful is that assuming exponential event (failure or repair) times allows us to characterize the process at any time t, since the process depends only on what happens between t and $(t+\mathrm{d}t)$. The incremental transition probabilities can be arranged

into a matrix in a way that depicts all possible statewide movements. Thus, for parallel configurations,

$$[p_{ij}(\mathrm{d}t)] = \begin{pmatrix} 1 & 2 & 3 \\ 1-2\lambda\,\mathrm{d}t & 2\lambda\,\mathrm{d}t & 0 \\ 0 & 1-\lambda\,\mathrm{d}t & \lambda\,\mathrm{d}t \\ 0 & 0 & 1 \end{pmatrix}$$

for $i, j = 1, 2$, or 3. The matrix $[P_{ij}(\mathrm{d}t)]$ is called the incremental, one-step transition matrix. It is a stochastic matrix (the rows sum to 1.0). As mentioned earlier, this matrix, along with the initial conditions, completely describes the process.

Now, $[P_{ij}(\mathrm{d}t)]$ gives the probabilities of remaining or moving to all of the various states during the interval t to $t+\mathrm{d}t$; hence,

$$\begin{aligned} P_1(t+\mathrm{d}t) &= (1-2\lambda\,\mathrm{d}t)P_1(t) \\ P_2(t+\mathrm{d}t) &= 2\lambda\,\mathrm{d}tP_1(t)(1-\lambda\,\mathrm{d}t)P_2(t) \\ P_3(t+\mathrm{d}t) &= \lambda\,\mathrm{d}tP_2(t)+P_3(t) \end{aligned}$$

By algebraic manipulation, we have

$$\begin{aligned} \frac{[P_1(t+\mathrm{d}t)-P_1(t)]}{\mathrm{d}t} &= -2\lambda P_1(t), \\ \frac{[P_2(t+\mathrm{d}t)-P_2(t)]}{\mathrm{d}t} &= 2\lambda P_1(t)-\lambda P_2(t), \\ \frac{[P_3(t+\mathrm{d}t)-P_3(t)]}{\mathrm{d}t} &= \lambda P_2(t). \end{aligned}$$

Taking limits of both sides as $\mathrm{d}t \to 0$, we obtain

$$\begin{aligned} P_1'(t) &= -2\lambda P_1(t), \\ P_2'(t) &= 2\lambda P_1(t)-\lambda P_2(t), \\ P_3'(t) &= \lambda P_2(t). \end{aligned}$$

The above system of linear first-order differential equations can be easily solved for $P_1(t)$ and $P_2(t)$, meaning that the reliability of the configuration can be obtained:

$$R(t) = \sum_{i=1}^{2} P_i(t).$$

Actually, there is no need to solve all three equations, only the first two, because $P_3(t)$ does not appear and also $P_3(t) = [1-P_1(t)]-P_2(t)$. The system of linear, first-order differential equations can be solved by various means, including both manual and machine methods. We use manual methods employing the Laplace transform (Appendix B) here.

$$\begin{aligned} L[P_i(t)] &= \int_0^\infty \mathrm{e}^{-st}P_i(t)\,\mathrm{d}t = f_i(s), \\ L[P_i'(t)] &= \int_0^\infty \mathrm{e}^{-st}P_i'(t)\,\mathrm{d}t = sf_i(s)-P_i(0). \end{aligned}$$

Application of the Laplace transform will allow us to transform the system of linear, first-order differential equations into a system of linear algebraic equations that can easily be solved, and solutions of $P_i(t)$ can be determined via the inverse transforms.

Returning to the example, the initial condition of a parallel configuration is assumed to be "fully up", such that

$$P_1(t=0) = 1,\ P_2(t=0) = 0,\ P_3(t=0) = 0.$$

Transforming the equations for $P_1'(t)$ and $P_2'(t)$ gives

$$\begin{aligned} sf_1(s)-P_1(t)|_{t=0} &= -2\lambda f_1(s), \\ sf_2(s)-P_2(t)|_{t=0} &= 2\lambda f_1(s)-\lambda f_2(s). \end{aligned}$$

Evaluating $P_1(t)$ and $P_2(t)$ at $t=0$ gives

$$\begin{aligned} sf_1(s)-1 &= -2\lambda f_1(s), \\ sf_2(s)-0 &= 2\lambda f_1(s)-\lambda f_2(s), \end{aligned}$$

from which we obtain

$$\begin{aligned} (s+2\lambda)f_1(s) &= 1, \\ -2\lambda f_1(s)+(s+\lambda)f_2(s) &= 0. \end{aligned}$$

Solving the above equations for $f_1(s)$ and $f_2(s)$, we have

$$\begin{aligned} f_1(s) &= \frac{1}{(s+2\lambda)}, \\ f_2(s) &= \frac{2\lambda}{[(s+2\lambda)(s+\lambda)]}. \end{aligned}$$

From the inverse Laplace transforms in Appendix B,

$$\begin{aligned} P_1(t) &= \mathrm{e}^{-2\lambda t}, \\ P_2(t) &= 2\mathrm{e}^{-\lambda t}-2\mathrm{e}^{-2\lambda t}, \\ R(t) &= P_1(t)+P_2(t) = 2\mathrm{e}^{-\lambda t}-\mathrm{e}^{-2\lambda t}. \end{aligned}$$

The example given above is that of a simple absorbing process where we are concerned about reliability. If a repair capability were added to the model in the form of a repair rate μ, the methodology would remain the same, with only the final result changing. With

a repair rate μ added to the parallel configuration, the incremental transition matrix would be

$$[P_{ij}(\mathrm{d}t)] = \begin{pmatrix} 1-2\lambda\,\mathrm{d}t & 2\lambda\,\mathrm{d}t & 0 \\ \mu\,\mathrm{d}t & 1-(\lambda+\mu)\,\mathrm{d}t & \lambda\,\mathrm{d}t \\ 0 & 0 & 1 \end{pmatrix}.$$

The differential equations would become

$$P_1'(t) = -2\lambda P_1(t) + \mu P_2(t),$$
$$P_2'(t) = 2\lambda P_1(t) - (\lambda+\mu) P_2(t),$$

and the transformed equations would become

$$(s+2\lambda) f_1(s) - \mu f_2(s) = 1,$$
$$-2\lambda f_1(s) + (s+\lambda+\mu) f_2(s) = 0.$$

Hence, we obtain

$$f_1(s) = \frac{(s+\lambda+\mu)}{(s-s_1)(s-s_2)},$$
$$f_2(s) = \frac{2\lambda}{(s-s_1)(s-s_2)},$$

where

$$s_1 = \frac{-(3\lambda+\mu)+\sqrt{(3\lambda+\mu)2-8\lambda^2}}{2},$$
$$s_2 = \frac{-(3\lambda+\mu)-\sqrt{(3\lambda+\mu)2-8\lambda^2}}{2}. \qquad (1.70)$$

Using the Laplace transform, we obtain

$$P_1(t) = \frac{(s_1+\lambda+\mu)\mathrm{e}^{-s_1 t}}{(s_1-s_2)} + \frac{(s_2+\lambda+\mu)\mathrm{e}^{-s_2 t}}{(s_2-s_1)},$$
$$P_2(t) = \frac{2\lambda\,\mathrm{e}^{-s_1 t}}{(s_1-s_2)} + \frac{2\lambda\,\mathrm{e}^{-s_2 t}}{(s_2-s_1)},$$

where s_1 and s_2 are given in (1.70).

Thus, the reliability of two components in a parallel system is given by

$$R(t) = P_1(t) + P_2(t) = \frac{(s_1+3\lambda+\mu)\mathrm{e}^{-s_1 t} - (s_2+3\lambda+\mu)\mathrm{e}^{-s_2 t}}{(s_1-s_2)} \qquad (1.71)$$

System Mean Time Between Failures

Another parameter of interest for absorbing Markov processes is the MTBF. Recalling the previous example of a parallel configuration with repair, the differential equations $P_1'(t)$ and $P_2'(t)$ describing the process were

$$P_1'(t) = -2\lambda P_1(t) + \mu P_2(t),$$
$$P_2'(t) = 2\lambda P_1(t) - (\lambda+\mu) P_2(t).$$

Integrating both sides of the above equations yields

$$\int_0^\infty P_1'(t)\,\mathrm{d}t = -2\lambda \int_0^\infty P_1(t)\,\mathrm{d}t + \mu \int_0^\infty P_2(t)\,\mathrm{d}t,$$
$$\int_0^\infty P_2'(t)\,\mathrm{d}t = 2\lambda \int_0^\infty P_1(t)\,\mathrm{d}t - (\lambda+\mu) \int_0^\infty P_2(t)\,\mathrm{d}t.$$

For the repairable system and from (1.4),

$$\int_0^\infty R(t)\,\mathrm{d}t = \text{MTBF}.$$

Similarly,

$$\int_0^\infty P_1(t)\,\mathrm{d}t = \text{mean time spent in state 1, and}$$
$$\int_0^\infty P_2(t)\,\mathrm{d}t = \text{mean time spent in state 2.}$$

Designating these mean times as T_1 and T_2, respectively, we have

$$P_1(t)\,\mathrm{d}t|_0^\infty = -2\lambda T_1 + \mu T_2,$$
$$P_2(t)\,\mathrm{d}t|_0^\infty = 2\lambda T_1 - (\lambda+\mu) T_2.$$

But $P_1(t) = 0$ as $t \to \infty$ and $P_1(t) = 1$ for $t = 0$. Likewise, $P_2(t) = 0$ as $t \to \infty$ and $P_2(t) = 0$ for $t = 0$. Thus,

$$-1 = -2\lambda T_1 + \mu T_2,$$
$$0 = 2\lambda T_1 - (\lambda+\mu) T_2,$$

or, equivalently,

$$\begin{pmatrix} -1 \\ 0 \end{pmatrix} = \begin{pmatrix} -2\lambda & \mu \\ 2\lambda & -(\lambda+\mu) \end{pmatrix} \begin{pmatrix} T_1 \\ T_2 \end{pmatrix}.$$

Therefore,

$$T_1 = \frac{(\lambda+\mu)}{2\lambda^2}, \quad T_2 = \frac{1}{\lambda},$$
$$\text{MTBF} = T_1 + T_2 = \frac{(\lambda+\mu)}{2\lambda^2} + \frac{1}{\lambda} = \frac{(3\lambda+\mu)}{2\lambda^2}.$$

The MTBF for unmaintained processes is developed in exactly the same way as just shown.

The last case to consider for absorbing processes is that of the availability of a maintained system. The difference between reliability and availability is somewhat subtle for absorbing processes. A good example is that of a communications system where the mission would

continue if such a system failed temporarily, but if it failed permanently the mission would be aborted. Consider a cold-standby system consisting of two units: one main unit and one spare unit [1.1]:

State 1: Main unit operating and the spare is OK;
State 2: Main unit out and restoration underway;
State 3: Spare unit is installed and operating;
State 4: Permanent failure (no spare available).

The incremental transition matrix is given by

$$[P_{ij}(\mathrm{d}t)] = \begin{pmatrix} 1-\lambda\,\mathrm{d}t & \lambda\,\mathrm{d}t & 0 & 0 \\ 0 & 1-\mu\,\mathrm{d}t & \mu\,\mathrm{d}t & 0 \\ 0 & 0 & 1-\lambda\,\mathrm{d}t & \lambda\,\mathrm{d}t \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

We obtain

$$P_1'(t) = -\lambda P_1(t),$$
$$P_2'(t) = \lambda P_1(t) - \mu P_2(t),$$
$$P_3'(t) = \mu P_2(t) - \lambda P_3(t).$$

Using the Laplace transform, we obtain the following results.

The probability of full-up performance $P_1(t)$ is given by

$$P_1(t) = \mathrm{e}^{-\lambda t}.$$

The probability of a down system that is under repair $P_2(t)$ is

$$P_2(t) = \left(\frac{\lambda}{(\lambda-\mu)}\right)\left(\mathrm{e}^{-\mu t} - \mathrm{e}^{-\lambda t}\right).$$

Similarly, the probability of a fully up system with no spare available $P_3(t)$ is

$$P_3(t) = \left(\frac{\lambda\mu}{(\lambda-\mu)^2}\right)[\mathrm{e}^{-\mu t} - \mathrm{e}^{-\lambda t} - (\lambda-\mu)t\,\mathrm{e}^{-\lambda t}].$$

Hence, the point availability $A(t)$ is given by

$$A(t) = P_1(t) + P_3(t).$$

If average or interval availability is required, this is achieved by

$$\left(\frac{1}{t}\right)\int_0^T A(t)\,\mathrm{d}t = \left(\frac{1}{t}\right)\int_0^T [P_1(t) + P_3(t)]\,\mathrm{d}t,$$

where T is the interval of concern.

Ergodic processes, as opposed to absorbing processes, do not have any absorbing states, and hence movement between states can go on indefinitely. For the latter reason, availability (point, steady-state, or interval) is the only meaningful measure. As an example of an ergodic process, we will use a ground-based power unit configured in parallel.

The parallel units are identical, each with exponential failure and repair times with means $1/\lambda$ and $1/\mu$, respectively. Assume a two-repairmen capability if required (both units down), then

State 1: Fully up (both units operating);
State 2: One unit down and under repair (other unit up);
State 3: Both units down and under repair.

It should be noted that, as in the case of failure events, two or more repairs cannot be made in the $\mathrm{d}t$ interval.

$$[P_{ij}(\mathrm{d}t)] = \begin{pmatrix} 1-2\lambda\,\mathrm{d}t & 2\lambda\,\mathrm{d}t & 0 \\ \mu\,\mathrm{d}t & 1-(\lambda+\mu)\,\mathrm{d}t & \lambda\,\mathrm{d}t \\ 0 & 2\mu\,\mathrm{d}t & 1-2\mu\,\mathrm{d}t \end{pmatrix}.$$

Case I: *Point Availability – Ergodic Process.* For an ergodic process, as $t \to \infty$ the availability settles down to a constant level. Point availability allows us to study the process before this "settling down", and it reflects the initial conditions in the process. We can obtain a solution for the point availability in a similar way to that for absorbing processes, except that the last row and column of the transition matrix must be retained and entered into the system of equations. For example, the system of differential equations becomes

$$\begin{pmatrix} P_1'(t) \\ P_2'(t) \\ P_3'(t) \end{pmatrix} = \begin{pmatrix} -2\lambda & \mu & 0 \\ 2\lambda & -(\lambda+\mu) & 2\mu \\ 0 & \lambda & -2\mu \end{pmatrix} \begin{pmatrix} P_1(t) \\ P_2(t) \\ P_3(t) \end{pmatrix}.$$

Similar to the absorbing case, the Laplace transform can be used to solve for $P_1(t)$, $P_2(t)$ and $P_3(t)$; the point availability $A(t)$ is given by

$$A(t) = P_1(t) + P_2(t).$$

Case II: *Interval Availability – Ergodic Process.* This is the same as the absorbing case, with integration over the time period T of interest. The interval availability, $A(T)$, is

$$A(T) = \frac{1}{T}\int_0^T A(t)\,\mathrm{d}t.$$

Case III: *Steady State Availability – Ergodic Process.* Here, the process is examined as $t \to \infty$, with complete "washout" of the initial conditions. By letting $t \to \infty$,

the system of differential equations can be transformed into linear algebraic equations. Thus,

$$\lim_{t\to\infty}\begin{pmatrix}P_1'(t)\\P_2'(t)\\P_3'(t)\end{pmatrix} = \lim_{t\to\infty}\begin{pmatrix}-2\lambda & \mu & 0\\ 2\lambda & -(\lambda+\mu) & 2\mu\\ 0 & \lambda & -2\mu\end{pmatrix}\begin{pmatrix}P_1(t)\\P_2(t)\\P_3(t)\end{pmatrix}.$$

As $t\to\infty$, $P_i(t)\to$ constant and $P_i'(t)\to 0$. This leads to an unsolvable system, namely,

$$\begin{pmatrix}0\\0\\0\end{pmatrix} = \begin{pmatrix}-2\lambda & \mu & 0\\ 2\lambda & -(\lambda+\mu) & 2\mu\\ 0 & \lambda & -2\mu\end{pmatrix}\begin{pmatrix}P_1(t)\\P_2(t)\\P_3(t)\end{pmatrix}.$$

To avoid the above difficulty, an additional equation is introduced:

$$\sum_{i=1}^{3} P_i(t) = 1.$$

With the introduction of the new equation, one of the original equations is deleted and a new system is formed:

$$\begin{pmatrix}1\\0\\0\end{pmatrix} = \begin{pmatrix}1 & 1 & 1\\ -2\lambda & \mu & 0\\ 2\lambda & -(\lambda+\mu) & 2\mu\end{pmatrix}\begin{pmatrix}P_1(t)\\P_2(t)\\P_3(t)\end{pmatrix}$$

or, equivalently,

$$\begin{pmatrix}P_1(t)\\P_2(t)\\P_3(t)\end{pmatrix} = \begin{pmatrix}1 & 1 & 1\\ -2\lambda & \mu & 0\\ 2\lambda & -(\lambda+\mu) & 2\mu\end{pmatrix}^{-1}\begin{pmatrix}1\\0\\0\end{pmatrix}.$$

We now obtain the following results:

$$P_1(t) = \frac{\mu^2}{(\mu+\lambda)^2},$$
$$P_2(t) = \frac{2\lambda\mu}{(\mu+\lambda)^2},$$

and

$$P_3(t) = 1 - P_1(t) - P_2(t),$$
$$= \frac{\lambda^2}{(\mu+\lambda)^2}.$$

Therefore, the steady state availability $A(\infty)$ is given by

$$A_3(\infty) = P_1(t) + P_2(t)$$
$$= \frac{\mu(\mu+2\lambda)}{(\mu+\lambda)^2}.$$

Note that Markov methods can also be employed when failure or repair times are not exponential but can be represented as the sum of exponential times with identical means (an Erlang distribution or gamma distribution with integer-valued shape parameters). Basically, the method involves introducing "dummy" states which, although being of no particular interest in themselves, change the hazard function from constant to increasing.

1.4.2 Counting Processes

Among various discrete stochastic processes, counting processes are widely used in engineering statistics to describe the appearance of events in time, such as failures, the number of perfect repairs, etc. The simplest counting process is a Poisson process. The Poisson process plays a special role in many applications related to reliability [1.1]. A classic example of such an application is the decay of uranium. Here, radioactive particles from nuclear material strike a certain target in accordance with a Poisson process of some fixed intensity. One well-known counting process is the so-called renewal process. This process is described as a sequence of events where the intervals between the events are independent and identically distributed random variables. In reliability theory, this type of mathematical model is used to describe the number of occurrences of an event over a time interval. In this section, we also discuss the quasi-renewal process and the nonhomogeneous Poisson process.

A non-negative, integer-valued stochastic process $N(t)$ is called a counting process if $N(t)$ represents the total number of occurrences of an event in the time interval $[0, t]$ and satisfies these two properties:

1. if $t_1 < t_2$, then $N(t_1) \le N(t_2)$,
2. if $t_1 < t_2$, then $N(t_2) - N(t_1)$ is the number of occurrences of the event in the interval $[t_1, t_2]$.

For example, if $N(t)$ equals the number of persons who have entered a restaurant at or prior to time t, then $N(t)$ is a counting process in which an event occurs whenever a person enters the restaurant.

Poisson Processes

One of the most important counting processes is the Poisson process.

Definition 1.3

A counting process $N(t)$ is said to be a Poisson process with intensity λ if

1. the failure process $N(t)$ has stationary independent increments;
2. the number of failures in any time interval of length s has a Poisson distribution with a mean of λs; in other words

$$P\{N(t+s)-N(t)=n\}=\frac{e^{-\lambda s}(\lambda s)^n}{n!} \qquad n=0,1,2,\ldots; \qquad (1.72)$$

3. the initial condition is $N(0)=0$.

This model is also called a homogeneous Poisson process, indicating that the failure rate λ does not depend on time t. In other words, the number of failures that occur during the time interval $(t, t+s]$ does not depend on the current time t, only the length of the time interval s. A counting process is said to possess independent increments if the number of events in disjoint time intervals are independent.

For a stochastic process with independent increments, the autocovariance function is

$$\mathrm{Cov}[X(t_1), X(t_2)] = \begin{cases} \mathrm{Var}[N(t_1+s)-N(t_2)] & \text{for } 0<t_2-t_1<s \\ 0 & \text{otherwise} \end{cases},$$

where

$$X(t)=N(t+s)-N(t).$$

If $X(t)$ is Poisson-distributed, then the variance of the Poisson distribution is

$$\mathrm{Cov}[X(t_1), X(t_2)] = \begin{cases} \lambda[s-(t_2-t_1)] & \text{for } 0<t_2-t_1<s \\ 0 & \text{otherwise} \end{cases}.$$

This result shows that the Poisson increment process is covariance stationary. We now present several properties of the Poisson process.

Property 1.3

The sum of independent Poisson processes $N_1(t)$,$N_2(t)$, $\ldots$, $N_k(t)$ with mean values $\lambda_1 t, \lambda_2 t, \ldots, \lambda_k t$, respectively, is also a Poisson process with mean $\left(\sum_{i=1}^{k}\lambda_i\right)t$. In other words, the sum of the independent Poisson processes is also a Poisson process with a mean that is equal to the sum of the means of the individual Poisson processes.

Property 1.4

The difference between two independent Poisson processes, $N_1(t)$, and $N_2(t)$, with mean $\lambda_1 t$ and $\lambda_2 t$, respectively, is not a Poisson process. Instead, it has a probability mass function of

$$P[N_1(t)-N_2(t)=k] = e^{-(\lambda_1+\lambda_2)t}\left(\frac{\lambda_1}{\lambda_2}\right)^{\frac{k}{2}} I_k\left(2\sqrt{\lambda_1\lambda_2}t\right), \qquad (1.73)$$

where $I_k(.)$ is a modified Bessel function of order k.

Property 1.5

If the Poisson process $N(t)$ with mean λt is filtered such that not every occurrence of the event is counted, then the process has a constant probability p of being counted. The result of this process is a Poisson process with mean $\lambda pt[]$.

Property 1.6

Let $N(t)$ be a Poisson process and Y_n a family of independent and identically distributed random variables which are also independent of $N(t)$. A stochastic process $X(t)$ is said to be a compound Poisson process if it can be represented as

$$X(t)=\sum_{i=1}^{N(t)} Y_i.$$

Renewal Processes

A renewal process is a more general case of the Poisson process in which the inter-arrival times of the process or the times between failures do not necessarily follow the exponential distribution. For convenience, we will call the occurrence of an event a renewal, the inter-arrival time the renewal period, and the waiting time the renewal time.

Definition 1.4

A counting process $N(t)$ that represents the total number of occurrences of an event in the time interval $(0, t]$ is called a renewal process if the times between the failures are independent and identically distributed random variables.

The probability that exactly n failures occur by time t can be written as

$$P[N(t)=n] = P[N(t)\geq n] - P[N(t)>n]. \quad (1.74)$$

Note that the times between the failures are $T_1, T_2, \ldots, T_n$, so the failures occurring at time W_k are

$$W_k = \sum_{i=1}^{k} T_i$$

and

$$T_k = W_k - W_{k-1}.$$

Thus,

$$\begin{aligned} P[N(t)=n] &= P[N(t)\geq n] - P[N(t)>n] \\ &= P[W_n \leq t] - P[W_{n+1} \leq t] \\ &= F_n(t) - F_{n+1}(t), \end{aligned}$$

where $F_n(t)$ is the cumulative distribution function for the time of the nth failure and $n = 0, 1, 2, \ldots$.

Example 1.21: Consider a software testing model for which the time at which an error is found during the testing phase has an exponential distribution with a failure rate of X. It can be shown that the time of the nth failure follows the gamma distribution with parameters k and n. From (1.74), we obtain

$$\begin{aligned} P[N(t)=n] &= P[N(t)\leq n] - P[N(t)\leq n-1] \\ &= \sum_{k=0}^{n} \frac{(\lambda t)^k}{k!} e^{-\lambda t} - \sum_{k=0}^{n-1} \frac{(\lambda t)^k}{k!} e^{-\lambda t} \\ &= \frac{(\lambda t)^n}{n!} e^{-\lambda t} \quad \text{for } n = 0, 1, 2, \ldots. \end{aligned}$$

Several important properties of the renewal function are given below.

Property 1.7

The mean value function of the renewal process, denoted by $m(t)$, is equal to the sum of the distribution functions for all renewal times, that is,

$$\begin{aligned} m(t) &= E[N(t)] \\ &= \sum_{n=1}^{\infty} F_n(t). \end{aligned}$$

Property 1.8

The renewal function $m(t)$ satisfies the following equation:

$$m(t) = F_a(t) + \int_0^t m(t-s)\, dF_a(s), \quad (1.75)$$

where $F_a(t)$ is the distribution function of the interarrival time or the renewal period.

In general, let $y(t)$ be an unknown function to be evaluated and $x(t)$ be any non-negative and integrable function associated with the renewal process. Assume that $F_a(t)$ is the distribution function of the renewal period. We can then obtain the following result.

Property 1.9

Let the renewal equation be

$$y(t) = x(t) + \int_0^t y(t-s)\, dF_a(s). \quad (1.76)$$

Then its solution is given by

$$y(t) = x(t) + \int_0^t x(t-s)\, dm(s),$$

where $m(t)$ is the mean value function of the renewal process.

The proof of the above property can be easily derived using the Laplace transform. Let $x(t) = a$. Thus, in Property 1.9, the solution $y(t)$ is given by

$$\begin{aligned} y(t) &= x(t) + \int_0^t x(t-s)\, dm(s) \\ &= a + \int_0^t a\, dm(s) \\ &= a\{1 + E[N(t)]\}. \end{aligned}$$

Quasi-Renewal Processes

In this section we discuss a general renewal process: the quasi-renewal process. Let $\{N(t), t > 0\}$ be a counting process and let X_n be the time between the $(n-1)$th and the nth event of this process, $n \geq 1$.

Definition 1.5

[1.10]: If the sequence of non-negative random variables $\{X_1, X_2, \dots\}$ is independent and

$$X_i = \alpha X_{i-1} \tag{1.77}$$

for $i \geq 2$ where $\alpha > 0$ is a constant, then the counting process $\{N(t), t \geq 0\}$ is said to be a quasi-renewal process with parameter α and the first inter-arrival time X_1.

When $\alpha = 1$, this process becomes the ordinary renewal process. This quasi-renewal process can be used to model reliability growth processes in software testing phases and hardware burn-in stages for $\alpha > 1$, and in hardware maintenance processes when $\alpha \leq 1$.

Assume that the probability density function, cumulative distribution function, survival function and failure rate of random variable X_1 are $f_1(x)$, $F_1(x)$, $s_1(x)$ and $r_1(x)$, respectively. Then the pfd, cdf, survival function, and failure rate of X_n for $n = 1, 2, 3, \dots$ are, respectively, given below [1.10]:

$$f_n(x) = \frac{1}{\alpha^{n-1}} f_1\left(\frac{1}{\alpha^{n-1}}x\right),$$
$$F_n(x) = F_1\left(\frac{1}{\alpha^{n-1}}x\right),$$
$$s_n(x) = s_1\left(\frac{1}{\alpha^{n-1}}x\right),$$
$$f_n(x) = \frac{1}{\alpha^{n-1}} r_1\left(\frac{1}{\alpha^{n-1}}x\right).$$

Similarly, the mean and variance of X_n is given as

$$E(X_n) = \alpha^{n-1} E(X_1),$$
$$\mathrm{Var}(X_n) = \alpha^{2n-2}\mathrm{Var}(X_1).$$

Because of the non-negativity of X_1, and the fact that X_1 is not identically 0, we obtain

$$E(X_1) = \mu_1 \neq 0.$$

It is worth noting that the shape parameters for X_n are the same for $n = 1, 2, 3, \dots$ for a quasi-renewal process if X_1 follows the gamma, Weibull, or log normal distribution.

This means that the shape parameters of the inter-arrival time will not change after "renewal". In software reliability, the assumption that the software debugging process does not change the error-free distribution seems reasonable. Thus, if a quasi-renewal process model is used, the error-free times that occur during software debugging will have the same shape parameters. In this sense, a quasi-renewal process is suitable for modeling the increase in software reliability. It is worth noting that

$$\lim_{n\to\infty} \frac{E(X_1 + X_2 + \cdots + X_n)}{n} = \lim_{n\to\infty} \frac{\mu_1(1-\alpha^n)}{(1-\alpha)n},$$
$$= 0 \quad \text{if } \alpha < 1,$$
$$= \infty \text{ if } \alpha > 1.$$

Therefore, if the inter-arrival time represents the error-free time of a software system, then the average error-free time approaches infinity when its debugging process has been operating for a long debugging time.

Distribution of N(t). Consider a quasi-renewal process with parameter α and a first inter-arrival time X_1. Clearly, the total number of renewals $N(t)$ that occur up to time t has the following relationship to the arrival time of the nth renewal SS_n:

$$N(t) \geq n \quad \text{if and only if } SS_n \leq t.$$

In other words, $N(t)$ is at least n if and only if the nth renewal occurs prior to time t. It is easily seen that

$$SS_n = \sum_{i=1}^{n} X_i = \sum_{i=1}^{n} \alpha^{i-1} X_1 \quad \text{for } n \geq 1. \tag{1.78}$$

Here, $SS_0 = 0$. Thus, we have

$$P\{N(t) = n\} = P\{N(t) = n\} - P\{N(t) \geq n+1\}$$
$$= P\{SS_n \leq t\} - P\{SS_{n+1} \leq t\}$$
$$= G_n(t) - G_{n+1}(t),$$

where $G_n(t)$ is the convolution of the inter-arrival times $F_1, F_2, F_3, \dots, F_n$. In other words,

$$G_n(t) = P\{F_1 + F_2 + \cdots + F_n \leq t\}.$$

If the mean value of $N(t)$ is defined as the renewal function $m(t)$, then

$$m(t) = E[N(t)]$$
$$= \sum_{n=1}^{\infty} P\{N(t) \geq n\}$$
$$= \sum_{n=1}^{\infty} P\{SS_n \leq t\}$$
$$= \sum_{n=1}^{\infty} G_n(t).$$

The derivative of $m(t)$ is known as the renewal density

$$\lambda(t) = m'(t).$$

In renewal theory, random variables representing inter-arrival distributions assume only non-negative values, and the Laplace transform of its distribution $F_1(t)$ is defined by

$$\mathcal{L}\{F_1(s)\} = \int_0^\infty \mathrm{e}^{-sx}\,\mathrm{d}F_1(x).$$

Therefore,

$$\mathcal{L}F_n(s) = \int_0^\infty \mathrm{e}^{-a^{n-1}st}\,\mathrm{d}F_1(t) = \mathcal{L}F_1(\alpha^{n-1}s)$$

and

$$\begin{aligned}\mathcal{L}m_n(s) &= \sum_{n=1}^{\infty} \mathcal{L}G_n(s)\\ &= \sum_{n=1}^{\infty} \mathcal{L}F_1(s)\mathcal{L}F_1(\alpha s)\cdots\mathcal{L}F_1(\alpha^{n-1}s).\end{aligned}$$

Since there is a one-to-one correspondence between distribution functions and its Laplace transform, it follows that the first inter-arrival distribution of a quasi-renewal process uniquely determines its renewal function.

If the inter-arrival time represents the error-free time (time to first failure), a quasi-renewal process can be used to model reliability growth in both software and hardware.

Suppose that all software faults have the same chance of being detected. If the inter-arrival time of a quasi-renewal process represents the error-free time of a software system, then the expected number of software faults in the time interval $[0, t]$ can be defined by the renewal function, $m(t)$, with parameter $\alpha > 1$. Denoted by $m_\mathrm{r}(t)$, the number of remaining software faults at time t, it follows that

$$m_\mathrm{r}(t) = m(T_\mathrm{c}) - m(t)$$

where $m(T_\mathrm{c})$ is the number of faults that will eventually be detected through a software lifecycle T_c.

Nonhomogeneous Poisson Processes

The nonhomogeneous Poisson process model (NHPP), which represents the number of failures experienced up to time t, is a nonhomogeneous Poisson process $\{N(t)$ with $t \geq 0\}$. The main issue with the NHPP model is to determine an appropriate mean value function to denote the expected number of failures experienced up to a certain time.

Different assumptions mean that the model will end up with different functional forms of the mean value function. Note that the exponential assumption for the inter-arrival time between failures is relaxed in a renewal process, and the stationary assumption is relaxed in the NHPP.

The NHPP model is based on the following assumptions:

- The failure process has an independent increment; in other words, the number of failures during the time interval $(t, t+s)$ depends on the current time t and the length of the time interval s, and does not depend on the past history of the process.
- The failure rate of the process is given by

$$\begin{aligned}&P\{\text{exactly one failure in } (t, t+\Delta t)\}\\ &\quad = P\{N(t+\Delta t) - N(t) = 1\}\\ &\quad = \lambda(t)\Delta t + o(\Delta t),\end{aligned}$$

  where $\lambda(t)$ is the intensity function.
- During a small interval Δt, the probability of more than one failure is negligible; that is,

$$P\{\text{two or more failures in } (t, t+\Delta t)\} = o(\Delta t),$$

- The initial condition is $N(0) = 0$.

Based on these assumptions, the probability that exactly n failures occur during the time interval $(0, t)$ for the NHPP is given by

$$\Pr\{N(t) = n\} = \frac{[m(t)]^n}{n!}\,\mathrm{e}^{-m(t)} \quad n = 0, 1, 2, \ldots, \tag{1.79}$$

where $m(t) = E[N(t)] = \int_0^t \lambda(s)\mathrm{d}s$ and $\lambda(t)$ is the intensity function. It is easily shown that the mean value function $m(t)$ is nondecreasing.

The reliability $R(t)$, defined as the probability that there are no failures in the time interval $(0, t)$, is given by

$$\begin{aligned}R(t) &= P\{N(t) = 0\}\\ &= \mathrm{e}^{-m(t)}.\end{aligned}$$

In general, the reliability $R(x|t)$ – the probability that there are no failures in the interval $(t, t+x)$ – is given by

$$\begin{aligned}R(x|t) &= P\{N(t+x) - N(t) = 0\}\\ &= \mathrm{e}^{-[m(t+x)-m(t)]}\end{aligned}$$

and its density is given by

$$f(x) = \lambda(t+x)\,\mathrm{e}^{-[m(t+x)-m(t)]},$$

where

$$\lambda(x) = \frac{\partial}{\partial x}[m(x)].$$

The variance of the NHPP can be obtained as follows:

$$\mathrm{Var}[N(t)] = \int_0^t \lambda(s)\,\mathrm{d}s$$

and the autocorrelation function is given by

$$\begin{aligned}\mathrm{Cor}[s] &= E[N(t)]E[N(t+s)-N(t)] + E[N^2(t)] \\ &= \int_0^t \lambda(s)\,\mathrm{d}s \int_0^{t+s} \lambda(s)\,\mathrm{d}s + \int_0^t \lambda(s)\,\mathrm{d}s \\ &= \int_0^t \lambda(s)\,\mathrm{d}s \left[1 + \int_0^{t+s} \lambda(s)\,\mathrm{d}s\right].\end{aligned}$$

Example 1.22: Assume that the intensity λ is a random variable with pdf $f(\lambda)$. Then the probability that exactly n failures occur during the time interval $(0, t)$ is given by

$$P\{N(t) = n\} = \int_0^\infty \mathrm{e}^{-\lambda t}\frac{(\lambda t)^n}{n!} f(\lambda)\,\mathrm{d}\lambda.$$

If the pdf $f(\lambda)$ is given as the following gamma density function with parameters k and m:

$$f(\lambda) = \frac{1}{\Gamma(m)} k^m \lambda^{m-1}\,\mathrm{e}^{-k\lambda} \quad \text{for } \lambda \geq 0$$

then it can be shown that

$$P\{N(t) = n\} = \binom{n+m-1}{n} p^m q^n \quad n = 0, 1, 2, \ldots$$

(this is also called a negative binomial density function), where

$$p = \frac{k}{t+k} \quad \text{and} \quad q = \frac{t}{t+k} = 1 - p.$$

1.B Appendix: Laplace Transform

If a function $h(x)$ can be obtained from some prescribed operation on a function $f(x)$, then $h(x)$ is often called a transform of $f(x)$. For example,

$$h(x) = \sqrt{2 + f(x)},$$

$$h(x) = \frac{\partial}{\partial x} f(x).$$

The Laplace transform of $f(t)$ is the function $f^*(s)$, where

$$f^*(s) = \int_0^\infty \mathrm{e}^{-st} f(t)\,\mathrm{d}t.$$

The Laplace transform is often denoted by $f^*(s)$ or $\mathcal{L}(f(t))$ or $\mathcal{L}(f)$. The results of the Laplace transform for a few simple functions are presented below.

Results

1.

$$\mathcal{L}(1) = \int_0^\infty \mathrm{e}^{-st}\,\mathrm{d}t = \frac{1}{s};$$

2.

$$\mathcal{L}(\mathrm{e}^{-at}) = \int_0^\infty \mathrm{e}^{-st}\,\mathrm{e}^{-at}\,\mathrm{d}t = \int_0^\infty \mathrm{e}^{-(s+a)t}\,\mathrm{d}t = \frac{1}{s+a}.$$

3. If $f(t) = \frac{1}{a}\mathrm{e}^{-\frac{t}{a}}$, then

$$\mathcal{L}[f(t)] = \int_0^\infty \mathrm{e}^{-st}\frac{1}{a}\mathrm{e}^{-\frac{t}{a}}\,\mathrm{d}t = \frac{1}{1+sa}.$$

4. If $f(t) = t\,\mathrm{e}^{at}$, then

$$\mathcal{L}[f(t)] = \int_0^\infty \mathrm{e}^{-st}\,t\,\mathrm{e}^{at}\,\mathrm{d}t = \frac{1}{(s-a)^2}.$$

5. If $f(t) = \frac{1}{a}(\mathrm{e}^{at} - 1)$, then

$$\mathcal{L}[f(t)] = \int_0^\infty \mathrm{e}^{-st}\frac{1}{a}(\mathrm{e}^{at} - 1)\,\mathrm{d}t = \frac{1}{s(s-a)}.$$

6. If $f(t) = (1 + at)\mathrm{e}^{at}$, then

$$\mathcal{L}[f(t)] = \int_0^\infty \mathrm{e}^{-st}(1 + at)\mathrm{e}^{at}\,\mathrm{d}t = \frac{s}{(s-a)^2}.$$

Similarly, we can obtain the following results:

7. If $f(t)=\frac{a\mathrm{e}^{at}-b\mathrm{e}^{bt}}{a-b}$, then
$$\mathcal{L}[f(t)]=\frac{s}{(s-a)(s-b)} \quad \text{for } a\neq b.$$
8. If $f(t)=\frac{\alpha^k t^{k-1}\mathrm{e}^{-at}}{\Gamma(k)}$ then
$$\mathcal{L}[f(t)]=\left(\frac{\alpha}{\alpha+s}\right)^k.$$
9. If $f(t)=\frac{\mathrm{e}^{at}-\mathrm{e}^{bt}}{a-b}$, for $a\neq b$, then
$$\mathcal{L}[f(t)]=\frac{1}{(s-a)(s-b)}.$$
10. If $f(t)=\lambda\mathrm{e}^{-\lambda t}$, then
$$\mathcal{L}[f(t)]=\frac{\lambda}{\lambda+s}.$$
11.
$$\begin{aligned}&\mathcal{L}[c_1f_1(t)+c_2f_2(t)]\\&=\int_0^\infty \mathrm{e}^{-st}[c_1f_1(t)+c_2f_2(t)]\,\mathrm{d}t\\&=c_1\mathcal{L}[f_1(t)]+c_2\mathcal{L}[f_2(t)]\,.\end{aligned}$$
12. If $f_i(t)=\lambda_i\mathrm{e}^{-\lambda_i t}$, then
$$\mathcal{L}\left[\sum_{i=1}^n f_i(t)\right]=\sum_{i=1}^n\frac{\lambda_i}{\lambda_i+s}.$$
13.
$$\mathcal{L}\left[\sum_{i=1}^n f_i(t)\right]=\sum_{i=1}^n\mathcal{L}\,[f_i(t)].$$
14.
$$\begin{aligned}\mathcal{L}[f'(t)]&=\int_0^\infty \mathrm{e}^{-st}f'(t)\,\mathrm{d}t\\&=f(t)\mathrm{e}^{-st}\Big|_0^\infty+s\int_0^\infty f(t)\mathrm{e}^{-st}\,\mathrm{d}t\\&=-f(0^+)+sf^*(s)\\&=-f(0^+)+s\mathcal{L}[f(t)].\end{aligned}$$

2. Statistical Reliability with Applications

This chapter reviews fundamental ideas in reliability theory and inference. The first part of the chapter accounts for lifetime distributions that are used in engineering reliability analysis, including general properties of reliability distributions that pertain to lifetime for manufactured products. Certain distributions are formulated on the basis of simple physical properties, and other are more or less empirical. The first part of the chapter ends with a description of graphical and analytical methods to find appropriate lifetime distributions for a set of failure data.

The second part of the chapter describes statistical methods for analyzing reliability data, including maximum likelihood estimation and likelihood ratio testing. Degradation data are more prevalent in experiments in which failure is rare and test time is limited. Special regression techniques for degradation data can be used to draw inference on the underlying lifetime distribution, even if failures are rarely observed.

The last part of the chapter discusses reliability for systems. Along with the components that comprise the system, reliability analysis must take account of the system configuration and (stochastic) component dependencies. System reliability is illustrated with an analysis of logistics systems (e.g., moving goods in a system of product sources and retail outlets). Robust reliability design can be used to construct a supply chain that runs with maximum efficiency or minimum cost.

2.1 Introduction and Literature Review

In every day use, words like reliability and quality have meanings that vary depending on the context. In engineering, *reliability* is defined as the ability of an item to perform its function, usually measured in terms of probability as a function of time. *Quality* denotes how the item conforms to its specifications, so reliability is a measure of the item's quality over time.

Since the time of *Birnbaum* and *Sanders* [2.1], when system reliability emerged as its own discipline, research has centered on the operation of simple systems with identical parts working independently of each other. Today's systems do not fit this mold; system representation must include multifaceted components with several component states that can vacillate between perfect operation and terminal failure. Not only do components interact within systems, but many systems are dynamic in that the system configuration can be expected to change during its operation, perhaps due to component failures or external stresses. Computer software, for example, changes its failure structure during the course of design, testing and implementation.

Statistical methods for reliability analysis grew from this concept of system examination, and system reliability is often gauged through component lifetime testing. This chapter reviews the current framework for statistical reliability and considers some modern needs from experimenters in engineering and the physical sciences.

Statistical analysis of reliability data in engineering applications cannot be summarized comprehensively in a single book chapter such as this. The following books (listed fully in the reference section) serve as an excellent basis for a serious treatment of the subject:

1. Statistical Theory of Reliability and Life Testing by *Barlow* and *Proschan* [2.2]
2. Practical Methods for Reliability Data Analysis by *Ansell* and *Phillips* [2.3]
3. Reliability: Probabilistic Models and Statistical Methods by *Leemis* [2.4]
4. Applied Reliability by *Tobias* and *Trindade* [2.5]
5. Engineering Reliability by *Barlow* [2.6]
6. Reliability for Technology, Engineering and Management by *Kales* [2.7]
7. Statistical Methods for Reliability Data by *Meeker* and *Escobar* [2.8]
8. Reliability Modeling, Prediction, and Optimization by *Blischke* and *Murthy* [2.9]
9. Statistical Methods for the Reliability of Repairable Systems by *Rigdon* and *Basu* [2.10] and
10. Modern Reliability Analysis: A Bayesian Perspective by *Johnson* et al. [2.11]

Some of the books in this list focus on reliability theory, and others focus exclusively on reliability engineering. From the more inclusive books, [2.8] provides a complete, high-level guide to reliability inference tools for an engineer, and most examples have an engineering basis (usually in manufacturing). For reliability problems closely associated with materials testing, *Bogdanoff* and *Kozin* [2.12] connects the physics of degradation to reliability models. *Sobczyk* and *Spencer* [2.13] also relate fatigue to reliability through probability modeling. For reliability prediction in software performance, *Lyu* [2.14] provides a comprehensive guide of engineering procedures for software reliability testing, while a more theoretical alternative by *Singpurwalla* and *Wilson* [2.15] emphasizes probability modeling for software reliability, including hierarchical Bayesian methods. Closely related to reliability modeling in engineering systems, *Bedford* and *Cooke* [2.16] goes over methods of probabilistic risk assessment, which is an integral part of reliability modeling for large and complex systems.

Other texts emphasize reliability assessment in a particular engineering field of interest. For statistical reliability in geotechnical engineering, *Baecher* and *Christian* [2.17] is recommended as it details statistical problems with soil variability, autocorrelation (i. e., Kriging), and load/resistance factors. *Ohring* [2.18] provides a comprehensive guide to reliability assessment for electrical engineering and electronics manufacturing, including reliability pertaining to degradation of contacts (e.g., crack growth in solder), optical-fiber reliability, semiconductor degradation and mass-transport-induced failure. For civil engineering, *Melchers'* [2.19] reliability text has a focus on reliability of structural systems and loads, time-dependent reliability and resistance modeling.

2.2 Lifetime Distributions in Reliability

While engineering research has contributed a great deal of the current methods for reliability life testing, an equally great amount exists in the biological sciences, especially relating to epidemiology and biostatistics. Life testing is a crucial component to both fields, but the bio-related sciences tend to focus on mean lifetimes and numerous risk factors. Engineering methods, on the other hand, are more likely to focus on upper (or lower) percentiles of the lifetime distribution as well as the stochastic dependencies between working components. Another crucial difference between the two research areas is that engineering models are more likely to be based on principles of physics that lead to well-known distributions such as Weibull, log–normal, extreme value and so on.

The failure-time distribution is the most widely used probability tool for modeling product reliability in science and industry. If $f(x)$ represents the probability density function for the product's failure time, then the its reliability is $R(x) = \int_x^\infty f(u)\,\mathrm{d}u$, and $R(t) = 1 - F(t)$ where F is the cumulative distribution function (CDF) corresponding to f. A *quantile* is the CDF's inverse; The p-th quantile of F is the lifetime value t_p such that $F(t_p) = p$. To understand the quality of a manufactured product through these lifetime probability functions, it is often useful to consider the notion of *aging*. For example, the (conditional) reliability of a product that has been working t units of time

is

$$R(x|t) = \frac{R(t+x)}{R(t)}, \text{ if } R(t) > 0\,. \tag{2.1}$$

The rate of change of $R(x|t)$ is an important metric for judging a product's quality, and the conditional *failure rate* function $h(t)$ is defined as

$$h(t) = \lim_{x\to\infty} x^{-1}\frac{R(t)-R(t+x)}{R(t)} = \frac{f(t)}{R(t)}\,. \tag{2.2}$$

The *cumulative failure rate* (sometimes called the *hazard function*) is $H(t) = \int_0^t h(u)\,\mathrm{d}u$, and has many practical uses in reliability theory because of its monotonicity and the fact that $H(t) = -\log R(t)$.

The failure rate clearly communicates how the product ages during different spans of its lifetime. Many manufactured products have an increasing failure rate, but the rate of increase is rarely stable throughout the product's lifetime. If $r(t)$ remains constant, it is easy to show the lifetime distribution is exponential $\left[f(x) = \theta\exp(-\theta x), x > 0\right]$ and the product exhibits no aging characteristics. Many electronic components and other manufactured items have brief initial period when failure rate is relatively high and decrease toward a steady state, where it stays until aging causes the rate to increase. This is called a bath-tub failure rate. The period in which early failures occur (called *infant mortality*) is called the *burn-in* period, and is often used by manufacturers to age products and filter out defectives (early failures) before being making it available to the consumer.

2.2.1 Alternative Properties to Describe Reliability

The failure rate function, reliability function, cumulative hazard function, and probability density describe different aspects of a lifetime distribution. The expected lifetime, or *mean time to failure* (MTTF) is an important measure for repairable systems. Several alternatives for characterizing properties of the lifetime distribution include:

- *Mean residual life* $= L(t) = E_X(X - t|X \geq t)$ is the expected residual life of a component that has already lasted t units of time. If $L(t)$ is less than the expected lifetime μ, the product is exhibiting aging by the time t.
- *Reversed hazard rate* $= \nu(t) = f(x)/F(x)$ provides a different aspect of reliability: the conditional failure frequency at the time just before t given that the product failed in $(0, t]$ (see Chapt. 1 of [2.20], for example).
- *Percentile residual life* $= Q_\alpha = F^{-1}\left[1-(1-\alpha)\times R(t)\right] - t$ is the α quantile of the residual life (the conditional lifetime distribution given that the product has lasted t units of time). The median residual life, where $\alpha = 1/2$ compares closely to $L(t)$.
- *Mill's ratio* $= R(x)/f(x) = 1/h(x)$, used in economics, is not an ordinary way to characterize reliability, but it is worth noting because of its close connection to failure rate.

2.2.2 Conventional Reliability Lifetime Distributions

So far, only one distribution (exponential) has been mentioned. Rather than presenting a formal review of commonly used reliability distributions, a summary of commonly applied lifetime distributions is presented in Table 2.1, including the exponential, gamma, Weibull, log–normal, logistic, Pareto and extreme value. In the table, $\Gamma(t) = \int_0^\infty x^{t-1}\,\mathrm{e}^{-x}\,\mathrm{d}x$ is the ordinary gamma function, and $IG(t, x)$ represents the corresponding incomplete Gamma function.

For manufacturing centers and research laboratories that conduct lifetime tests on products, lifetime data is an essential element of reliability analysis. However, a great deal of reliability analysis is based on field data, or reliability information sampled from day-to-day usage of the product. In many of these instances, lifetime data is a luxury not afforded to the reliability inference. Instead, historical event data and inspection counts are logged for the data analysis. Consequently, several discrete distributions (e.g., Poisson, binomial, geometric) are important in reliability applications. Chapter 4 has a more detailed discussion of these and other statistical distributions applied in engineering problems.

2.2.3 From Physics to Failure Distributions

Many of the distributions in Table 2.1 are derived based on physical principles. For example, *Weibull* [2.21] derived the distribution that takes his name to represent the breaking strength of materials based on the idea that some components are comparable to a chain that is no stronger than its weakest link. From this premise, the distribution can be derived from properties of minimums, in contrast to the extreme value distribution, which can be derived through the properties of maximums (see [2.22], for example). In a short time after its introduction, the Weibull distribution was successfully applied to numerous modeling problems in engineering and has become the hallmark distribution in applied re-

Table 2.1 Common lifetime distributions used in reliability data analysis

Distribution	$f(t),\quad t>0$	$h(t)$	μ	σ^2	Parameter space
Exponential	$\theta\,\mathrm{e}^{-\theta t}$	θ	$1/\theta$	$1/\theta^2$	$\theta>0$
Weibull	$\lambda\kappa t^{\kappa-1}\,\mathrm{e}^{-\lambda t^{\kappa}}$	$\lambda\kappa t^{\kappa-1}$	$\lambda^{-1/\kappa}\Gamma\left(1+\frac{1}{\kappa}\right)$	$\lambda^{-2/\kappa}\left[\Gamma\left(1+\frac{2}{\kappa}\right)-\Gamma^2\left(1+\frac{1}{\kappa}\right)\right]$	$\kappa>0,\lambda>0$
Gamma	$\lambda^r\Gamma^{-1}(r)t^{r-1}\,\mathrm{e}^{-\lambda t}$	$\frac{\lambda^r t^{r-1}\,\mathrm{e}^{-\lambda t}}{\Gamma(r)\,[1-IG(r,\lambda t)]}$	r/λ	r/λ^2	$r>0,\lambda>0$
Log–normal	$\frac{1}{\sigma\sqrt{2\pi}}\,\mathrm{e}^{\frac{-(\log t-\mu)^2}{2\sigma^2}}$	$f(t)/R(t)$	$\mathrm{e}^{\mu+\sigma^2/2}$	$\mathrm{e}^{2\mu+2\sigma^2}-\mathrm{e}^{2\mu+\sigma^2}$	$-\infty<\mu<\infty,\sigma>0$
Logistic	$\frac{\mathrm{e}^{-(t-\lambda)/\beta}}{\beta\left(1+\mathrm{e}^{-(t-\lambda)/\beta}\right)^2}$	$\left[\beta\left(1+\mathrm{e}^{-(t-\lambda)/\beta}\right)\right]^{-1}$	λ	$(\beta\pi)^2/3$	$-\infty<\lambda<\infty,\beta>0$
Pareto	$\frac{m\theta^m}{t^{m+1}}$	$\frac{m}{t}$	$\frac{m\theta}{m-1}$	$\frac{m\theta^2}{(m-1)^2(m-2)}$	$t>\theta,m>0$
Extreme value	$\frac{\exp[-(t-a)/b]}{b\exp[-\exp(-(t-a)/b)]}$	$\frac{\exp[-(t-a)/b]}{b\exp[-\exp(-(t-a)/b)]-1}$	$a-b\Gamma'(1)$	$(b\pi)^2/6$	$-\infty<a<\infty,b>0$

liability. A primary reason for its suitability to lifetime analysis is its flexible failure rate; unlike other distributions listed in Table 2.1, the Weibull failure rate is simple to model, easy to demonstrate and it can be either increasing or decreasing. A mixture of two Weibull distributions can be used to portray a bath-tub failure rate (as long as only one of the shape parameters is less than one). *Mudholkar* et al. [2.23] introduce a new shape parameter to a generalized Weibull distribution that allows bath-tub-shaped failure rates as well as a broader class of monotone failure rates.

For materials exposed to constant stress cycles with a given stress range, lifetime is measured in number of cycles until failure (N). The Whöler curve (or S–N curve) relates stress level (S) to N as $NS^b=k$, where b and k are material parameters (see [2.13] for examples). By taking logarithms of the S–N equation, we can express cycles to failure as a linear function: $Y=\log N=\log k-b\log S$. If N is log–normally distributed, then Y is normally distributed and regular regression models can be applied for predicting cycles to failure (at a given stress level). In many settings, the log–normal distribution is applied as the failure time distribution when the corresponding degradation process based on rates that combine multiplicatively. Despite having a concave-shaped (or upside-down bath-tub shape) failure rate, the log–normal is especially useful in modeling fatigue crack growth in metals and composites.

Birnbaum and *Saunders* [2.1] modeled the damage to a test item after n cycles as $B_n=\zeta_1+\cdots+\zeta_n$, where ζ_i represents the damage amassed in the i-th cycle. If failure is determined by B_n exceeding a fixed damage threshold value B^*, and if the ζ_i are identically and independently distributed,

$$P(N\le n)=P(B_n>B^*)\approx\Phi\left(\frac{B^*-n\mu}{\sigma\sqrt{n}}\right)\,, \tag{2.3}$$

where Φ is the standard normal CDF. This results because B_n will be approximately normal if n is large enough. The reliability function for the test unit is

$$R(t)\approx\Phi\left(\frac{B^*-n\mu}{\sigma\sqrt{n}}\right) \tag{2.4}$$

which is called the *Birnbaum–Saunders* distribution. It follows that

$$W=\frac{\mu\sqrt{N}}{\sigma}-\frac{B^*}{\sigma\sqrt{N}} \tag{2.5}$$

has a normal distribution, which leads to accessible implementation in lifetime modeling (see [2.24] or [2.12] for more properties).

2.2.4 Lifetime Distributions from Degradation Modeling

These examples show how the product's lifetime distribution can be implied by knowledge of how it degrades in time. In general, degradation measurements have great potential to improve lifetime data analysis, but they also introduce new problems to the statistical inference. Lifetime models have been researched and refined for

many manufactured products that are put on test. On the other hand, degradation models tend to be empirical (e.g., nonparametric) or based on simple physical properties of the test item and its environment (e.g., the Paris crack law, Arrhenius rule, power law) which often lead to obscure lifetime models. *Meeker* and *Escobar* [2.8] provide a comprehensive guide to degradation modeling, and show that many valid degradation models will not yield lifetime distributions with closed-form solutions. Given the improving computational tools available to researchers, this is no deterrent to using degradation analysis; users of the S-plus programming software can access advanced tools for degradation analysis from SPLIDA (S-plus functions for life data analysis) developed by *Meeker* [2.25].

In a setting where the lifetime distribution is known, but the degradation distribution is unknown, degradation information does not necessarily complement the available lifetime data. For example, the lifetime data may be distributed as Weibull, but conventional degradation models will contradict the Weibull assumption (actually, the rarely used *reciprocal Weibull* distribution for degradation with a fixed failure threshold leads to Weibull lifetimes).

In selecting a degradation model based on longitudinal measurements of degradation, monotonic models are typically chosen under the assumption that degradation is a one-way process. In some cases, such as the measured luminosity of light displays (vacuum fluorescent displays, plasma display devices), the degradation is not necessarily monotonic because, during the first phase of product life, impurities inside the light display's vacuum are slowly burned off and luminosity increases. After achieving a peak level, usually before 100 hours of use, the light slowly degrades in a generally monotonic fashion. See *Bae* and *Kvam* [2.26, 27] for details on the modeling of non-monotonic degradation data. Degradation data analysis is summarized in Sect. 2.3.3.

2.2.5 Censoring

For most products tested in regular-use conditions (as opposed to especially harsh conditions), the allotted test time is usually too short to allow the experimenter to witness failure times for the entire set that is on test. When the item is necessarily taken off test after a certain amount of test time, its lifetime is *right censored*. This is also called type I censoring. Type II censoring corresponds to tests that are stopped after a certain number of failures (say k out of n, $1 \le k \le n$) occur.

Inspection data are lifetimes only observed at fixed times of inspection. If the inspection reveals a failed test item, it must be *left censored* at that fixed time. Items that are still working at the time of the last inspection are necessarily right censored. This is sometimes called *interval censoring*.

Censoring is a common hindrance in engineering applications. Lifetime data that are eclipsed by censoring cause serious problems in the data analysis, but it must be kept in mind that each observation, censored or not, contributes information and increases precision in the statistical inference, overall.

2.2.6 Probability Plotting

Probability plotting is a practical tool for checking the adequacy of a fitted lifetime distribution to a given set of data. The rationale is to transform the observed data according to a given distribution so a linear relationship exists if the distribution was specified correctly. In the past, probability plotting paper was employed to construct the transformation, but researchers can find plotting options on many computer packages that feature data analysis (e.g., SAS, S-Plus, Matlab, Minitab, SPSS) making the special plotting paper nearly obsolete. Despite the applicability of this technique, few engineering texts feature in-depth discussion on probability plotting and statistics texts tend to focus on theory more than implementation. *Rigdon* and *Basu* [2.10] provide a thorough discussion of basic probability plotting, and *Atkinson* [2.28] provides a substantial discussion of the subject in the context of regression diagnostics. Advanced plotting techniques even allow for censored observations (see *Waller* and *Turnbull* [2.29], for example).

To illustrate how the plot works, we first linearize the CDF of the distribution in question. For example, if we consider the two-parameter Weibull distribution, the *quantile function* is

$$t_p = \left(\frac{-\log p}{\lambda}\right)^{1/\kappa}, \tag{2.6}$$

which implies that the plot of $\log t$ has a linear relationship with the log–log function of $p = F(t)$. Hence, Weibull probability plots are graphed on log–log probability paper. Figure 2.1 shows a Weibull plot (using Minitab) for the fatigue life of 67 alloy specimens that failed before $n = 300\,000$ cycles. This data set is from *Meeker* and *Escobar* [2.8] and the plot also includes 95% confidence bands that identify the uncertainty associated with the plot. In this case the curvature (especially

2.3 Analysis of Reliability Data

Once the lifetime distribution of a test item is determined, the data can be used to estimate important properties of the distribution, including mean, standard deviation, failure rate, reliability (at a fixed time t) and upper or lower quantiles that pertain to early or late failure times.

There are two fundamental methods for approaching the analysis of lifetime data: Bayesian methods and, for the lack of an optimal term, non-Bayesian methods. Although Bayesian methods are accepted widely across many fields of engineering and physical science, non-Bayesian statistics, mostly frequentist and likelihood methods, are still an industry standard. This chapter will not detail how methods of statistical inference are derived in various frameworks of statistical ideology. Accelerated life testing, an important tool for designing reliability experiments, is discussed in detail in Chapt. 22 and is only mentioned in this chapter. Instead, a summary of important procedures is outlined for statistical estimation, confidence intervals and hypothesis tests.

2.3.1 Maximum Likelihood

Parametric likelihood methods examine a family of probability distributions and choose the parameter combination that best fits the data. A likelihood function is generally defined by the observed probability model; if the lifetime data $X_1, \ldots, X_n$ are independently and identically (i.i.d.) distributed with density function $f_X(x;\theta)$, the likelihood function is

$$L(\theta) = \prod_{i=1}^{n} f_X(x_i;\theta) \tag{2.7}$$

and the *maximum likelihood estimator* (MLE) is the value of θ that maximizes $L(\theta)$. Single-parameter distributions such as the exponential generate easily solved MLEs, but distributions with two or more parameters are not often straightforward. Samples that are not IID lead to complicated likelihood functions and numerical methods are usually employed to solve for MLEs. If an observation x represents a right-censoring time, for example, then $P(\text{censor}) = R(x)$ and this information contributes the term $R(x)$ to the likelihood instead of $f(x)$. *Leemis* [2.4] provides a thorough introduction to likelihood theory for reliability inference.

For most parametric distributions of interest, the MLE $(\hat{\theta})$ has helpful limit properties. As the sample size $n \to \infty$, $\sqrt{n}(\hat{\theta} - \theta) \to N\left[0, i(\theta)^{-1}\right]$, where

$$i(\theta) = \mathrm{E}\left[\left(\frac{\partial}{\partial\theta}\log f\right)^2\right] = -\mathrm{E}\left(\frac{\partial^2}{\partial\theta^2}\log f\right) \tag{2.8}$$

is the estimator's *Fisher information*. For other parameters of interest, say $\psi(\theta)$, we can construct approximate confidence intervals based on an estimated variance using the Fisher information:

$$\hat{\sigma}^2\left[\psi(\hat{\theta})\right] \approx \frac{1}{\psi(\hat{\theta})^2 i(\hat{\theta})} \,. \tag{2.9}$$

This allows the analyst to make direct inference for the component reliability $\left[\psi(\theta;t) = R_\theta(t)$, for example$\right]$.

Example. MLE for failure rate with exponential data $(X_1, \ldots, X_n)$: the likelihood is based on $f(x) = \theta\exp(-\theta x)$ and is easier to maximize in its natural-log form

$$\log L(\theta) = \log\left(\prod_{i=1}^{n}\theta\,\mathrm{e}^{-\theta x_i}\right) = n\log\theta - \theta\sum_{i=1}^{n} x_i \,.$$

The maximum occurs at $\hat{\theta} = 1/\bar{x}$, and the Fisher information $i(\theta) = n/\theta^2$, so an approximate $(1-\alpha)$ confidence interval is

$$\frac{1}{\bar{x}} \pm z_{\frac{\alpha}{2}}\, i(\hat{\theta})^{-1/2} = \frac{1}{\bar{x}} \pm z_{\frac{\alpha}{2}}\frac{\hat{\theta}}{\sqrt{n}} = \frac{1}{\bar{x}} \pm z_{\frac{\alpha}{2}}\left(\bar{x}\sqrt{n}\right)^{-1} . \tag{2.10}$$

In this case, the approximation above is surpassed by an exact interval that can be constructed from the statistic $2\theta(X_1 + \cdots + X_n)$ which has a chi-squared distribution with $2n$ degrees of freedom. The confidence statement $P\left[\chi^2_{2n}(1-\alpha/2) \le (X_1 + \cdots + X_n) \le \chi^2_{2n}(\alpha/2)\right] = 1-\alpha$, where $\chi^2_{2n}(\alpha)$ represents the α quantile of the chi-squared distribution with $2n$ degrees of freedom, leads to a $1-\alpha$ confidence interval for θ of

$$\left(\frac{\chi^2_{2n}(1-\alpha/2)}{2n\bar{x}}, \frac{\chi^2_{2n}(\alpha/2)}{2n\bar{x}}\right) . \tag{2.11}$$

2.3.2 Likelihood Ratio

Uncertainty bounds, especially for multidimensional parameters, are more directly computed using the likelihood ratio (LR) method. Here we consider θ to have p components. Confidence regions are constructed by

actual contours (in p-dimensions) of the likelihood function. Define the LR as

$$\Lambda(\theta, \hat{\theta}) = \frac{L(\theta)}{L(\hat{\theta})} , \tag{2.12}$$

where $\hat{\theta}$ is the MLE of L. If θ is the true value of the parameter, then

$$-2 \log \Lambda \sim \chi_p^2 ,$$

where χ_p^2 is the chi-squared distribution with p degrees of freedom. A $(1-\alpha)$ confidence region for θ is

$$\left\{ \theta : -2 \log \Lambda(\theta, \hat{\theta}) \le \chi_p^2(\alpha) \right\} , \tag{2.13}$$

where $\chi_p^2(\alpha)$ represents the $1-\alpha$ quantile of the χ_p^2 distribution.

Example. Confidence region for Weibull parameters: In this case, the MLEs for $\theta = (\lambda, r)$ must be computed using numerical methods. Many statistical software packages compute such estimators along with confidence bounds. With $(\hat{\lambda}, \hat{r})$, $L(\hat{\lambda}, \hat{r})$ standardizes the likelihood ratio so that $0 \le \Lambda(\theta, \hat{\theta}) \le 1$ and Λ peaks at $(\lambda, r) = (\hat{\lambda}, \hat{r})$. Figure 2.2 shows 50%, 90% and 95% confidence regions for the Weibull parameters based on a simulated sample of $n = 100$.

Empirical likelihood provides a powerful method for providing confidence bounds on parameters of inference without necessarily making strong assumptions about the lifetime distribution of the product (i. e., it is *nonparametric*). This chapter cannot afford the space needed to provide the reader with an adequate description of its method and theory; *Owen* [2.30] provides a comprehensive study of empirical likelihood including its application to lifetime data.

2.3.3 Degradation Data

As an alternative to traditional life testing, degradation tests can be effective in assessing product reliability when measurements of degradation leading to failure are observable and quantifiable. *Meeker* and *Escobar* [2.8] provide the most comprehensive discussion on modeling and analyzing degradation data for manufactured items that have either a soft failure threshold (i. e., an arbitrary fixed point at which the device is considered to have failed) or items that degrade before reaching a failed state. In the electronics industry, product lifetimes are far too long to test in a laboratory; some products in the lab will tend to become obsolete long before they actually fail. In such cases, accelerated degradation testing (ADT) is used to hasten product failure. In the manufacture of electronic components, this is often accomplished by increasing voltage or temperature. See Chapt. 22 for a review of recent results in ALT.

If the degradation path is modeled as

$$y_i(t) = \eta_i(t) + \epsilon_i(t) , \tag{2.14}$$

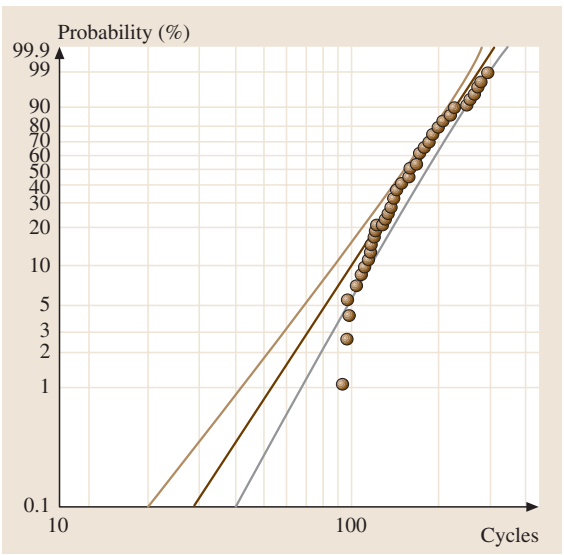

Fig. 2.1 Weibull probability plot for alloy T7987 fatigue life [2.8]

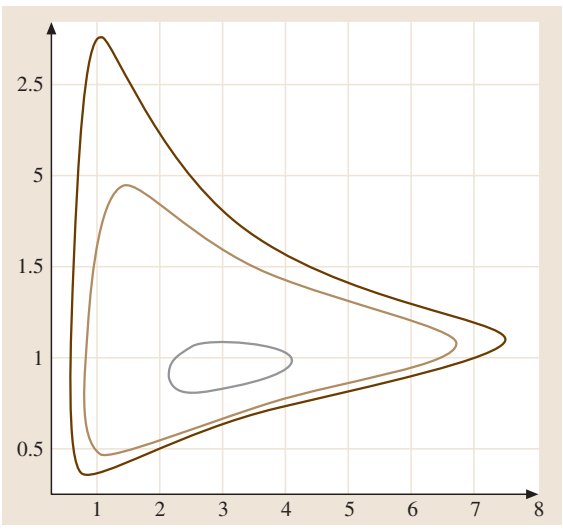

Fig. 2.2 $1-\alpha = 0.50, 0.90, 0.95$ confidence regions for Weibull parameters (λ, r) based on simulated data of size $n = 100$

where η_i is the path of the i-th tested unit ($i = 1, \ldots, n$) and ϵ_i represents an error term that has a distribution $H(\epsilon; \Sigma)$ with parameter Σ unknown. Failure would be declared once $y_i(t)$ passes a certain degradation threshold, say y^*. The lifetime distribution can be computed as (assuming degradation is an increasing function)

$$F(t) = P\left[y(t) > y^*\right] = P\left[\epsilon_i(t) > y^* - \eta_i(t)\right] . \tag{2.15}$$

If η is a deterministic function, the lifetime distribution is driven completely by the error term. This is not altogether realistic. In most cases, item-to-item variability exists and the function η contains *random coefficients*; that is, $\eta(t) = \eta(t, \lambda, \theta)$, where λ is a vector of unknown parameters (common to all units) and θ is a vector of random coefficients which have a distribution G (with further unknown parameters β) so that realizations of θ change from unit to unit. With an accumulated set of unknown parameters (λ, β, Σ), this makes for a difficult computation of the lifetime distribution. Numerical methods and simulations are typically employed to generate point estimates and confidence statements.

Least squares or maximum likelihood can be used to estimate the unknown parameters in the degradation model. To estimate $F(t_0)$, one can simulate M degradation curves (choosing M to be large) from the estimated regression by generating M random coefficients $\theta_1, \ldots, \theta_M$ from the estimated distribution $G(\theta; \hat{\beta})$. Next compute the estimated degradation curve for y_i based on the model with θ_i and $\hat{\lambda}$: $y_i(t) = \eta_i(t; \hat{\lambda}, \theta_i)$. Then $\hat{F}(t_0)$ is the proportion of the M generated curves that have reached the failure threshold y^* by time t_0.

Meeker and Escobar use *bootstrap confidence intervals* for measuring the uncertainty in the lifetime distribution estimate. Their method follows the general algorithm for nonparametric bootstrap confidence intervals described in *Efron* and *Tibshirani* [2.31]. There are numerous bootstrap sampling methods for various uncertainty problems posed by complex models. This algorithm uses a nonparametric bootstrap sampling procedure which *resamples* n of the sample degradation curves *with replacement* (i. e., so some curves may not be represented in the sample while others may be represented multiple times). This resampled set will be termed the bootstrap sample in the following procedure for constructing confidence intervals.

1. Compute estimates of the parameters β, λ, Σ.
2. Use simulation (as above) to construct $\hat{F}(t_0)$.
3. Generate $N \geq 1000$ bootstrap samples, and for each one, compute estimates $\hat{F}^{(1)}(t_0), \ldots, \hat{F}^{(N)}(t_0)$. This is done as before except now the M simulated degradation paths are constructed with an error term generated from $H(\eta; \hat{\Sigma})$ to reflect variability in any single degradation path.
4. With the collection of bootstrap estimates from step 3, compute a $1 - \alpha$ confidence interval for $F(t_0)$ as $\left[\hat{F}^l(t_0), \hat{F}^u(t_0)\right]$, where the indexes $1 \leq l \leq u \leq N$ are calculated as $l/N = \Phi[2\Phi^{-1/2}(p_0) + \Phi^{-1/2} \times (\alpha/2)]$ and $u/N = \Phi[2\Phi^{-1/2}(p_0) + \Phi^{-1/2} \times (1 - \alpha/2)]$, and p_0 is the proportion of bootstrap estimates of $F(t_0)$ less than $\hat{F}(t_0)$.

Procedures based on realistic degradation models can obviously grow to be computationally cumbersome, but for important applications the increase in statistical efficiency can be dramatic. In the past, these computations have impeded degradation analysis from being a feature of reliability problem solving. Such analyses are easier to implement now, and the reliability analyst need not be coerced into using an overly simplistic model—for instance, a linear model that does not allow for random coefficients.

2.4 System Reliability

A *system* is an arrangement of components that work together for a common goal. So far, the discussion has fixated on the lifetime analysis of a single component, so this represents an extension of single-component reliability study. At the simplest level, a system contains n components of an identical type that are assumed to function independently. The mapping of component outcomes to system outcomes is through the system's structure function. The *reliability function* describes the system reliability as a function of component reliability.

A *series* system is such that the failure of any of the n components in the working group causes the system to fail. If the probability that a single component fails in its mission is p, the probability the system fails is $1 - P(\text{system succeeds}) = 1 - P(\text{all } n \text{ components succeed}) = 1 - (1 - p)^n$. More generally, in terms of component reliabili-

ties $(p_1, \ldots, p_n)$, the system reliability function Ψ is

$$\Psi(p_1, \ldots, p_n) = \prod_{i=1}^{n} (1 - p_i) \,. \tag{2.16}$$

A *parallel* system is just the opposite; it fails only after every one of its n working components fail. The system failure probability is then

$$\Psi(p_1, \ldots, p_n) = 1 - \prod_{i=1}^{n} p_i \,. \tag{2.17}$$

The parallel system and series system are special cases of a k-out-of-n system, which is a system that works as long as at least k out of its n components work. Assuming $p_i = p, i = 1, \ldots, n$, the reliability of a k-out-of-n systems is

$$\Psi(p) = \sum_{i=k}^{n} \binom{n}{i} (1-p)^i p^{n-1} \,. \tag{2.18}$$

Of course, most component arrangements are much more complex that a series or parallel system. With just three components, there are five unique ways of arranging the components in a coherent way (that is, so that each component success contributes positively to the system reliability). Figure 2.3 shows the *system structure* of those five arrangements in terms of a *logic diagram* including a series system (1), a 2-out-of-3 system (3), and a parallel system (5). Note that the 2-out-of-3 system cannot be diagrammed with only three components, so each component is represented twice in the logic diagram. Figure 2.4 displays the corresponding reliabilities, as a function of the component reliability $0 \le p \le 1$ of those five systems. Fundamental properties of coherent systems are discussed in [2.2] and [2.4].

2.4.1 Estimating System and Component Reliability

In many complex systems, the reliability of the system can be computed through the reliability of the components along with the system's structure function. If the exact reliability is too difficult to compute explicitly, reliability bounds might be achievable based on *minimum cut sets* (MCS) and *minimum path sets* (MPS). An MPS is the collection of the smallest component sets that are required to work in order to keep the system working. An MCS is the collection of the smallest component sets that are required to fail in order for the system to fail. Table 2.2 shows the minimum cuts sets and path sets for the three-component systems from Fig. 2.3.

In most industrial systems, components have different roles and varying reliabilities, and often the component reliability depends on the working status of other components. System reliability can be simplified through fault-tree analyses (see Chapt. 7 of [2.16], for example), but uncertainty bounds for system reliability are typically determined through simulation.

In laboratory tests, component reliabilities are determined and the system reliability is computed as a function of the statistical inference of component lifetimes. In field studies, the tables are turned. Component manufacturers seeking reliability data outside laboratory

Table 2.2 Minimum cut sets and path sets for the systems in Fig. 2.3

System	Minimum path sets	Minimum cut sets
1	{A,B,C}	{A}, {B}, {C}
2	{A,B}, {C}	{A,C}, {B,C}
3	{A,B}, {A,C}, {B,C}	{A,B}, {A,C}, {B,C}
4	{A,B}, {A,C}	{A}, {B,C}
5	{A}, {B}, {C}	{A,B,C}

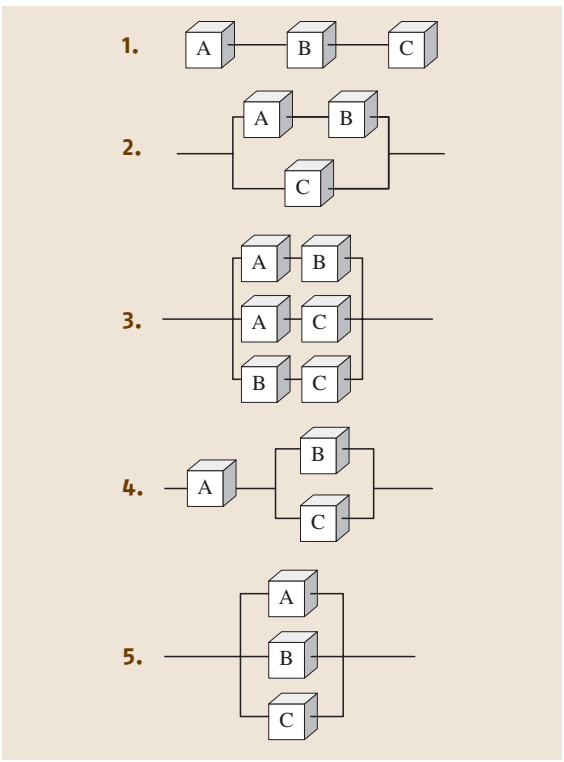

Fig. 2.3 Five unique systems of three components: (1) is series, (3) is 2-out-of-3 and (5) is parallel

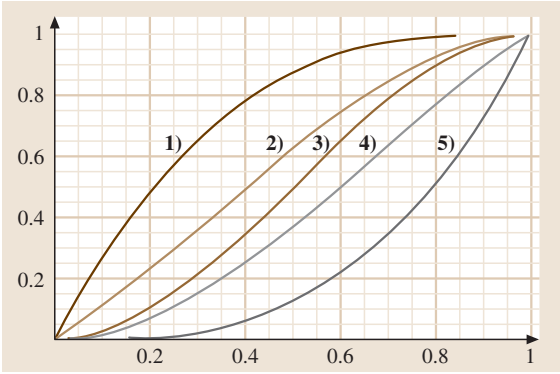

Fig. 2.4 System reliabilities of five system configurations in Fig. 2.3 from the series system (1) to the parallel system (5)

tests look to component lifetime data within a working system. For a k-out-of-n system, for example, the system lifetime represents an order statistic of the underlying distribution function. That is, if the ordered lifetimes form a set of independent and identically distributed components ($X_{1:n} \le X_{2:n} \le \cdots \le X_{n:n}$), then $X_{n-k+1:n}$ represents the k-out-of-n system lifetime. The density function for $X_{r:n}$ is

$$f_{r:n}(t) = r\binom{n}{r} F(t)^{r-1}\,[1-F(t)]^{n-r}\,f(t), t>0\,. \tag{2.19}$$

Kvam and *Samaniego* [2.32] derived the nonparametric maximum likelihood estimator for $F(t)$ based on a sample of k-out-of-n system data, and showed that the MLE $\hat{F}(t)$ is consistent. If the i-th system ($i = 1, \ldots, m$) observed is a k_i-out-of-n_i system, the likelihood can be represented as

$$L(F) = \prod_{i=1}^{m} f_{k_i:n_i}(t_i) \tag{2.20}$$

and numerical methods are employed to find $\hat{F}$. *Huang* [2.33] investigated the asymptotic properties of this MLE, and *Chen* [2.34] provides an ad hoc estimator that examines the effects of censoring.

Compared to individual component tests, observed system lifetimes can be either advantageous or disadvantageous. With an equal number of k-out-of-n systems at each $1 \le k \le n$, *Takahasi* and *Wakimoto* [2.35] showed that the estimate of MTTF is superior to that of an equal number of individual component tests. With an unbalanced set of system lifetimes, no such guarantee can be made. If only series systems are observed, *Kvam* and *Samaniego* [2.36] show how the uncertainty in $\hat{F}(t)$ is relatively small in the lower quantiles of F (where system failures are observed) but explodes in the upper quantiles.

2.4.2 Stochastic Dependence Between System Components

Almost all basic reliability theory is based on systems with independently operating components. For realistic modeling of complex systems, this assumption is often impractical; system components typically operate at a level related to the quality and operational state of the other system components.

External events that cause the simultaneous failure of component groups is a serious consideration in reliability analysis of power systems. This can be a crucial point in systems that rely on built-in component redundancy to achieve high target system reliability. Shock models, such as those introduced by *Marshall* and *Olkin* [2.37], can be employed to demonstrate how multiple component failures can occur. An extra failure process is added to the otherwise independent component failure processes, representing the simultaneous failure of one or more components, thus making the component lifetimes positively dependent. This is the basis for most dependent failure models in probabilistic risk assessment, including *common cause failure* models used in the nuclear industry (alpha-factor model, beta-factor model, binomial failure rate model). See Chapt. 8 of *Bedford* and *Cooke* [2.16] for discussion about how these models are used in risk assessment.

In dynamic systems, where system configurations and component reliability can change after an external event or a failure of one or more of the system components, the shock model approach cannot be applied effectively. In some applications, a load-share model applies.

Early applications of the load-share system models were investigated by *Daniels* [2.38] for studying the reliability of composite materials in the textile industry. Yarns and cables fail after the last fiber (or wire) in the bundle breaks, thus a bundle of fibers can be considered a parallel system subject to a constant tensile load. An individual fiber fails in time with an individual rate that depends on how the unbroken fibers within the bundle share the load of this stress. Depending on the physical properties of the fiber composite, this load sharing has different meanings in the failure model. Yarn bundles or untwisted cables tend to spread the stress load uniformly after individual failures which defines an *equal*

load-share rule, implying the existence of a constant system load that is distributed equally among the working components.

As expected, a load-sharing structure within a system can increase reliability (if the load distribution saves the system from failing automatically) but reliability inference is hampered even by the simplest model. *Kvam* and *Peña* [2.39] show how the efficiency of the load-share system, as a function of component dependence, varies between that of a series system (equivalent to sharing an infinite load) and a parallel system (equivalent to sharing zero load).

2.4.3 Logistics Systems

Numerous studies have examined fundamental problems in network reliability [2.40], system performance degradation and workload rerouting for telecommunication, power and transportation networks [2.41, 42]. In comparison, the literature on modeling logistics system reliability or performance degradation is scarce. Logistics systems that transport goods, energy (e.g., electricity and gas), water, sewage, money or information from origins to destinations are critical to every nation's economic prosperity. Unlike the hub in the typical Internet or telecommunication or network, where the messages are not mixed together, logistics distribution centers (DCs) tend to mix products from various sources for risk-pooling purposes [2.35]. Past studies [2.43] of road-network reliability mainly addressed connectivity and travel-time reliability. These developments have limited use in providing a first-cut analysis for system-level planning that involves robust logistics network design to meet reliability requirements or supply-chain cost and delivery-time evaluation for contract decisions [2.44].

Consider a logistics network consisting of many suppliers providing goods to several DCs, which support store operations to meet customer demands. The reliability of such a network can be evaluated in terms of the probability of delivering goods to stores in a prespecified time limit t_0. Traveling time in transport routes contains uncertainty, as does the processing time for products shipped through DCs. Random traveling time is a function of routing distances, road and traffic conditions and possible delays from seaport or security checkpoint inspections. Traveling distance depends on the configuration of logistics networks. Some retail chains use single-layer DCs, but others use multiple-layer DCs similar to airline hubs (e.g., regional DCs and global DCs) in aggregating various types of goods. Vehicle routing procedures typically involve trucks that carry similar products to several stores in an assigned region. Different products are consolidated in shipment for risk-pooling purposes and to more easily control delivery-time and store-docking operations.

When one DC cannot meet the demands from its regional stores (due to demand increase or the DC's limited capability), other DCs provide backup support to maintain the overall network's service reliability. Focusing on the operations between DCs and stores, *Ni* et al. [2.45] defined the following network reliability as a weighted sum of the individual reliabilities from each DC's operations:

$$r^*_{\text{system},k} = \left[\sum_{i=1, i\neq k}^{M} d_i P\left(T^*_{m,i} < t_0\right) + \sum_{i=1, i\neq k}^{M} p_i d_k P\left(T^*_{m,k,i} < t_0\right) \right] \Big/ \sum_{i=1}^{M} d_i \,, \tag{2.21}$$

where d_i is the demand aggregated at the i-th DC, $T^*_{m,i}$ is the motion time defined as the sum of traveling time from DC_i to its assigned stores (including material processing time at DC_i), p_i is the proportion of products rerouted from DC_k through DC_i due to the limited capability in DC_k and $T^*_{m,k,i}$ is the modified motion time including the rerouted traveling time.

For modeling the aggregated demand d_i and calculating routing distance, *Ni* et al. [2.45] proposed a multiscale approximation model to quantify demand patterns at spatially located clustered stores. Then, they evaluated product rerouting strategies for maintaining system service reliability, defined in (2.19). Based on the store locations of a major retail chain, several examples show the importance of designing a robust logistics network to limit service reliability degradation when a *contingency* (e.g., multiple DC failure) occurs in the network. Future work includes:

1. Modeling the low-probability but high-impact contingency in the DCs [2.45] and routes for calculating their relative importance to network reliability
2. Examining the tradeoff between the cost of adding more DCs and the improvement of service reliability
3. Resolving the *domino effect* when the added workload to DCs after a local DC failure causes further DC failures due to faulty predetermined rules of rerouting to maintain system reliability (e.g., the 2003 electricity blackout in the Northeastern region of the US).

2.4.4 Robust Reliability Design in the Supply Chain

Past studies of robust parameter design [2.46] focused on product quality issues and assumed that all the controllable variables are under single ownership. Recent outsourcing trends in automobile and electronic manufacturing processes motivate the presentation in this section. In an automobile manufacturing enterprize system, various parts suppliers have control of variables determining quality and reliability. Most of the automobile supply-chain systems assemble these parts into a subsystem and then move these systems to other locations owned by different partners for the final system-level assembly and testing. Every segment of the assembly operation controls a subset of variables leading to different levels of system reliability. Because the warranty policy is addressed to all of the part manufacturing and assembly processes in making the final product, it is important to extend the robust parameter design concept to the supply-chain-oriented manufacturing processes.

Supply-chain partners have their own operation objectives (e.g., maximize the profit of manufacturing parts to supply several automobile companies). Some of the objectives are aligned to manufacturing a specific type of product, but there are many potential situations with conflicting objectives. When there is no single ownership of all controllable variables in the manufacturing processes, negotiation is needed to resolve potential conflicts. Game theory [2.47] is commonly used in supply-chain contract decisions. Following the framework of *Chen* and *Lewis* [2.48], we can decompose the set of controllable variables into a few subsets owned by distinct partners and formulate the objectives of these partners. The supply-chain manager can define the product quality and reliability measures and build models to link them to the controllable and uncontrollable variables that are seen in robust parameter design.

Different negotiation situations (e.g., the final product assembly company has more bargaining power than other partners) will lead to distinct levels selected for the controllable variables (see *Charoensiriwath* and *Lu* [2.49] for examples in negotiations). As a result, the reliability of the final product can vary. Designing a supply-chain system that leads to the most reliable products (with minimum cost) presents an acute challenge, and warranty policies can be designed correspondingly. Because parts and subsystems are made by various partners, warranty responsibilities for certain parts are distributed among partners under the negotiated supply-chain contracts.

3. Weibull Distributions and Their Applications

Weibull models are used to describe various types of observed failures of components and phenomena. They are widely used in reliability and survival analysis. In addition to the traditional two-parameter and three-parameter Weibull distributions in the reliability or statistics literature, many other Weibull-related distributions are available. The purpose of this chapter is to give a brief introduction to those models, with the emphasis on models that have the potential for further applications. After introducing the traditional Weibull distribution, some historical development and basic properties are presented. We also discuss estimation problems and hypothesis-testing issues, with the emphasis on graphical methods. Many extensions and generalizations of the basic Weibull distributions are then summarized. Various applications in the reliability context and some Weibull analysis software are also provided.

The Weibull distribution is one of the best-known lifetime distributions. It adequately describes observed failures of many different types of components and phenomena. Over the last three decades, numerous articles have been written on this distribution. *Hallinan* [3.1] gives an insightful review by presenting a number of historical facts, the many forms of this distribution as used by practitioners, and possible confusions and errors that arise due to this non-uniqueness. *Johnson* et al. [3.2] devote a comprehensive chapter to a systematic study of this distribution. More recently, *Murthy* et al. [3.3] presented a monograph that contains nearly every facet relating to the Weibull distribution and its extensions.

In Sect. 3.1, we first define the three-parameter Weibull distribution and then look at its historical development and relations to other distributions. Section 3.2 studies the properties of the Weibull distribution, in particular those relevant to reliability. A brief discussion on simulation of Weibull variates is also included. We consider estimation problems and hypothesis testing in Sect. 3.3. In particular, we emphasize the graphical methods as a tool for selection and parameter estimation of a Weibull model. We devote Sect. 3.4 to Weibull-derived models, which includes many extensions and generalizations. Finally, in Sect. 3.5, we outline various applications, especially those in the reliability context. Because of the vast literature, we are unable to refer to all the source authors and we apologize in advance for any omissions in this regard.

WPP	Weibull probability plot

3.1 Three-Parameter Weibull Distribution

According to *Hallinan* [3.1] the Weibull distribution has appeared in five different forms. The two common forms of the distribution function are as follows:

$$F(t) = 1 - \exp\left[-\left(\frac{t-\tau}{\alpha}\right)^{\beta}\right], \; t \geq \tau \tag{3.1}$$

and

$$F(t) = 1 - \exp\left[\lambda(t-\tau)^{\beta}\right], \; t \geq \tau \, . \tag{3.2}$$

The parameters of the distribution are given by the set $\boldsymbol{\theta} = \{\alpha, \beta, \tau\}$ with $\alpha > 0$, $\beta > 0$ and $\tau \geq 0$; where α is a scale parameter, β is the shape parameter that determines the appearance or shape of the distribution and τ is the location parameter. The parameter λ combines both scale and shape features as $\lambda = \alpha^{-\beta}$.

Although one should use $F(t, \boldsymbol{\theta})$ instead of $F(t)$, where $\boldsymbol{\theta} = (\alpha, \beta, \tau)$ denotes the vector of parameters, for notational convenience we suppress the parameter and use $F(t)$ to denote $F(t, \boldsymbol{\theta})$ in this chapter. Also, we do not intend to give an exhaustive review. Rather, we confine our discussion to aspects that are of relevance to the context of reliability theory.

For $\tau = 0$, (3.1) and (3.2) become the two-parameter Weibull distribution with

$$F(t) = 1 - \exp\left[-\left(\frac{t}{\alpha}\right)^{\beta}\right], t \geq 0 \tag{3.3}$$

and

$$F(t) = 1 - \exp\left(-\lambda t^{\beta}\right), \; t \geq \tau \, . \tag{3.4}$$

Murthy et al. [3.3] refer to this as the *standard* Weibull model, *Johnson* et al. [3.2] refer to a standard Weibull when $\alpha = 1$ (or $\lambda = 1$) in (3.3), (3.4).

3.1.1 Historical Development

The Weibull distribution is named after its originator, the Swedish physicist Waloddi Weibull, who in 1939 used it to model the distribution of the breaking strength of materials [3.4] and in 1951 for a wide range of other applications [3.5]. The distribution has been widely studied since its inception. It has been known that Weibull may not be the first to propose this distribution. The name Fréchet distribution is also sometimes used due to the fact that it was *Fréchet* [3.6] who first identified this distribution to be an extremal distribution (later shown to be one of the three possible solutions by *Fisher* and *Tippett* [3.7]). According to *Hallinan* [3.4], it was Weibull who suggested a scale parameter and a location parameter that made the distribution meaningful and useful.

3.1.2 Relations to Other Distributions

The Weibull distribution includes the exponential ($\beta = 1$) and the Rayleigh distribution ($\beta = 2$) as special cases. If X denotes the Weibull variable, then $-X$ has a type 3 extreme-value distribution [3.8, Chapt. 22]. A simple log transformation will transform the Weibull distribution into the Gumbel distribution (type 1 extreme-value distribution).

The Burr XII distribution, is given by

$$F(t) = 1 - \left[1 + \left(\frac{t}{\alpha}\right)\right]^{-k}, t \geq 0 \, ; k \, , \alpha > 0 \, . \tag{3.5}$$

Let $k = \alpha$; as $k \to \infty$, then the Burr distribution approaches the Weibull (see, for example, [3.9]).

3.2 Properties

3.2.1 Basic Properties

Density Function

The probability density functions (PDF) (Fig. 3.1) of (3.1) and (3.2) are

$$f(t) = \beta\alpha^{-\beta}(t-\tau)^{\beta-1} \exp\left[-\left(\frac{t-\tau}{\alpha}\right)^{\beta}\right], \; t \geq \tau \tag{3.6}$$

and

$$f(t) = \beta\lambda(t-\tau)^{\beta-1} \exp\left[-\lambda(t-\tau)^{\beta}\right], \; t \geq \tau \, . \tag{3.7}$$

Mode

It follows from (3.6) that the mode is at $t = \alpha((\beta-1)/\beta)^{1/\beta} + \tau$ for $\beta > 1$ and at τ for $0 < \beta \leq 1$.

Median

It follows from (3.3) that the median of the distribution is at $\alpha(\log 2)^{1/\beta} + \tau$.

Moments

Let T denote the random variable from the three-parameter Weibull distribution given by (3.1). Then the transformed variable $T' = (T - \tau)/\alpha$, is the stan-

dard form (in the sense of *Johnson* et al. [3.2]) with the density function given by

$$f(t) = \beta t^{\beta-1} \exp\left(-t^{\beta}\right) \ , x > 0 \ , \beta > 0 \ . \tag{3.8}$$

The moments of T (about zero) are easily obtained from the moments of T' which are given below:

$$\mu_r^{'} = E(T'^r) = \Gamma\left(\frac{r}{\beta}+1\right) \ , \tag{3.9}$$

from which we get

$$E(T') = \Gamma\left(\frac{1}{\beta}+1\right) \ , \tag{3.10}$$

$$\mathrm{Var}(T) = \Gamma\left(\frac{2}{\beta}+1\right) - \left[\Gamma\left(\frac{1}{\beta}+1\right)\right]^2 \ . \tag{3.11}$$

Skewness and Kurtosis

The distribution is positively skewed for small values of β. The skewness index $\sqrt{\beta_1}$ decreases and equals zero for $\beta = 3.6$ (approximately). Thus, for values of β in the vicinity of 3.6, the Weibull distribution is similar in shape to a normal distribution. The coefficient of kurtosis β_2 also decreases with β and then increases, β_2 has a minimum value of about 2.71 when $\beta = 3.35$ (approximately).

Order Statistics

Let $T_1, T_2, \cdots, T_n$ denote n independent and identically distributed three-parameter Weibull random variables with density function given in (3.6) and cumulative distribution function (CDF) in (3.1). Further, let $T_{(1)} \le T_{(2)} \le \cdots \le T_{(n)}$ denote the order statistics from a sample of n observations. The probability density function of $T_{(1)}$, is given by

$$\begin{aligned} f_{(1)}(t) &= n[1-F(t)]^{n-1} f(x) \\ &= \frac{n\beta}{\alpha}\left(\frac{t-\tau}{\alpha}\right)^{\beta-1} \mathrm{e}^{-n[(t-\tau)/\alpha]^{\beta}}, t \ge \tau \ . \end{aligned} \tag{3.12}$$

It is obvious from (3.12) that $T_{(1)}$ is also distributed as a Weibull random variable, except that α is replaced by $\alpha n^{-1/\beta}$.

The density function of $T_{(r)} (1 \le r \le n)$ is given by

$$\begin{aligned} f_{(r)}(t) = \frac{n!}{(r-1)!(n-r)!}&\left(1-\mathrm{e}^{-[(t-\tau)/\alpha]^{\beta}}\right)^{r-1} \\ &\mathrm{e}^{-[(t-\tau)/\alpha]^{\beta}(n-r+1)} \beta\alpha^{-\beta}(t-\tau)^{\beta-1}, \ t \ge 0 \ . \end{aligned} \tag{3.13}$$

It can be shown that

$$E\left[\left(T_{(r)}\right)^k\right] = \sum_{i=0}^{k} \tau^i \alpha^{k-i} \omega_{(r)}^{k-i} \ , \tag{3.14}$$

where

$$\begin{aligned} \omega_{(r)}^{k} = &\frac{n!}{(r-1)!(n-r)!}\Gamma\left(1+\frac{k}{\beta}\right) \\ &\times \sum_{i=0}^{r-1} \frac{(-1)^r \binom{r-1}{i}}{(n-r+i+1)^{1+(k/\beta)}} \ . \end{aligned}$$

3.2.2 Properties Related to Reliability

In this section, we consider only the first form of the Weibull distribution.

The survival function of the Weibull distribution is

$$\bar{F}(t) = 1 - F(t) = \exp\left[-\left(\frac{t-\tau}{\alpha}\right)^{\beta}\right], \ t \ge \tau \ . \tag{3.15}$$

Note that at $t = \tau + \alpha$, $\bar{F}(\tau+\alpha) = 1 - \mathrm{e}^{-1} \approx 0.3679$.

Failure Rate

The failure rate function (also known as the hazard rate) for the three-parameter Weibull is

$$h(t) = \frac{f(t)}{\bar{F}(t)} = \frac{\beta}{\alpha}\left(\frac{t-\tau}{\alpha}\right)^{\beta-1} \ . \tag{3.16}$$

For the two-parameter case, it is given by

$$h(t) = \frac{f(t)}{\bar{F}(t)} = \frac{\beta}{\alpha}\left(\frac{t}{\alpha}\right)^{\beta-1} \ . \tag{3.17}$$

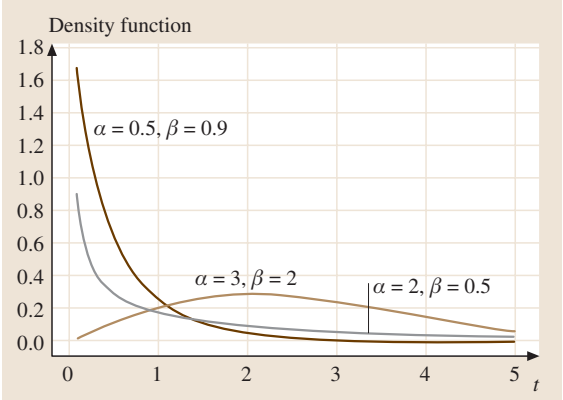

Fig. 3.1 Two-parameter Weibull density plots

It is obvious that $h(t)$ is a decreasing function when $\beta < 1$, constant when $\beta = 1$ (the exponential case), and an increasing function when $\beta > 1$. Because of the behaviour of the failure rate function, the Weibull distribution often becomes suitable when the conditions for *strict randomness* of the exponential distribution are not satisfied, with the shape parameter β having a value depending upon the fundamental nature being considered.

In some way, having a failure rate function of monotonic shape has limitations in reliability applications. For this reason, several generalized or modified Weibull distributions have been proposed (see Sect. 3.4 for more details). Figure 3.2 shows plots of the failure rate functions for some selected parameters values.

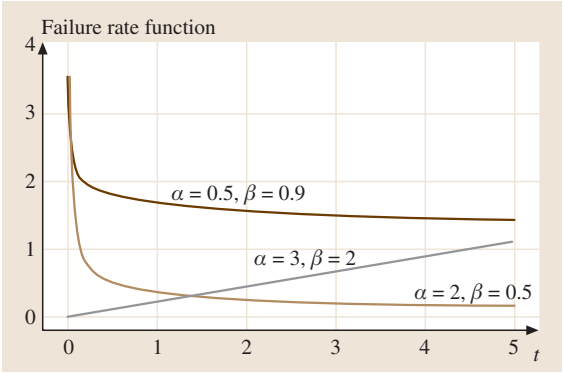

Fig. 3.2 Two-parameter Weibull failure rate functions

Mean Residual Life

The mean residual life (MRL) of a lifetime random variable T is defined as

$$\mu(t) = E(T - t | T > t) = \frac{\int_t^\infty \bar{F}(x)\,\mathrm{d}x}{\bar{F}(t)} \,. \tag{3.18}$$

For the Weibull distribution, the MRL is complicated except for the two special cases $\beta = 1$ (exponential) and $\beta = 2$ (Rayleigh distribution). Assuming the location parameter $\tau = 0$, the MRL of the Rayleigh distribution with scale parameter $\alpha = \sqrt{2}\sigma$ is

$$\mu(t) = \sqrt{2\pi}\sigma\,[1 - \Phi(t/\sigma)]\,\mathrm{e}^{\frac{1}{2\sigma^2}t^2} \,, \quad t > 0 \,, \tag{3.19}$$

where $\Phi(t/\sigma)$ denotes the distribution function of the standard normal variable.

Relative Ageing of Two Two-Parameter Weibull Distributions

Suppose we have two Weibull random variables X and Y with distribution functions $F(x)$ and $G(y)$, respectively, given by

$$\begin{aligned} F(x) &= 1 - \exp\left[-(x/\alpha_2)^{\beta_2}\right] \,, \\ G(y) &= 1 - \exp\left[-(y/\alpha_1)^{\beta_1}\right] \,. \end{aligned} \tag{3.20}$$

We say that X ages faster than Y if the ratio of the failure rate of X over the failure rate of Y is an increasing function of t. This ratio is given by

$$\frac{\alpha_1\beta_2}{\alpha_2\beta_1} \times \frac{\alpha_1^{\beta_2 - 1}}{\alpha_2^{\beta_1 - 1}} t^{\beta_2 - \beta_1} \tag{3.21}$$

which is an increasing function of t if $\beta_2 > \beta_1$.

Suppose $E(X) = E(Y)$, i. e., $\alpha_2\Gamma(1 + 1/\beta_2) = \alpha_1\Gamma(1 + 1/\beta_1)$. *Lai* and *Xie* [3.10] show that $\mathrm{Var}(X) \le \mathrm{Var}(Y)$.

Effectiveness of Parallel Redundancy – The Weibull Case

Denote the lifetime of one component by T and the lifetime of a parallel system of two such independent components by T_p. The effectiveness of parallel redundancy of the component is defined by [3.11]

$$e_\mathrm{p} = [E(T_\mathrm{p}) - E(T)]/E(T) \,. \tag{3.22}$$

Suppose that T is a two-parameter Weibull distribution with shape parameter β and scale parameter α. *Xie* and *Lai* [3.11] show that

$$e_\mathrm{p} = 1 - 2^{-1/\beta} \,, \tag{3.23}$$

which decreases as β increases. Thus, a parallel redundancy is more effective for $\beta < 1$.

3.2.3 Simulation

The two-parameter Weibull distribution with parameters β and λ has the probability density function

$$f(x) = \lambda\beta x^{\beta - 1}\,\mathrm{e}^{-\lambda x^\beta} \,. \tag{3.24}$$

The simple inverse-probability integral-transform method applied to the standard Weibull distribution ($\lambda = 1$) is quite efficient. The formula is simply

$$x = (-\log u)^{1/\beta} \,,$$

where u is a uniform number between 0 and 1. Of course, an acceptance/rejection method could also be used to avoid the evaluation of the logarithm in the distribution function. The standard Weibull variate is then scaled by $\lambda^{-(1/\beta)}$ to obtain a two-parameter Weibull observation with density (3.24).

3.3 Modeling Failure Data

Failure data can be classified into two types: complete and incomplete (censored). For complete data, the actual realized values are known for each observation in the data set, whereas for censored data, the actual realized values are not known for some or all of the observations. Further, there are at least two types of censoring, details of which may be found *Lawless* [3.12] and *Nelson* [3.13].

In their introduction, *Murthy* et al. [3.3] point out that the two different approaches to building mathematical models are as follows.

1. *Theory-based modeling*: here, the modeling is based on the established theories for component failures. This kind of model is also called a *physics based model* or *white-box model*.
2. *Empirical modeling*: here, the data available forms the basis for the model building. This kind of model is also called a *data-dependent model* or *black-box model*.

In empirical modeling, the type of mathematical formulations needed for modeling is dictated by a preliminary analysis of data available. If the analysis indicates that there is a high degree of variability, then one needs to use models that can capture this variability. This requires probabilistic and stochastic models to model a given data set.

The process of black box modeling involves the following steps:

- Step 1 – Model selection,
- Step 2 – Parameter estimation,
- Step 3 – Model validation.

To select a model out of many possible models, one requires a good understanding of their different properties. This often is a trial-and-error process. *Liao* and *Shimokawa* [3.14] consider goodness-of-fit testing as a key procedure for selecting the statistical distribution that best fits the observed data. To execute the remaining two steps, we need various tools and techniques.

A large number of Weibull-related models have been derived in the literature. In Sect. 3.4, various such models are grouped into several categories. Selecting an appropriate model from the family of Weibull-related distributions can often be based on some of the probability plots to be discussed below. Moreover, they can provide crude estimates of model parameters. There are many different statistical tests for validating a model and we postpone this discussion until the next section.

3.3.1 Probability Plots

Weibull Probability Plot

Weibull probability plots (WPP) can be constructed in several ways [3.15]. In the early 1970s a special paper was developed for plotting the data in the form of $F(t)$ versus t on a graph paper with a log–log scale on the vertical axis and a log scale on the horizontal axis. A WPP plotting of data involves computing the empirical distribution function, which can be estimated in different ways; the two standard methods are:

- $\hat{F}(t_i) = i/(n+1)$, the "mean rank" estimator, and
- $\hat{F}(t_i) = (i-0.5)/n$, the "median rank" estimator.

Here, the data consists of successive failure times t_i, $t_1 < t_2 < \ldots t_n$. For censored data (right-censored or interval), the approach to obtain the empirical distribution functions needs to be modified; see, for example, *Nelson* [3.13].

These days, most computer reliability software packages contain programs to produce these plots automatically given a data set. A well-known statistical package MINITAB provides a Weibull probability plot under the Graph menu ≫ Probability Plot.

We may use an ordinary graph paper or spreadsheet software with unit scale for plotting. Taking logarithms twice of both sides of each of the CDF in (3.3) yields

$$\log[-\log \bar{F}(t)] = \beta \log(t-\tau) - \beta \log \alpha \,. \tag{3.25}$$

Let $y = \log\left[-\log \bar{F}(t)\right]$ and $x = \log(t-\tau)$. Then we have

$$y = \beta x - \beta \log \alpha \,. \tag{3.26}$$

The plot is now on a linear scale.

Weibull Hazard Plot

The hazard plot is analogous to the probability plot, the principal difference being that the observations are

plotted against the cumulated hazard (failure) rate rather than the cumulated probability value. Moreover, this is designed for censored data.

Let $H(t)$ denote the cumulative hazard rate, then $\bar{F}(t) = \exp[-H(t)]$, so

$$H(t) = -\log \bar{F}(t) = \left(\frac{t-\tau}{\alpha}\right)^{\beta}, \tag{3.27}$$

$$H(t)^{1/\beta}/\alpha = (t-\tau)\,. \tag{3.28}$$

Let $y = \log(t-\tau)$ and $x = \log H(t)$, then we have

$$y = \log\alpha + \frac{1}{\beta}x\,. \tag{3.29}$$

Rank the n survival times (including the censoreddata) in ascending order and let K denote the reverse ranking order of the survival time, i. e., $K = n$ for the smallest survival time and $K = 1$ for the largest survival time. The hazard is estimated from $100/K$ (a missing value symbol is entered at a censored failure time). The cumulative hazard is obtained by cumulating the hazards. The Weibull hazard plot is simply the plot arising from (3.29). See *Nelson* [3.16] for further details.

3.3.2 Estimation and Hypothesis Testing

Parameter estimation is the second step of our modeling process. We consider both graphical and statistical methods for the three-parameter Weibull distribution.

Graphical Methods

Graphical plots are designed not just to assess if the data follows a Weibull population, they are also useful for estimating Weibull parameters (at least for initial estimates). These can be obtained from the smooth fit to a WPP plot of data and involve exploiting properties such as asymptotes, intersection points, slope, or points of inflection.

Estimation of Location Parameter. The determination of a suitable location parameter τ is not a simple task. If a data set graphs as a straight line on a WPP, then the data set is indeed adequately described by a Weibull distribution. However, an incorrect selection of τ will yield a curved plot of data that is in fact Weibull-distributed.

If the graph of a set of data appears concave upward, then the plot can be straightened by decreasing the value of τ. Conversely, if the data are concave downward, then the plot can be straightened by increasing the value of τ. The value of τ cannot be chosen larger than the smallest failure-time value, say $T_{(1)}$, in the sample. It is generally suggested to set the initial value of $\tau = T_{(1)}$ and then adjust this estimate to achieve a straight line. We also note that it is common for τ to be 0.

Estimation of the Shape Parameter. It follows from (3.26) that the shape parameter can be estimated from the slope of the WPP. However, care needs need to be given because possible confusion may arise due to several possible forms of the Weibull distribution.

Estimation of the Scale Parameter. To estimate the scale parameter, we first observe from the standard Weibull that, when t is at the 63.2 percentile, $F(t) = 1 - e^{-1}$, i. e., $\bar{F}(t) = e^{-1}$. Or equivalently, for $t = \tau + \alpha$, $\bar{F}(\tau+\alpha) = e^{-1}$ (so $\tau+\alpha$ is the 63.2 percentile). It now follows from (3.26) that $\log(t-\tau) = \log\alpha$ so that $\hat{\alpha} = t - \hat{\tau}$, where t is the 63.2 percentile. Hence the scale parameter is simply estimated from the x-intercept of the plot (3.26): $\hat{\alpha} = e^{(x\text{-intercept})}$.

Under the probability plot option, MINITAB not only gives a WPP, but also provides an estimate for the scale and shape parameters α and β.

Figure 3.3 illustrates how a WPP plot appears in a MINITAB graph with $\hat{\alpha} = 9.062$ and $\hat{\beta} = 1.661$.

Statistical Methods of Estimation

There are several statistical methods for estimating the model parameters. These include the method of moment, the method of percentile, the method of maximum likelihood, and the Bayesian method. The estimates can be

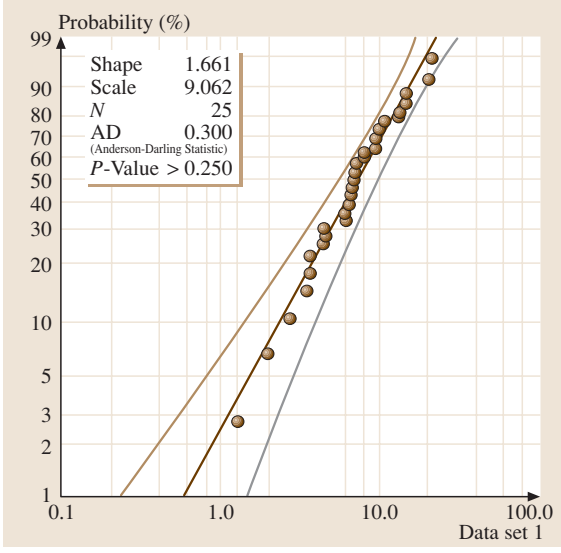

Fig. 3.3 A typical Weibull probability plot

either point estimates or interval estimates. The details of these methods can be found, for example, in *Kalbfleisch* and *Prentice* [3.17].

We note that these methods may not be appropriate for small data sets. Hence, the estimates obtained from the WPP plot may be taken as the final estimates when the data size is small.

Moment Estimation. By equating the first three moments of the Weibull distribution to the first three sample moments and solving, it is possible to find the moment estimators of α, β and τ. Now, the first moment ratio $\sqrt{\beta_1}$ depends only on the shape parameter β, and hence once $\sqrt{\beta_1}$ has been estimated from the sample coefficient of skewness, $\hat{\beta}$ can be determined numerically. Using $\hat{\beta}$, $\hat{\alpha}$ can be determined from the standard deviation, and lastly $\hat{\tau}$ is determined from the sample mean. If τ is known, then β can be estimated from the ratio (standard deviation/(mean-τ).

For modified moment estimation, see *Cohen* et al. [3.18].

Maximum-Likelihood Method. Maximum-likelihood methods for the three-parameter Weibull distribution have been reviewed by *Zanakis* and *Kyparisis* [3.19]; see also *Johnson* et al. [3.2, Chapt. 21] for other details.

The most common situation is when the location parameter τ is known. Without loss of generality, we may assume that $\tau = 0$ so that the model becomes the two-parameter Weibull distribution.

The maximum-likelihood estimators, $\hat{\beta}$ and $\hat{\alpha}$ of β and α, respectively, satisfy the equations

$$\hat{\alpha} = \left(\frac{1}{n} \sum_{i=1}^{n} X_i^{\hat{\beta}} \right)^{1/\hat{\beta}} \tag{3.30}$$

and

$$\hat{\beta} = \left[\left(\sum_{i=1}^{n} X_i^{\hat{\beta}} \log X_i \right) \left(\sum_{i=1}^{n} X_i^{\hat{\beta}} \right)^{-1} - \frac{1}{n} \sum_{i=1}^{n} \log X_i \right]^{-1} , \tag{3.31}$$

where X_i, $i = 1, 2, \ldots n$ are n independent observations from the two-parameter Weibull distribution. If $\tau \neq 0$, then each X_i is replaced by $X_i - \tau$ in the above equations. The value $\hat{\beta}$ needs to be solved from (3.31) and then (3.30) is used to obtain $\hat{\alpha}$.

Suppose the location parameter τ is also unknown, then the maximum-likelihood estimates $\hat{\alpha}$, $\hat{\beta}$ and $\hat{\tau}$ satisfy the following equations

$$\hat{\alpha} = \left[\frac{1}{n} \sum_{i=1}^{n} (X_i - \hat{\tau})^{\hat{\beta}} \right]^{1/\hat{\beta}} \tag{3.32}$$

$$\hat{\beta} = \left\{ \left[\sum_{i=1}^{n} (X_i - \hat{\tau})^{\hat{\beta}} \log(X_i - \hat{\tau}) \right] \times \left[\sum_{i=1}^{n} (X - \hat{\tau})^{\hat{\beta}} \right]^{-1} - \frac{1}{n} \sum_{i=1}^{n} \log(X_i - \hat{\tau}) \right\}^{-1} \tag{3.33}$$

and

$$(\hat{\beta} - 1) \sum_{i=1}^{n} (X_i - \hat{\tau})^{-1} = \hat{\beta} \hat{\alpha}^{-\hat{\beta}} \sum_{i=1}^{n} (X_i - \hat{\tau})^{\hat{\beta}-1} . \tag{3.34}$$

If the value $\hat{\tau}$ satisfying (3.32)–(3.34) is larger than $X_1 = \min X_i$, then it is the maximum-likelihood estimate of τ. Otherwise, we set that $\hat{\tau} = X_1$ and then (3.32) and (3.33) must be solved for $\hat{\alpha}$ and $\hat{\beta}$.

The method is suitable for large data sets because of its asymptotic properties. Modifications of these estimates can be found, for example, in *Johnson* et al. [3.2].

The reader may consult Chapt. 21 of *Johnson* et al. [3.2] and Chapt. 4 of *Murthy* et al. [3.3] for the following methods of estimation,

- Best linear unbiased estimation,
- Percentile estimator,
- Bayesian estimator,
- Interval estimation,
- Minimum quantile distance estimation.

For the two-parameter Weibull distribution (i. e., $\tau = 0$), methods of inference can be obtained via the type 1 extreme-value distribution.

3.3.3 Hypothesis Testing

Goodness-of-Fit Tests for the Weibull Distribution

There are other general goodness-of-fit tests based on the empirical distribution functions derived. For example, the chi-square test, Kolmogorov–Smirnov test, Cramer–von Mises test and Anderson–Darling test, and so on, could also be used to test the goodness of fit of the Weibull model.

Generally, a goodness-of-fit test for Weibull distribution can be described as: H_0: the population follows a Weibull model, versus H_1: the Weibull model is not suitable.

MINITAB under probability plot gives the Anderson–Darling statistic as well as the confidence bands.

Lawless [3.12] summarizes the goodness-of-fit tests for the Weibull or extreme-value distribution. Four tests (the likelihood ratio test as a sub-model of the gamma distribution, Mann–Scheuer–Fertig test, Tiku test and Cramer–von Mises test) are discussed in detail. *Dodson* [3.20] also includes and compares some goodness-of-fit tests for Weibull distributions in Chapt. 4 of his book. *Liao* and *Shimokawa* [3.14] construct a new goodness-of-fit test for the two-parameter Weibull and its power is compared with other traditional goodness-of-fit tests.

Hypothesis Testing

Hypothesis testing of Weibull parameters may be performed by the likelihood ratio, score and Wald tests. It is well known that all these tests are asymptotically optimal.

For testing Weibull versus the exponential distribution, we test $\alpha = 1$ (or $\lambda = 1$ of the second form) versus $\alpha \neq 0$.

3.4 Weibull-Derived Models

There are many extensions, generalizations and modifications to the Weibull distribution. They arise out of the need to model features of empirical data sets that cannot be adequately described by a three-parameter Weibull model: for example, the monotonic property of the Weibull, which is unable to capture the behaviour of a data set that has a bathtub-shape failure rate. *Xie* et al. [3.21] review several Weibull-related distributions that exhibit bathtub-shaped failure rates. Plots of mean residual life from several of these Weibull-derived models are given in *Lai* et al. [3.22]. For simplicity, we simply refer to these Weibull-related models as Weibull models.

3.4.1 Taxonomy for Weibull Models

According to *Murthy* et al. [3.3], the taxonomy for Weibull models involves seven types, each of which divided into several sub-types. These models can be grouped into three groups:

1. Univariate models (types I–V),
2. Multivariate models (type VI),
3. Stochastic process models (type VII).

In this chapter we confine our discussion to univariate and stochastic process models, while *Murthy* et al. [3.23] looks at bivariate models (a special case of multivariate models). In this chapter, only some selective models will be included. We refer our readers to the book by *Murthy* et al. [3.3] for more details.

3.4.2 Univariate Models

The starting point is the two-parameter Weibull model with distribution function $F(t)$. Let $G(t)$ denote the derived Weibull model. T is a random variable from $F(t)$ and Z is a random variable from $G(t)$.

Type I Models (Transformation of Weibull Variable)

Here Z and T are related by a transformation. The transformation can be either linear or nonlinear. These include the following:

Reflected Weibull Distribution.

$$G(t) = \exp\left[-\left(\frac{\tau - t}{\alpha}\right)^{\beta}\right], -\infty < t < \tau\,. \quad (3.35)$$

This is also known as a type 3 extreme-value distribution (see *Johnson* et al. [3.8], Chapt. 22).

Double Weibull Distribution.

$$g(t) = \beta(1/2)\,|t|^{(\beta-1)} \exp(-|t|^{\beta})\,, -\infty < t < \infty\,. \quad (3.36)$$

This is an obvious extension to include the negative real line as its support.

Log Weibull Distribution. The distribution is derived from the logarithmic transformation of the two-parameter Weibull distribution. The distribution function is

$$G(t) = 1 - \exp\left[-\exp\left(\frac{t - \tau}{\alpha}\right)\right], -\infty < t < \infty\,. \quad (3.37)$$

This is also known as a type 1 extreme-value distribution or Gumbel distribution. In fact, it is the most commonly referred to in discussions of extreme-value distributions

(see [3.8], Chapt. 22). The density function is

$$g(t) = \frac{1}{\alpha} \exp\left(\frac{t-\tau}{\alpha}\right) \exp\left[-\exp\left(\frac{t-\tau}{\alpha}\right)\right] ,$$

and the failure rate function is quite simple and given by

$$h(t) = \frac{1}{\alpha} \exp\left(\frac{t-\tau}{\alpha}\right) .$$

Inverse (or Reverse) Weibull Model. Let $Z = \alpha^2/T$, where T has a two-parameter Weibull distribution, then the distribution function of T is

$$G(t) = \exp[-(t/\alpha)^{-\beta}] , t \geq 0 . \tag{3.38}$$

This is also known as a type 2 extreme-value distribution or Fréchet distribution (see [3.8], Chapt. 22). The failure rate function is as follows:

$$h(t) = \frac{\beta\alpha^{\beta} t^{-\beta-1} \mathrm{e}^{-(\alpha/t)^{\beta}}}{1 - \mathrm{e}^{-(\alpha/t)^{\beta}}} .$$

Type II Models (Modification/Generalization of the Weibull Distribution)

Here $G(t)$ is related to $F(t)$ by some relationship.

Extended Weibull Distribution [3.24].

$$G(t) = 1 - \frac{\nu \mathrm{e}^{-(\lambda t)^{\beta}}}{1 - (1-\nu)\mathrm{e}^{-(\lambda t)^{\beta}}} . \tag{3.39}$$

The failure rate function is

$$h(t) = \frac{\nu\beta(\lambda t)^{\beta-1}}{\left[1 - (1-\nu)\mathrm{e}^{-(\lambda t)^{\beta}}\right]} .$$

The failure rate function is increasing if $\nu \geq 1$, $\beta \geq 1$ and decreasing if $\nu \leq 1$, $\beta \leq 1$.

Modified Weibull Distribution [3.25].

$$G(t) = 1 - \exp(-\lambda t^{\beta} \mathrm{e}^{\nu t}) , t \geq 0 \tag{3.40}$$

with

$$h(t) = \lambda(\beta + \nu t) t^{\beta-1} \exp(\nu t) . \tag{3.41}$$

For $\nu = 0$, this reduces to a Weibull distribution. For $0 < \beta < 1$, $h(t)$ is initially decreasing and then increasing in t, implying that the failure rate function has a bathtub shape. When $\beta > 1$, $h(t)$ is increasing in t.

Exponentiated Weibull Distribution [3.26].

$$G(t) = [F(t)]^{\nu} = \{1 - \exp[-(t/\alpha)^{\beta}]\}^{\nu} , t \geq 0 . \tag{3.42}$$

The density function is

$$g(t) = \frac{\beta\nu}{\alpha^{\beta}} t^{\beta-1} \mathrm{e}^{-(t/\alpha)^{\beta}} \left\{1 - \mathrm{e}^{-(t/\alpha)^{\beta}}\right\}^{\nu-1} .$$

For an appropriate choice of the parameter set, it will give rise to a bathtub-shaped failure function. *Jiang* and *Murthy* [3.27] use a graphical approach to study this distribution. The failure rate function is given by

$$h(t) = \frac{\beta\nu}{\alpha^{\beta}} t^{\beta-1} \mathrm{e}^{-(t/\alpha)^{\beta}} \frac{\left(1 - \mathrm{e}^{-(t/\alpha)^{\beta}}\right)^{\nu-1}}{\left[1 - (1 - \mathrm{e}^{-(t/\alpha)^{\beta}})^{\nu}\right]} .$$

Four-Parameter Weibull Distribution [3.28].

$$G(t) = 1 - \exp\left[-\lambda\left(\frac{t-a}{b-t}\right)^{\beta}\right] ,$$
$$0 \leq a \leq t \leq b < \infty . \tag{3.43}$$

Doubly Truncated Weibull Distribution.

$$G(t) = \frac{F(t) - F(a)}{F(b) - F(a)} ,$$
$$0 < a \leq t \leq b < \infty . \tag{3.44}$$

Modified Weibull Extension [3.29].

$$G(t) = 1 - \exp\left[-\lambda\alpha\left(\mathrm{e}^{(t/\alpha)^{\beta}} - 1\right)\right] ,$$
$$t \geq 0, \alpha, \beta, \lambda > 0 . \tag{3.45}$$

This is known as the generalized exponential power model originally studied by *Smith* and *Bain* [3.30]. The case of $\alpha = 1$ is also studied in *Chen* [3.31]. The failure rate function is

$$h(t) = \lambda\beta(t/\alpha)^{\beta-1} \exp\left[(t/\alpha)^{\beta}\right] . \tag{3.46}$$

It approaches to a two-parameter Weibull distribution when $\lambda \to \infty$ with α in such a manner that $\alpha^{\beta-1}/\lambda$ is held constant.

Type III Models (Models Involving Two or More Distributions)

These are univariate models derived from two or more distributions with at least one being either the standard Weibull model or a distribution derived from it.

n-Fold Mixture Model.

$$G(t) = \sum_{i=1}^{n} p_i F_i(t)\,,\ p_i \geq 0\,,\ \sum_{i=1}^{n} p_i = 1\,. \qquad (3.47)$$

Jiang and *Murthy* [3.32, 33] categorize the possible shapes of the failure rate function for a mixture of any two Weibull distributions in terms of five parameters. *Gurland* and *Sethurama* [3.34] also consider a mixture of the Weibull distribution with failure rate $\lambda\beta t^{\beta-1}$ and the exponential distribution with failure rate λ_1. For $\beta > 1$, the Weibull distribution is IFR (Increasing failure rate). They found that the resulting mixture distribution is ultimately DFR (Decreasing failure rate). In fact, the mixture has a failure rate with an upside-down bathtub shape.

n-Fold Competing Risk Model.

$$G(t) = 1 - \prod_{i=1}^{n} [1 - F_i(t)]\,. \qquad (3.48)$$

Jiang and *Murthy* [3.35] also give a parametric study of a competing risk model involving two Weibull distributions.

n-Fold Multiplicative Model (Complementary Risk Model).

$$G(t) = \prod_{i=1}^{n} F_i(t)\,. \qquad (3.49)$$

The multiplicative model involving two Weibull distribution is considered in *Jiang* and *Murthy* [3.36].

n-Fold Sectional Model.

$$G(t) = \begin{cases} k_1 F_1(t)\,, & 0 \leq t \leq t_1\,, \\ 1 - k_2 \bar{F}_2(t)\,, & t_1 < t \leq t_2\,, \\ \cdots & \\ 1 - k_n \bar{F}_n(t)\,, & t > t_{n-1}\,, \end{cases} \qquad (3.50)$$

where the sub-populations $F_i(t)$ are two- or three-parameter Weibull distributions and the t_is (called partition points) are an increasing sequence. *Jiang* and *Murthy* [3.37] and *Jiang* et al. [3.38] consider the case $n = 2$ in details.

Type IV Models (Weibull Models with Varying Parameters)

For models belonging to this group, the parameters of the model are either functions of the independent variable (t) or some other variables (such as the stress level s, etc.), or are random variables.

Arrhenius Weibull Model.

$$\alpha(S) = \exp(\gamma_0 + \gamma_1 S)\,. \qquad (3.51)$$

Power Weibull Model.

$$\alpha(S) = \frac{e^{\gamma_0}}{S^{\gamma_1}}\,. \qquad (3.52)$$

These types of models have been used extensively in accelerated life testing [3.39] in reliability theory. As a result, they are referred to as *accelerated failure models*.

Weibull Proportional Hazard Models.

$$h(t) = \psi(S) h_0(t)\,, \qquad (3.53)$$

where $h_0(t)$ is called the baseline hazard for a two-parameter Weibull distribution. The only restriction on the scalar function $\psi(S)$ is that it be positive. Many different forms for $\psi(S)$ have been proposed. One such is the following:

$$\psi(S) = \exp\left(b_0 + \sum_{i=1}^{k} b_i s_i\right)\,. \qquad (3.54)$$

For more on such models, see *Cox* and *Oakes* [3.39] and *Kalbfleisch* and *Prentice* [3.17].

Type V Models (Discrete Weibull Models)

Here T can only assume non-negative integer values and this defines the support for $F(t)$.

Model 1 [3.40].

$$F(t) = \begin{cases} 1 - q^{t^\beta} & t = 0, 1, 2, 3 \cdots\,, \\ 0 & t < 0\,. \end{cases} \qquad (3.55)$$

Model 2 [3.41]. The cumulative hazard function is given by

$$H(t) = \begin{cases} c t^{\beta-1} & t = 1, 2, \cdots, m \\ 0 & t < 0\,, \end{cases} \qquad (3.56)$$

where m is given by

$$m = \begin{cases} \text{int}\left(c^{-[1/(\beta-1)]}\right) & \text{if} \quad \beta > 1\,, \\ \infty & \text{if} \quad \beta \leq 1\,, \end{cases} \qquad (3.57)$$

and int(•) represents the integer part of the quantity inside the brackets.

Model 3 [3.42].

$$F(t) = 1 - \exp\left[-\sum_{i=1}^{t} r(i)\right] = 1 - \exp\left[-\sum_{i=1}^{t} ci^{\beta-1}\right], \quad t = 0, 1, 2, \cdots . \tag{3.58}$$

3.4.3 Type VI Models (Stochastic Point Process Models)

These are stochastic point process models with links to the standard Weibull model.

Power Law Process (*Bassin* [3.43])

This is a point process model with the intensity function given by

$$\lambda(t) = \left(\frac{\beta t^{\beta-1}}{\alpha^{\beta}}\right) . \tag{3.59}$$

This model has been called by many different names: *power law process*; *Rasch–Weibull process*; *Weibull intensity function*); *Weibull–Poisson process* and *Weibull process*. We note that the inter-event times do not have Weibull distributions. For further discussion on the Weibull process, see for example, *Bain* and *Engelhart* [3.44, Chapt. 9].

Proportional Intensity Model (*Cox* and *Oaks* [3.45])

The intensity function is given by

$$\lambda(t; S) = \lambda_0(t)\psi(S) , t \geq 0 , \tag{3.60}$$

where $\lambda_0(t)$ is of the form given above and $\psi(S)$ is a function of the explanatory variables S. The only restriction on $\psi(S)$ is that $\psi(S) > 0$.

Ordinary Renewal Process (*Yannaros* [3.46])

Here the point process is a renewal process with the time between events being independent and identically distributed with the distribution function given by the standard Weibull distribution.

Modified Renewal Process

Here the distribution function for the time to first event, $F_0(t)$, is different from that for the subsequent inter-event times, which are identical and independent random variables with distribution function $F(\cdot)$. Note that $F_0(t)$ and/or $F(t)$ are standard Weibull distributions. When $F_0(t) = F(t)$, this reduces to the ordinary renewal process.

3.5 Empirical Modeling of Data

We have seen a large number of Weibull-related models which we simply refer as Weibull models. They exhibit a wide range of shapes for the density and failure rate functions, which make them suitable for modeling complex failure-data sets.

Recall, we mention that empirical modeling usually involves three steps: model selection, estimation of model parameters and model validation. In the context of Weibull models, a selection procedure may be based on WPP plots. This is possible due to the availability of WPP or generalized WPP plots for all the Weibull models of types I–III. Of course, the shape of the density and failure rate functions will also be valuable in the selection step. An added advantage of the WPP plots is that they provide crude estimates of model parameters; these serve as a starting point for steps 2 and 3.

It has been suggested that an alternative method to estimate model parameters is through a least-squares fit. Basically speaking, this involves selecting the parameters the parameters to minimize a function given

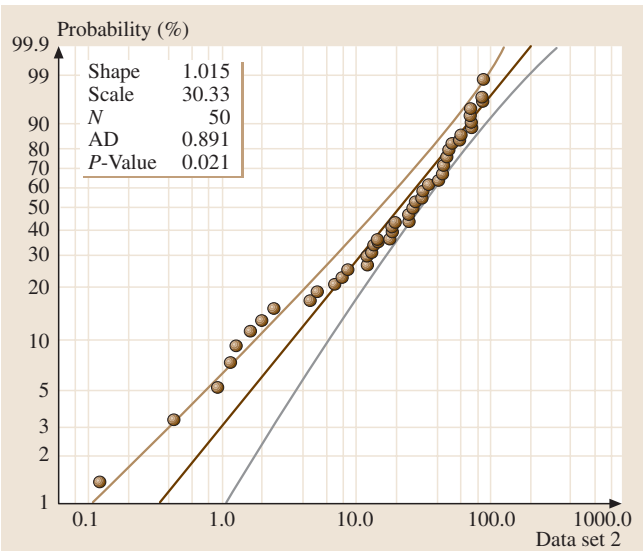

Fig. 3.4 Probability plot of data set from Table 3.1

Table 3.1 Data set of failure test (data set 2)

0.12	0.43	0.92	1.14	1.24	1.61	1.93	2.38	4.51	5.09

by

$$J(\boldsymbol{\theta}) = \sum_{i=1}^{n} [y(t_i; \boldsymbol{\theta}) - y_i]^2 \,, \tag{3.61}$$

where $y(t_i; \boldsymbol{\theta})$ uses the vector parameter $\boldsymbol{\theta}$ and y_i is the corresponding value obtained from the data. The optimization can be carried out using any standard optimization package. The least-squares method not only furnishes us with parameter estimates, but also helps to select a Weibull model. If one of the potential candidates has a value for $J(\boldsymbol{\theta})$ which is considerably smaller than that for the other models, then this can undoubtedly be accepted as the most appropriate model for modeling the given data set. If two or more Weibull models give rise to roughly the same value of $J(\boldsymbol{\theta})$, one would need to examine additional properties of the WPP plots to decide on the final model. Other approaches such as bootstrap and jackknife may be employed for the final selection. For more on this, see *Murthy* et al. [3.3, 47].

A couple of comments on step 3 of our empirical modeling may be in order. There are many statistical tests for validating a model. These generally require data that is different from the data used for model selection and parameter estimation. A smaller data set may pose a problem, as there will be no separate data left after model selection and parameter estimation. Various solutions have been proposed in the case of a small data set. We refer the readers to the book by *Meeker* and *Escobar* [3.48] for further details.

Example 3.1:
50 items are tested to failure. The failure times are automatically recorded and given in Table 3.1. The Weibull probability plot indicates that the two-parameter Weibull model is not appropriate.

Based on the plot, we observe that the plot shows a decreasing slope at the beginning, and an increasing slope at the end. This is an indication of a distribution with a bathtub-shaped failure-rate function. Some of the models of type II or type III can be used. One possibility is to fit the early part and last part of the plot with separate lines (Fig. 3.4). This will result in a two-fold competing risk model (3.48).

3.6 Applications

3.6.1 Applications in Reliability

Product reliability depends on the design, development and manufacturing decisions made prior to the launch (pre-launch stage) of the product and it in turn affects the failures when the product is put into operation after launch (post-launch stage).

The pre-launch stage involves several phases. In the feasibility phase, study is carried out using the specified target value for product reliability. During the design phase, product reliability is assessed in terms of part and component reliabilities. Product reliability increases as the design is improved. However, this improvement has an upper limit. If the target value is below this limit, then the design using available parts and components achieves the desired target value. If not, then a program to improve the reliability through test–fix–test cycles is carried out during the development phase. Here the prototype is tested until a failure occurs and the causes of the failure are analyzed. Based on this, design changes are made to overcome the identified failure causes. This process is continued until the reliability target is achieved. The reliability of the items produced during manufacturing tends to vary from the design target value due to variations resulting from the manufacturing process. Through proper process and quality control during the manufacturing phase, these variations are controlled.

In the post-launch stage, the reliability of an item decreases due to deterioration resulting from age and/or usage. This deterioration is affected by several factors, including the environment, operating conditions and maintenance. The rate of deterioration can be controlled through effective preventive maintenance actions. Poor reliability results in higher maintenance cost for the

Li et al. [3.56]	Concrete components

buyer. It also leads to higher warranty cost for the manufacturer resulting from the cost of rectifying all failures within the warranty period subsequent to the sale of the product.

Most products are composed of several components and the failure of the product is due to failure of its components. Weibull models (the two- and three-parameter models as well as a variety of types I–III Models) have been used to model the failures of many components and the literature is vast. A very small sample of the literature follows.

These models allow the determination of product reliability in terms of component reliabilities during the design phase.

During the development phase, it is often necessary to use accelerated testing to hasten the process leading to component failures. A variety of type IV models have been used for the design of experiments to carry out this testing. For more on such models, see *Nelson* [3.39] and *Meeker* and *Escobar* [3.48].

The improvement in reliability (also referred to as reliability growth) during the development phase has been modeled in many different ways. *Duane* [3.57] used a Weibull intensity model formulation to model the improvement in failure rate as a function of the development time. The breakthroughs leading to improvements can be viewed as random points along the time axis. *Crow* [3.58] modeled this by a Weibull power-law process (type VI Weibull model). For models that are modification of this model, see *Murthy* et al. [3.3].

In the manufacturing phase, the fraction of nonconforming items is small when the process is in-control while it increases significantly when the process goes out-of-control. The Weibull distribution has been used to model the in-control duration in the design of control charts to detect the change from in-control to out-of-control. For more on this, see *Rahim* [3.59], *Costa* and *Rahim* [3.60], and *Chen* and *Yang* [3.61]. *Nelson* [3.62] deals with control charts for items with Weibull failure distributions where conforming and nonconforming items differ in the scale parameter but have the same shape parameter. *Murthy* et al. [3.63] and *Djamaludin* et al. [3.64] deal with lot production and look at optimal lot size to control the occurrence of nonconforming items.

When the failure rate has a bathtub shape, it is prone to early failure. For products modeled by Weibull models exhibiting bathtub failure rates, burn-in is a technique that can be used to weed out such failures and improve product reliability before it is released for sale. For more on burn-in, see, e.g., *Kececioglu* and *Sun* [3.65].

Warranty cost analysis for products with a Weibull failure distribution has received a lot of attention. For more on this, see, e.g., *Blischke* and *Murthy* [3.66, 67] and *Murthy* and *Djamaludin* [3.68].

Preventive maintenance of products with a Weibull failure distribution has received considerable attention. In the age policy, an item is replaced preventively when it reaches some specified age and *Tadikmalla* [3.69] deals with this in the context of the Weibull failure distribution. In the block policy, items are replaced preventively at set clock times and *Blischke* and *Murthy* [3.70] deals with this in the context of the Weibull failure distribution.

3.6.2 Applications in Other Areas

Weibull distribution has been used as a model in diverse disciplines to study many different issues. There are

several thousand papers and we give a very small sample of this vast literature

3.6.3 Weibull Analysis Software

In any analysis of statistical data, computer software is required. In addition to standard statistical software such as MINITAB, SPSS, SAS, etc., or spreadsheet software such as Excel, some specialized Weibull analysis software are also available. Below is a list of some common ones.

- Weibull++ 6 by ReliaSoft Corp., Tucson, AZ; http://weibull.reliasoft.com/
- Relex Weibull by Relex Software Corp., Greensburg, PA; http://www.relexsoftware.com/products/weibull.asp
- WeibullPro by Isograph Inc., Newport Beach, CA; http://www.isograph-software.com/avsoverwbl.htm
- WinSMITH Weibull by Barringer & Associates, Inc., Humble, TX; http://www.barringer1.com/wins.htm

4. Characterizations of Probability Distributions

A characterization is a certain distributional or statistical property of a statistic or statistics that uniquely determines the associated stochastic model. This chapter provides a brief survey of the huge literature on this topic. Characterizations based on random (complete or censored) samples from common univariate discrete and continuous distributions, and some multivariate continuous distributions are presented. Characterizations that use the properties of sample moments, order statistics, record statistics, and reliability properties are reviewed. Applications to simulation, stochastic modeling and goodness-of-fit tests are discussed. An introduction to further resources is given.

Suppose X is the population random variable (RV) with cumulative distribution function (CDF) $F(x) = \Pr(X \le x)$ from which the data are generated according to a specified sampling scheme. Let $\mathcal{F}$ be the family of probability distributions used as an initial model to describe X and $\mathcal{F}_0$ be a subclass of $\mathcal{F}$ that is of interest to the modeler. If $T = T(X)$ is a statistic arising from F, and if a certain distributional property it possesses implies that $F \in \mathcal{F}_0$, then this property of $T(X)$ produces a characterization of $\mathcal{F}_0$. If the concerned property of $T(X)$ holds if and only if $F \in \mathcal{F}_0$, then we have a complete characterization of $\mathcal{F}_0$ and it is particularly helpful when this subfamily has a single member or members from a single parametric family of distributions. This is the essence of the abundant literature on this fascinating area of characterizations, produced by probabilists and mathematical statisticians, mostly over the past half-century.

In Sect. 4.1 we describe characterizing functions and their role in characterizations. Various types of data settings and associated characterizing properties discussed in the literature are reviewed in Sect. 4.2. A general classification of characterization results is given in Sect. 4.3. Treatment of continuous distributions begins with that of the exponential in Sect. 4.4, and continues with the normal in Sect. 4.5, and other distributions in Sect. 4.6. Characterizations for the Poisson distribution and Poisson process are given in Sect. 4.7, and Sect. 4.8 contains characterizations for other common discrete distributions. A brief look at the characterizations of multivariate distributions is provided in Sect. 4.9, where some characterizations based on conditional specification are presented. Special attention is drawn to the Marshall–Olkin bivariate exponential model and the multivariate normal distribution. Stability of characterization results is discussed in Sect. 4.10 and applications of characterizations in Sect. 4.11. The last section (Sect. 4.12) contains a listing of major resources.

4.1 Characterizing Functions

There are several functions associated with a probability distribution that uniquely identify it. We call these characterizing functions and describe a few of them.

4.1.1 Cumulative Distribution Function (CDF)

The CDF $F(x)$ of a RV X, defined for all real x, describes $P(X \in A)$ for any Borel set A on the real line. It is right-continuous, nondecreasing, and $F(-\infty) = 0$ and $F(+\infty) = 1$. If X is a discrete RV, $\Pr(X = x) = F(x) - F(x-) > 0$ for any possible value x. A closely associated function, the *survival function* (SF), is defined by

$$S(x) = \Pr(X \geq x) = 1 - F(x-)\,. \tag{4.1}$$

4.1.2 Probability Density Function (PDF)

The PDF $f(x)$ is a nonnegative function with the property that, for any Borel set A, $\Pr(X \in A)$ can be obtained by either summing or integrating $f(x)$ over A. When X is absolutely continuous, $f(x) = F'(x)$ almost everywhere (a. e.). In many cases, the PDF provides the most convenient way to describe the probability assignment.

4.1.3 Quantile Function

Also known as the inverse CDF, it is often defined as

$$F^{-1}(u) = \inf\{x : F(x) \geq u\},\ 0 < u < 1\,. \tag{4.2}$$

The quantile function is nondecreasing and, in this form, is left-continuous. It describes the probability assignment in terms of the quantiles of the distribution. When X is absolutely continuous, $F^{-1}(u)$ is differentiable with derivative $1/f[F^{-1}(u)]$.

The *probability integral transformation* $U = F(X)$ transforms any continuous RV X with CDF $F(x)$ into a standard uniform RV U that has PDF $f(u) = 1$, $0 < u < 1$. For *any* RV X with CDF $F(x)$,

$$X \stackrel{d}{=} F^{-1}(U)\,, \tag{4.3}$$

where $\stackrel{d}{=}$ stands for equality in distribution. This valuable distributional identity is helpful in simulating arbitrary RVs and also plays an important role in the theoretical developments associated with moments of X and of order statistics generated from random samples.

For a nonnegative RV with finite mean $\mu = \mathrm{E}(X) = \int_0^1 F^{-1}(u)\,\mathrm{d}u$, the quantile function yields the *Lorenz curve* used for describing the discrepancy in income distributions. The Lorenz curve is described by the function

$$L(t) = \frac{1}{\mu}\int_0^t F^{-1}(u)\,\mathrm{d}u,\quad 0 \leq t \leq 1\,. \tag{4.4}$$

It identifies F^{-1} and consequently F, up to the scale parameter.

4.1.4 Characteristic Function (CF) and Other Generating Functions

For any RV X, a CF exists and is defined by $\psi(t) = \mathrm{E}[\exp(\mathrm{i}tX)]$, where t is real and $\mathrm{i} = \sqrt{-1}$. This complex-valued function (it is real for F symmetric about 0) uniquely determines the CDF ([4.1], p. 104). It has played a major role in the proof of the central limit theorem and in numerous characterizations, especially of the normal distribution. An associated function, the moment generating function (MGF), given by $\mathrm{E}[\exp(tX)]$, may not exist for $t \neq 0$. If the MGF exists for t in a neighborhood of 0, then moments of X of all orders exist. Furthermore, the jth moment of X, $\mathrm{E}(X^j)$, can be obtained by a Taylor-series expansion of either

the CF or the MGF of X. A one-to-one function of the MGF is its logarithm, the cumulant generating function. A discrete distribution with support over nonnegative integers is uniquely determined by its probability generating function, given by $\mathrm{E}\{s^X\}$, defined at least for $|s| \le 1$ ([4.1], p. 101).

4.1.5 Reliability Considerations

Several characterizing functions that are based on reliability properties have appeared in the area of life-testing experiments. There are many classes of distributions in the reliability literature that are based on the properties of such functions [4.2]. We introduce three such functions where we assume X to be nonnegative for practical reasons, and to be absolutely continuous for convenience.

Failure Rate and Hazard Functions

The failure (or hazard) rate function is defined for all x in the support of the RV X and is given by

$$h(x) = \frac{f(x)}{S(x)} = \frac{f(x)}{1 - F(x)} , \tag{4.5}$$

where $S(x)$ is the SF defined in (4.1), and in this case, equals $1 - F(x)$. Clearly,

$$H(x) \equiv \int_0^x h(w)\,\mathrm{d}w = -\log[1 - F(x)] , \tag{4.6}$$

and thus $h(x)$ uniquely determines $F(x)$. Further, $H(x)$, the integrated failure-rate function, also called the *hazard function*, identifies $F(x)$ as well, through the relationship $F(x) = 1 - \exp[-H(x)]$. The family of distributions for which the failure rate (FR) $h(x)$ is increasing (decreasing) is the IFR (DFR) family. If $H(x)/x$ is increasing (decreasing) one obtains the IFRA (DFRA) family since the average failure rate in that case will be increasing (decreasing).

Mean Residual Life (MRL) Function

The MRL is of practical interest in life-testing experiments and is defined whenever $\mathrm{E}(X)$ is finite. For a nonnegative X, with $t > 0$, it is given by

$$\begin{aligned} m(t) &\equiv \mathrm{E}(X - t | X > t) \\ &= \frac{1}{1 - F(t)} \int_t^\infty [1 - F(w)]\,\mathrm{d}w , \end{aligned} \tag{4.7}$$

if the CDF F is continuous. Equation (4.7) can be used to recover $F(x)$ from $m(t)$. In fact, when F is continuous, and $F^{-1}(0) = 0$,

$$1 - F(x) = \frac{m(0)}{m(x)} \exp\left(- \int_0^x \frac{\mathrm{d}y}{m(y)} \right) , x > 0 , \tag{4.8}$$

where $m(0) = \mathrm{E}(X)$. Another closely related characterizing function is the truncated mean $\mathrm{E}(X | X > t) \equiv t + m(t)$, sometimes referred to as the conditional tail expectation. Increasing (decreasing) $m(t)$ produces the family of IMRL (DMRL) life distributions. Yet another characterizing function is the total time on test transform ([4.3], p. 91), defined as

$$\tau(t) = \int_0^{F^{-1}(t)} [1 - F(x)]\,\mathrm{d}x, 0 \le t \le 1 . \tag{4.9}$$

This is concave if and only if (iff) F is IFR.

Characterization of a probability distribution then refers to the identification of any of $F(x)$, $F^{-1}(x)$, $f(x)$, $\psi(t)$, $h(x)$, $H(x)$, $m(t)$, $\tau(t)$, or of families for which these functions possess a certain property.

Example. Consider the exponential distribution with rate parameter λ whose PDF is given by

$$f(x) = \lambda\,\mathrm{e}^{-\lambda x}, x \ge 0 . \tag{4.10}$$

If (4.10) holds, we say that X is an $\exp(\lambda)$ RV. For such an RV, the CDF is given by $F(x) = 1 - \exp(-\lambda x)$, $x \ge 0$; the quantile function is given by $F^{-1}(u) = -\log(1-u)/\lambda$, $0 \le u \le 1$; the characteristic function by $\psi(t) = 1/(1 - \mathrm{i}t/\lambda)$; the failure-rate function by $h(x) = \lambda$, $x \ge 0$; the hazard function by $H(x) = \lambda x$, $x \ge 0$; the MRL function by $m(t) = 1/\lambda$, $t \ge 0$; and the total time on test transform by $\tau(t) = t/\lambda$, $t \ge 0$.

4.2 Data Types and Characterizing Conditions

A characterization result is based on the assumed model for the data and the specified property of a particular statistic of interest. We now describe some common scenarios.

4.2.1 Data Models

The most basic data set consists of a single observation X from the CDF $F(x)$. Next, one may encounter either

a random sample $X_1, \ldots, X_n$ from $F(x)$, i. e., the X_j are independent, identically distributed (IID) RVs with CDF $F(x)$. Or the X_j are just independent and their CDFs belong to a family $\mathcal{F}_0$. Type II right-censored samples from (absolutely) continuous distributions that appear naturally in life-testing experiments are considered as well.

Let $X_{1:n} \le \cdots \le X_{k:n} \le \cdots \le X_{n:n}$ be the order statistics of the random sample [4.3]. Then the CDF of $X_{k:n}$ is given by

$$\sum_{j=k}^{n} \binom{n}{j} F^j(x)[1-F(x)]^{n-j}$$

$$= \frac{n!}{(k-1)!(n-k)!} \int_0^{F(x)} t^{k-1}(1-t)^{n-k}\,\mathrm{d}t\,, \qquad (4.11)$$

and the joint PDF of $X_{1:n}, \cdots, X_{k:n}$, a type II right censored sample, is given by

$$\frac{n!}{(n-k)!} f(x_1)\cdots f(x_k)[1-F(x_k)]^{n-k},$$

$$x_1 < \cdots < x_k\,. \qquad (4.12)$$

Models that use the properties of upper or lower record values for characterizations do exist. For an infinite sequence $\{X_j, j \ge 1\}$ from a continuous parent, for $j \ge 1$, X_j is called an *upper record value* of this sequence if $X_j = \max(X_1, \ldots, X_j)$ [4.4]. By convention, X_1 is the first upper record value (or reference value). The joint PDF of the first m upper record values, $R_1, \ldots, R_m$, is given by

$$f(r_1, \ldots, r_m) = f(r_m) \prod_{j=1}^{m-1} h(r_j) \quad r_1 < \cdots < r_m\,, \qquad (4.13)$$

where $h(x)$ is given by (4.5). From (4.12) and (4.13), we can, respectively, conclude that (see, e.g., [4.4], p. 114), for a continuous parent

$$\Pr(X_{k+1:n} > y | X_{k:n} = x)$$

$$= [\Pr(X > y | X > x)]^{n-k}, x < y\,, \qquad (4.14)$$

and

$$\Pr(R_{m+1} > y | R_m = x) = \Pr(X > y | X > x)$$

$$= \frac{1-F(y)}{1-F(x)}, x < y\,. \qquad (4.15)$$

4.2.2 Characterizing Conditions

There are many types of characterizing properties. For example, the property could be based on identical distribution of two statistics, or independence of them, or on constancy of regression of one on the other. Alternatively, the characterization may be based on properties of admissibility and optimality of certain estimators based on random samples [4.5]. Characterizations based on fixed or random sample sizes and on damaged/missing observations do exist. Basically, the assumed condition is shown to yield a functional equation satisfied by a characterizing function, leading to the identification of the parent distribution. Other conditions involve recurrence relations satisfied by the ordinary moments, or moments of order statistics. There are characterizations based on certain inequalities for the moments, Fisher information or entropy measures, where equality holds for a unique family of distributions.

4.2.3 General Techniques

For the normal distribution, identification via the characteristic function is the common approach. The proofs involve results on complex variables. Numerous results for the exponential or geometric distributions have been based on the SF and rely on the Cauchy functional equation (CFE) ([4.6], Sect. 1.1), namely,

$$g_0(x+y) = g_0(x)g_0(y), \text{ for all } x, y \ge 0\,. \qquad (4.16)$$

The only continuous solution is the exponential SF. The well-known lack-of-memory property (LMP) of the exponential distribution, namely

$$\Pr(X > x+y | X > x) = \Pr(X > y),$$

$$\text{for all } x, y \ge 0\,, \qquad (4.17)$$

leads to (4.16). In (4.17), the exponential SF $\Pr(X > x) = \exp(-\lambda x)$ is recovered even if the equation holds for all $x \ge 0$ and for two y values y_1, y_2 such that y_1/y_2 is irrational.

In recent years, the integrated CFE (ICFE) whose solution goes back to Deny's Theorem ([4.6, 7], Chapt. 2) has been used for several characterizations of the exponential and geometric distributions. We say that g_1 satisfies an ICFE if it is a function defined on $[0, \infty)$ and satisfies the condition (4.18) (see below). The following characterization result due to *Lau* and *Rao* [4.8] is taken from [4.7] (p. 29).

Theorem 4.1

Let g be a nonnegative locally integrable function on $[0, \infty)$ that is not a function identically equal to 0 a.e. ν_0, the Lebesgue measure defined on $[0, \infty)$. Suppose g satisfies (4.18) given below where ν is a σ-finite measure

satisfying the condition $\nu(\{0\}) < 1$:

$$g(x) = \int_0^\infty g(x+y)\, \mathrm{d}\nu(y), \qquad \text{a. e. } \nu_0 \text{ for } x \geq 0\,. \tag{4.18}$$

Then either

$$g(x+n\delta) = g(x)b^n, n \geq 0, \qquad \text{a. e. } \nu_0 \text{ for } x \geq 0\,, \tag{4.19}$$

where b is such that $\sum_{n=0}^\infty b^n \nu(\{n\delta\}) = 1$ for some $\delta > 0$, or

$$g(x) \propto \mathrm{e}^{\alpha x} \quad \text{a. e. } \nu_0 \text{ for } x \geq 0\,, \tag{4.20}$$

where α satisfies the condition $\int_0^\infty \mathrm{e}^{\alpha y}\, \mathrm{d}\nu(y) = 1$.

If g_0 satisfying (4.16) is integrable with respect to a σ-finite measure ν_1 on $[0, \infty)$, the integral being a positive quantity c, then it also satisfies (4.18) with $\nu = c^{-1}\nu_1$.

The above result has provided elegant unified proofs of several characterizations of exponential and geometric distributions. See the review in [4.9] and the monograph [4.7]. A nice account of the role of functional equations in probability theory and in characterization theorems is given in [4.6].

A handy technique is based on complete families of functions. Suppose $\{f_n(x),\, n \geq 1\}$ is a sequence such that if, for any integrable function $g(x)$, the condition

$$\int_A g(x) f_n(x)\, \mathrm{d}x = 0 \qquad \text{for all } n \geq 1 \tag{4.21}$$

implies that $g(x) = 0$ a.e. on A, where A is an interval. Then we say that the sequence of functions $f_n(x)$ is complete on A. For example, $f_n(x) = x^n$ is complete on $[0, 1]$ and leads to the characterization of F based on the sequence $\mathrm{E}(X_{n:n})$. A classical completeness result due to Müntz and Szász shows that even an appropriately chosen subsequence would do. (See [4.10] for a good summary.) The *method of intensively monotone operators* is another general method of showing uniqueness of solutions to the functional equations generated by the characterizing conditions [4.11].

An approach involving inequalities such as the Cauchy–Schwarz (or Cramér–Rao) has produced some characterizations. The distribution being characterized corresponds to the case where equality holds. For example,

$$\mathrm{Cor}(X_{j:n}, X_{k:n}) \leq \sqrt{\frac{j(n-k+1)}{k(n-j+1)}},\ j < k\,, \tag{4.22}$$

where "Cor" represents the correlation coefficient, and equality holds iff F is a uniform CDF.

The *method of limit laws*, elaborated in [4.12], is found to be helpful in establishing some characterizations.

4.3 A Classification of Characterizations

We attempt below a general classification of characterization results.

4.3.1 Uniqueness Conditions

These are properties that provide a one-to-one correspondence with the parent CDF F. For example, from (4.11) it is clear that the CDF of $X_{k:n}$ for any fixed k and n identifies $F(x)$, and thus provides a trivial characterization.

A more interesting question is considered in the *classical moment problem* [4.13]. It is concerned with the determination of the CDF $F(x)$ from the sequence of population moments $\{\mathrm{E}(X^j),\, j \geq 1\}$, which are assumed to exist. Two distinct distributions can have the same moment sequence. Under certain conditions, however, the associated CDF is unique. One such condition is that

$$\sum_{j=1}^\infty \frac{\mathrm{E}(X^j)}{j!} t^j \tag{4.23}$$

is absolutely convergent for some $t > 0$ ([4.1], p. 106).

In the context of order statistics, the moment problem has the goal of identifying F based on the moment sequence $\{\mathrm{E}(X_{k(n):n}),\, 1 \leq k(n) \leq n,\, n \geq 1\}$. There is no loss of generality in choosing $k(n)$ [or $n - k(n)$] to be a constant. It is known that the subsequence $\{\mathrm{E}(X_{n_j:n_j}),\, n_1 < n_2 < \cdots,\, j \geq 1\}$ characterizes F provided that $\sum_{j=1}^\infty 1/n_j$ diverges [4.14]. Such a subsequence will not suffice when we consider $\mathrm{E}(R_n)$—the moment sequence of record values. One needs the entire sequence and identification can be

achieved only within the family of continuous distributions ([4.4], Sect. 4.2.1).

It is clear from (4.15) that $E(R_{n+1} - R_n | R_n = x) = m(x)$ a.s., and hence, in view of (4.8), one can recover $F(x)$ from the regression function $E(R_{n+1}|R_n)$. Similarly $E(X_{k+1:n}|X_{k:n})$ or even $E[h(X_{k+1:n})|X_{k:n}]$ where $h(.)$ is a real, continuous and strictly monotonic function, would identify F in the family of *arbitrary* distributions [4.15].

4.3.2 Characterizations of Families of Distributions

There are characterizations of distributions defined by their reliability properties, of the exponential-family distributions, or of spherically symmetric (multivariate) distributions, and other large families. Such results identify the general properties possessed by the members without actually providing an explicit form for the CDF or other characterizing functions. For example, certain properties of order statistics characterize various classes of life distributions [4.16]. A specific characterization of this sort is the following. Among nonnegative distributions with finite mean, a CDF F is IFR iff $E[(n-k+1)(X_{k:n} - X_{k-1:n})]$ is decreasing in k $(2 \le k \le n)$ for infinitely many n. A one-parameter exponential family is characterized (under some conditions) by the fact that, for a single random sample of size $n \ge 3$, the sample mean $\bar{X}$ is the maximum-likelihood estimator (MLE) of the mean of the distribution (see also [4.17]). Such results are interesting theoretically and provide some reality checks for the model assumptions.

4.3.3 Characterizations of Specific Parametric Families

Of maximal interest in terms of applications and creation of goodness-of-fit tests are the characterizations that identify specific parametric family of distributions. In subsequent sections we will discuss a few such results for some common distributions; in fact, we consider only a tiny subset of the voluminous, ever-growing literature. We only list the characterization results with no details on the other needed conditions, some of which could be very technical and hard to verify. We refrain from proving any of our claims.

4.4 Exponential Distribution

Arnold and *Huang* [4.18], in their survey of characterizations of the exponential distribution, mentioned about 275 citations 10 years ago, and one could safely add 50 more to the list, making it perhaps the most popular distribution on this topic. In recent years results based on the properties of order statistics and record values have been in vogue. In most cases, the condition imposed will result in the CFE or the ICFE discussed in Sect. 4.2. Apart from the exponential characterizations stemming from the general results [e.g., if $E(X_{1:n}) = \lambda/n$, $n \ge 1$, then F must be an exp(λ) CDF], the conditions imposed could be based on: (i) truncated moments or regression functions associated with order statistics or (upper) records, (ii) distributional identities among order statistics, their spacings, or the spacings of records, (iii) independence of certain linear functions of order statistics or records, (iv) reliability properties of order statistics or records, or (v) *geometric compounding*, where the RV of interest is a random sum of IID RVs where the number in the sum is determined by an independent geometric RV.

Consider the order statistics case. For the exp(λ) parent: (a) $X_{j:n}$ and $X_{k:n} - X_{j:n}$, $j < k$, are independent, (b) $nX_{1:n} \stackrel{d}{=} X_1$, $n \ge 2$, and the normalized spacings, $Y_j = (n-j+1)(X_{j:n} - X_{j-1:n})$, $j = 1, \ldots, n$ (with $X_{0:n} = 0$), have the following properties: (c) the Y_j are independent, (d) they are identically distributed as X_1 for all $j = 1, \ldots, n$, and (e) $E(Y_j) = 1/\lambda$, $1 \le j \le n$. Under some mild conditions each of these provides a characterization of the exponential CDF. In (b), it is known that, if the distributional equality holds for two values of n, say n_1 and n_2 such that $\log n_1 / \log n_2$ is irrational, then the exponential RV is identified in the family of nonnegative RVs.

If F is an exponential CDF, from the joint PDF of the record values given in (4.13), it can be shown that, for $j \le m < n$:

1. R_m and $R_n - R_m$ are independent,
2. R_j and $R_n - R_m$ are independent,
3. $E(R_{n+1} - R_n | R_n)$ does not depend on R_n,
4. $\mathrm{Var}(R_{n+1} - R_n | R_n)$ does not depend on R_n,
5. $R_n - R_m$ and R_{n-m} are identically distributed,
6. $E((R_n - R_m)^s | R_j)$ does not depend on R_j,
7. $E(R_n) = n/\lambda$, and
8. $E(R_{n+1}|R_n)$ and $E(R_n|R_{n+1})$ are both linear in conditioning variables.

Each of these provides a characterization of the exponential distribution (possibly with a location shift) in

an appropriately chosen $\mathcal{F}$ (such as continuous CDF). There are many more that dwell on the properties of the spacings of upper record values or order statistics.

Using (4.13) and (4.14), characterizations involving record or order statistic spacings can be linked to those based on truncated distributions. For example, assuming that $\mathrm{E}(R_{n+1} - R_n | R_n)$ does not depend on R_n is basically the same as saying $\mathrm{E}(X - x | X > x)$ is free of x. This means that the MRL is a constant—a characterizing property of the exponential distribution. Conditions such as $X_{j+1:n} - X_{j:n} \stackrel{d}{=} X_{1:n-j}$ or $R_n - R_m \stackrel{d}{=} R_{n-m}$ result in the ICFE (see Theorem 4.1), yielding an exponential characterization in the family of continuous CDFs.

In the context of life-testing experiments, the statistic representing the *total time on test* by time $X_{i:n}$, $T_{i,n} = \sum_{j=1}^{i} Y_j = \sum_{j=1}^{i} X_{j:n} + (n-i)X_{i:n}$, is of considerable interest. For an exponential parent, for $2 \le k \le n$,

$$\left(\frac{T_{1,n}}{T_{k,n}}, \cdots, \frac{T_{k-1,n}}{T_{k,n}} \right) \tag{4.24}$$

behaves like the vector of order statistics from a random sample of size $k-1$ from the standard uniform distribution. The converse is shown to be true assuming that the order-statistic property holds for some k and n such that $5 \le k \le n$ [4.9].

There is a characterization of the exponential distribution based on records that is similar to that of the uniform distribution based on the order statistics [see (4.22)]. If $\mathrm{Var}(R_m)$ and $\mathrm{Var}(R_n)$ are both finite, $\mathrm{Cor}(R_m, R_n)$ does not exceed $\sqrt{m/n}$, $m < n$. Furthermore, the upper bound is attained if F is an exponential CDF, possibly with a location shift.

Numerous characterizations of the exponential distribution exist when $\mathcal{F}$ is restricted to families defined by the reliability properties (such as the *new better/worse than used* families). Characterizations of the exponential distribution arising from queueing models are rare; for a few results, see [4.19].

The survey of characterizations using order statistics by *Gather* et al. [4.20] contains an excellent compendium of results for the exponential distribution based on their properties. Other important references include the monograph by *Azlarov* and *Volodin* specializing on exponential characterizations [4.21], the survey [4.18] mentioned earlier, and [4.22], Chapt. 19.

Remarks. The memoryless property (LMP) of the exponential distribution is also shared by the geometric distribution, which can be extracted as $[X]$ where $[\cdot]$ represents the greatest integer function. This results in many parallel characterizations for the geometric parent among distributions on nonnegative integers (see Sect. 4.8; [4.23]). Homogeneous Poisson processes, characterized by the fact that the inter-arrival times of the events are IID exponential, can be identified by the characterizing properties of the exponential distributions. Also, for any RV X with continuous CDF F, $-\log[1 - F(X)]$ is standard exponential and thus exponential characterizations naturally lead to characterizations of such distributions. For example, results based on exponential spacings will lead to the characterizations of the uniform, power-function or Pareto distributions on the basis of the properties of the ratios of order statistics.

4.5 Normal Distribution

The earliest characterization results were for the normal distribution. In 1923 Pólya showed that, if X_1 and X_2 are IID with finite variance, and $X_1 \stackrel{d}{=} a_1 X_1 + a_2 X_2$, then the X_j must necessarily be normal. *Cramér* showed in 1937 that, if X_1 and X_2 are independent and the sum is assumed to be normal, then each of them must be normal (see [4.24], p. 53). *Skitovich* and *Darmois* established in 1953 the following result:

Theorem 4.2

If $X_1, \ldots, X_n$ are independent and the linear functions

$$L_1 = \sum_{j=1}^{n} a_j X_j, \; L_2 = \sum_{j=1}^{n} b_j X_j \tag{4.25}$$

are independent, then the RVs X_j for which $a_j b_j \neq 0$ must all be normal.

The work on normal characterizations accelerated from the 1950s and it was an extremely active area of research until the late 1970s. Extensive accounts are available, particularly in the influential book on characterizations by *Kagan* et al. [4.5], and also in the monograph on the applications of characteristic functions by *Lukacs* and *Laha* [4.25], all major contributors to the area. A short book devoted to normal characterizations by *Mathai* and *Pederzolli* [4.26] also provides a good account. An excellent brief summary of the normal characterizations and an extensive reference list is provided in [4.22],

Chapt. 13. Another recent account of normal characterizations is provided by the monograph [4.27]. We now record a listing of assorted types of characterizations, mostly those that are easy to describe. These hold under usually mild conditions. Many normal characterizations hold under technical conditions that are hard to verify and often it is difficult to assess their practical implications.

Characterizations

We begin with characterizations based on the properties of a single observation from the parent distribution.

Among absolutely continuous distributions with support $(-\infty, \infty)$ and specified mean and variance, the entropy $-\int_{-\infty}^{\infty} f(x)\log f(x)\mathrm{d}x$ is the largest for the normal distribution ([4.5], p. 410).

Assume $\mathcal{F}$ is the location family of absolutely continuous distributions with support $(-\infty, \infty)$ and differentiable density $f(x-\theta)$, where θ is the location parameter. Then the Fisher information in this location family is given by

$$I_f(\theta) = \int\limits_{f(x)>0} \left(\frac{f'(x)}{f(x)}\right)^2 f(x)\mathrm{d}x\,. \tag{4.26}$$

The distribution in this family with the smallest $I_f(\theta)$ is normal ([4.5], p. 406).

The following properties based on a random sample $X_1, \ldots, X_n$ of size n, characterize the normal parent:

1. X_1 has zero mean and unit variance, and for some $a_1, a_2 \neq 0$, $(a_1X_1 + a_2X_2)^2/(a_1^2 + a_2^2) \stackrel{d}{=} (a_1X_1 - a_2X_2)^2/(a_1^2 + a_2^2) \stackrel{d}{=} \chi^2_{(1)}$ ([4.22], p. 105).
2. X_1 has zero mean and is nondegenerate and with $ab = -1$ and $n = 2$, $\mathrm{E}(X_1 + aX_2|X_1 + bX_2) = \mathrm{E}(X_1 + bX_2|X_1 + aX_2) = 0$ ([4.5], p. 158).
3. The sample mean $\bar{X}$ and sample variance S^2 are independent for some $n \geq 2$ ([4.5], p. 103).
4. For some $n \geq 5$, the vector
$$\left(\frac{X_1 - \bar{X}}{(n-1)S^2}, \cdots, \frac{X_n - \bar{X}}{(n-1)S^2}\right) \tag{4.27}$$
is uniformly distributed on the $(n-2)$-dimensional sphere $\left\{(w_1, \ldots, w_n) : \sum_{i=1}^n w_i = 0, \sum_{i=1}^n w_i^2 = 1\right\}$ ([4.7], p. 142).
5. $\mathcal{F}$ is the location family of distributions $F_0(x-\theta)$, with mean θ, the location parameter, and finite variance, and, for some $n \geq 3$, $\bar{X}$ is admissible under squared error loss among all unbiased estimators of θ ([4.5], p. 228).
6. In the above location family (with finite variance and θ as the mean), take the null hypothesis $H_0 : \theta = 0$ and the alternative $H_1 : \theta > 0$. Suppose that, for some $n \geq 3$, the critical region $\{\bar{X} > c_\alpha\}$ is the uniformly most powerful among all tests with level of significance $\leq \alpha$ for all $\alpha \in (0, 1)$, where $c_\alpha = \max\{c : \Pr(\bar{X} > c|\theta = 0) = \alpha\}$ ([4.5], p. 451).
7. In the above location family with θ as the mean, $\bar{X}_n$ is the MLE of θ for $n = 2, 3$ ([4.5], p. 411).
8. $\mathcal{F}$ is the location-scale family of continuous distributions $F_0[(x-\theta)/\sigma]$, θ real, $\sigma > 0$, and $(\bar{X}, S)$ is a sufficient statistic for (θ, σ) ([4.22], p. 106).
9. In the above location-scale family with mean θ, $\bar{X}_n$ is a best linear unbiased estimation (BLUE) of θ for *all* $n \geq 1$ [4.28].
10. In the linear regression model under the Bayesian framework, the distributions with posterior expectation is linear in data values [4.29].

When the X_j are independent RVs, some of the above results have appropriate generalizations. For example,

1. In (4.25), if the sequences $\{a_j/b_j\}$ and $\{b_j/a_j\}$ for which $a_jb_j \neq 0$ are bounded and as $n \to \infty$ L_1 and L_2 converge with probability 1 to independent RVs, then the X_j for which $a_jb_j \neq 0$ are normal ([4.5], p. 94).
2. If $X_1 \stackrel{d}{=} L_1$ in (4.25), where $a_1 \neq -1, 0, 1$, $n \geq 2$, and the X_j have finite variance, then X_1 is normal ([4.22], p. 104).
3. Suppose X_1, X_2, X_3 are independent symmetric RVs with median 0 and CDF that are continuous at 0. If $W_1 = X_1/X_3$, $W_2 = X_2/X_3$ have joint characteristic function $\mathrm{E}[\exp(it_1W_1 + it_2W_2)] = \exp(t_1^2 + t_2^2)^{1/2}$, then the X_j are IID normal ([4.22], p. 104). (Here W_1, W_2 are identically distributed Cauchy RVs.)

Remarks. Some of the above results have parallel versions that characterize the gamma populations when the support is restricted to positive values or when $\mathcal{F}$ is the scale family distribution. Some provide characterizations of the Poisson distribution when the support is restricted to nonnegative integers.

4.6 Other Continuous Distributions

4.6.1 Uniform

As noted earlier, some characterizations of the exponential lead to similar results for the uniform. In addition, several characterizations based on the properties of order statistics and sums of IID RVs do exist. We have noted earlier [see (4.18)] that the maximum correlation for any two order statistics is attained only for the uniform distribution. Below are some other conditions that characterize the uniform distribution over an interval whose endpoints are chosen appropriately. (See [4.30], p. 282–285 for original references.)

1. $\mathrm{Cov}(X_{1:2}, X_{2:2}) = (1/3)\mathrm{Var}(X)$ or equivalently $\mathrm{E}(X_{2:2} - X) = [(1/3)\mathrm{Var}(X)]^{1/2}$.
2. $[\mathrm{E}(X_{2:2})]^2 = (4/3)\mathrm{E}(X^2)$. Here and above, the right side represents the maximum possible value for the left side expression.
3. $X_{2:2} - X_{1:2} \stackrel{d}{=} X_{1:2}$.
4. For some $n \geq 3$, $\mathrm{E}(X_1 | X_{1:n}, X_{n:n}) = (1/2)(X_{1:n} + X_{n:n})$ almost surely and F is continuous.

4.6.2 Gamma

The following conditions characterize the gamma distribution, whose PDF is given by

$$f(x) = \frac{1}{\beta^\alpha \Gamma(\alpha)} \exp(-x/\beta) x^{\alpha-1}, \; x > 0\,, \tag{4.28}$$

where $\alpha > 0$ and $\beta > 0$ are the shape and scale parameters, respectively ([4.22], p. 350–354; [4.5], p. 407–410).

1. X_1 and X_2 are independent nondegenerate RVs, and $X_1 + X_2$ and X_1/X_2 are independent.
2. For independent RVs $X_1, \ldots, X_n$, and $T = \sum_{j=1}^n X_j$, $\left(\frac{X_1}{T}, \ldots, \frac{X_n}{T}\right)$ and T are independent.
3. In a random sample of size n from a positive RV X for which $\mathrm{E}(1/X)$ is finite, the conditional expectation $\mathrm{E}(\sum_{j=1}^n X_j^{-1} | X_1 - \bar{X})$ is a constant.
4. The distribution in the scale family of distributions with support $(0, \infty)$ that has the smallest attainable Fisher information measure.
5. The distribution with the maximum entropy among distributions with support $(0, \infty)$ and have specified $\mathrm{E}(X)$ and $\mathrm{E}(\log(X))$.

4.6.3 Weibull

Some exponential characterizations easily lead to characterizations of the Weibull distribution with the PDF

$$f(x) = \frac{\alpha x^{\alpha-1}}{\beta^\alpha} \mathrm{e}^{-(x/\beta)^\alpha}, \; x > 0\,, \tag{4.29}$$

where $\alpha > 0$ is the shape parameter and $\beta > 0$ is the scale parameter. This is also a distribution that is *min-stable* and is one of the extreme-value distributions to which the sample minima from random samples may converge. Further, each of the following properties characterize it ([4.22], Sect. 21.9).

1. X_1, X_2 are independent nonnegative RVs and for some $a, b \in (0, 1)$
$$\min(X_1, X_2) \stackrel{d}{=} aX_1 \stackrel{d}{=} bX_2\,. \tag{4.30}$$
2. $\mathrm{Var}(X_{k+1:n}^\alpha | X_{k:n} = x)$ is a constant.
3. $X_1, \ldots,$ are IID and N is an independent RV with support $\{2, 3, \ldots, \}$, and $N^{1/\alpha} X_{1:N} \stackrel{d}{=} X_1$.
4. In the scale family of distributions, the distribution for which the Fisher information in the right-censored sample $X_{1:n}, \ldots, X_{k:n}$ is the same as in a random sample of size k for all n and $k \leq n$ ([4.3], p. 226).

4.6.4 Gumbel and Other Extreme-Value Distributions

For an arbitrary parent distribution, if $X_{n:n}$ has a nondegenerate limiting distribution, possibly after suitable standardization, then it is known that the limiting CDF has one of the following forms, except for a change of location and scale:

$$\begin{aligned} \text{(Fréchet)} \quad G_1(x;\alpha) &= 0 \quad x \leq 0, \alpha > 0\,, \\ &= \exp(-x^{-\alpha}) \quad x > 0\,; \end{aligned} \tag{4.31}$$

$$\begin{aligned} \text{(Weibull)} \quad G_2(x;\alpha) &= \exp\left[-(-x)^\alpha\right] \\ &\quad x \leq 0, \alpha > 0\,, \\ &= 1 \quad x > 0\,; \end{aligned} \tag{4.32}$$

$$\begin{aligned} \text{(Gumbel)} \quad G_3(x) &= \exp\left(-\mathrm{e}^{-x}\right) \\ &\quad -\infty < x < \infty\,. \end{aligned} \tag{4.33}$$

The CDF $G_2(x;\alpha)$ above is that of $-X$ where X has the Weibull PDF given in (4.29). These distributions form the class of *max-stable* distributions characterized by the following result ([4.31], p. 38).

Theorem 4.3

Let F be a nondegenerate CDF and a_n and b_n be two sequences such that $(X_{n:n}-a_n)/b_n \stackrel{d}{=} X_1$ for integers n_1 and n_2 such that $b_{n_2} \neq 1$ and $\log(b_{n_1})/\log(b_{n_2})$ is irrational. Then there are constants a, $b>0$ and $\alpha>0$ such that $F(a+bx)$ is either (4.31) or (4.32). If $b_{n_2}=1$ and a_{n_1}/a_{n_2} is irrational, then $F(a+bx)$ is given by (4.33).

Additional results for the Gumbel distribution are available. Here are two characterizing properties.

1. $\mathrm{E}(R'_n - R'_{n+1}|R'_{n+1})$ is a constant for some n, where the R'_n is the nth lower record value.
2. $R'_n - R'_m$ and R'_m are independent for some $n<m$.

4.6.5 Pareto

The Pareto distribution, used as a model for income distributions and as the limit distribution of residual lifetime, has the CDF

$$F(x) = 1-\left\{1+[(x-\mu)/\sigma]^{1/\gamma}\right\}^{-\alpha}, \quad x \geq \mu, \sigma>0, \gamma>0, \alpha>0\,. \tag{4.34}$$

Several characterizations exist for this distribution, especially when $\gamma=1$, in which case the resulting distribution is called the Pareto distribution of the second kind (II); one obtains the Pareto distribution of the first kind (I) when, in addition, $\mu=\sigma$. (See [4.32], Sect. 3.7. or [4.22], Sect. 21.9.) Since $-\log[1-F(X)] = \alpha\log\{1+[(X-\mu)/\sigma]^{1/\gamma}\}$ is the standard exponential, its numerous characterizations provide simple counterparts for the Pareto distribution. For example, independence of exponential spacings is equivalent to the independence of the ratios of order statistics from a Pareto I distribution. The Pareto II (with $\alpha>1$) is the only distribution for which $h(x)m(x)$ is a constant where the failure rate $h(x)$ and the MRL function $m(x)$ are given by (4.5) and (4.7), respectively. Another characterization is that, if W is a continuous RV with support (0, 1) and is independent of X, and $\{WX|WX\geq\mu\} \stackrel{d}{=} X$, then X must be a Pareto II RV. Here W can be seen as the proportion *underreported* or *undamaged*. For some recent results on generalized Pareto distributions, see [4.33].

4.6.6 Inverse Gaussian (IG)

This distribution has the PDF

$$f(x) = \sqrt{\frac{\lambda}{2\pi x^3}}\exp\left(-\frac{\lambda}{2\nu^2}\frac{(x-\nu)^2}{x}\right), \quad x>0\,, \tag{4.35}$$

where the parameters are $\nu>0$ and $\lambda>0$. It arises as the waiting time to cross a certain threshold in Brownian motion. Its characterizations often mimic those for the normal distribution. For example, the IG distribution has the maximum entropy subject to certain restrictions on $\mathrm{E}(X)$ and $\mathrm{E}(1/X)$. For a random sample $X_1,\ldots,X_n$, let $Y=(1/n)\sum_{i=1}^n X_i^{-1} - \bar{X}^{-1}$. Then the population is IG if either $\bar{X}$ and Y are independent, or the regression $\mathrm{E}(Y|\bar{X})$ is a constant ([4.34], Chapt. 3).

4.7 Poisson Distribution and Process

The Poisson distribution, commonly known through its PDF

$$\Pr(X=j) = \mathrm{e}^{-\lambda}\frac{\lambda^j}{j!}, \quad j=0,1,2,\ldots;\lambda>0\,, \tag{4.36}$$

appears often in the engineering literature as a model for rare events and in queueing or reliability studies. We write X is Poi(λ) if (4.36) holds. The earliest result seems to be due to *Raikov* (1938) ([4.35], Sect. 4.8) who showed that, if X_1 and X_2 are independent and X_1+X_2 is Poisson, then each of them should be Poisson RVs. It is known that, if X_1 is Poi(λ_1) and X_2 is Poi(λ_2) and they are independent, the conditional distribution of X_1 given $X_1+X_2=n$ is Bin[n, $\lambda_1/(\lambda_1+\lambda_2)$], i. e., binomial with n trials and success probability $p=\lambda_1/(\lambda_1+\lambda_2)$. This property has led to various characterizations of the Poisson distribution. For example, if the conditional distribution is binomial, then X_1 and X_2 are both Poisson RVs.

One particularly interesting set up that identifies the Poisson distribution is the *damage model* due to *Rao*. The associated characterization result due to *Rao* and *Rubin* is the following ([4.7], p. 164):

Theorem 4.4

Let X and Y be nonnegative integer-valued RVs such that $\Pr\{X=0\}<1$ and, given $X=n$, Y is Bin(n, p) for each $n \geq 0$ and a fixed $p \in (0,1)$. Then the Rao–Rubin condition, given by

$$\Pr(Y=j)=\Pr(Y=j|Y=X), \quad j=0,1,\ldots, \tag{4.37}$$

holds iff X is Poisson.

The condition (4.37) is equivalent to the condition

$$\Pr(Y=j|Y=X)=\Pr(Y=j|Y<X) \tag{4.38}$$

which can be interpreted as follows. Suppose X is the number of original counts and Y is the number actually available, the remaining being lost due to damage according to the binomial model. Then if the probability distribution of the actual counts remains the same whether damage has taken place or not, the number of original counts must be Poisson. Incidentally, the number of observations that survived is also Poisson. The above damage model can be seen as binomial *splitting* or *thinning* and a similar notion is that of binomial *expanding*. It also leads to a characterization of the Poisson distribution.

A weaker version of (4.37) can be used to characterize the Poisson distribution by restricting the family $\mathcal{F}$ under consideration. Let X belong to the family of the power-series distribution, i. e., it has the PDF

$$\Pr(X=j)=\frac{a_j\theta^j}{A(\theta)}, \quad j=0,1,\ldots \tag{4.39}$$

Suppose that given $X=n$, Y has support $0,\ldots,n$, and has mean np and variance $np(1-p)$, where p does not depend on θ. Then $\mathrm{E}(Y|Y=X)=\mathrm{E}(Y)$ and $\mathrm{Var}(Y|Y=X)=\mathrm{Var}(Y)$ iff X is Poisson.

Poisson characterizations based on the properties of the sample mean $\bar{X}$ and variance S^2 from a random sample are known. In the power-series family (4.39), if $\mathrm{E}(S^2|\bar{X}>0)=1$, then the population is necessarily Poisson. When X is assumed to be nonnegative, if $\mathrm{E}(S^2|\bar{X})=\bar{X}$, the parent is Poisson also. See [4.35], Sect. 4.8, for relevant references. Characterizations based on the discrete analogue of the Skitovich–Darmois theorem (Theorem 4.2) are available [4.36]. It is also known that, in a wide class of distributions on the set of integers, the Poisson distribution is characterized by the equality sign in a discrete version of the Stam inequality for the Fisher information; the continuous version yields a normal characterization [4.37]. Another *normal-like* result is the Poisson characterization by the identity $\mathrm{E}(X)\mathrm{E}[g(X+1)]=\mathrm{E}[Xg(X)]$ assumed to hold for every bounded function $g(.)$ on the integers [4.38].

Poisson Process

A renewal process is a counting process $\{N(t), t \geq 0\}$ where the inter-arrival times of events are IID with CDF F. The (homogeneous) Poisson process is characterized by the fact that F is exponential. Several characterizations of a Poisson process in the family of renewal processes do exist. For example, if a renewal process is obtained by the superposition of two independent renewal processes, then the processes must be Poissonian. Several are tied to the exponential characterizations from random samples. Other characterizations of interest are based on the properties of the *current age* and *residual lifetime* distributions.

Let X_i represent the IID inter-arrival times and $S_n=X_1+\cdots+X_n$, so that $N(t)=\sup(m: S_m \leq t)$. Then $A(t)=t-S_{N(t)}$ represents the current age or *backward recurrence time* at t and $W(t)=S_{N(t)+1}-t$ is the residual lifetime or *forward recurrence time* at t, $t \geq 0$. A good summary of the available results is provided in [4.39], p. 674–684. Chapter 4 of [4.31] contains an early account of various characterizations of the Poisson process that include thinned renewal processes and geometric compounding. We state below a few simple characterizing properties of the Poisson process:

1. Either $\mathrm{E}[W(t)]$ or $\mathrm{Var}[W(t)]$ is a finite constant for all $t>0$.
2. F is continuous with $F^{-1}(0)=0$, and for some fixed t, $A(t)$ and $W(t)$ are independent.
3. F is continuous and $\mathrm{E}[A(t)|N(t)=n]=\mathrm{E}[X_1|N(t)=n]$ for all $t>0$ and all $n \geq 1$.
4. F is continuous and $\mathrm{E}[A(t)]=\mathrm{E}[\min(X_1,t)]$ for all $t>0$.

4.8 Other Discrete Distributions

4.8.1 Geometric

Numerous versions of the LMP of the geometric distribution have led to several characterizations of the geometric distribution with PDF

$$\Pr(X = j) = (1-p)^j p,\ j = 0, 1, \ldots \tag{4.40}$$

Here the LMP means $\Pr(X > x + j | X \geq x) = \Pr(X > j)$, $j, x = 0, 1, \ldots$ When X has the above PDF, the following properties hold:

1. $\mathrm{E}(X - x | X \geq x) = \mathrm{E}(X)$, $x = 0, 1, \ldots$.
2. $|X_1 - X_2| \stackrel{d}{=} X$.
3. $\Pr(X_{1:n} \geq 1) = \Pr(X_1 \geq n)$, $n \geq 1$.
4. $X_{j+1:n} - X_{j:n} \stackrel{d}{=} X_{1:n-j}$, $1 \leq j < n$.
5. $(X_{k:n} - X_{j:n} | X_{j+1:n} - X_{j:n} > 0) \stackrel{d}{=} 1 + X_{k-j:n-j}$, $1 \leq j < k \leq n$.
6. $X_{1:n}$ and $X_{j:n} - X_{1:n}$ are independent.

Each of these is shown to be a characteristic property of the geometric or slightly modified versions of that distribution, under mild conditions [4.40].

In terms of the upper record values, the following properties hold for the geometric parent and characterize it ([4.4], Sect. 4.6).

1. $R_1, R_2 - R_1, R_3 - R_2, \ldots$ are independent.
2. $E(R_{n+1} - R_n \mid R_n)$, $E(R_{n+2} - R_{n+1} \mid R_n)$, and $E[(R_2 - R_1)^2 \mid R_1]$ are constants.
3. $R_{n+1} - R_n \stackrel{d}{=} R_1$, $n \geq 1$.

4.8.2 Binomial and Negative Binomial

The damage model, discussed in Theorem 4.4, also produces a characterization of the binomial distribution in that, if (4.37) holds and X is Poisson, then the damage process is binomial. Another characterization of the binomial distribution assumes that the RVs X and Y are independent, and that the conditional distribution of X given $X + Y$ is hypergeometric [4.41]. When the conditional distribution is negative hypergeometric, a similar result for the negative binomial distribution is obtained.

Remarks. Characterizations of other discrete distributions are limited. For results on hypergeometric and logarithmic distributions, see [4.35]. Characterizations of discrete distributions based on order statistics are discussed in [4.40]. See [4.42] for characterizations based on weighted distributions when $\mathcal{F}$ is the power-series family in (4.39).

4.9 Multivariate Distributions and Conditional Specification

Characterization results are less common for multivariate distributions. Notable exceptions are the multivariate normal and the Marshall–Olkin multivariate exponential distribution. First we discuss another dimension to multivariate characterizations, namely the specification of the properties of the conditional distribution(s). For example, can one identify the joint PDF $f(x, y)$ using the properties of the conditional PDFs $f(x|y)$ and $f(y|x)$? This has been an active area of research in recent years. See [4.43] for an excellent account of the progress. We present one such result.

Theorem 4.5

Let $f(x, y)$ be a bivariate PDF where conditional PDFs belong to natural parameter exponential families with full rank given by

$$f(x|y) = r_1(x)\beta_1[\boldsymbol{\theta}_1(y)] \exp\left[\boldsymbol{\theta}_1(y)'\boldsymbol{q}_1(x)\right] \tag{4.41}$$

and

$$f(y|x) = r_1(y)\beta_2[\boldsymbol{\theta}_2(x)] \exp\left[\boldsymbol{\theta}_2(x)'\boldsymbol{q}_2(y)\right] \tag{4.42}$$

where $\boldsymbol{\theta}_1(y)$ and $\boldsymbol{q}_1(x)$ are $k_1 \times 1$ vectors, and $\boldsymbol{\theta}_2(x)$ and $\boldsymbol{q}_1(y)$ are $k_2 \times 1$ vectors, and the components of $\boldsymbol{q}_1$ and $\boldsymbol{q}_2$ are linearly independent. Then the joint PDF is of the form

$$f(x, y) = r_1(x)r_2(y) \exp[\boldsymbol{A}(x, y)] \tag{4.43}$$

where $\boldsymbol{A}(x, y) = [1, \boldsymbol{q}_1(x)']\boldsymbol{M}[1, \boldsymbol{q}_2(y)']'$ for a suitable matrix $\boldsymbol{M} = (m_{ij})$, whose elements are chosen so that $f(x, y)$ integrates to 1.

When both the conditional distributions are normal, this result implies that

$$f(x, y) \propto \exp[(1, x, x^2)\boldsymbol{M}(1, y, y^2)'] \tag{4.44}$$

and the classical bivariate normal corresponds to the condition $m_{23} = m_{32} = m_{33} = 0$ [4.44].

Instead of the conditional PDF, the conditional distribution may be specified using regression functions, say $\mathrm{E}(Y|X=x)$. Then the joint distribution can be determined in some cases. For example, suppose X given $Y=y$ is $\mathrm{N}(\alpha y, 1)$, i. e., normal with mean αy and unit variance, and $\mathrm{E}(Y|X=x)=\beta x$. Then $0<\alpha\beta<1$ and (X, Y) is bivariate normal [4.44].

The conditional specification could be in terms of the conditional SF $\Pr(Y>y|X>x)$, or in the form of the marginal distribution of X and the conditional distribution of X given $Y=y$. Sometimes these together can also identify the joint distribution.

4.9.1 Bivariate and Multivariate Exponential Distributions

Marshall and *Olkin* [4.45] introduced a bivariate exponential (BVE) distribution to model the component lifetimes in the context of a shock model. Its (bivariate) SF, with parameters $\lambda_1>0$, $\lambda_2>0$, and $\lambda_{12}\geq 0$, is given by

$$\Pr(X>x, Y>y)=\mathrm{e}^{-\lambda_1 x-\lambda_2 y-\lambda_{12}\max(x,y)}, \quad x, y>0\,. \tag{4.45}$$

Here X is $\exp(\lambda_1+\lambda_{12})$ and Y is $\exp(\lambda_2+\lambda_{12})$. The joint distribution is characterized by the following conditions: (a) X and Y are marginally exponential. (b) $\min(X, Y)$ is exponential, and (c) $\min(X, Y)$ and $|X-Y|$ are independent.

The LMP in (4.18) that characterized the univariate exponential can be extended as

$$\Pr(X>x+t_1, Y>y+t_2|X>x, Y>y) = \Pr(X>t_1, Y>t_2)\,. \tag{4.46}$$

If (4.46) is assumed to hold for all $x, y, t_1, t_2\geq 0$, then X and Y are necessarily independent exponential RVs. The SF (4.45) would satisfy (4.46) for all $x, y\geq 0$ and $t_1=t_2=t\geq 0$. This condition, often referred to as *bivariate* LMP, is equivalent to assuming that both (b) and (c) above hold. While the Marshall–Olkin BVE distribution has exponential marginals and bivariate LMP, it is not absolutely continuous. If one imposes the LMP and absolute continuity, the marginal distributions will no longer be exponential [4.46].

There are other multivariate distributions that are characterized by the multivariate versions of the failure-rate function (see [4.47], p. 403–407).

4.9.2 Multivariate Normal

An early characterization of the classical multivariate normal (MVN) random vector, known as Cramér–Wold Theorem, is that every linear combination of its components is univariate normal. Most of the characterizations of the univariate normal distribution discussed in Sect. 4.5 easily generalize to the MVN distribution. For example, the independence of nonsingular transforms of independent random vectors [see (4.25) for the univariate version], independence of the sample mean vector and sample covariance matrix, maximum entropy with a given mean vector and covariance matrix, are all characteristic properties of the MVN distribution. There are, of course, results based on conditional specifications. We mention two.

For an m-dimensional RV $\boldsymbol{X}$, let $\boldsymbol{X}_{(i,j)}$ be the vector $\boldsymbol{X}$ with coordinates i and j deleted. If, for each i, j the conditional distribution of (X_i, X_j) given $\boldsymbol{X}_{(i,j)}=\boldsymbol{x}_{(i,j)}$ is BVN for each $\boldsymbol{x}_{(i,j)}$, then $\boldsymbol{X}$ is MVN ([4.43], p. 188).

If $X_1, \cdots, X_m$ are jointly distributed RVs such that $(X_1, \cdots, X_{m-1})\stackrel{d}{=}(X_2, \cdots, X_m)$, and X_m given $\{X_1=x_1, X_2=x_2, \cdots, X_{m-1}=x_{m-1}\}$ is $\mathrm{N}\left(\alpha+\sum_{j=1}^{m-1}\beta_j x_j, \sigma^2\right)$, then $(X_1, \cdots, X_m)$ are jointly m-variate normal ([4.47], p. 157).

Excellent summaries of characterizations of the bivariate and multivariate normal distributions are available, respectively, in Sect. 46.5 and Sect. 45.7 of [4.47] (see also, the review [4.48]).

4.9.3 Other Distributions

Characterization results for other multivariate distributions are not common. A few characterizations of the *multinomial distribution* are available ([4.49], Sect. 35.7), and these are natural extensions of the binomial characterizations. One result is that, if the sum of two independent vectors is multinomial, then each is multinomial. There are also a few characterizations of the Dirichlet distribution, a multivariate extension of the beta distribution over $(0, 1)$ ([4.47], Sect. 49.5). It has the characteristic property of *neutrality*, which can be described for $m=2$ components as follows. For two continuous RVs X and Y such that $X, Y\geq 0$ and $X+Y\leq 1$, neutrality means X and $Y/(1-X)$ are independent, and Y and $X/(1-Y)$ are independent.

The multivariate Pareto distribution due to Mardia, having the multivariate SF

$$\Pr(X_1 > x_1, \ldots, X_m > x_m) = \left[1 + \sum_{i=1}^{m} \left(\frac{x_i}{\sigma_i}\right)\right]^{-\alpha},$$
$$x_1, \ldots, x_m > 0\,, \tag{4.47}$$

accepts characterizations that are based on conditional specifications. Marginally, the X_i here are Pareto II RVs.

A few papers that characterize bivariate distributions with geometric marginals do exist. Some are related to the Marshall–Olkin BVE.

4.10 Stability of Characterizations

Consider the LMP in (4.18) that characterizes the exponential distribution. Now suppose the LMP holds approximately in the sense

$$\sup_{x\geq 0, y\geq 0} \left|\Pr(X > x+y | X > x) - \Pr(X > y)\right| \leq \epsilon\,. \tag{4.48}$$

The question of interest is how close the parent CDF F is to an exponential CDF. It is known ([4.21], p. 7) that, when X is nondegenerate and $F^{-1}(0) = 0$, if (4.48) holds then $\mathrm{E}(X)$ is finite and, with $\mathrm{E}(X) = 1/\lambda$,

$$\sup_{x\geq 0} \left|\Pr(X > x) - \exp(-\lambda x)\right| \leq 2\epsilon\,. \tag{4.49}$$

This result provides an idea about the stability of the LMP of the exponential distribution. There are many such results—mostly for the exponential and normal distributions. Such results involve appropriate choices of metrics for measuring the distance between: (a) the characterizing condition and the associated perturbation, and (b) the CDF being characterized and the CDF associated with the perturbed condition. We will mention below a few simple stability theorems. It is helpful to introduce one popular metric measuring the distance between two distributions with associated RVs X and Y:

$$\rho(X, Y) \equiv \sup_{-\infty < x < \infty} |\Pr(X \leq x) - \Pr(Y \leq x)|\,. \tag{4.50}$$

Note that (4.49) basically says that $\rho(X, Y) \leq 2\epsilon$, where Y is an $\exp(\lambda)$ RV.

For the exponential parent, the constancy of $\mathrm{E}[(X_{k+1:n} - X_{k:n})|X_{k:n}]$ is a characterizing property. The associated stability result is the following [4.22, p. 545], [4.50]:

If F has support $(0, \infty)$ and is strictly increasing in its domain, and $\gamma > 0$ is such that

$$\left|\mathrm{E}\left[(X_{k+1:n} - X_{k:n})\middle| X_{k:n} = x\right] - \gamma\right| \leq \epsilon\,,$$
$$\text{for almost all } x \geq 0\,, \tag{4.51}$$

then, there exist positive constants λ_1, λ_2 and c that depend only on γ and $n-k$ such that $\rho(X, Y) \leq c\epsilon^{1/(n-k)} \exp(-\lambda_2 x)$, where Y is $\exp(\lambda_1)$.

For the normal distribution, we state stability results for two classical characterizations.

1. *Pólya's characterization* [4.5, p. 298]. Let X_1 and X_2 be IID with zero mean, unit variance and $\mathrm{E}(|X_1|^3) \leq M < \infty$. Let $Y = (X_1 + X_2)/\sqrt{2}$. If $\rho(X_1, Y) \leq \epsilon$, then $\rho(X_1, Z) \leq c\epsilon^{1/3}$, where c depends only on M and Z is standard normal. (See the recent work [4.51] for another metric of comparison.)
2. *Independence of $\bar{X}$ and S^2* [4.52]. Suppose that for all x, y,

$$\left|\Pr(\bar{X} \leq x, S^2 \leq y) - \Pr(\bar{X} \leq x)\Pr(S^2 \leq y)\right| \leq \epsilon\,. \tag{4.52}$$

Then there exists a (possibly degenerate) $\mathrm{N}(\mu, \sigma^2)$ RV Y such that $\rho(X, Y) \leq c[\log(1/\epsilon)]^{-1/2}$, where c depends only on n, and ρ is given by (4.50).

Many such results are available in the several monographs on stability of characterizations edited by *Kalashnikov* and *Zolotarov* and others (see e.g., [4.52, 53]). These have come from the periodic conferences held in Eastern Europe.

4.11 Applications

A characterization can be of use in the construction of goodness-of-fit tests and in the examination of the consequences of the modeling assumptions. It can be helpful in some simulation studies. A full characterization states that a condition C on the sample data is necessary and sufficient for the condition $F \in \mathcal{F}_0$ to hold. The *neces-*

sity part can be used for the simulation study of the properties of the sample statistics involved in the condition C. For example, if one is interested in the properties of a function of the random sample mean $\bar{X}$ and variance S^2 from a standard normal population, one can start with two *independent* statistics, one normal and the other a χ^2. We can simulate these statistics directly, and study the empirical properties of the function of interest. The characterization of the exponential based on the independence and exponentially distributed nature of spacings of order statistics, can be used to simulate all or a selected set of exponential order statistics without any sorting.

The *sufficiency* part can be used for checking implications of modeling assumptions or of their compatibility. Again consider the situation where the researcher is willing to accept, based on past data, say, that $\bar{X}$ and variance S^2 are independent. This is equivalent to assuming that the sample is from a normal population. As another example, consider the early characterization result, proved by *Cramér* in 1937, which states that, if X and Y are independent and the sum is assumed to be normal, then each of them must be normal (see [4.24], p. 53). Thus, if a researcher is willing to assume the independence of these RVs and that the sum is normal, this is the same as assuming that both X and Y are individually normal and are independent. This implication can be gainfully employed to infer that $aX+bY$ is $N(a\mu_X+b\mu_Y, a^2\sigma_X^2+b^2\sigma_Y^2)$.

Characterizing properties, when used as necessary and sufficient conditions, naturally lead to both informal (graphical) and formal goodness-of-fit tests. The various plots such as the quantile–quantile (Q–Q) plots, hazard function plots, or the MRL plots are all based on the characterizing properties of these functions. For example, in Q–Q plots, the sample quantile $X_{j:n}$ is plotted against the corresponding hypothesized population quantile $F_0^{-1}(p_j)$, where F_0 is the standardized form of F, and p_j is sometimes chosen as $(j-(1/2))/n$. (See [4.3], p. 270 for other choices for p_j.) If a linear fit is unreasonable, then one may infer that the assumption that F is the parent CDF is untenable. Probability plots (see [4.54], Chapt. 3), and the hazard-function plots ([4.54], Chapt. 4), popular in reliability studies, also provide similar informal checks of the fit of the assumed distribution. MRL plots, where $\frac{1}{k}\sum_{j=n-k+1}^{n}(x_{j:n}-x_{n-k:n})$ is plotted against the $x_{n-k:n}$ (see, [4.55], p. 296), are used to determine the appropriate domain of attraction for the extreme order statistics.

In theory, a formal goodness-of-fit test can be constructed from any characterization. For example, the independence of spacings of order statistics of a random sample from a continuous distribution implies the CDF is exponential, and thus can be used to construct a goodness-of-fit test even with a (type II) censored sample. Such a test does have good power properties. Another example is the test based on the maximum-entropy property of the normal distribution [4.56]. See [4.57–59] for some goodness-of-fit tests inspired by characterizations. A nice overview is provided in [4.60]. However, not all characterizations lead to powerful tests. Also, creation of goodness-of-fit tests that exploit the concerned characterizing property to the full extent may not be easy. Perhaps this explains the sparsity of such applications of characterizations.

4.12 General Resources

The literature on characterization is extensive. Over 1000 papers have appeared to date; however, several review articles, monographs (e.g., [4.5, 7, 31, 43]) and encyclopedic books on distributions by *Johnson*, *Kotz*, and their coauthors ([4.22, 30, 35, 47, 49]) have served as excellent filters. Other sources include the volume [4.61], which contains papers on characterizations presented at the Calgary conference in 1974, and the monograph [4.62], which treats characterization (identification) in a broader context. For results based on order statistics see [4.3, Sect. 6.7]; see also [4.63].

Here, we have given an informal introduction to characterizations using a small fraction of the available results. For economy, we have cited the above general and other (distribution-specific) secondary resources in this survey. To get a full appreciation of this active area of research, one should consult many of the primary as well as secondary sources.

5. Two-Dimensional Failure Modeling

For many products (for example, automobiles), failures depend on age and usage and, in this case, failures are random points in a two-dimensional plane with the two axes representing age and usage. In contrast to the one-dimensional case (where failures are random points along the time axis) the modeling of two-dimensional failures has received very little attention. In this chapter we discuss various issues (such as modeling process, parameter estimation, model analysis) for the two-dimensional case and compare it with the one-dimensional case.

All products are unreliable in the sense that they degrade and fail with age and/or usage, and ultimately fail. Reliability of a product conveys the concept of dependability and the absence of failures. Reliability theory deals with various aspects of product reliability and encompasses various reliability issues. These include the following:

1. Reliability science to understand the degradation leading to failures.
2. Reliability engineering to design and manufacture reliable products.
3. Reliability management to manage the activities during the design and manufacture of products and the operation of unreliable products.
4. Reliability modeling to build models to obtain solutions to a variety of reliability-related problems in predicting, estimating, and optimizing the performance of unreliable products, the impact of unreliability and actions to mitigate the impact.

The modeling of failures is an important element of reliability modeling. In one-dimensional failure modeling, failures are random points along a one-dimensional axis representing age or usage. For many products (for example, automobiles), failures depend on age and usage and, in this case, failures are random points in a two-dimensional plane with the two axes representing age and usage. Models play an important role in decision-making. Many different types of models are used and these can be found in [5.1–4]. One-dimensional modeling has received considerable attention and so there is a vast literature covering this area. In contrast, two-dimensional failure modeling has received relatively little attention. In this chapter we discuss various issues relating to two-dimensional failure modeling.

The outline of the chapter is as follows. In Sect. 5.1 we discuss various issues relating to the modeling of failures. Section 5.2 deals with the black-box approach (or empirical modeling) where the modeling is based

on failure and operational data. One-dimensional modeling based on the black-box approach is reviewed in Sect. 5.3, where we discuss the different issues and illustrate through an example involving a real case. This sets the background for the two-dimensional modeling discussed in Sect. 5.4. Two different approaches have been proposed for two-dimensional failure modeling. We discuss these two approaches and indicate topics for future research. In Sect. 5.5 we discuss a new approach and this is illustrated using the case discussed earlier. Finally, we conclude with some comments and remarks in Sect. 5.6.

5.1 Modeling Failures

In this section we briefly discuss various issues of importance in the modeling of failures.

5.1.1 Product Failures

Products can vary from simple (such as an electric kettle) to complex (such as an aeroplane). A product can be viewed as a system consisting of several parts and can be decomposed into a hierarchy of levels with the system at the top level and components at the lowest level and several levels (such as sub-system, assembly, sub-assembly and so on) in between. The failure of a product is due to the failure of one or more of its components.

The occurrence of failure depends on several factors. These include decisions made during the design and manufacture of the product, usage intensity and operating environment, and the maintenance actions (corrective and preventive) carried out during the operating life.

The modeling of failures can be done at any level ranging from system to component level.

5.1.2 Approaches to Modeling

The approach to modeling depends on the kind of information available and the goal of the modeling. There are two basic approaches to modeling failures, as indicated below.

1. Black-box approach: here the modeling is based solely on failure and censored data for similar items. This approach is used when there is very little understanding of the different mechanisms that lead to product failure or when the unit is too complex. This approach is also known as *data-based or empirical modeling*.
2. White-box approach: here the failure modeling at the component level is based on the different mechanisms that lead to failure. At the system level, the failure is done in terms of the failures of the different components. This approach is also known as *physics-based modeling*.

It should be noted that most statistical modeling incorporates features from both approaches and that the collaborative nature of such modeling is critical. The engineer or scientist needs to bring their expertise to develop the appropriate models in the white-box approach, whereas the statistician needs to be able to determine the appropriate data analysis for the given data set in its context.

5.1.3 First and Subsequent Failures

One needs to differentiate between the first failure and subsequent failures. The subsequent failures depend on the type of actions used to rectify the failures. In the case of a nonrepairable item (component, system or something in between), the failed item needs to be replaced by either a new or used item to make the product functional. In the case of a repairable item, the product can be made operational through the repair of the failed item. Three types of repair are indicated below:

1. Minimal repair, which restores the item to the condition just before failure;
2. Perfect repair (which makes the item as good as new); and
3. Imperfect repair that results in the item being better than it was prior to failure but not as good as new.

5.2 Black-Box Modeling Process

In the black-box approach to modeling failures, the data are the starting point that forms the basis for the model building. In this section we briefly discuss the different data types and then outline the modeling process.

5.2.1 Data Types

The data can be either item failure times or counts of item failures over an interval. In the former case, the data are continuous-valued and in the latter case they are integer-valued.

Lifetime data can be complete, censored or truncated. In the case of complete data, the data relate to the age at failure. With censored data, the lifetimes are only known to exceed some value(s). This could result from the item not having failed during the period of observation and hence still being operational for a certain length of time afterwards (right-censored data). When the data are the failures of an item over different disjoint time intervals we have grouped data. When failures of different components are pooled together, we have pooled data. In both cases, the data can be considered as categorical or, if they are in the form of counts, they are discrete-valued.

5.2.2 Modeling Process

The modeling process involves the following four steps.

Step 1: Exploratory analysis of data
Step 2: Model selection
Step 3: Parameter estimation
Step 4: Model validation

These are discussed further in Sects. 5.3–5.5.

5.3 One-Dimensional Black-Box Failure Modeling

In this section we give a brief review of one-dimensional failure modeling. The item under consideration can be the product or some component of the product.

5.3.1 Modeling First Failure

Let T denote the time to first failure. It is modeled by a failure distribution function, $F(t\,;\theta)$, which characterizes the probability $P\{T \le t\}$ and is defined as

$$F(t\,;\theta) = P(T \le t)\,,\ t \ge 0 \tag{5.1}$$

θ denotes the parameters (or parameter set) of the distribution function. If $F(t\,;\theta)$ is a differentiable function, then the failure density function, $f(t\,;\theta)$, is given by

$$f(t) = \mathrm{d}F(t;\theta)/\mathrm{d}t\,. \tag{5.2}$$

The survivor function, $\bar{F}(t)$, is given by

$$\bar{F}(t\,;\theta) = 1 - F(t\,;\theta) = P(T > t)\,. \tag{5.3}$$

The hazard function, $h(t\,;\theta)$, is given by

$$h(t\,;\theta) = f(t\,;\theta)/\bar{F}(t\,;\theta)\,. \tag{5.4}$$

The cumulative hazard function, $H(t\,;\theta)$, is given by

$$H(t\,;\theta) = \int_0^t h(u\,;\theta)\mathrm{d}u = -\log[1 - F(t\,;\theta)]\,. \tag{5.5}$$

Many different distributions have been used for modeling lifetimes. The shapes of the density and hazard functions depend on the form of the distribution and the parameter values.

Note: in the future we will omit θ for notational ease so that we have $h(t)$ instead of $h(t\,;\theta)$ and similarly for the other functions.

A commonly used model is the two-parameter Weibull distribution, which is given by

$$F(t\,;\theta) = 1 - \exp[-(t/\alpha)]^{\beta}\,,\ t \ge 0 \tag{5.6}$$

with $\theta = \{\alpha, \beta\}$. Here, α is the scale parameter and β is the shape parameter.

The Weibull models are a family of distributions derived from the two-parameter Weibull distribution. *Lai* et al. [5.5] discuss a few of these models and, for more details, see *Murthy* et al. [5.6]. Many other distributions have been used in modeling time to failure and these can be found in most books on reliability. See, for example, *Blischke* and *Murthy* [5.2], *Meeker* and *Escobar* [5.4], *Lawless* [5.3], *Nelson* [5.7] and *Kalbfleisch* and *Prentice* [5.8]. *Johnson* and *Kotz* [5.9, 10] give more details of other distributions that can be used for failure modeling.

5.3.2 Modeling Subsequent Failures

Minimal Repair

In minimal repair, the hazard function after repair is the same as that just before failure. In general, the repair time is small relative to the mean time between failures so that it can be ignored and the repairs treated as instantaneous. In this case, failures over time occur according to a nonhomogeneous Poisson point process with intensity function $\lambda(t) = h(t)$, the hazard function. Let $N(t)$

denote the number of failures over the interval $[0, t)$. Define

$$\Lambda(t) = \int_o^t \lambda(u)\,\mathrm{d}u \tag{5.7}$$

Then we have the following results:

$$P(N(t) = n) = \frac{\mathrm{e}^{-\Lambda(t)}[\Lambda(t)]^n}{n!}\,, n = 0\,,1\,,2\,,\ldots \tag{5.8}$$

and

$$E[N(t)] = \Lambda(t) \tag{5.9}$$

For more details, see *Nakagawa* and *Kowada* [5.11] and *Murthy* [5.12].

Perfect Repair

This is identical to replacement by a new item. If the failures are independent, then the times between failures are independent, identically distributed random variables from $F(t)$ and the number of failures over $[0, t)$ is a renewal process with

$$P\{N(t) = n\} = F^{(n)}(t) - F^{(n+1)}(t)\,, \tag{5.10}$$

where $F^{(n)}(t)$ is the n-fold convolution of $F(t)$ with itself, and

$$E[N(t)] = M(t)\,, \tag{5.11}$$

where $M(t)$ is the renewal function associated with $F(x\,;\theta)$ and is given by

$$M(t) = F(t) + \int_0^t M(t-u)\,\mathrm{d}F(u)\,. \tag{5.12}$$

For more on renewal processes, see *Cox* [5.13], *Cox* and *Isham* [5.14]) and *Ross* [5.15].

Imperfect Repair

Many different imperfect repair models have been proposed. See *Pham* and *Wang* [5.16] for a review of these models. In these models, the intensity function $\lambda(t)$ is a function of $\Im_t$, the history of failures over $[0, t)$. Two models that have received considerable attention are: (i) reduction in failure intensity, and (ii) virtual age. See *Doyen* and *Gaudoin* [5.17] for more on these two models.

5.3.3 Exploratory Data Analysis

The first step in constructing a model is to explore the data through plots of the data. By so doing, information can be extracted to assist in model selection. The plots can be either nonparametric or parametric and the plotting is different for perfect repair and imperfect repair situations. The data comprises both the failure times and the censored times.

Perfect Repair

Plot of Hazard Function (Nonparametric). The procedure (for complete or censored data) is as follows:

Divide the time axis into cells with cell i defined by $[t_i, t_{i+1})$, $i \geq 0$, $t_0 = 0$ and $t_i = i\delta$, where δ is the cell width. Define the following quantities:

N_i^{f} : Number of items with failure times in cell $i\,, i \geq 0$;

N_i^{c} : Number of items with censoring times in cell $i\,, i \geq 0$;

$N_i^{\mathrm{f}|ri}$: Number of failures in cells i and beyond $\left(= \sum_{j=i}^{\infty} N_j^{\mathrm{f}}\right)$.

Similarly define $N_i^{\mathrm{c}|ri}$ for censored data.

The estimator of the hazard function is given by

$$\hat{h}_i = \frac{N_i^{\mathrm{f}}}{N_i^{\mathrm{f}|ri} + N_i^{\mathrm{c}|ri}}\,, i \geq 0 \tag{5.13}$$

Plot of Density Function (Nonparametric). The simplest form of nonparametric density estimator is the histogram. Assuming the data is complete, the procedure is to calculate the relative frequencies for each cell,

$$\hat{f}_i = \frac{N_i^{\mathrm{f}}}{\sum_{j=0}^{\infty} N_j^{\mathrm{f}}}\,, \tag{5.14}$$

and then plot these against the cell midpoints. As histograms can be very unreliable for exploring the shape of the data, especially if the data set is not large, it is desirable to use more sophisticated density-function estimators (*Silverman* [5.18]).

Weibull Probability Plots (Parametric). The Weibull probability plot (WPP) provides a systematic procedure to determine whether one of the Weibull-based models is suitable for modeling a given data set or not, and is more reliable than considering just a simple histogram. It is based on the Weibull transformations

$$y = \ln\{-\ln[1 - F(t)]\} \quad \text{and} \quad x = \ln(t)\,. \tag{5.15}$$

The plot of y versus x gives a straight line if $F(t)$ is a two-parameter Weibull distribution.

Thus, if $F(t)$ is estimated for (complete) data from a Weibull distribution and the equivalent transformations and plot obtained, then a *rough* linear relationship should be evident. To estimate $F(t)$, we need an empirical estimate of $F(t_i)$ for each failure time t_i.

Assuming the t_i's are ordered, so that $t_1 \le t_2 \le \ldots \le t_n$, a simple choice (in the case of complete data) is to take the empirical distribution function

$$\hat{F}(t_i) = i/(n+1)\,. \tag{5.16}$$

We then plot $\hat{y}_i = \ln\left\{-\ln\left[1-\hat{F}(t_i)\right]\right\}$ versus $x_i = \ln(t_i)$ and assess visually whether a straight line could describe the points.

We illustrate by considering real data. The data refers to failure times and usage (defined through distance traveled between failures) for a component of an automobile engine over the warranty period given by three years and 60 000 miles. Here we only look at the failure times in the data set. Figure 5.1 shows a Weibull probability plot of the inter-failure times of a component that we shall call component C-1. This clearly shows a curved relationship and so a simple Weibull model would not be appropriate.

Note: the plotting of the data depends on the type of data. So, for example, the presence of censored observations would necessitate a change in the empirical failure estimates (see *Nelson* [5.7] for further details).

Minimal Repair

Plot of Cumulative Intensity Function (Nonparametric). The procedure is as follows: With δ and the cells defined as before, define the following:

M : Number of items at the start;
N_i^{f} : Total number of failures over $[0\,,\,i\delta)$;
M_i^{c} : Number of items censored in cell i;
λ_i : Cumulative intensity function till cell i.

The estimator of the cumulative intensity is given by

$$\hat{\lambda}_0 = \frac{N_0^{\mathrm{f}}}{M} \quad \text{and}$$
$$\hat{\lambda}_i = \frac{N_i^{\mathrm{f}} - \sum_{j=0}^{i-1} M_j^{\mathrm{c}}\hat{\lambda}_j}{\left[M - \sum_{j=0}^{i-1} M_j^{\mathrm{c}}\right]}\,,\ i \ge 1\,. \tag{5.17}$$

Graphical Plot (Parametric). When the failure distribution is a two-parameter Weibull distribution, from (5.9) we see that a plot of $y = \ln\{E[N(t)]/t\}$ versus $x = \ln(t)$ is a straight line. *Duane* [5.19] proposed plotting $y = \ln[N(t)/t]$ versus $x = \ln(t)$ to determine if a Weibull distribution is a suitable model or not to model a given data set. For a critical discussion of this approach, see *Rigdon* and *Basu* [5.20].

5.3.4 Model Selection

We saw in Fig. 5.1 that a simple Weibull model was clearly not adequate to model the failures of component C-1. However, there are many extensions of the Weibull model that can fit a variety of shapes. *Murthy* et al. [5.6] give a taxonomic guide to such models and give steps for model selection. This particular curve is suited to modeling with a mixture of two Weibull components. Figure 5.2 shows the WPP plot of Fig. 5.1 with the transformed probability curve for this mixture. (Details about estimating this curve are given in Sect. 5.3.5.) This seems to fit the pattern quite well, although it misses

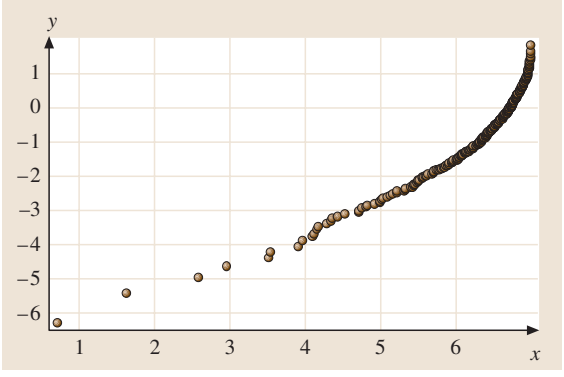

Fig. 5.1 WPP of days to failure of component C-1

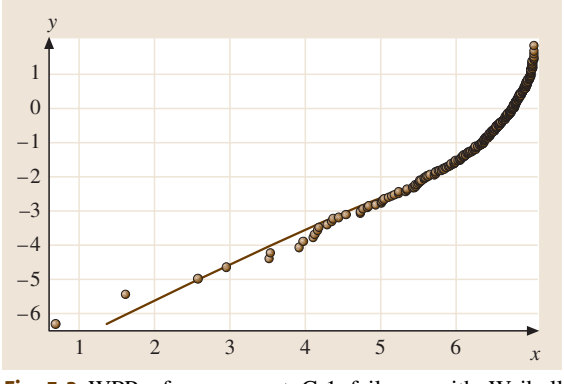

Fig. 5.2 WPP of component C-1 failures with Weibull mixture

the shape of the curve present in the few small failure times.

Figure 5.3 gives the empirical plot of the density function and the density function based on the mixture model. As can be seen, the model matches the data reasonably well. The plots illustrate the way in which the second Weibull component is being used. The nonparametric density estimate suggests that there is a small failure mode centered around 200 d. The second Weibull component, with a weight of 24.2%, captures these early failure times while the dominant component, with a weight of 75.8%, captures the bulk of the failures.

5.3.5 Parameter Estimation

The model parameters can be estimated either based on the graphical plots or by using statistical methods. Many different methods (method of moments, method of maximum likelihood, least squares, Bayesian and so on) have been proposed. The graphical methods yield crude estimates whereas the statistical methods are more refined and can be used to obtain confidence limits for the estimates. Most books on statistical reliability (some of which are mentioned in Sect. 5.3.1) deal with this topic in detail.

The parameters for the Weibull mixture model in Fig. 5.3 were estimated by minimizing the squared error between the points and the curve on the Weibull probability plot. The estimates are

$$\hat{p} = 0.242\,, \quad \hat{\beta}_1 = 1.07\,, \quad \hat{\beta}_2 = 4.32\,,$$
$$\hat{\eta}_1 = 381 \quad \text{and} \quad \hat{\eta}_2 = 839\,.$$

Similar estimates can be obtained without computer software using the graphical methods given by *Jiang* and *Murthy* [5.21].

Alternatively, we can use the standard statistical approach of maximum-likelihood estimation to get the parameter estimates. We find

$$\hat{p} = 0.303\,, \hat{\beta}_1 = 1.46\,, \hat{\beta}_2 = 5.38\,,$$
$$\hat{\eta}_1 = 383 \quad \text{and} \quad \hat{\eta}_2 = 870\,.$$

These values are less affected by the small failures times.

5.3.6 Model Validation

Validation of statistical models is highly dependent on the nature of the models being used. In many situations, it can simply involve an investigation of the shape of the data through plots such as quantile–quantile plots (for example, normal probability plots and WPP) and through tests for goodness of fit (general tests, such as the χ^2 goodness-of-fit test, or specific tests, such as the Anderson–Darling test of normality). Many introductory statistics texts cover these plots and tests (see, for example, *Vardeman* [5.22] and *D'Agostino* and *Stephen* [5.23]). In more complex situations, these approaches need to be used on residuals obtained after fitting a model involving explanatory variables. An alternative approach, which can be taken when the data set is large, is to take a random sample from the data set, fit the model(s) to this sub-sample and then evaluate (through plots and tests) how well the model fits the sub-sample consisting of the remaining data.

To exemplify model validation, 80% of the data was randomly taken and the mixed Weibull model above fitted. The fitted model was then compared using a WPP to the remaining 20% of the data. The upper top of Fig. 5.4 shows a Weibull plot of 80% of the failure data for component C-1, together with the Weibull mixture fit to the data. The remaining 20% of failure data are

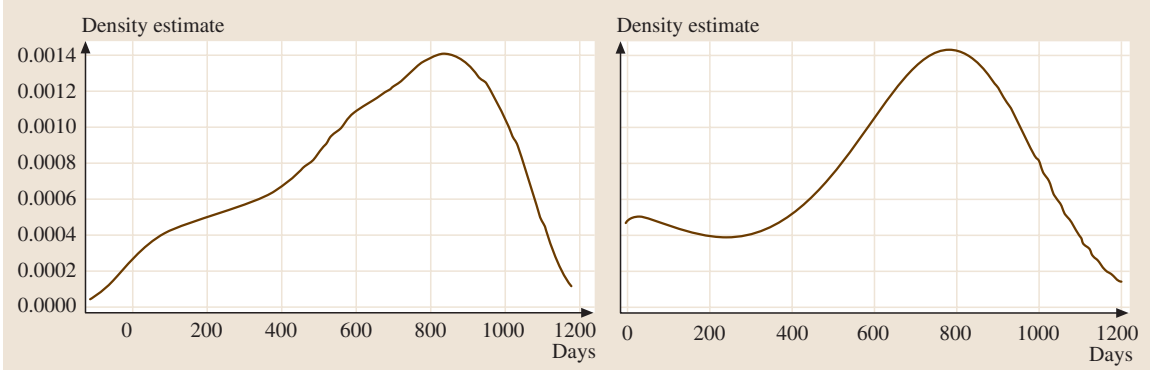

Fig. 5.3 Empirical density (*left*) and Weibull mixture density (*right*) for component C-1

plotted in the lower plot. The Weibull mixture curve with the same parameters as in the upper plot has been added here. Apart from the one short failure time, this curve seems to fit the test data quite well. This supports the use of the Weibull mixture for modeling the failures of this component.

5.4 Two-Dimensional Black-Box Failure Modeling

When failure depends on age and usage, one needs a two-dimensional failure model. Two different approaches (one-dimensional and two-dimensional) have been proposed and we discuss both of these in this section.

5.4.1 One-Dimensional Approach

Here, the two-dimensional problem is effectively reduced to a one-dimensional problem by treating usage as a random function of age.

Modeling First Failure

Let $X(t)$ denote the usage of the item at age t. In the one-dimensional approach, $X(t)$ is modeled as a linear function of t and so given by

$$X(t) = \Gamma t \tag{5.18}$$

where Γ, $0 \le \Gamma < \infty$, represents the usage rate and is a nonnegative random variable with a distribution function $G(r)$ and density function $g(r)$.

The hazard function, conditional on $\Gamma = r$ is given by $h(t|r)$. Various forms of $h(t|r)$ have been proposed; one such is the following polynomial function:

$$h(t|r) = \theta_0 + \theta_1 r + \theta_2 t + \theta_3 X(t) + \theta_4 t^2 + \theta_5 t X(t) \,. \tag{5.19}$$

The conditional distribution function for the time to first failure is given by

$$F(t|r) = 1 - \exp\left[-\int_0^t h(u|r)\,\mathrm{d}u \right] \,. \tag{5.20}$$

On removing the conditioning, we have the distribution function for the time to first failure, given by

$$F(t) = \int_0^\infty \left\{ 1 - \exp\left[-\int_0^t h(u|r)\,\mathrm{d}u \right] \right\} g(r)\,\mathrm{d}r \,. \tag{5.21}$$

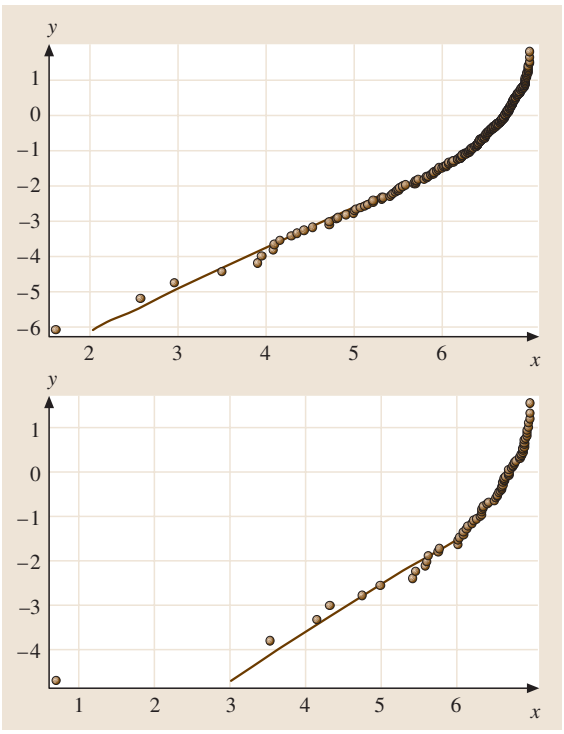

Fig. 5.4 Weibull plots of fitting data (*top*) and test data (*bottom*) for component C-1

Modeling Subsequent Failures

The modeling of subsequent failures, conditional on $\Gamma = r$, follows along lines similar to that in Sect. 5.3.2. As a result, under minimal repair, the failures over time occur according to a nonhomogeneous Poisson process with intensity function $\lambda(t|r) = h(t|r)$ and, under perfect repair, the failures occur according to the renewal process associated with $F(t|r)$.

The bulk of the literature deals with a linear relationship between usage and age. See, for example, *Blischke* and *Murthy* [5.1], *Lawless* et al. [5.24] and *Gertsbakh* and *Kordonsky* [5.25]. *Iskandar* and *Blischke* [5.26] deal with motorcycle data. See *Lawless* et al. [5.24] and *Yang* and *Zaghati* [5.27] for automobile warranty data analysis.

5.4.2 Two-Dimensional Approach

Modeling First Failure

Let T and X denote the system's age and usage at its first failure. In the two-dimensional approach to modeling, (T, X) is treated as a nonnegative bivariate random variable and is modeled by a bivariate distribution function

$$F(t\,,x) = P(T \le t\,, X \le x)\,; t \ge 0\,, x \ge 0\,. \quad (5.22)$$

The survivor function is given by

$$\bar{F}(t\,,x) = Pr(T > t\,, X > x) = \int_t^\infty \int_x^\infty f(u,v)\,\mathrm{d}v\,\mathrm{d}u\,. \quad (5.23)$$

If $F(t,x)$ is differentiable, then the bivariate failure density function is given by

$$f(t\,,x) = \frac{\partial^2 F(t\,,x)}{\partial t \partial x}\,. \quad (5.24)$$

The hazard function is defined as

$$h(t\,,x) = f(t\,,x)/\bar{F}(t\,,x)\,, \quad (5.25)$$

with $h(t\,,x)\delta t\delta x$ defining the probability that the first system failure will occur in the rectangle $[t\,, t+\delta t)\times[x\,, x+\delta x)$ given that $T > t$ and $X > x$. Note, however, that this is not the same as the probability that the first system failure will occur in the rectangle $[t\,, t+\delta t)\times[x\,, x+\delta x)$ given that it has not occurred *before* time t and usage x, which is given by $(f(t\,,x)/[1-F(t\,,x)])\,\delta t\delta x$.

Bivariate Weibull Models

A variety of bivariate Weibull models have been proposed in the literature. We indicate the forms of the models, and interested readers can obtain more details from *Murthy* et al. [5.6].

Model 1 [*Marshall* and *Olkin* [5.28]]

$$\bar{F}(t\,,x) = \exp\left\{-\left[\lambda_1 t^{\beta_1} + \lambda_2 x^{\beta_2} + \lambda_{12}\max(t^{\beta_1}\,, x^{\beta_2})\right]\right\}\,. \quad (5.26)$$

Model 2 [*Lee* [5.29]]

$$\bar{F}(t\,,x) = \exp\left\{-\left[\lambda_1 c_1^{\beta} t^{\beta} + \lambda_2 c_2^{\beta} x^{\beta} + \lambda_{12}\max\left(c_1^{\beta} t^{\beta}\,, c_2^{\beta} x^{\beta}\right)\right]\right\}\,. \quad (5.27)$$

Model 3 [*Lee* [5.29]]

$$\bar{F}(t\,,x) = \exp\left[-\lambda_1 t^{\beta_1} - \lambda_2 x^{\beta_2} - \lambda_0 \max(t\,,x)^{\beta_0}\right]\,. \quad (5.28)$$

Model 4 [*Lu* and *Bhattacharyya* [5.30]]

$$\bar{F}(t\,,x) = \exp\left\{-\left[(t/\theta_1)^{\beta_1/\delta} + (x/\theta_2)^{\beta_2/\delta}\right]^{\delta}\right\}\,, \quad (5.29)$$

$$\bar{F}(t\,,x) = \left[1 + \left(\left\{\exp\left[(t/\theta_1)^{\beta_1}\right] - 1\right\}^{1/\gamma} + \left\{\exp\left[(x/\theta_2)^{\beta_2}\right] - \right\}^{1/\gamma}\right)^{\gamma}\right]^{-1}\,, \quad (5.30)$$

$$\bar{F}(t\,,x) = \exp\left[-(t/\alpha_1)^{\beta_1} - (x/\alpha_2)^{\beta_2} - \delta h(t\,,x)\right]\,. \quad (5.31)$$

Different forms for the function of $h(t\,,x)$ yield a family of models. One form for $h(t\,,x)$ is the following:

$$h(t\,,x) = \left[(t/\alpha_1)^{\beta_1/m} + (x/\alpha_2)^{\beta_2/m}\right] \quad (5.32)$$

which results in

$$\bar{F}(t\,,x) = \exp\left\{-(t/\alpha_1)^{\beta_1} - (x/\alpha_2)^{\beta_2} - \delta\left[(t/\alpha_1)^{\beta_1/m} + (x/\alpha_2)^{\beta_2/m}\right]^m\right\}\,. \quad (5.33)$$

Two other variations are

$$\bar{F}(t\,,x) = \exp\left(-(t/\alpha_1)^{\beta_1} - (x/\alpha_2)^{\beta_2} - \delta\left\{1 - \exp\left[-(t/\alpha_1)^{\beta_1}\right]\right\} \times\left\{1 - \exp\left[-(x/\alpha_2)^{\beta_2}\right]\right\}\right)\,, \quad (5.34)$$

$$\bar{F}(t\,,x) = \left\{1 + \left[\left\{\exp\left[(t/\alpha_1)^{\beta_1}\right] - 1\right\}^{1/\gamma} + \left\{\exp\left[(x/\alpha_2)^{\beta_2}\right] - 1\right\}^{1/\gamma}\right]^{\gamma}\right\}^{-1}\,. \quad (5.35)$$

Model 5 (*Sarkar* [5.31])

$$\bar{F}(t\,,x) = \begin{cases} \exp\left(\left[-(\lambda_1+\lambda_{12})t^{\beta_1}\right] \times\left\{1 - \left[A\left(\lambda_2 t^{\beta 1}\right)\right]^{-\gamma} \times\left[A(\lambda_2 x^{\beta_2})\right]^{1+\gamma}\right\}\right)\,, \\ \qquad t \ge x > 0\,; \\ \exp\left(\left[-(\lambda_2+\lambda_{12})x^{\beta_2}\right] \times\left\{1 - \left[A(\lambda_1 x^{\beta_2})\right]^{-\gamma} \times\left[A(\lambda_1 t^{\beta_1})\right]^{1+\gamma}\right\}\right)\,, \\ \qquad x \ge t > 0\,; \end{cases} \quad (5.36)$$

where $\gamma = \lambda_{12}/(\lambda_1+\lambda_2)$ and $A(z) = 1-\mathrm{e}^{-z}$, $z>0$.
Model 6 [*Lee* [5.29]]

$$\bar{F}(t\,,x) = \exp\left[-\left(\lambda_1 t^{\beta_1}+\lambda_2 x^{\beta_2}\right)^{\gamma}\right]\,. \tag{5.37}$$

Comment: many other non-Weibull models can also be used for modeling. For more on this see *Johnson* and *Kotz* [5.32] and *Hutchinson* and *Lai* [5.33]. *Kim* and *Rao* [5.34], *Murthy* et al. [5.35], *Singpurwalla* and *Wilson* [5.36], and *Yang* and *Nachlas* [5.37] deal with two-dimensional warranty analysis.

Modeling Subsequent Failures

Minimal Repair. Let the system's age and usage at the j-th failure be given by t_j and x_j, respectively. Under minimal repair, we have that

$$h\left(t_j^+\,,x_j\right) = h\left(t_j^-\,,x_j\right)\,, \tag{5.38}$$

as the hazard function after repair is the same as that just before failure. Note that there is no change in the usage when the failed system is undergoing minimal repair.

Let $\{N(t\,,x): t\geq 0\,,x\geq 0\}$ denote the number of failures over the region $[0\,,t)\times[0\,,x)$. Unfortunately, as there is no complete ordering of points in two dimensions, there is no analogous result to that obtained for minimal repair in one dimension. In particular, the hazard rate does not provide an intensity rate at a point $(t\,,x)$ as the failure after the last failure prior to $(t\,,x)$ may be either prior to time t (though after usage x) or prior to usage x (though after time t), as well as possibly being after both time t and usage x. Hence, not only is it more difficult to obtain the distribution for $\{N(t,x): t\geq 0, x\geq 0\}$, it is also more difficult to obtain even the mean function for this process.

Perfect Repair. In this case, we have a two-dimensional renewal process for system failures and the following results are from *Hunter* [5.38]:

$$p_n(t\,,x) = F^{(n)}(t\,,x) - F^{(n+1)}(t\,,x)\,,\, n\geq 0\,, \tag{5.39}$$

where $F^{(n)}(t\,,x)$ is the n-fold bivariate convolution of $F(t\,,x)$with itself. The expected number of failures over $[0\,,t)\times[0\,,x)$ is then given by the solution of the two-dimensional integral equation

$$M(t\,,x) = F(t\,,x) + \int_0^t\int_0^x M(t-u\,,x-v) \times f(u\,,v)\,\mathrm{d}v\,\mathrm{d}u\,. \tag{5.40}$$

Imperfect Repair. This has not been studied and hence is a topic for future research.

Comparison with 1-D Failure Modeling

For the first failure, in the one-dimensional failure modeling, we have

$$F(t) + \bar{F}(t) = 1\,, \tag{5.41}$$

and

$$\bar{F}(t) = \exp\left[-\int_0^t h(u)\,\mathrm{d}u\right]\,. \tag{5.42}$$

In two-dimensional failure modeling, however, we have

$$F(t\,,x) + \bar{F}(t\,,x) < 1\,, \tag{5.43}$$

since

$$F(t\,,x)+\bar{F}(t\,,x)+P\,(T\leq t\,,X>x) +P\,(T>t\,,X\leq x) = 1\,. \tag{5.44}$$

A Numerical Example

We confine our attention to a model proposed by *Lu* and *Bhattacharyya* [5.30], where the survivor function is given by (5.31) with $h(t\,,x)$ given by (5.32) with $\alpha_1\,,\alpha_2\,,\beta_1\,,\beta_2>0, \delta\geq 0$ and $0<m\leq 1$. If $m=1$ then the hazard function is given by

$$h(t\,,x) = (1+\delta)^2\frac{\beta_1}{\alpha_1}\left(\frac{t}{\alpha_1}\right)^{\beta_1-1}\frac{\beta_2}{\alpha_2}\left(\frac{t}{\alpha_2}\right)^{\beta_2-1}\,. \tag{5.45}$$

Let the model parameters be as follows:

$$\alpha_1 = 2\,,\alpha_2 = 3\,,\beta_1 = 1.5\,,\beta_2 = 2.0\,,$$
$$\delta = 0.5\,,m = 1$$

The units for age and usage are years and 10 000 km, respectively. The expected age and usage at first system failure are given by

$E(T_1) = \theta_1\Gamma(1/\beta_1+1) = 1.81$ (years) and
$E(X_1) = \theta_2\Gamma(1/\beta_2+1) = 2.66$ (10^3 km).

Figure 5.5 is a plot of the survivor function $\bar{F}(t\,,x)$ and Fig. 5.6 is a plot of the hazard function $h(t\,,x)$. Note that $h(t\,,x)$ increases as t (age) and x (usage) increase, since β_1 and β_2 are greater than 1.

Replacement. The expected number of system failures in the rectangle $[0\,,t)\times[0\,,x)$ under replacement is given by the renewal function $M(t\,,x)$ in (5.40). Figure 5.7 is

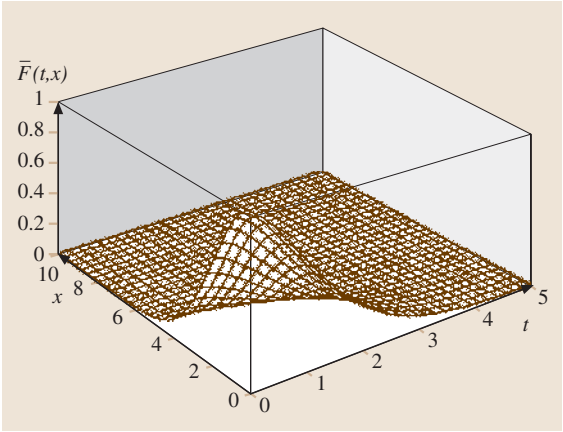

Fig. 5.5 Plot of the survivor function $\bar{F}(t\,,x)$

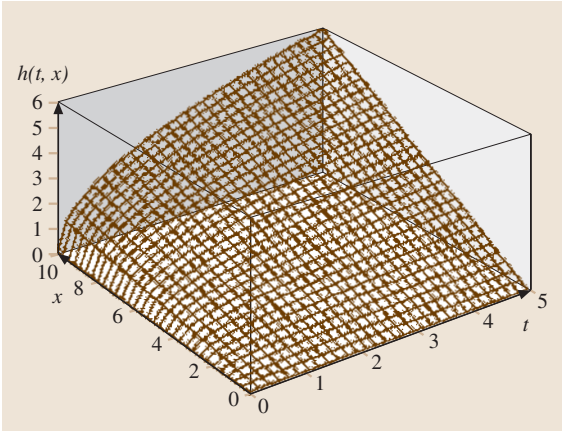

Fig. 5.6 Plot of the hazard function $h(t\,,x)$

a plot of $M(t\,,x)$, obtained using the two-dimensional renewal-equation solver from *Iskandar* [5.39].

5.4.3 Exploratory Data Analysis

In the one-dimensional case, the presence of censored observations causes difficulties in estimating the various functions (hazard rate, density function). When usage is taken into account, these difficulties are exacerbated, due to the information about usage being only observed at failure times. In particular, models which build conditional distributions for the failure times given usage (or usage rates) have to determine a strategy for assigning the censored failure times to some usage (or usage group).

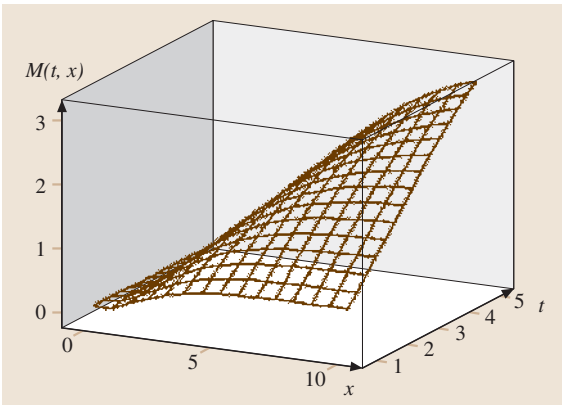

Fig. 5.7 Plot of the renewal function $M(t\,,x)$

1-D Approach

Perfect Repair. Firstly, we group the data into different groups based on the usage rate. Each group has a mean usage rate and the data is analyzed using the approach discussed in Sect. 5.3. This yields the model for the failure distribution *conditioned* on the usage rate. One then needs to determine whether the model structure is the same for different usages or not and whether the linear relationship [given by (5.16)] is valid or not. Next, exploratory plots of the usage rate need to be obtained to determine the kind of distribution appropriate to model the usage rate.

If the conditional failure distributions are two-parameter Weibull distributions then the WPP plots are straight lines. If the shape parameters do not vary with usage rate, then the straight lines are parallel to each other. One can view usage in a manner similar to stress level and use accelerated life-test models [*Nelson* [5.7]] to model the effect of usage on failure.

Imperfect Repair. The plotting (for a given usage rate) follows along the lines discussed in Sect. 5.3.3 and this allows one to determine the distribution appropriate to model the data. Once this is done, one again needs to examine exploratory plots of the usage rate to decide on the appropriate model.

2-D Approach

We confine our discussion to the case of perfect repair.

Plot of Hazard Function (Nonparametric Approach). We divide the region into rectangular cells. Cell $(i\,,j)$ is given by $[i\delta_1\,,(i+1)\delta_1)\times[j\delta_2\,,(j+1)\delta_2)$, where δ_1 and δ_2 are the cells' width and height respectively.

Let us define:

N_{ij}^{f} : Number of items with failures times in cell $(i\,,\,j)\,, i \geq 0\,,\, j \geq 0\,;$

N_{ij}^{c} : Number of items with censoring times in cell $(i\,,\,j)\,, i \geq 0\,,\, j \geq 0\,;$

$N_{ij}^{\mathrm{f|sw}}$: Number of failures in cells to the southwest of

$$\mathrm{cell}(i\,,\,j)\left(=\sum_{i'=0}^{i-1}\sum_{j'=0}^{j-1} N_{i'j'}^{\mathrm{f}}\right)\,;$$

$N_{ij}^{\mathrm{f|ne}}$: Number of failures in cells to the northeast of

$$\mathrm{cell}(i-1\,,\,j-1)\left(=\sum_{i'=i}^{\infty}\sum_{j'=j}^{\infty} N_{i'j'}^{\mathrm{f}}\right)\,.$$

Similarly define $N_{ij}^{\mathrm{c|ne}}$ and $N_{ij}^{\mathrm{c|sw}}$ for censored data.

A nonparametric estimator of the hazard function is

$$\hat{h}_{ij} = \frac{N_{ij}^{\mathrm{f}}}{N_{ij}^{\mathrm{f|ne}} + N_{ij}^{\mathrm{c|ne}}}\,, i \geq 0\,,\, j \geq 0\,. \tag{5.46}$$

Plot of Renewal Function (Nonparametric Approach). A simple estimator of the renewal function in the case of complete data is given by the partial mean function over the cells; that is,

$$\hat{M}(t_i\,,\,x_i) = \frac{N_{ij}^{\mathrm{f|sw}}}{N}\,, \tag{5.47}$$

where N is the total number of observations. A contour plot of this versus t and x can then be obtained.

5.4.4 Model Selection

To determine if the estimate of the renewal function above corresponds to the renewal function for a given model, plots similar to quantile–quantile plots can be investigated. Firstly, the renewal function for the given model is estimated and then its values are plotted against the corresponding values of the nonparametric estimator above. If a (rough) linear relationship is present, then this would be indicative that the model is reasonable.

5.4.5 Parameter Estimation and Validation

Once an appropriate model for $h(t\,,\,x) = f(t\,,\,x)/\bar{F}(t\,,\,x)$ is determined, estimation of the parameters can be carried out using standard statistical procedures (least squares, maximum likelihood, and so on) in a similar fashion to the one-dimensional case, although we are unaware of any equivalent graphical methods which may be used. Similarly, model validation can be carried out as before. It should be noted that the procedure indicated in the previous section can also be used to validate the model, if not used to select it. In fact, a common approach when faced with a complex model may be to fit the model using an estimation procedure such as maximum-likelihood estimation (or generalized least squares using an empirical version of a functional such as the renewal function), then investigating the relationship between some other functional of the model and its empirical version. This area requires further investigation.

5.5 A New Approach to Two-Dimensional Modeling

One of the attractions of the one-dimensional approach taken in Sect. 5.4.1 is that it matches the manner in which the failures occur in practice; that is, the expectation is that the failure time is dependent on the amount of usage of the item—different usage leads to different distributions for the time until failure, with these distributions reflecting the ordering that higher usage leads to shorter time until failure. However, usage may vary over time for individual items and the one-dimensional approach does not allow for this aspect. The model described in this section overcomes this shortcoming by allowing usage to vary between failures.

5.5.1 Model Description

For convenience, consider a single item. Suppose that T_i is the time until the i-th failure and that X_i is the total usage at the i-th failure. Analogously to the one-dimensional approach, let $\Gamma_i = (X_i - X_{i-1})/(T_i - T_{i-1})$ be the usage rate between the $(i-1)$th and the i-th failures. Assuming that these usage rates are independent and come from a common distribution (an oversimplification but a useful starting point for developing models), the marginal distribution of the usage rates can be modeled, followed by the times until failure modeled for different usage rates after each failure in

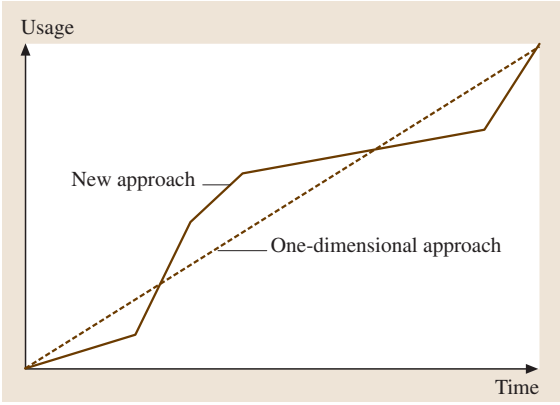

Fig. 5.8 Plot of usage versus time

a similar manner to the one-dimensional approach. This approach combines the two approaches discussed earlier. Figure 5.8 shows the plots of usage versus time for the proposed model and the model based on the one-dimensional approach.

Note that a more general approach is to model the usage as a cumulative stochastic process. This approach has received some attention. See *Lawless* et al. [5.24] and *Finkelstein* [5.40] and the references cited therein for further details.

5.5.2 An Application

We illustrate by considering the failure and usage data for component C-1 over the warranty period.

Modeling the Usage Rates

Before investigating the relationship between usage rate and time to failure, it is worthwhile investigating the days to failure and usage at failure for claims made within the warranty period. This is shown in Fig. 5.9. Only three of the failures were a second failure on the component; all of the others are the first failure since manufacture. There are three considerations to take into account when interpreting Fig. 5.9.

Firstly, the censoring by both time and usage ensures that only the initial part of the bivariate distribution of usage at failure and time to failure can be explored and the relationship between usage at failure and time to failure is distorted. Secondly, the proportions of components according to usage rate vary considerably, with very few components having high or low usage rates (as would be expected). Lastly, there are a greater number of short failure times than might be expected, suggesting that many early failures may not be related to usage and are more likely to be the result of quality-related problems during production. What seems like a linear trend (around the line $Usage = 50\times Days$) is not valid in light of the above discussion.

Figure 5.10 looks at the conditional distribution of days to failures against the usage rate (miles/day) averaged over the time before the claim. Again, care needs to be taken in interpreting this plot. In the left of this plot, censoring due to time and the low number of components having low usage rate has distorted the distribution of failure times for each usage rate. From a usage rate of around 60 km/d, the key feature of the plot is the censoring due to reaching the usage limit. Thus, although it would be expected that the failure-time distribution would be concentrated around a decreasing

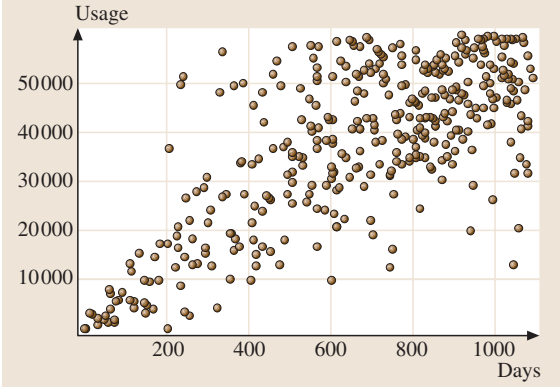

Fig. 5.9 Plot of days to failure and usage at failure for claims within warranty for component C-1

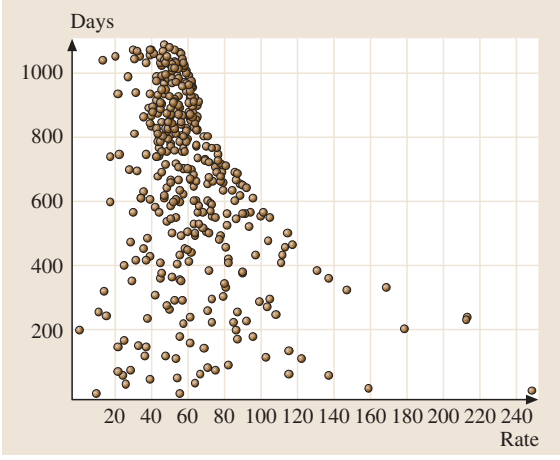

Fig. 5.10 Plot of days to failure against usage rate for component C-1

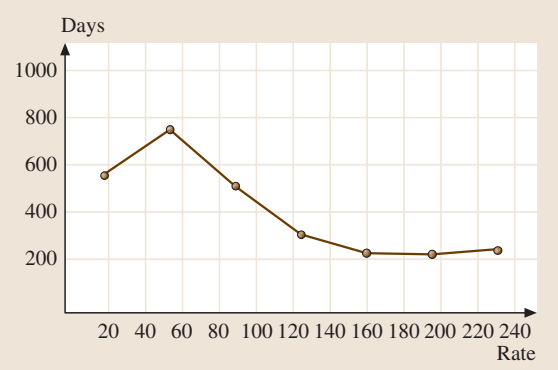

Fig. 5.11 Mean time to failure for usage-rate bands for component C-1

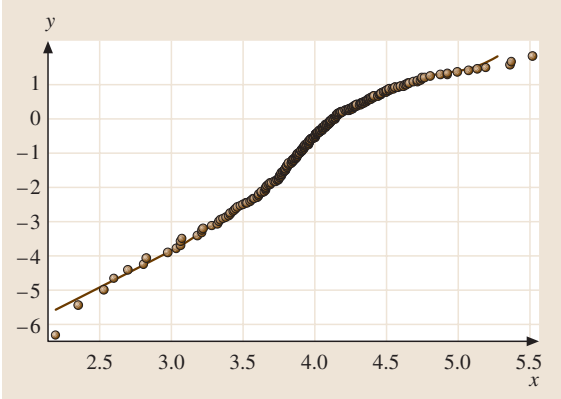

Fig. 5.12 WPP of usage rates for component C-1 with Weibull mixture

mean as usage rate increases, this is exaggerated by the censoring.

Figure 5.11 shows a plot of the mean time to failure for a split of failures into usage-rate bands. In this plot, we see the effects of the censoring, as indicated above. Thus, the mean time to failure actually increases in the low-usage-rate regime. For usage rate greater than 60 km/d, the mean time to failure decreases as the usage rate increases, as is expected (although, as discussed above, this is exaggerated by the censoring due to reaching the usage limit).

Figure 5.12 is a WPP plot of the usage rate. The plot indicates that a Weibull mixture involving two subpopulations is appropriate to model the usage rate. The parameter estimates of the fitted curve in Fig. 5.12 are

$$\hat{p} = 0.647\,,\ \hat{\beta}_1 = 5.50\,,\ \hat{\beta}_2 = 1.99\,,$$
$$\hat{\eta}_1 = 57.7\,,\ \hat{\eta}_2 = 75.7\,.$$

These give mean usage rates to failure of 53.3 km/d and 75.7 km/d, respectively.

Figure 5.13 gives the empirical plot of the density function and the density function based on the mixture model. As can be seen, the model matches the data reasonably well. The model estimates that around 65% of the failures come from a subpopulation with a mean usage rate of 53.3 km/d, giving a dominant peak in the observed density. The other subpopulation, with a higher mean usage rate of 75.7 km/d, accounts for the extra failures occurring for usage rates between around 50 and 100 km/d.

For different usage rates (one for each band in Fig. 5.11) one can obtain the conditional failure distribution $F(t|r)$ in a manner similar to that in Sect. 5.3. It is important to note that this ignores the censored data and as such would yield a model that gives conservative estimates for the conditional mean time to failure. Combining this with the distribution function for the usage rate yields the two-dimensional failure model that can be used to find solutions to decision problems.

5.6 Conclusions

In this chapter we have looked at two-dimensional failure modeling. We have discussed the two approaches that have been proposed and suggested a new approach. However, there are several issues that need further study. We list these and hope that it will trigger more research in the future.

1. Different empirical plotting of two-dimensional failure data.
2. Study of models based on the two-dimensional approach and how this can be used in conjunction with the empirical plots to help in model selection.
3. Further study of the models based on the new approach discussed in Sect. 5.6.
4. Most failure data available for modeling is the data collected for products sold with two-dimensional warranties. In this case, the warranty can cease well before the time limit due to the usage limit being exceeded. This implies censored data with uncertainty in the censoring. This topic has received very little attention and raises several challenging statistical problems.

6. Prediction Intervals for Reliability Growth Models with Small Sample Sizes

The first section of this chapter provides an introduction to the types of test considered for this growth model and a description of the two main forms of uncertainty encountered within statistical modelling, namely aleatory and epistemic. These two forms are combined to generate prediction intervals for use in reliability growth analysis.

The second section of this chapter provides a historical account of the modelling form used to support prediction intervals. An industry-standard model is described and will be extended to account for both forms of uncertainty in supporting predictions of the time to the detection of the next fault.

The third section of this chapter describes the derivation of the prediction intervals. The approach to modelling growth uses a hybrid of the Bayesian and frequentist approaches to statistical inference. A prior distribution is used to describe the number of potential faults believed to exist within a system design, while reliability growth test data is used to estimate the rate at which these faults are detected.

After deriving the prediction intervals, the fourth section of this chapter provides an analysis of the statistical properties of the underlying distribution for a range of small sample sizes.

The fifth section gives an illustrative example used to demonstrate the computation and interpretation of the prediction intervals within a typical product development process.

The strengths and weaknesses of the process are discussed in the final section.

Predicting the time until a fault will be detected in a reliability growth test is complex due to the interaction of two sources of uncertainty, and hence often results in wide prediction intervals that are not practically credible. The first source of variation corresponds to the selection of an appropriate stochastic model to explain the random nature of the fault detection process. The second source of uncertainty is associated with the model itself, as even if the underlying stochastic process is known, the realisations will be random.

Statistically, the first source of uncertainty can be measured through confidence intervals. However, using these confidence intervals for prediction can result in naive underestimates of the time to realise the next failure because they will only infer the mean time to the next fault detection rather than the actual time of the fault detection.

Since the confidence in parameter estimates increases as sample size increase, the degree of underestimation arising from the use of confidence rather than prediction intervals will be lower for large sample sizes compared with small sample sizes. Yet, in reliability growth tests it is common, indeed desirable, to have a small number of failures. Therefore there is a need for prediction intervals, although their construction is more challenging for small samples since they are driven by the second source of variation.

The type of reliability growth test considered will be of the form test, analyse and fix (TAAF). This implies that a system is tested until it fails, at which time analy-

sis is conducted to investigate potential causes and hence identify the source of the fault. Once found, a corrective action is implemented and the 'new' system design is returned to test. This cyclical process is repeated until all weaknesses have been flushed out and the system design is deemed mature. The data generated through testing are analysed using reliability growth models and the information generated is used to support product development decisions. Examples of these data are the duration of the growth test to achieve the required reliability or the efficacy of the stresses experienced by the prototype designs during test within a specified test plan.

Procedures for the construction of prediction intervals for the time to realise the next failure are developed for a standard reliability growth model called the modified IBM model. This model is particularly suited for test situations where few data exist and some expert engineering judgement is available. The model consists of two parameters: one that reflects the number of faults within the system design; and a second that reflects the rate at which the faults are detected on test. Estimation procedures have been developed as a mixture of Bayesian and frequentist methods. Processes exist to elicit prior distributions describing the number of potential faults within a design. However prior distributions describing the test time by which these faults will be realised are more challenging to elicit and, as such, inference for this parameter is supported by data observed from the test.

Section 6.1 provides background history and a description of the model and its underlying assumptions. In Sect. 6.2, prediction intervals are derived for this model from the frequentist perspective. Section 6.3 presents an analysis of the statistical properties of the proposed estimators, while Sect. 6.4 provides an illustrative example of their application to a typical reliability growth test. Finally the use of such procedures is discussed in Sect. 6.5.

6.1 Modified IBM Model – A Brief History

The IBM model was proposed by [6.1] and was the first reliability growth model to represent formally two different types of failures: namely those that result in a corrective action to the system; and those that result in a replacement of a component part. By formally accounting for failures that occur but which are not addressed at the system level, the failure rate is estimated by an asymptote corresponding to a residual failure rate relating to faults that would have been detected and corrected, but were not, due to the termination of testing. The model was developed assuming the following differential equation

$$\frac{\mathrm{d}D(t)}{\mathrm{d}t} = -\mu D(t)\,, \quad \mu, t > 0\,, \tag{6.1}$$

where $D(t)$ represents the number of faults remaining in the system at accumulated test time t. Therefore the expected number of faults detected by accumulated test time t is

$$N(t) = D(0)\left(1 - \mathrm{e}^{-\mu t}\right)\,, \quad \mu, t > 0\,. \tag{6.2}$$

The model proposes that spurious failures would be realised according to a homogeneous Poisson process independent of the fault detection process. This latter process is not of direct concern to the model developed here and hence we do not develop it further. Instead we focus on the fault detection process only.

The deterministic approach to reliability growth modelling was popular in the late 1950s and early 1960s. However, this approach was superseded by the further development and popularity of statistical methods based upon stochastic processes. This is because the deterministic arguments relating to reliability growth could just as easily be interpreted through probabilistic methods, which also facilitated more descriptive measures for use in test programmes.

Cozzolino [6.2] arrived at the same form for an intensity function, $\iota(t)$, assuming that the number of initial defects within a system, $D(0)$, has a Poisson distribution with mean λ and that the time to failure of each initial defect followed an exponential distribution with hazard rate μ.

$$\iota(t) = \lambda\mu\,\mathrm{e}^{-\mu t}\,, \quad \mu\,, \lambda\,, t > 0 \tag{6.3}$$

implying that

$$E\left[N(t)\right] = \lambda\left(1 - \mathrm{e}^{-\mu t}\right)\,. \tag{6.4}$$

Jelenski and *Moranda* [6.3] proposed a model to describe the detection of faults within software testing assuming that there were a finite number of faults [i.e. $D(0)$] within the system and that the time between the detection of the i-th and $(i-1)$-th (i.e. W_i) fault had the following exponential cumulative distribution function

(CDF):

$$F(w_i) = 1 - \mathrm{e}^{-[D(0)-i+1]\,\mu\, w_i}\,,$$
$$i = 1, 2, \ldots, D(0)\,; \quad w_i, \mu > 0\,. \tag{6.5}$$

This model is the most referenced software reliability model [6.4]. It is assumed for this model that there exist $D(0)$ faults within the system, whose failure times are all independently and identically exponentially distributed with a hazard rate μ. It is interesting to note the similarities between this model, Cozzolino's model (6.4) and the IBM (6.2) deterministic model; the mean number of faults detected at accumulated test time t is the same in all three models.

Jelenski and Moranda advocated that maximum likelihood estimators (MLEs) be pursued for this model. However it was shown by *Forman* and *Singpurwalla* [6.5], and later by *Littlewood* and *Verrall* [6.6], that the MLEs were inconsistent, often did not exist or produced confidence regions so large that they were practically meaningless.

Meinhold and *Singpurwalla* [6.7] proposed an adaptation with a Poisson prior distribution to estimate the number of faults that will ultimately be exposed. This is similar to *Cozzolino* [6.2] but from a Bayesian perspective, so the variability described through the prior distribution captures knowledge uncertainty in the number of faults within the system design only. This Bayesian approach results in the following estimating equation for μ:

$$\hat{\mu} = \frac{j}{\lambda t' \mathrm{e}^{-t'\mu} + \sum_{i=1}^{j} t_i}\,, \quad t_1 < t_2 < \ldots < t_j \le t'\,, \tag{6.6}$$

where: t_i is the time of the i-th fault detected on test, t' is the test time when the analysis is conducted, and j is the number of faults detected by time t'.

This Bayesian adaptation was further explored in [6.8] and its advantages over the industry-standard model, the so-called power-law model [6.9, 10], was demonstrated. A process was developed to elicit the prior distribution for this model in [6.11] and procedures for estimating confidence intervals for μ were developed in [6.12]. Extensions of this model to assess the cost effectiveness of reliability growth testing are addressed in [6.13], and for managing design processes see [6.14]. This model is incorporated into the international standard, IEC 61164, as the modified IBM model.

The model assumes that there are an unknown but fixed number of faults within a system design. It is further assumed that the system undergoes a TAAF regime that gives rise to times to detect faults that are independently and identically exponentially distributed. A prior distribution describing the number of faults existing within the system design is assumed to be Poisson. Finally, it is assumed that when a fault is identified it is removed completely and no new fault is introduced into the design.

6.2 Derivation of Prediction Intervals for the Time to Detection of Next Fault

We assume that a system contains $D(0)$ faults. The time to detect a fault is exponentially distributed with hazard rate μ, and a prior distribution exists on $D(0)$, in the form of a Poisson distribution with mean λ. It is further assumed that j faults will be observed on test at times $t_1, \ldots t_j$ and we seek a prediction interval for the time to detect the next fault. Let x denote the time between t_j and t_{j+1} and assume that the times to detection are statistically independent.

The statistic R is defined as the ratio of x to the sum of the first j fault detection times, denoted by T:

$$R = \frac{x}{T}\,. \tag{6.7}$$

First, the distribution of T is derived. T is the sum of the first j order statistics from a sample of $D(0)$ independent and identically exponentially distributed random variables with hazard rate μ. Thus, the time between any two consecutive such order statistics are exponentially distributed with hazard rate $[D(0) - i + 1]\,\mu$. Moreover, the times between successive order statistics are independent. For a derivation of this results see [6.15]. Therefore T can be expressed as a weighted sum of independent and identically distributed exponential random variables with hazard rate μ. We denote these random variables as W_i in the following:

$$T = \sum_{i=1}^{j} t_i = \sum_{i=1}^{j} \frac{j-i+1}{N-i+1} W_i\,. \tag{6.8}$$

As an exponential random variable is closed under scale transformation, we can consider T, as expressed in (6.8), as a sum of independent exponential random variables with different hazard rates. As such, using *Goods* formula [6.16] we can express the CDF of T, conditional on there being j faults realised and the design initially having $D(0)$ faults, as:

$$\Pr\left(\sum_{i=1}^{j}\frac{(j-i+1)\,W_i}{n-i+1}<t\,\middle|\,j,\,D(0)=n\right)$$
$$=\sum_{i=1}^{j}\prod_{\substack{k=1\\k\neq i}}^{j}\left(\frac{\frac{n-k+1}{j-k+1}}{\frac{n-k+1}{j-k+1}-\frac{n-i+1}{j-i+1}}\right)\left[1-\mathrm{e}^{-\mu\frac{n-i+1}{j-i+1}t}\right]. \tag{6.9}$$

Consider the following:

$$P[R<r|\,D(0),\,j]$$
$$=P\left(\frac{x}{T}<r\,\middle|\,D(0),\,j\right)$$
$$=\int_0^{\infty}P[x<rt|\,D(0),\,j,\,T=t]P(T=t)\,\mathrm{d}t\,. \tag{6.10}$$

Since we know that x will have an exponential distribution with hazard rate $[D(0)-j]\,\mu$, we obtain:

$$P[R<r|\,D(0)=n]$$
$$=1-\int_{t=0}^{\infty}\mathrm{e}^{-(n-j)\mu rt}\sum_{i=1}^{j}\prod_{k=1,k\neq i}^{j}\left(\frac{\frac{n-k+1}{j-k+1}}{\frac{n-k+1}{j-k+1}-\frac{n-i+1}{j-i+1}}\right)$$
$$\times\mu\frac{n-i+1}{j-i+1}\mathrm{e}^{-\mu\frac{n-i+1}{j-i+1}t}\,\mathrm{d}t$$
$$=1-\sum_{i=1}^{j}\frac{(n-i+1)}{[n-i+1+(j-i+1)(n-j)r]}$$
$$\times\prod_{k=1,k\neq i}^{j}\left(\frac{\frac{n-k+1}{j-k+1}}{\frac{n-k+1}{j-k+1}-\frac{n-i+1}{j-i+1}}\right). \tag{6.11}$$

This probability distribution is a pivotal since it does not depend on μ and can therefore be used to construct a prediction distribution for the time to detect the next fault (6.11), which can be simplified to give

$$P[R<r|\,D(0)=n]$$
$$=1-\frac{n!}{(n-j)!\,(n-j)^{j-1}}$$
$$\times\sum_{i=1}^{j}\left\{\frac{(j-i+1)^{j-1}(-1)^{i-1}}{[n-i+1+(j-i+1)(n-j)r]}\right.$$
$$\left.\times\frac{1}{(i-1)!(j-i)!}\right\}. \tag{6.12}$$

Taking the expectation with respect to $D(0)$, for which it is assumed we have a Poisson prior distribution, provides a CDF that can be used to obtain prediction intervals. The CDF in (6.13) for the ratio, i.e. R, is calculated assuming that there is at least one more fault remaining in the system design. The probability that all faults have been exposed given there has been j faults detected is expressed in (6.14)

$$P[R<r|\,D(0)\geq j+1,\,j]$$
$$=1-\left(\frac{\sum_{n=j+1}^{\infty}\frac{n!}{(n-j)!(n-j)^{j-1}}}{1-\sum_{k=0}^{j}\frac{\lambda^k\mathrm{e}^{-\lambda}}{k!}}\right.$$
$$\times\sum_{i=1}^{j}\left\{\frac{(j-i+1)^{j-1}\,(-1)^{i-1}}{[n-i+1+(j-i+1)\,(n-j)\,r]}\right.$$
$$\left.\left.\times\frac{1}{(i-1)!(j-i)!}\frac{\lambda^n\mathrm{e}^{-\lambda}}{n!}\right\}\right), \tag{6.13}$$

$$P(R=\infty|\,j)=\frac{\frac{\lambda^j\mathrm{e}^{-\lambda}}{j!}}{1-\sum_{k=0}^{j-1}\frac{\lambda^k\mathrm{e}^{-\lambda}}{k!}}. \tag{6.14}$$

Consider how this distribution changes as we expose all faults within the design. As the number of faults detected, j, increases towards $D(0)$, then the distribution of T approaches a gamma distribution as follows:

$$\lim_{j\to D(0)}T=\lim_{j\to D(0)}\sum_{i=1}^{j}t_i$$
$$=\lim_{j\to D(0)}\sum_{i=1}^{j}\frac{j-i+1}{D(0)-i+1}W_i=\sum_{i=1}^{j}W_i\,,$$

where W_i are independent and identically exponentially distributed and their sum has a gamma distribution with

parameters j and μ. Therefore, as j approaches $D(0)$, the distribution of R should approach the following:

$$P[R<r|\,D(0)=n,\,j] = \int_0^\infty P[x<rt|\,D(0)=n,\,j,\,T=t]\,P(T=t)\,\mathrm{d}t$$

$$= 1-\left(\frac{1}{1+r}\right)^j . \qquad (6.15)$$

Computationally, (6.15) will be easier to apply than (6.13), assuming that there exists at least one more fault in the design. In the following section the quality of (6.15) as an approximation to (6.13) will be evaluated.

6.3 Evaluation of Prediction Intervals for the Time to Detect Next Fault

In this section the CDF in (6.13) is investigated to assess how it is affected by parameter changes in λ, which represents the subjective input describing the expected number of faults within the design. The degree of closeness of the approximation of the simple distribution in (6.15) to the more computationally intensive distribution in (6.13) will be examined. Finally a table of key values for making predictions with this model are presented.

The model assumes that the time between the i-th and $(i+1)$-th fault detection is exponentially distributed with hazard rate $\mu[D(0)-i+1]$. Consequently, if $D(0)$ increases then the expected time to realise the next fault reduces. Therefore as λ, which is the expectation of $D(0)$, increases, the CDF for the ratio R shifts upwards. This is illustrated in Fig. 6.1, where the CDF in (6.13) is shown for various values of λ assuming there have been 1, 5, 10 and 25 faults detected.

Figure 6.2 illustrates the CDF in (6.13) assuming a mean number of faults of 1 and 25 and compares it to the asymptotic distribution (6.15). Interestingly the approximation improves when the number of faults observed is moderately lower than the mean, compared with when it is greater than the mean. However, convergence is slow. For example, there is a noticeable

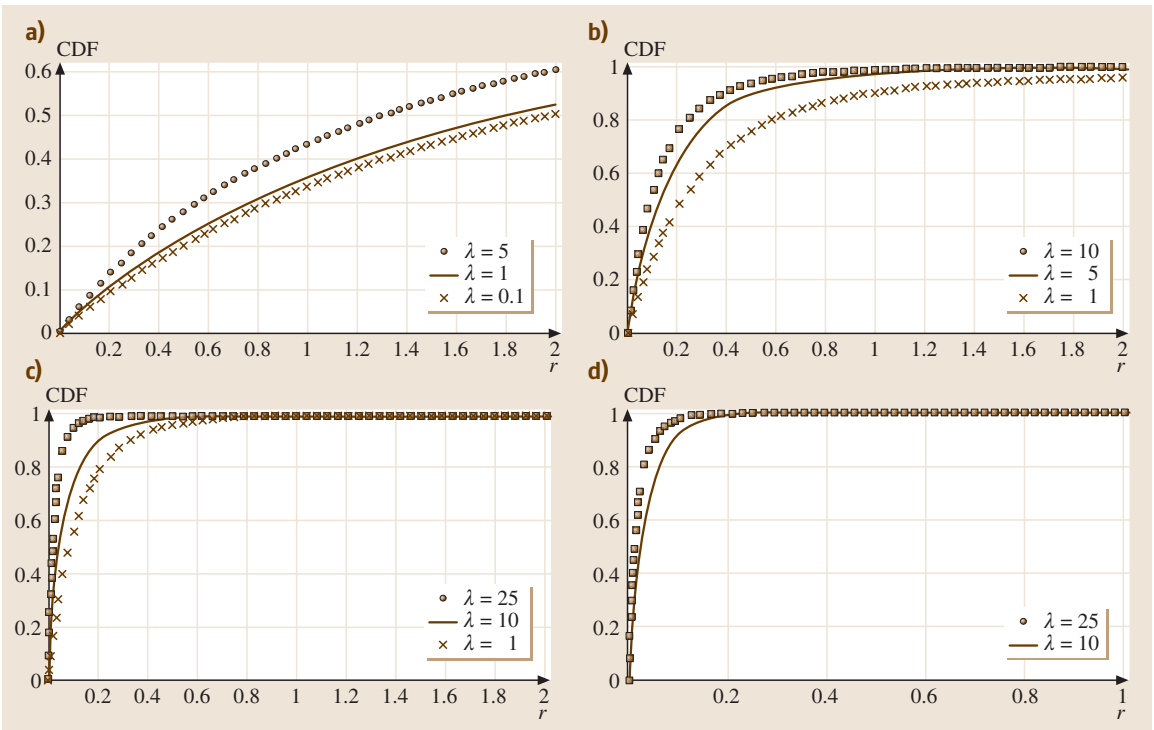

Fig. 6.1a–d Comparison of CDF for ratio R as λ changes; **(a)** 1 fault detected; **(b)** 5 faults detected; **(c)** 10 faults detected; **(d)** 25 faults detected

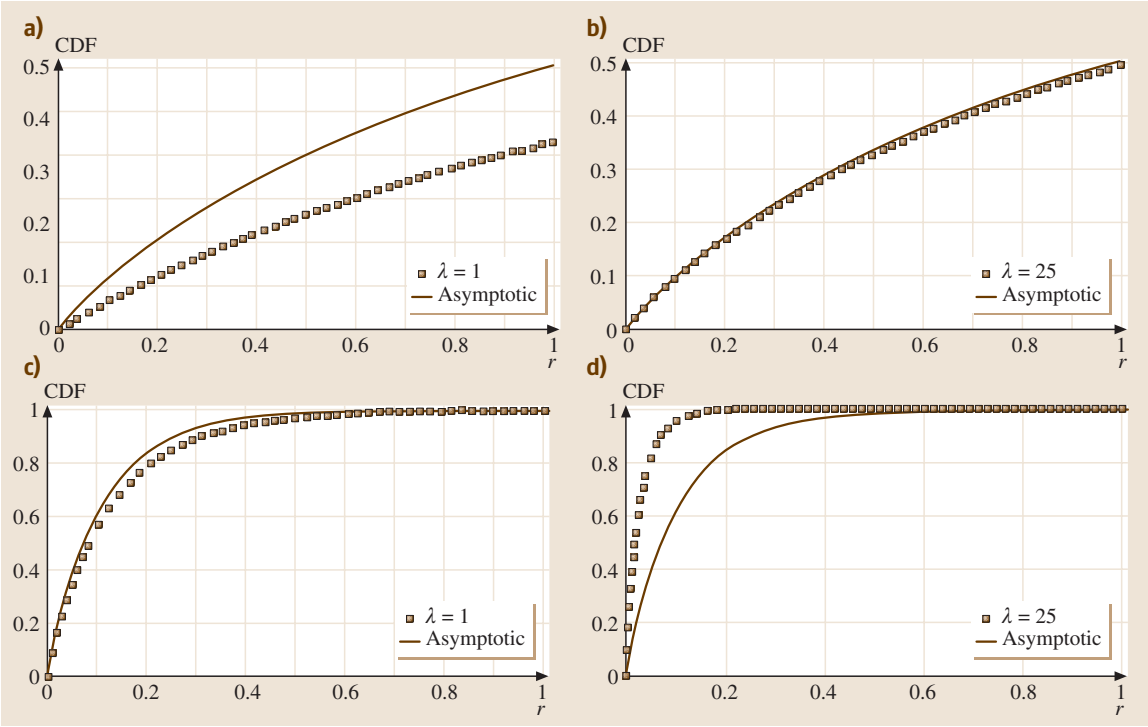

Fig. 6.2a–d Comparison of CDF for ratio R and asymptotic distribution; **(a)** 1 fault detected; **(b)** 1 fault detected; **(c)** 10 faults detected; **(d)** 10 faults detected

difference between the two CDFs in Fig. 6.2c, where there have been 10 faults exposed but the engineering experts expected only one.

The data in the plots in Figs. 6.1 and 6.2 was generated using Maple version 8, which has been used to support numerical computations. To avoid the need to reproduce calculations, summaries of the key characteristics of the CDF are presented in the following tables.

Table 6.1 provides a summary of the expectation of the ratio of the time to next fault detection and the sum of the preceding fault detection times. We consider the mean number of faults λ as it increases from 1 to 20 and the number of observed faults detected as it increases from 1 to 10. For the situation where there is one fault detected the mean is infinite. However, for the case of two or more faults detected the mean is finite. Therefore, the median may provide a more appropriate point estimate of a prediction if there is only one fault detected. In addition, the skewness of the distribution of the mean suggests that median estimators may be appropriate more generally. Note also that as both the number of faults detected increases and the mean number of faults within the design increases the differences in the mean of the distribution of the ratio decrease.

Table 6.1 Values of the mean of the distribution of R

$j\backslash\lambda$	1	5	10	15	20
1	∞	∞	∞	∞	∞
2	1.60	1.13	0.86	0.78	0.76
3	0.74	0.52	0.36	0.31	0.3
4	0.46	0.34	0.22	0.18	0.17
5	0.33	0.25	0.16	0.12	0.11
10	0.13	0.11	0.08	0.05	0.04

4	1.57	1.18	0.77	0.61	0.56
5	1.11	0.87	0.56	0.41	0.36
10	0.43	0.37	0.28	0.18	0.12
c) 99-th percentile					
$j\backslash\lambda$	1	5	10	15	20
1	181.61	132.03	112.14	106.73	104.54
2	14.53	10.42	7.83	7.15	6.9
3	5.45	4.04	2.76	2.35	2.22
4	3.07	2.38	1.56	1.21	1.16
5	2.07	1.67	1.10	0.78	0.68
10	0.72	0.65	0.52	0.36	0.22

Table 6.2 presents a summary of the median values from the distribution of R. For comparison the same values of j and λ have been chosen as in Table 6.1. The skew in the distribution is noticeable through the difference between the mean and the median. This difference decreases as the number of faults detected increases. The changes in the median are greater for smaller values of λ.

Table 6.3 presents summaries of the 90-th, 95-th and 99-th percentiles of the distribution of R. The skew is noticeable by the difference between the 95-th and 99-th percentile, where there is a larger difference for the situation where there have been fewer faults detected.

6.4 Illustrative Example

This example is based around the context and data from a reliability growth test of a complex electronic system. A desensitised version of the data is presented; however, this does not detract from the key issues arising through this reliability growth test and the way in which the data are treated. The aim of this example is to illustrate the process of implementing the modified IBM (MIBM) model for prediction and to reflect upon the strengths and weaknesses of this approach.

6.4.1 Construction of Predictions

A TAAF test regime has been used in this growth development test. The duration of the test was not determined a priori but was to be decided based upon the analysis of the test data. Two units have been used for testing. Both units have been tested simultaneously. The test conditions were such that they approximated the stress levels expected to be experienced during operation.

A prior distribution has been elicited before testing is commenced. The experts used to acquire this information are the engineers involved in the design and development of the system and specialists in specification of the test environment. The process for acquiring such a prior distribution is described in [6.11]. This process involves individual interviews with each expert, discussing novel aspects of the design, identifying engineering concerns and eliciting probabilities that measure their degree of belief that the concern will be realised as a fault during test. Group interviews are conducted where overlapping concerns are identified to explore correlation in the assessment. The probabilities are convoluted to obtain a prior distribution describing the number of faults that exist within the design. Typically a Poisson distribution provides a suitable form for this prior, and this is assumed within the MIBM model. For this illustration we use a Poisson distribution with a mean of 15.

The test was conducted for a total of 7713 test hours. This was obtained by combining the exposure on both test units. Nine faults were exposed during this period. Figure 6.3 illustrates the cumulative number of faults detected against test time. Visually, there is evidence of reliability growth, as the curve appears concave, implying that the time between fault detection is, on average, decreasing. There were two occasions where faults were detected in relatively short succession:

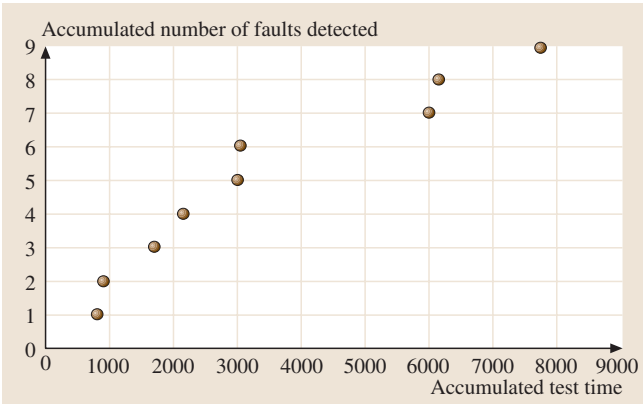

Fig. 6.3 Faults detected against accumulated test time

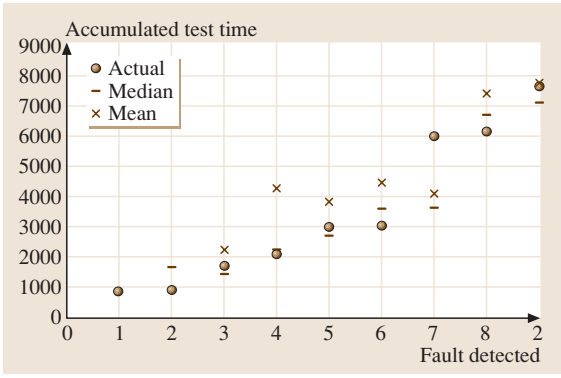

Fig. 6.4 Comparison between actual and model prediction fault detection times

this occurred between 3000 to 4000 hours and 6000 to 7000 hours.

For illustrative purposes we consider the realisations of faults sequentially and use the MIBM model to predict the time to the next fault detection. These predictions are conditioned on there being at least one more fault in the design at the time of prediction. The probability that all faults have been detected will also form part of the prediction.

Table 6.4 provides a summary of the estimates provided by the MIBM and these are also illustrated in Fig. 6.4. The median estimator appears to perform better than the mean. This is due to the large skew in the tail of the distribution of the predicted ratio resulting in a mean that is much greater than the median. All nine faults were observed at earlier times than the upper 95% prediction limit. The point estimates were poorest at the time of the seventh fault detection, which had been realised after an unusually long period of no fault detection.

Table 6.5 provides the point estimate of the number of faults remaining undetected within the design at each fault detection time. This is obtained using the formula (6.16), the derivation of which can be found in [6.12]. The MLE of μ was substituted in place of the parameter:

$$E\left[D\left(0\right)-N\left(t\right)|\,\mu\right]=\lambda\,\mathrm{e}^{-\mu t}\,. \tag{6.16}$$

Table 6.5 provides some confidence in the model we are using for this process. The expected number of faults remaining undetected decreases in line with the detection

Table 6.4 Predictions of fault detection times based on model

Fault number	Actual	Upper 95% prediction	Median prediction	Mean prediction
1	800			
2	900	17184	1664	
3	1700	5541	1444	2226
4	2150	5406	2244	4284
5	3000	5536	2705	3815
6	3050	7788	3599	4454
7	6000	6646	3630	4094
8	6150	10400	6704	7408
9	7713	11375	7100	7813

Table 6.5 Expected faults remaining undetected

Fault detected	Accumulated test time	$\hat{\mu}$	Expected faults remaining
1	800	8.31×10^{-5}	14.0
2	900	0.000148	13.1
3	1700	0.000125	12.1
4	2150	0.000135	11.2
5	3000	0.000127	10.2
6	3050	0.000147	9.6
7	6000	0.000108	7.8
8	6150	0.000116	7.3
9	7713	0.000112	6.3

Table 6.6 Probability of having detected all faults

Number of faults detected	Probability all faults have been detected
1	$4.588\,54\times10^{-6}$
2	$3.441\,42\times10^{-5}$
3	0.0002
4	0.0006
5	0.0019
6	0.0049
7	0.0105
8	0.0198
9	0.0337

of the faults and there is some stability in the estimation of μ.

The analysis conducted to obtain predictions assumes that there is at least one more fault remaining undetected within the design. However, we are assuming that there are a finite number of faults within the design described through the Poisson prior distribution with a mean of 15 at the start of test. Table 6.6 provides the probability that all faults have been detected at each fault detection times. This is a conditional probability calculated from the Poisson distribution. The formula used, which assumes j faults have been detected and a mean of λ, is provided in (6.17):

$$P\left[D\left(0\right)=j\,\middle|\,N\left(t'\right)=j\right]=\frac{\frac{\lambda^{j}\,\mathrm{e}^{-\lambda}}{j!}}{1-\sum_{k=0}^{j-1}\frac{\lambda^{k}\,\mathrm{e}^{-\lambda}}{k!}}\,. \quad (6.17)$$

The probability of having detected all faults increases as the number of faults increase, which is consistent with intuition. By the detection of the ninth fault there is still a small probability of all faults having been detected.

6.4.2 Diagnostic Analysis

Although visually the model appears to describe the variability within the data, the formal assessment of the validity of the CDF of the ratio R is assessed in this section.

Firstly, consider the number of fault detections where the time of detection was earlier than the median. This occurred four out of the eight times where a prediction was possible. Secondly, we compare the observed ratio of the time between successive fault detections and the sum of the proceeding fault detection times. Our hypothesis is that these observations have been generated from the CDF of R. Table 6.7 presents a summary of the observed ratio and the percentile to which the ratio corresponds in the CDF. Assuming that the model is appropriate then these observed percentiles should be consistent with eight observations being observed from a uniform distribution over the range [0, 1]. These percentiles appear to be uniformly distributed across [0, 1] with possibly a slight central tendency between 0.6 and 0.7.

Table 6.7 Observed ratios

Fault detected	Observed ratio	Percentile of ratio
1		
2	0.13	0.1
3	0.47	0.61
4	0.13	0.44
5	0.15	0.64
6	0.01	0.06
7	0.25	0.93
8	0.01	0.13
9	0.07	0.68

A formal test can be constructed to assess whether the percentiles in Table 6.7 are appropriately described as belonging to a uniform distribution. From *Bates* [6.17] the average of at least four uniform random variables is sufficient for convergence with the normal distribution. Therefore, the average of the eight uniform random variables in Table 6.7 is approximately normally distributed with a mean of 0.5 and a standard deviation of 0.029. The average of the observed percentiles is 0.449, which corresponds to a Z-score of -1.76, which is within the 95% bounds for a normal random variable and, as such, we conclude that these percentiles are uniformly distributed. Therefore, the model cannot be rejected as providing an appropriate prediction of the variability of the time to the next fault detection within the test.

6.4.3 Sensitivity with Respect to the Expected Number of Faults

The predictions require a subjective input describing the expected number of faults within the design and as such it is worth exploring the impact of a more pessimistic or optimistic group of experts.

From Sect. 6.3 it is known that the CDF of the ratio R is most sensitive to changes in λ about the median and the impact is lower for the upper prediction limits. The error is defined as the observed minus the predicted value. A summary of selected performance measures for the error corresponding to various values of λ, specifically a pessimistic estimate of 20 and an optimistic

Table 6.8 Prediction errors

	$\lambda = 10$	$\lambda = 15$	$\lambda = 20$
Error (median)	9	197	−612
Error (mean)	−911	−619	−821
MAD (median)	657	687	612
MAD (mean)	1323	1163	1053

estimate of 10 have been computed and are summarised in Table 6.8. The average error is smallest for the optimistic estimate using the median to predict, but greatest for the optimistic estimate using the mean to predict. The mean absolute deviation (MAD) has also been calculated as a method of assessing accuracy, but there is little difference between these values.

6.4.4 Predicting In-Service Failure Times

Accessing in-service data is much more challenging than obtaining data from a controlled reliability growth test. Consequently, assessing the quality of the predictions for in-service performance cannot be expected to be as thorough. However, for this system summary statistics have been obtained from the first two years of operation. The observed Mean Time Between Failure (MTBF) was 1610 h at 18 mon, 3657 h after 19 mon and 1876 h after 22 mon of operation. The model predicts an MTBF of 1888 h, assuming λ is 15. The optimistic estimate of λ of 10 results in an estimate of 1258 h, while the pessimistic estimate of 20 results in an MTBF of 2832 h.

6.5 Conclusions and Reflections

A simple model for predicting the time of fault detection on a reliability growth test with small sample sizes has been described. The model requires subjective input from relevant engineers describing the number of faults that may exist within the design and estimates the rate of detection of faults based on a mixture of the empirical test data and the aforementioned expert judgement.

An illustrative example has been constructed based on a desensitised version of real data where the model has been used in anger. Through this example the processes of constructing the predictions and validating the model have been illustrated.

Despite their complexity, modern electronic systems can be extremely reliable and hence reliability growth tests are increasingly being viewed as a luxury that industry can no longer afford. Obviously, omitting reliability growth tests from development programmes would not be sensible for systems with complex interactions between subassemblies, since potentially much useful information could be gained to inform development decisions. This reinforces that there remains a need to model the fault detection process to provide appropriate decision support. The modelling framework considered here lends itself easily to test data on partitions of the system, as the key drivers are the number of faults in the design and the rate at which there are detected. These are easily amalgamated to provide an overall prediction of the time until next system failure.

The approach considered here combines both Bayesian and frequentist approaches. The main reason for this is that, in our experience, we were much more confident of the subjective data obtained describing the number of faults that may exist within a design and less so about subjective assessments describing when these would realised.

The recent paradigm shift in industry to invest more in reliability enhancement in design and early development means that observable failures have decreased and hence presented new growth modelling challenges. Analysis during product development programmes is likely to become increasingly dependent upon engineering judgement, as the lack of empirical data will result in frequentist techniques yielding uninformative support measures. Therefore, Bayesian methods will become a more realistic practical approach to reliability growth modelling for situations where engineering judgement exists. However, Bayesian models will only be as good as the subjective judgement used as input.

7. Promotional Warranty Policies: Analysis and Perspectives

Warranty is a topic that has been studied extensively by different disciplines including engineering, economics, management science, accounting, and marketing researchers [7.1, p. 47]. This chapter aims to provide an overview on warranties, focusing on the cost and benefit perspective of warranty issuers.

After a brief introduction of the current status of warranty research, the second part of this chapter classifies various existing and several new promotional warranty policies to extend the taxonomy initiated by *Blischke* and *Murthy* [7.2].

Focusing on the quantitative modeling perspective of both the cost and benefit analyses of warranties, we summarize five problems that are essential to warranty issuers. These problems are: i) what are the warranty cost factors; ii) how to compare different warranty policies; iii) how to analyze the warranty cost of multi-component systems; iv) how to evaluate the warranty benefits; v) how to determine the optimal warranty policy.

A list of future warranty research topics are presented in the last part of this chapter. We hope that this will stimulate further interest among researchers and practitioners.

Warranty is an obligation attached to products (items or systems) that requires the warranty issuers (manufacturers or suppliers) to provide compensation to consumers according to the warranty terms when the warranted products fail to perform their pre-specified functions under normal usage within the warranty coverage period. Similar definitions can be found in *Blischke* and *Murthy* [7.1, 3], *McGuire* [7.4], and *Singpurwalla* and *Wilson* et al. [7.5]. Based on this definition, a warranty contract should contain at least three characteristics: the coverage period (fixed or random), the method of compensations, and the conditions under which such compensations would be offered. The last characteristic is closely related to warranty execution since it clarifies consumers' rights and protects warranty issuers from excessive false claims. From the costing perspective, the first two characteristics are more important to manufacturers because they determine the depth of the protection against premature failures and the direct cost related to those failures.

Traditionally, warranty serves as a protection instrument attached to products sold to consumers. There are two facets of the protection role: on one hand, it guarantees a properly functioning product for at least a period of w, either financially or physically. On the other hand, it also specifies an upper bound on the liability of the supplier induced by the warranty. In addition to the protection role, warranty has always been one of the most important elements in business marketing strategy. As indicated in [7.4, p.1], manufacturers' primary rationale for offering warranty is to support their products to gain some advantage in the market, either by expressing the company's faith in the product quality, or by competing with other firms. Due to the more than ever fierce competition in the modern economy, the market promotion role of warranty has become even more significant. Manufacturers are fighting with each other through various

channels from competitive pricing, improved product reliability, to more comprehensive warranties. Because of technology constraints or time constraint, it is usually difficult to improve product quality in a short time. As a result, warranty has evolved as an essential part of marketing strategy, along with pricing and advertising, which is especially powerful during the introduction period of new, expensive products such as automobiles and complex machinery.

In the last two decades, warranty has been studied extensively among many disciplines such as engineering, economics, statistics, marketing and management science, to name a few. Consequently, the literature on warranty is not only vast, but also disjoint [7.1]. There are three books and hundreds of journal articles that have addressed warranty-related problems within the last ten years. A comprehensive collection of related references up to 1996 can be found in [7.3]. In general, researchers in engineering are interested in quality control and improving product reliability to reduce production and service costs. Some of the major references are *Chen* et al. [7.6], *Djamaludin* et al. [7.7], *Hedge* and *Kubat* [7.8], *Mi* [7.9], *Murthy* and *Hussain* [7.10], *Nguyen* and *Murthy* [7.11], and *Sahin* [7.12]. Economists usually treat warranty as a special type of insurance. Consequently, they developed the economic theory of warranties as one of many applications of microeconomics. We refer readers to *DeCroix* [7.13], *Emons* [7.14, 15], *Lutz* and *Padmanabhan* [7.16], *Padmanabhan* and *Rao* [7.17], *Murthy* and *Asgharizadeh* [7.18] and the references therein. Statisticians mainly focus on warranty claim prediction, statistical inference of warranty cost, and estimation of product reliability or availability. Some of the key references are *Frees* [7.19, 20], *Ja* et al. [7.21], *Kalbfleisch* [7.22], *Kao* and *Smith* [7.23, 24], *Menzefricke* [7.25], *Padmanabhan* and *Worm* [7.26] and *Polatoglu* [7.27]. A long-term trend in warranty study is the focus on various warranty-management aspects. Some recent references are *Chun* and *Tang* [7.28], *Ja* et al. [7.21], *Lam* and *Lam* [7.29], *Wang* and *Sheu* [7.30], and *Yeh* et al. [7.31, 32]. *Blischke* and *Murthy* [7.33] developed a framework for the analytical study of various issues related to warranty. Recently, *Murthy* and *Djamaludin* [7.34] enriched the framework by summarizing the literature since 1992 from an overall business perspective. Another review by *Thomas* and *Rao* [7.35] provided some suggestions for expanding the analysis methods for making warranty decisions.

In this chapter, we briefly review some recent work in warranty literature from the manufacturers' perspective. The objectives of this chapter are to classify various existing and relatively new warranty policies to extend the taxonomy proposed in [7.2], and to summarize and illustrate some fundamental warranty economic problems.

7.1 Classification of Warranty Policies

Numerous warranty policies have been studied in the last several decades. *Blischke* and *Murthy* [7.2] presented a taxonomy of more than 18 warranty policies and provided a precise statement of each of them. In this section, we extend the taxonomy by addressing several recently proposed policies that might be of interests to warranty managers. It should be noted that we mainly focus on type *A* policies [7.2], which, based on the taxonomy, are referred to as policies for single items and not involving product development.

7.1.1 Renewable and Nonrenewable Warranties

One of the basic characteristics of warranties is whether they are renewable or not. For a regular renewable policy with warranty period w, whenever a product fails within w, the buyer is compensated according to the terms of the warranty contract and the warranty policy is renewed for another period w. As a result, a warranty cycle T, starting from the date of sale, ending at the warranty expiration date, is a random variable whose value depends on w, the total number of failures under the warranty, and the actual failure inter-arrival times. Renewable warranties are often offered for inexpensive, nonrepairable consumer electronic products such as microwaves, coffee makers, and so forth, either implicitly or explicitly. One should notice that theoretically the warranty cycle for a renewable policy can be arbitrarily large. For example, consumers can induce the failures so that they keep on getting new warranties indefinitely. Such moral hazard problems might be one of the reasons that renewable policies are not as popular as nonrenewable ones among warranty issuers.

One way to remedy this problem is to modify the regular renewable policy in the following way: instead of offering the original warranty with a period of w repeatedly upon each renewing, warranty issuers

could set $w_i = \alpha w_{i-1}$, $\alpha \in (0, 1]$, for $i = 1, 2, \cdots$, where w_i is the warranty length for the i-th renewing, and $w_0 = w$. Actually, this defines a new type of renewable warranty, which we refer to as geometric renewable warranty policies. Clearly, a geometric renewable policy is a generalization of a regular renewable policy, which degenerates to the latter when $\alpha = 1$.

The majority of warranties in the market are nonrenewable; for these the warranty cycle, which is the same as the warranty period, is not random, but predetermined (fixed), since the warranty obligation will be terminated as soon as w units of time pass after sale. This type of policies is also known as a fixed-period warranty.

7.1.2 FRW, FRPW, PRW, CMW, and FSW Policies

According to the methods of compensation specified in a warranty contract upon premature failures, there are three basic types of warranties: free replacement warranty (FRW), free repair warranty (FRPW), and pro-rata warranty (PRW). Combination warranty (CMW) contains both features of FRW/FRPW and PRW. Full-service warranty, (FSW), which is also known as preventive maintenance warranty, is a policy that may be offered for expensive deteriorating complex products such as automobiles. Under this type of policies, consumers not only receive free repairs upon premature failures, but also free (preventive) maintenance.

For nonrepairable products, the failed products under warranty will usually be replaced free of charge to consumers. Such a policy is often referred to as a free replacement warranty or an unlimited warranty. In practice, even if a product is technically repairable, sometimes it will be replaced upon failure since repair may not be economically sound. As a result, for inexpensive repairable products, warranty issuers could simply offer FRW policies. Consequently, these inexpensive repairable products can be treated as nonrepairable. However, for repairable products, if the warranty terms specify that, upon a valid warranty claim, the warranty issuer will repair the failed product to working condition free of charge to buyers, then such a policy is a so-called free repair warranty. In practice, it is not rare that a warranty contract specifies that the warranty issuer would repair or replace a defective product under certain conditions. This is the reason why most researchers do not treat FRW and FRPW separately. Nevertheless, we feel that it is necessary to differentiate these two type of policies based on the following reasoning: first, repair cost is usually much lower than replacement cost except for inexpensive products; secondly, by clearly defining the compensation terms, warranty issuers may establish a better image among consumers, which can surely be helpful for the marketing purpose.

Under a FRW policy, since every failed product within T is replaced by a new one, it is reasonable to model all the subsequent failure times by a single probability distribution. However, under a FRPW, it is necessary to model the repair impact on failure times of a warranted product. If it is assumed that any repair is as-good-as-new (perfect repair), then from the modeling perspective, there is little difference between FRW and FRPW. For deteriorating complex systems, minimal repair is a commonly used assumption. Under this assumption, a repair action restores the system's failure rate to the level at the time epoch when the last failure happened. Minimal repair was first introduced by *Barlow* and *Proschan* [7.36]. Changing a broken fan belt on an engine is a good example of minimal repair since the overall failure rate of the car is nearly unchanged. Perfect repair and minimal repair represent two extremes relating to the degree of repair. Realistically, a repair usually makes a system neither as-good-as-new, nor as-bad-as-old (minimal repair), but to a level in between. This type of repair is often referred to as imperfect repair. In the literature of maintenance and reliability, many researchers have studied various maintenance policies considering imperfect repair. A recent review on imperfect maintenance was given by *Pham* and *Wang* [7.37]. In the warranty literature, the majority of researchers consider repairs as either perfect or minimal. Little has been done on warranty cost analysis considering imperfect repair.

Both FRW and FRPW policies provide full coverage to consumers in case of product failures within T. In contrast, a PRW policy requires that buyers pay a proportion of the warranty service cost upon a failure within T in exchange for the warranty service such as repair or replacement, cash rebate or a discount on purchasing a new product. The amount that a buyer should pay is usually an increasing function of the product age (duration after the sale). As an example, suppose the average repair/replacement cost per failure is c_s, which could be interpreted as the seller's cost per product without warranty, if a linear pro-rata function is used, then the cost for a buyer upon a failure at time t, $t < w$, is $c_s \frac{t}{w}$. The corresponding warranty cost incurred to the manufacturer is $c_s\left(1 - \frac{t}{w}\right)$. PRW policies are usually renewable and are offered for relatively inexpensive products such as tires, batteries, and so forth.

Generally speaking, FRW and FRPW policies are in the favor of buyers since manufacturers take all the re-

sponsibility of providing products that function properly during the whole warranty cycle [7.1, p. 221]. In other words, it is the manufacturers that bear all the warranty cost risk. In contrast, for PRW policies manufacturers have the relative advantage with regard to the warranty cost risk. Although they do have to offer cash rebates or discounts to consumers if failures happen during T, they are usually better off no matter what consumers choose to do. If a consumer decides not to file a warranty claim, then the manufacturer saves himself the cash rebate or other type of warranty service. If instead a warranty claim is filed, the manufacturer might enjoy the increase in sales or at least the warranty service cost is shared by the consumer.

To balance the benefits between buyers and sellers, a combination warranty (CMW) that contains both features of FRW/FRPW and PRW policies was created. CMW is a policy that usually includes two warranty periods: a free repair/replacement period w_1 followed by a pro-rata period w_2. This type of warranties is not rare today because it has significant promotional value to sellers while at the same time it provides adequate control over the costs for both buyers and sellers [7.3, p. 12].

For deteriorating complex products, it is essential to perform preventive maintenance to achieve satisfactory reliability performance. Maintenance involves planned and unplanned actions carried out to retain a system at, or restore it to, an acceptable operating condition [7.38]. Planned maintenance is usually referred to as preventive maintenance while unplanned maintenance is labeled as corrective maintenance or repair. The burden of maintenance is usually on the consumers' side. In [7.39], *Bai* and *Pham* proposed a renewable full-service warranty for multi-component systems under which the failed component(s) or subsystem(s) will be replaced; in addition, a (preventive) maintenance action will be performed to reduce the chance of future product failures, both free of charge to consumers. They argue that such a policy is desirable for both consumers and manufacturers since consumers receive better warranty service compared to traditional FRPW policies, while at the same time manufacturers may enjoy cost savings due to the improved product reliability by the maintenance actions. By assuming perfect maintenance, they derived the probability distributions and the first two moments of the warranty cost per warranty cycle for series, parallel, series–parallel, and parallel–series systems.

Many researchers have studied warranty-maintenance problems. Among them Chun [7.40] determined the optimal number of periodic maintenance actions during the warranty period by minimizing the expected warranty cost (EWC). *Jack* and *Dagunar* [7.41] generalized Chun's idea by considering unequal preventive maintenance intervals. *Yeh* [7.32] further extended the work by including the degree of maintenance as one of the decision variables along with the number of maintenance actions and the maintenance schedule. All of these three researches aim to obtain the optimal maintenance warranty to assist manufacturers' decision-making. A related problem is the determination of the optimal maintenance strategy following the expiration of warranty from the consumers' perspective. *Dagpunar* and *Jack* [7.42] studied the problem by assuming minimal repair. Through a general approach, *Sahin* and *Polatoglu* [7.43] discussed both stationary and non-stationary maintenance strategies following the expiration of warranty. They proved the pseudo-convex property of the cost rate function under some mild conditions.

7.1.3 Repair-Limit Warranty

In maintenance literature, many researchers studied maintenance policies set up in such a way that different maintenance actions may take place depending on whether or not some pre-specified limits are met. Three types of limits are usually considered: repair-number-limit, repair-time-limit, and repair-cost-limit. Those maintenance policies are summarized by *Wang* [7.44].

Similarly, three types of repair-limit warranties may be considered by manufacturers: repair-number-limit warranty (RNLW), repair-time-limit warranty (RTLW), and repair-cost-limit warranty (RCLW). Under a RNLW, the manufacturer agrees to repair a warranted product up to m times within a period of w. If there are more than m failures within w, the failed product shall be replaced instead of being repaired again. *Bai* and *Pham* [7.45] recently studied the policy under the imperfect-repair assumption. They derived the analytical expressions for the expected value and the variance of warranty cost per product sold through a truncated quasi-renewal-process approach.

AN RTLW policy specifies that, within a warranty cycle T, any failures shall be repaired by the manufacturer, free of charge to consumers. If a warranty service cannot be completed within τ unit of time, then a penalty cost occurs to the manufacturer to compensate the inconvenience of the consumer. This policy was analyzed by *Murthy* and *Asgharizadeh* [7.18] in the context of maintenance service operation.

For a RCLW policy, there is a repair cost limit τ in addition to an ordinary FRPW policy. That is, upon each

failure within the warranty cycle T, if the estimated repair cost is greater than τ, then replacement instead of repair shall be provided to the consumer; otherwise, normal repair will be performed. This policy has been studied by *Nguyen* and *Murthy* [7.46] and others.

It should be noted that various repair limits as well as other warranty characteristics such as renewing may be combined together to define a new complex warranty. For example, it is possible to have a renewable repair-time-limit warranty for complex systems. Such combinations define a large set of new warranty policies that may appear in the market in the near future. Further study is needed to explore the statistical behavior of warranty costs of such policies to assist decisions of both manufacturers and consumers.

7.1.4 One-Attribute Warranty and Two-Attribute Warranty

Most warranties in practice are one-attribute, for which the warranty terms are based on product age or product usage, but not both. Compared to one-attribute warranties, two-attribute warranties are more complex since the warranty obligation depends on both the product age and product usage as well as the potential interaction between them. Two-attribute warranties are often seen in automobile industry. For example, Huyndai, the Korean automobile company, is currently offering 10 years/100 000 miles limited FRPW on the powertrain for most of their new models.

One may classify two-attribute warranties according to the shape of warranty coverage region. *Murthy* et al. defined four types of two-attribute warranties labeled as policy A to policy D (Fig. 1 in [7.47]). The shapes of the warranty regions are rectangular, L-shaped with no limits on age or usage, L-shaped with upper limits on age and usage, and triangular, respectively. Based on the concept of the iso-cost curve, *Chun* and *Tang* [7.28] proposed a set of two-attribute warranty policies for which the expected present values of future repair costs are the same. Some other plausible warranty regions for two-attribute warranty policies were discussed by *Singpurwalla* and *Wilson* [7.5].

In general, there are two approaches in the analysis of two-attribute warranties, namely, the one-dimensional (1-D) approach and the two-dimensional (2-D) approach. The 1-D approach assumes a relationship between product age and usage; therefore it eventually converts a two-attribute warranty into a corresponding one-attribute warranty. This approach is used by *Moskowitz* and *Chun* [7.48], and *Chun* and *Tang* [7.28]. The 2-D approach does not impose a deterministic relationship between age and usage. Instead, a bivariate probability distribution is employed for the two warranty attributes. *Murthy* et al. [7.47] followed the idea and derived the expressions for the expected warranty cost per item sold and for the expected life cycle cost based on a two-dimensional renewal processes. *Kim* and *Rao* [7.49] obtained the analytical expressions for the warranty cost for the policies A and B defined in [7.47] by considering a bivariate exponential distribution. Perhaps the most comprehensive study of two-attribute warranties so far is by *Singpurwalla* and *Wilson* [7.5], in which, through a game-theory set up, they discussed in detail both the optimum price-warranty problem and the warranty reserve determination problem.

7.2 Evaluation of Warranty Policies

Two phenomena make the study of warranties important. First, warranty has become common practice for manufacturers. According to the survey conducted by *McGuire*, nearly 95% percent of producers of industrial products provide warranties on all of their product lines [7.4, p. 1]; secondly, there is a huge amount of money involved in warranty programs. Based on a report by the Society of Mechanical Engineering (www.sme.org), the annual warranty cost is about 6 billion dollars for Ford, General Motors and Chrysler combined in the year 2001.

Among many issues related to warranty, there are two fundamental questions that must be answered, especially for warranty issuers: (1) how much a warranty will cost; (2) how much benefit can be earned from a certain warranty. This section summarizes some ideas and discussions appeared in the literature that are closely related to these two questions.

7.2.1 Warranty Cost Factors

Due to the random nature of many warranty cost factors such as product failure times, warranty cost is also a random variable whose statistical behavior can be determined by establishing mathematical links between warranty factors and warranty cost. There are numerous factors that may be considered in warranty

studies. Among them, we believe that the followings are of great importance: the characteristics of warranty policies; warranty service cost per failure; product failure mechanism; impact of warranty service on product reliability; warranty service time; and warranty-claim-related factors.

Different warranty policies may require different mathematical models for warranty cost. One way to model the warranty cost per item sold is through a stochastic counting process $[N(t), t \geq 0]$, which represents the number of failures over time of a warranted product. Let $S_1, S_2, \cdots$ be the subsequent failure times, and denote by C_{S_i} the warranty cost associated with the i-th failure. Assuming that all product failures are claimed, that all claims are valid, and instant warranty service, then the total warranty cost per item sold, $C(w)$, can be expressed as

$$C(w) = \begin{cases} \sum_{i=0}^{N[T(w)]} C_{S_i}, & \text{for } N[T(w)] = 1, 2, \cdots \\ 0, & \text{for } N[T(w)] = 0\,. \end{cases} \tag{7.1}$$

From (7.1), it is clear that the probabilistic behavior of $C(w)$ solely depends on $N[T(w)]$ (the number of failures within a warranty cycle T) and C_{S_i}, as well as the potential interaction between them. In general it is very difficult to determine the distribution of $C(w)$. However, it is possible to obtain the moments of $C(w)$ using modern stochastic process theory and probability theory.

For nonrepairable products or repairable products with a single component, warranty service cost per failure is often assumed to be constant. However, for repairable multi-component products, warranty service cost per failure in general is a random variable whose distribution is related to the product (system) structure and the warranty service cost for each component.

Product (system) failure mechanism can be described by the distributions of subsequent system failure times. This involves the consideration of system structure, the reliability of components and the impact of repair on components' reliability and system reliability. System structure is essential in determining system reliability. Extensive research on reliability modeling has been done for different systems such as series–parallel systems, parallel–series systems, standby systems, k-out-of-n systems, and so forth, in the literature of reliability [7.50]. Unfortunately, to our knowledge, there is no complete theory or methodology in warranty that incorporates the consideration of various system structure.

If a warranted product is nonrepairable or the as-good-as-new repair assumption is used for repairable products, then a single failure-time distribution can be adopted to describe the subsequent product failure times under warranty. However, if a warranted product is repairable and repairs are not as-good-as-new, then the failure time distribution(s) of repaired products differ(s) from that of a new product. This situation may be modeled by considering a failure-time distribution for all repaired products different from that of new products [7.1]. Strictly speaking, distributions of subsequent failure times of a repairable product are distinct, therefore, such an approach can be only viewed as an approximation.

As mentioned in Sect. 7.1, warranty compensation includes free replacement, free repair or cash rebate. For the case of free replacement, warranty service cost per failure for manufacturers is simply a constant that does not depend on the product failure times. In the case of cash rebate (pro-rata policy), warranty cost per failure usually relies on product failure time as well as the rebate function. When repair, especially the not as-good-as-new repair, is involved in warranty service, one has to model the repair impact on product reliability, which in turn has a great impact on warranty cost per failure. One way to model subsequent failure times under this situation is to consider them as a stochastic process. Consequently, modern stochastic theory of renewal processes, nonhomogeneous Poisson processes, quasi-renewal processes [7.38] and general point processes could be applied.

To our knowledge, most warranty literature assumes that warranty service is instant. This may be justified when the warranty service time is small compared to the warranty period or the warranty cycle. A better model is to incorporate explicitly the service times into warranty cost modeling. One recent attempt to include non-zero service time in warranty analysis is by *Murthy* and *Asgharizadeh* [7.18]. In this chapter, they developed a game-theoretic formulation to obtain the optimal decision in a maintenance service operation.

Warranty claims-related factors include the response of consumers to product failures and the validation of warranty claims by warranty issuers. It is no secret that not all consumers will make warranty claims even if they are entitled to do so. It is also true that warranty issuers, to serve their own benefits, usually have a formal procedure to validate warranty claims before honoring them. Such situations may be modeled by assigning two new parameters α and β, where α is the probability that

a consumer will file a claim upon a failure within T, and β is the proportion of the rejected claims [7.51].

There are other factors that may be of importance in warranty cost evaluation such as nonconforming product quality [7.6], multiple modes of failure, censored observations [7.20], and etc. Unfortunately, it is impossible to consider all the factors in one warranty cost model. Even if such a model exists, it would be too complicated to be applied.

7.2.2 Criteria for Comparison of Warranties

Warranty managers usually have several choices among various warranty policies that might be applied to a certain type of products. This requires some basic measures as the criteria to make the comparison among these policies.

There are several measures available, including expected warranty cost (EWC) per product sold, expected discounted warranty cost (EDWC) per warranty cycle, monetary utility function and weighted objective function. EWC and EDWC are more popular than the others since they are easy to understand and can be estimated relatively easily. The key difference between them is that the latter one considers the value of time, an important factor for warranty cost accounting and financial managers.

To our opinion, monetary utility function, $U(x)$, is a better candidate for the purpose of comparing warranty policies. The functional form of $U(x)$ reflects the manufacturer's risk attitude. If a manufacturer is risk-neutral, then $U(x)$ is linear in x. This implies that maximizing $\mathrm{E}[U(x)]$ is the same as maximizing $U[\mathrm{E}(x)]$. However, manufacturers may be risk-averse if they are concerned about the variations in profit or in warranty cost. For example, a particular manufacturer may prefer a warranty with less cost variation than another with much larger variation in warranty cost if the difference between the EWCs is small. If this is the case, then it can be shown that the corresponding utility function is concave [7.52]. The main difficulty of the utility theory approach is that utility functions are subjective.

Weighted objective functions could also be used for the purpose of comparing warranties for manufacturers. One commonly used weighted objective function is $\mathrm{E}[\pi(x)] - \rho \mathrm{V}[\pi(x)]$, where ρ is a positive parameter representing the subjective relative importance of the risk (variance or standard deviation) against the expectation and $\pi(x)$ is the manufacturers profit for a given warranty policy x. Interestingly, such an objective function coincides to a special case of the utility theory approach when the manufacturer's subjective utility function is assumed to only depend on the first two centered moments of $\pi(x)$ [7.53, 54].

In the above discussion, the term *warranty cost* refers to the manufacturer's cost per warranted product. In our opinion, this is the fundamental measure for the purpose of evaluating any warranty for manufacturers since it provides precise information on the additional cost incurred to manufacturers due to warranty. An equally useful measure is the discounted warranty cost (DWC) per cycle. This measure incorporates the value of time, therefore it is useful when warranty managers are interested in determining warranty reserve level. It is also of importance to financial managers performing warranty cost analysis.

Some researchers have proposed warranty cost per unit time, or warranty cost rate, as the primary warranty cost measure. As indicated by *Blischke* and *Murthy* [7.3], warranty cost rate is useful in managing warranty servicing resources, such as parts inventory over time with dynamic sales.

Another related measure is warranty cost over a product life cycle. *Blischke* and *Murthy* named this cost as *life cycle cost-II* (LCC-II) [7.1]. A product life cycle begins with the launch of the product onto the market and ends when it is withdrawn.

For consumers, warranty cost analysis is usually conducted over the life time of a product. In [7.1], this cost is labeled as *life cycle cost-I* (LCC-I). LCC-I is a consumer-oriented cost measure and it includes elements such as purchase cost, maintenance and repair costs following expiration of a warranty, operating costs as well as disposal costs.

7.2.3 Warranty Cost Evaluation for Complex Systems

Most products (systems), especially expensive ones, are composed of several nonrepairable components. Upon a failure, the common repair practice is to replace failed components instead of replacing the whole system. For such products, warranty may be offered for each of the individual components, or for the whole system. For the former case, the warranty cost modeling and analysis for single-component products can be applied readily. In fact, most warranty literature focuses on the analysis of warranty for single-component systems via a black-box approach. However, for the latter case, it is necessary to investigate warranty with explicit consideration of system structure because evidently system structure has

a huge impact on product reliability, therefore it is a crucial factor in warranty cost study. Unfortunately, as indicated by *Chukova* and *Dimitrov* [7.55, pp. 544], so far there has been only limited study on this topic.

Some researchers have discussed the warranty cost modeling for parallel systems. For example, *Ritchken* [7.56] provided an example of a two-component parallel system under a two-dimensional warranty. *Hussain* and *Murthy* [7.57] also discussed warranty cost estimation for parallel systems under the setting that uncertain quality of new products may be a concern for the design of warranty programs. *Chukova* and *Dimitrov* [7.55] presented a two-component parallel system under a FRPW policy. Actually, for nonrepairable parallel systems, the modeling techniques of warranty cost is essentially the same as that of black-box systems unless the system is considered as repairable.

To our knowledge, the only published work about warranty study on series systems is by *Chukova* and *Dimitrov* [7.55, p. 579–580]. They derived the EWC per system sold for a two-component series system under a FRPW policy which offers free replacement of the failed component if any system failure happens within the warranty period w. Recently, *Bai* and *Pham* [7.39] obtained the first two moments of a renewable FSW policy for series, parallel, series–parallel and parallel–series systems. The derivation of the first two moments of the DWC of nonrenewable FRPW and PRW policies for minimally repaired series systems can be found in [7.58].

It is possible to use a Markovian model to analyze warranty cost for complex systems. *Balachandran* et al. [7.59] dealt with the problem of determining warranty service cost of a three-component system using the Markovian approach. A similar discussion can be seen in [7.55] and the references therein. Although this approach is a powerful tool in the literature of reliability, queuing systems, and supply-chain management, there are some limitations in the applications of warranty. First of all, it is difficult to determine the appropriate state space and the corresponding transition matrix for the applications in warranty. Secondly, most Markovian models only provide the analysis of measures in the steady states by assuming infinite horizon. In other words, the statistical behavior of those measures in finite horizon (short-run) is either too difficult to obtain or not of practical interest. However, in warranty study, it is crucial to understand the finite-horizon statistical behavior of warranty cost. Thirdly, warranty claim data as well as reliability data are scarce and costly. Markovian models usually require more data since they contain more parameters than ordinary probability models that could be applied to warranty cost study.

7.2.4 Assessing Warranty Benefits

As mentioned in the introduction, warranty is increasingly used as a promotional device for marketing purposes. Consequently, it is necessary to predict and assess quantitatively the benefit that a manufacturer might generate from a specific warranty [7.35, p. 189]. For promotional warranties, such benefit is usually realized through the demand side. Manufacturers generally expect that the increase in profit as a result of the increase in sale, which is boosted by warranty, should cover the future warranty cost.

A simple way to quantify the benefit is to model it as a function of the parameter(s) of a warranty policy, for example, w, the warranty period. A linear form and a quadratic form of w were employed by *Thomas* [7.35, 60] for this purpose. As he acknowledged, both forms were not well-founded and shared the problem of oversimplification [7.35, p. 193]. Another approach is to estimate the demand function empirically. *Menezes* and *Currim* [7.61] posited a general demand function where the quantity sold by a firm offering a warranty with period w is a function of its price, warranty length, advertising, distribution, quality, product feature, and the corresponding values for the firm's competitor. Based on the data from *Ward's Automotive Yearbook, Consumer Reports, Advertising Age, Leading National Advertisers*, and other sources during the period 1981–1987, they obtained the price elasticity and the warranty elasticity, which enabled them to obtain the optimal warranty length through maximizing the present value of cumulative future profit over a finite planning horizon. One of the limitations of this approach, as pointed out by the authors, is that it requires the support of historical sales data. As a result, it cannot be applied to new products or existing products without such historical data [7.61, p. 188].

A related problem of the demand side of warranty is the modeling of sales over time. Mahajan et al. presented several variant diffusion models that may be appropriate for consumer durables [7.62]. *Ja* et al. obtained the first two moments of warranty cost in a product life cycle by assuming a nonhomogeneous Poisson sale process [7.21]. It seems that such models do not allow the interaction between warranty and sales, therefore, they may not be used in estimating warranty benefit.

There is some research (*Emons* [7.15], *Lutz* and *Padmanabhan* [7.16], and *Padmanabhan* and *Rao* [7.17], etc.) on the demand side of warranty concerning moral hazard, advertising, consumers satisfaction, and so forth. However, compared to the vast warranty literature on estimating total warranty cost, the study on the demand side of warranty is far behind. Hopefully we will see more studies on this aspect in the future.

7.2.5 On the Optimal Warranty Policy

One of the most important objectives of warranty study is to assist warranty management. In particular, in the design phase of a warranty program, there are often a set of warranties that might be appropriate for a specific type of products. The problem faced by warranty managers therefore is how to determine the optimal warranty policy.

An early attempt to address the warranty design problem is based on the concept of life-cycle costing (*Blischke* [7.63], *Mamer* [7.64]). It is assumed that a consumer requires the product over a certain time period or life cycle from the same producer repeatedly upon each product failure no matter whether under warranty or not. Under this idealized producer–consumer relationship, the producer's life-cycle profit and the consumer's life-cycle cost can be calculated. Consequently, a consumer indifference price may be determined by comparing consumer's life-cycle costs with or without warranty. Similarly, the producer's indifference price may be calculated based on the comparison of the life-cycle profits with or without warranty.

An alternative approach is to set up an optimization problem to determine the optimal price and warranty length combination jointly through a game-theoretic perspective. In general, two parties, a warranty issuer and a representative consumer, participate in the game. The latter acts as a follower who responses rationally to each potential warranty offer by maximizing his/her utility. The former, as a leader, makes the decision on the optimal warranty strategy, which maximizes the expected profit, based on the anticipated rational response by the consumer. *Singpurwalla* and *Wilson* [7.5] studied two-attribute warranties through this approach. Some others references are *Chun* and *Tang* [7.65], *DeCroix* [7.13], *Glickman* and *Berger* [7.66], *Ritchken* [7.67], *Thomas* [7.60] and the references therein. In the context of production planning and marketing, *Mitra* and *Patankar* [7.68] presented a multi-criteria model that could be used in warranty design.

Now, we present a general formulation of the warranty design problem with some discussion, which may raise more interest among researchers and practitioners for further study.

Let $\Psi = \{\psi_1, \psi_2, \cdots, \psi_n\}$ represent the set of appropriate warranty policies for a given type of products. Policy ψ_i may contain more than one parameter. Denote by $\boldsymbol{w}_i$ the set of warranty parameters for ψ_i; then we can represent ψ_i by $\psi(\boldsymbol{w}_i)$ or $\boldsymbol{w}_i$. If $\boldsymbol{w}_i$ contains only one parameter, say, w_i, the warranty period, then $\boldsymbol{w}_i = \{w_i\}$. Denote by $p(\boldsymbol{w}_i)$ the selling price under the policy ψ_i, and by $C_j(\boldsymbol{w}_i)$ the random warranty cost for the j-th product sold under the policy ψ_i. Let p_0 be the production cost per unit (not including the warranty cost), then the optimal warranty policy $\psi(\boldsymbol{w}^*)$ may be obtained by solving

$$\begin{aligned}
&\max_{\{\boldsymbol{w}_i, \forall i, i=1,2,\cdots,n\}} \mathrm{E}\{\mathrm{U}[\pi(\boldsymbol{w}_i)]\} \\
&\text{s.t.} \quad w_i^l \le w_i \le w_i^u, \forall i, i = 1, 2, \cdots, n \\
&\mathrm{P}\left[\sum_{j=1}^{d(\boldsymbol{w}_i)} C_j(\boldsymbol{w}_i) \ge R_0\right] \le \alpha, \forall i, i = 1, 2, \cdots, n\,,
\end{aligned}$$

where $U(\cdot)$ is the monetary utility function that reflects the risk attitude of the manufacturer. It is a linear function if the manufacturer is risk-neutral and a concave function in the case of a risk-averse manufacturer; $\pi(\boldsymbol{w}_i) = \sum_{j=1}^{d(\boldsymbol{w}_i)} [p(\boldsymbol{w}_i) - p_0 - C_j(\boldsymbol{w}_i)]$; w_i^l, w_i^u are some lower and upper bounds of w_i; $d(\boldsymbol{w}_i)$ represents the demand function for $\psi(\boldsymbol{w}_i)$; R_0 is the predetermined warranty budget level; and α is the risk-tolerance level of the manufacturer with regard to R_0.

One should note that the second set of constraints is actually related to *value at risk* (VaR), a concept widely used in risk management, which indicates the maximum percentage value of an asset that could be lost during a fixed period within a certain confidence level [7.69]. It is reasonable to assume that manufacturers want to control VaR such that the probability that the total warranty cost is over the budget is within the accepted level α.

Solving the optimization problem might be a challenge. First of all, it is difficult to determine the demand function $d(\boldsymbol{w}_i)$, although it is possible to estimate it through marketing surveys or historical data. Secondly, it is required that warranty managers have complete knowledge of the selling price $p(\boldsymbol{w}_i)$. This requires a pricing strategy in the design phase of warranty. It should be noted that we could have considered $p(\boldsymbol{w}_i)$ as one of the decision variables, but this makes the problem more complicated. Besides, it is not rare in practice that

the price is simply set by adding a fixed margin over the estimated production cost with warranty. Thirdly, it is required that the probability distribution of warranty cost should be known. Little research has been done with regard to this issue except *Polatoglu* and *Sahin* [7.27] and *Sahin* and *Polatoglu* [7.70]. In general, numerical methods are required for this purpose. Fourthly, the problem is formulated as a nonlinear optimization problem with some constraints, which may be solved by nonlinear optimization software such as GAMS. However, in general there is no guarantee of the existence of a global optimal solution.

7.3 Concluding Remarks

A warranty problem, by its nature, is a multi-disciplinary research topic. Many researchers ranging from the industry engineer, economist, statistician, to marketing researchers have contributed greatly to warranty literature. In this chapter, we present an overview of warranty policies, focusing on the cost and benefit analysis from warranty issuers' perspective. Although we have successfully addressed several problems in this area, there are still a lot of opportunities for future research, a few of which are listed below:

- To advance warranty optimization models and perform empirical study based on the new developed models.
- To develop and apply efficient algorithms to solve warranty optimization problems.
- To propose and analyze new warranty policies appropriate for complex systems.
- To Study the distribution and the moments of discounted warranty cost for various policies.
- Warranty cost modeling for systems with more complex structures, including standby systems, bridge systems and network systems, etc.
- Develop warranty models considering failure dependency between components due to environmental impact.

8. Stationary Marked Point Processes

Many areas of engineering and statistics involve the study of a sequence of random events, described by points occurring over time (or space), together with a *mark* for each such point that contains some further information about it (type, class, etc.). Examples include image analysis, stochastic geometry, telecommunications, credit or insurance risk, discrete-event simulation, empirical processes, and general queueing theory. In telecommunications, for example, the events might be the arrival times of requests for bandwidth usage, and the marks the bandwidth capacity requested. In a mobile phone context, the points could represent the locations (at some given time) of all mobile phones, and the marks 1 or 0 as to whether the phone is in use or not. Such a stochastic sequence is called a *random marked point process*, an MPP for short. In a stationary stochastic setting (e.g., if we have moved our origin far away in time or space, so that moving further would not change the distribution of what we see) there are two versions of an MPP of interest depending on how we choose our origin: point-stationary and time-stationary (space-stationary). The first randomly chooses an event point as the origin, whereas the second randomly chooses a time (or space) point as the origin. Fundamental mathematical relationships exists between these two versions allowing for nice applications and computations. In what follows, we present this basic theory with emphasis on one-dimensional processes over time, but also include some recent results for d-dimensional Euclidean space, $\mathbb{R}^d$.

This chapter will primarily deal with marked point processes with points on the real line (time). Spatial point processes with points in $\mathbb{R}^d$ will be touched upon in the final section; some of the deepest results in multiple dimensions have only come about recently.

Topics covered include point- and time-stationarity, inversion formulas, the Palm distribution, Campbell's formula, MPPs jointly with a stochastic process, the rate conservation law, conditional intensities, and ergodicity.

8.1 Basic Notation and Terminology

Here the basic framework is presented for MPPs on the real line, with the points distributed over time.

8.1.1 The Sample Space as a Sequence Space

A widely used class of MPPs has events corresponding to points in time,

$$0 \le t_0 < t_1 < t_2 < \cdots , \ \lim_{n\to\infty} t_n = \infty . \tag{8.1}$$

An MPP is then defined as a stochastic sequence; a sequence of random variable (RVs),

$$\Psi = \{(t_n, k_n) : n \ge 0\} ,$$

where the marks k_n take values in a general space $\mathbb{K}$, the mark space, which is assumed to be a complete separable metric space, where the sample-paths of Ψ satisfy (8.1). (It helps to imagine that the arrivals correspond to *customers* arriving to some fixed location over time, each one bringing with them an object called their mark: the n-th customer arrives at time t_n and brings mark k_n.) Alternatively, with $T_n \stackrel{\text{def}}{=} t_{n+1} - t_n, \ n \ge 0$ denoting the n-th *interevent* (interarrival) time, Ψ can equivalently be defined by its *interevent time representation* $\{t_0, \{(T_n, k_n) : n \ge 0\}\}$.

Letting $\mathbb{R}_+$ and $\mathbb{Z}_+$ denote the non-negative real numbers and non-negative integers respectively, $\mathbb{S} = (\mathbb{R}_+ \times \mathbb{K})^{\mathbb{Z}_+}$ denotes sequence space, endowed with the product topology and corresponding Borel σ-field. $\boldsymbol{s} = \{(y_n, k_n) : n \in \mathbb{Z}_+\} \in \mathbb{S}$ denotes a sequence.

$\mathbb{M} \stackrel{\text{def}}{=} \{\boldsymbol{s} \in \mathbb{S} : \boldsymbol{s}$ satisfies (8.1)$\}$, and is the space of marked point processes with mark space $\mathbb{K}$, that is, the *MPP space*. Elements of $\mathbb{M}$ are denoted by $\psi = \{(t_n, k_n)\} \in \mathbb{M}$; they are the sample paths of an MPP $\Psi : \Omega \to \mathbb{M}$, formally a mapping from a probability space Ω into $\mathbb{M}$ with some underlying probability P. [It is standard to suppress the dependency of the random elements on $\omega \in \Omega$; e.g., $t_n(\omega), k_n(\omega), \ \Psi(\omega)$.] When $\Omega = \mathbb{M}$, this is called the *canonical* representation of Ψ. The sequence of points themselves, without marks, $\{t_n\}$, is called a *point process*.

The probability distribution of Ψ is denoted by $\boldsymbol{P} \stackrel{\text{def}}{=} P(\Psi \in \cdot)$; it is a distribution on the Borel sets $\mathcal{E} \subset \mathbb{M}$; $\boldsymbol{P}(\mathcal{E}) = P(\Psi \in \mathcal{E})$.

Two MPPs Ψ_1 and Ψ_2 are said to have the same distribution if $P(\Psi_1 \in \mathcal{E}) = P(\Psi_2 \in \mathcal{E})$ for all Borel sets $\mathcal{E} \subset \mathbb{M}$; equivalently *all finite-dimensional distributions of the two sequences are identical*, e.g., they agree for all Borel sets of the form

$$\mathcal{E} = \{\psi \in \mathbb{M} : t_{n_0} \le s_0, k_{n_0} \in K_0, \ldots , \\ t_{n_l} \le s_l, k_{n_l} \in K_l\} ,$$

where $0 \le n_0 < \cdots < n_l, l \ge 0, s_i \ge 0, K_i \subset \mathbb{K}, 0 \le i \le l$.

The assumption (8.1) of strict monotonicity, $t_n < t_{n+1}, \ n \ge 0$, can be relaxed to $t_n \le t_{n+1}, \ n \ge 0$, to accommodate *batch* arrivals, such as busloads or other groups that arrive together, but if the inequalities are strict, then the MPP is called a *simple* MPP.

8.1.2 Two-sided MPPs

With $\mathbb{Z}$ denoting all integers, a *two-sided* MPP, $\Psi = \{(t_n, k_n) : n \in \mathbb{Z}\}$, has points defined on all of the real line $\mathbb{R}$ thus allowing for arrivals since the infinite past;

$$\cdots t_{-2} < t_{-1} < t_0 \le 0 < t_1 < t_2 < \cdots . \tag{8.2}$$

(In this case, by convention, $t_0 \le 0$.)

8.1.3 Counting Processes

For an MPP $\psi \in \mathbb{M}$, let $N(t) = \sum_j I\{t_j \in (0, t]\}$ denote the number of points that occur in the time interval $(0, t], \ t > 0$. ($I\{B\}$ denotes the indicator function for the event B.) $\{N(t) : t \ge 0\}$ is called the *counting process*. By convention $N(0) \stackrel{\text{def}}{=} 0$. For $0 \le s \le t$, $N(s, t] \stackrel{\text{def}}{=} N(t) - N(s)$, the number of points in $(s, t]$.

In a two-sided framework, counting processes can be extended by defining $N(-t) = \sum_j I\{t_j \in (-t, 0]\}$, the number of points in $(-t, 0], \ t \ge 0$. In this case

$$t_j = \begin{cases} \inf\{t > 0 : N(t) \ge j\}, & j \ge 1 ; \\ -\inf\{t > 0 : N(-t) \ge j + 1\}, & j \le 0 , \end{cases}$$

and, for $t > 0$, $N(t) = \max\{j \ge 1 : t_j \le t\}$; $t_{N(t)}$ is thus the last point before or at time t, and $t_{N(t)+1}$ is the first point strictly after time t; $t_{N(t)} \le t < t_{N(t)+1}$. $T_{N(t)} = t_{N(t)+1} - t_{N(t)}$ is the interarrival time that covers t. Note that $\{t_j \le t\} = \{N(t) \ge j\}, \ j \ge 1$: an obvious but useful identity. For example, in a stochastic setting it yields $P(N(t) = 0) = P(t_1 > t)$. [In the one-sided case, $P(N(t) = 0) = P(t_0 > t)$.]

For a fixed mark set $K \subset \mathbb{K}$, let $N_K(t) = \sum_j I\{t_j \in (0, t], \ k_j \in K\}$, the counting process of points restricted to the mark set K. The MPP corresponding to $\{N_K(t)\}$ is sometimes referred to as a *thinning* of ψ by the mark set K.

Counting processes uniquely determine the MPP, and can be extended to measures, as will be presented in Sect. 8.1.5.

8.1.4 Forward and Backward Recurrence Times

The *forward recurrence time* is defined by

$$A(t) \stackrel{\text{def}}{=} t_{N(t)+1} - t = \begin{cases} t_0 - t, & \text{if } 0 \le t < t_0 \,; \\ t_{n+1} - t, & \text{if } t_n \le t < t_{n+1},\ n \in \mathbb{Z}_+ \,. \end{cases}$$

It denotes the time until the next event strictly after time t and is also called the *excess* at time t. At an arrival time t_n, $A(t_n-) = 0$ and $A(t_n) = A(t_n+) = T_n$, then it decreases down to zero linearly with rate one, making its next jump at time t_{n+1} and so on.

Similarly we can define the *backward recurrence time*

$$B(t) \stackrel{\text{def}}{=} t - t_{N(t)} = \begin{cases} t, & \text{if } 0 \le t < t_0 \,; \\ t - t_n, & \text{if } t_n \le t < t_{n+1},\ n \in \mathbb{Z}_+ \,, \end{cases}$$

which denotes the time since the last event prior to or at time t. In particular, $B(t) \le t$ and $B(0) = 0$. $B(t)$ is also called the *age* at time t. At an arrival time t_{n+1}, $B(t_{n+1}-) = T_n$ and $B(t_{n+1}+) = 0$ and then increases to T_{n+1} linearly with rate one. The sample paths of A and B are mirror images of each other.

In a two-sided framework, $A(t) = t_{n+1} - t$ and $B(t) = t - t_n$, if $t_n \le t < t_{n+1}$, $n \in \mathbb{Z}$; $B(t)$ is no longer bounded by t, $B(0) = |t_0|$ and $A(0) = t_1$ [recall (8.2)].

$S(t) = B(t) + A(t) = t_{N(t)+1} - t_{N(t)} = T_{N(t)}$ is called the *spread* or *total lifetime* at time t; $S(t) = T_n$ if $t_n \le t < t_{n+1}$, and is therefore piecewise constant. In a two-sided framework, $S(0) = |t_0| + t_1$.

In the context of consecutively replaced light bulbs at times t_n with lifetimes $\{T_n\}$, $A(t)$ denotes the remaining lifetime of the bulb in progress at time t, while $B(t)$ denotes its age. $S(t)$ denotes the total lifetime of the bulb in progress.

8.1.5 MPPs as Random Measures: Campbell's Theorem

An MPP ψ can equivalently be viewed as a σ-finite $\mathbb{Z}_+$ valued measure

$$\psi = \sum_j \delta_{(t_j, k_j)} \,,$$

on (the Borel sets of) $\mathbb{R}\times\mathbb{K}$, where $\delta_{(t_j,k_j)}$ is the Dirac measure at (t_j, k_j). For $A \subset \mathbb{R}$ and $K \subset \mathbb{K}$, $\psi(A\times K) =$ the number of points that occur in the time set A with marks taking values that fall in K;

$$\psi(A\times K) = \sum_j I(t_j \in A,\ k_j \in K) \,.$$

$\psi(A\times\mathbb{K}) < \infty$ for all bounded sets A. If $g = g(t,k)$ is a real-valued measurable function on $\mathbb{R}\times\mathbb{K}$, then the integral $\psi(g)$ is given by

$$\psi(g) = \int g \,\mathrm{d}\psi = \int g(t,k)\psi(\mathrm{d}t,\,\mathrm{d}k) = \sum_j f(t_j, k_j) \,.$$

An MPP Ψ can thus be viewed as a random measure and ν denotes its *intensity measure* on $\mathbb{R}\times\mathbb{K}$, defined by $\nu(A\times K) = E[\Psi(A\times K)]$, the expected value; $\nu(\mathrm{d}t,\,\mathrm{d}k) = E[\Psi(\mathrm{d}t,\,\mathrm{d}k)]$. Starting first with simple functions of the form $g(t,k) = I\{t \in A, k \in K\}$ and then using standard approximation arguments leads to

Theorem 8.1 (Campbell's theorem)
For any non-negative measurable function $g = g(t,k)$,

$$E\big[\Psi(g)\big] = \int g \,\mathrm{d}\nu \,.$$

8.1.6 Stationary Versions

An MPP can be stationary in one of two ways, either with respect to point shifts or time shifts (but not both); the basics are presented here.

Define for each $s \ge 0$, the MPP ψ_s by

$$\psi_s = \{[t_n(s), k_n(s)] : n \in \mathbb{Z}_+\} \stackrel{\text{def}}{=} \{(t_{N(s)+n+1} - s,\, k_{N(s)+n+1});\, n \in \mathbb{Z}_+\} \,, \qquad (8.3)$$

the MPP obtained from ψ by shifting to s as the origin and relabeling the points accordingly. For $s \ge 0$ fixed, there is a unique $m \ge 0$ such that $t_m \le s < t_{m+1}$, in which case $t_0(s) = t_{m+1} - s$; $t_1(s) = t_{m+2} - s$; and $t_n(s) = t_{m+n+1} - s$ for $n \in \mathbb{Z}_+$. Similarly, the marks become $k_0(s) = k_{m+1}$; and $k_n(s) = k_{m+n+1}$ for $n \in \mathbb{Z}_+$.

When choosing $s = t_j$, a particular point, then ψ_s is denoted by $\psi_{(j)}$. In this case ψ is shifted to the point t_j so $\psi_{(j)}$ always has its initial point at the origin: $t_0(t_j) = 0$, $j \ge 0$.

The mappings from $\mathbb{M} \to \mathbb{M}$ taking ψ to ψ_s and ψ to $\psi_{(j)}$ are called *shift mappings*.

Applying these shifts to the sample paths of an MPP Ψ yields the shifted MPPs Ψ_s and $\Psi_{(j)}$. It is noteworthy

that, while Ψ_s is a deterministic shift of Ψ, $\Psi_{(j)}$ is a random shift because $t_j = t_j(\omega)$ depends upon the sample path.

In a two-sided framework, the shifts also include (and relabel) all points to the left of s, and s can be negative too.

Point Stationarity

Definition 8.1

Ψ is called a point-stationary MPP if $\Psi_{(j)}$ has the same distribution as Ψ for all $j \in \mathbb{Z}_+$. Equivalently its representation $\{t_0, \{(T_n, k_n) : n \in \mathbb{Z}_+\}\}$ has the properties that $P(t_0 = 0) = 1$ and $\{(T_n, k_n) : n \in \mathbb{Z}_+\}$ forms a stationary sequence of RVs.

If $\{(T_n, k_n) : n \in \mathbb{Z}_+\}$ is also ergodic, then Ψ is said to be a point-stationary and ergodic MPP.

For simplicity, we will always assume that a point-stationary MPP is ergodic.

In practical terms, ergodicity means that, for any measurable $f : \mathbb{M} \longrightarrow \mathbb{R}_+$,

$$\lim_{n\to\infty} \frac{1}{n} \sum_{j=1}^{n} f(\Psi_{(j)}) = E(f(\Psi)) \,, \quad \text{with probability 1 (wp1)} \,. \tag{8.4}$$

(This is *Birkoff's ergodic theorem in its ergodic form*.) For example, if $f(\psi) = T_0$, then $f(\psi_{(j)}) = T_j$ and (8.4) yields the strong law of large numbers for the stationary ergodic sequence $\{T_n\}$; $\lim_{n\to\infty} \frac{1}{n} \sum_{j=1}^{n} T_j = E(T_0)$, wp1. (The non-ergodic case is discussed in Sect. 8.8.)

Inherent in the definition of point-stationarity is the fact that there is a one-to-one correspondence between point-stationary point processes and stationary sequences of non-negative RVs; given any such stationary sequence $\{T_n\}$, $t_n \stackrel{def}{=} T_0 + \cdots + T_{n-1}$ (and $t_0 \stackrel{def}{=} 0$) defines a point-stationary point process.

When Ψ is point-stationary, we let T denote a generic interarrival time, define the *arrival rate* $\lambda = [E(T)]^{-1}$, and let $F(x) = P(T \le x)$, $x \ge 0$ denote the stationary interarrival time distribution with $\bar{F}(x) = 1 - F(x)$ being its tail. As in the classic *elementary renewal theorem*, it holds that $N(t)/t \to \lambda$ as $t \to \infty$, wp1.

From Kolmogorov's extension theorem in probability theory, a stationary sequence can be extended to be two-sided, $\{(T_n, k_n) : -\infty < n < \infty\}$, yielding a point-stationary MPP on all of $\boldsymbol{R}$:

$$\cdots t_{-2} < t_{-1} < t_0 = 0 < t_1 < t_2 < \cdots \,,$$

where $t_{-n} \stackrel{\text{def}}{=} -(T_{-1} + \cdots + T_{-n})$, $n \ge 1$.

Point-stationary MPPs arise naturally as limits (in distribution) of $\Psi_{(j)}$ as $j \to \infty$. In applications the limit can be taken in a *Cesàro* sense. Independently take a discrete RV J with a uniform distribution on $\{1, \ldots, n\}$, and define an MPP Ψ^0 by defining its distribution as

$$\boldsymbol{P}^0(\cdot) = P(\Psi^0 \in \cdot) \stackrel{\text{def}}{=} \lim_{n\to\infty} P(\Psi_{(J)} \in \cdot) = \lim_{n\to\infty} \frac{1}{n} \sum_{j=1}^{n} P(\Psi_{(j)} \in \cdot) \,. \tag{8.5}$$

If the limit holds for all Borel sets of $\mathbb{M}$, then it can be shown that it holds uniformly over all Borel sets; known as *Cesàro total variation convergence*. Assuming the existence of such a limiting distribution $\boldsymbol{P}^0$, it is unique and is called the *point-stationary distribution* of Ψ (or of $\boldsymbol{P}$) and Ψ is said to be *point asymptotically stationary*. Any MPP $\Psi^0 = \{(t_n^0, k_n^0)\}$ distributed as $\boldsymbol{P}^0$ is called a *point-stationary version* of Ψ. Intuitively this is obtained from Ψ by randomly selecting a point t_j so far in the infinite future that shifting further to the next point t_{j+1} does not change the distribution; it is stationary with respect to such point shifts.

It is important to remember that a point-stationary MPP has (wp1) a point at the origin.

Time Stationarity

Definition 8.2

Ψ is called *time-stationary* if Ψ_s has the same distribution as Ψ, for all $s \ge 0$. In this case $P(t_0 > 0) = 1$ and $\{N_K(t) : t \ge 0\}$ has stationary increments for each mark set K.

When Ψ is time-stationary, the interevent time sequence $\{(T_n, k_n)\}$ will not be stationary in general; in particular, the distribution of T_j will generally be different for different choices of j. However, the stochastic process $\{A(t)\}$ is a stationary process.

Ergodicity is defined as requiring that the measure-preserving flow of shifts $\theta_s : \mathbb{M}$ to $\mathbb{M}$, $s \ge 0$, $\theta_s \psi = \psi_s$ be ergodic under the distribution of Ψ. (In the point-stationary case, ergodicity is equivalent to requiring that the measure-preserving shift map $\theta_{(1)} = \theta_{t_1}$ be ergodic.)

For simplicity, we will always assume that a time-stationary MPP is ergodic. In practical terms,

ergodicity means that, for any measurable $f : \mathbb{M} \longrightarrow \mathbb{R}_+$ (satisfying $\int_0^t f(\Psi_s)\,\mathrm{d}s < \infty,\ t \geq 0,$ wp1),

$$\lim_{t\to\infty} \frac{1}{t} \int_0^t f(\Psi_s)\,\mathrm{d}s = E\big[f(\psi)\big],\ \text{wp1}\,. \tag{8.6}$$

When Ψ is time-stationary, the arrival rate is defined by $\lambda \stackrel{\text{def}}{=} E[N(1)]$ and it holds that $E[N(t)] = \lambda t,\ t \geq 0$. It also holds that $N(t)/t \to \lambda$ as $t \to \infty$, wp1.

Time-stationary MPPs can be extended to be two-sided

$$\cdots t_{-2} < t_{-1} < t_0 < 0 < t_1 < t_2 < \cdots\,, \tag{8.7}$$

where $P(t_0 < 0,\ t_1 > 0) = 1$. In this case $\{B(t)\}$ and $\{S(t)\}$ are stationary processes in which case $B(0) = |t_0|$ and $A(0) = t_1$ are identically distributed.

Time-stationary MPPs arise naturally as limits (in distribution) of Ψ_t as time $t \to \infty$. In applications the limit can be taken in a Cesàro sense: independently take a continuous RV, U, uniformly distributed over $(0, t)$, and define an MPP Ψ^* by defining its distribution as

$$\begin{aligned} \boldsymbol{P}^*(\cdot) = P(\Psi^* \in \cdot) &\stackrel{\text{def}}{=} \lim_{t\to\infty} P(\Psi_U \in \cdot) \\ &= \lim_{t\to\infty} \frac{1}{t} \int_0^t P(\Psi_s \in \cdot)\,\mathrm{d}s\,. \end{aligned} \tag{8.8}$$

If the limit holds for all Borel sets of $\boldsymbol{M}$, then it can be shown that it holds uniformly over all Borel sets; Cesàro total variation convergence. Assuming the existence of such a limiting distribution $\boldsymbol{P}^*$, it is unique and is called the *time-stationary distribution* of Ψ (or of $\boldsymbol{P}$) and Ψ is said to be *time asymptotically stationary*. Any MPP $\Psi^* = \{(t_n^*, k_n^*)\}$ distributed as $\boldsymbol{P}^*$ is called a *time-stationary version* of Ψ. Intuitively it is obtained from Ψ by randomly selecting a time t as the origin that is so far in the infinite future that shifting s time units further does not change the distribution; it is stationary with respect to such time shifts.

It is important to remember that a time-stationary MPP has (wp1) no point at the origin.

8.1.7 The Relationship Between Ψ, Ψ^0 and Ψ^*

Suppose that Ψ has a point-stationary version Ψ^0. What then is the time-stationary distribution of Ψ^0? Intuitively it should be the same as the time-stationary distribution of Ψ, and this turns out to be so:

Proposition 8.1

Ψ is point asymptotically stationary (defined as in (8.5)) with point-stationary (and ergodic) $\boldsymbol{P}^0$ under which $0 < \lambda < \infty$, if and only if Ψ is time asymptotically stationary (defined as in (8.8)) with time-stationary (and ergodic) $\boldsymbol{P}^*$ under which $0 < \lambda < \infty$. In this case $\boldsymbol{P}^*$ is the time-stationary distribution of $\boldsymbol{P}^0$, and $\boldsymbol{P}^0$ is the point-stationary distribution of $\boldsymbol{P}^*$. (All three of $\Psi,\ \Psi^0,\ \Psi^*$ share the same point- and time-stationary distributions.)

Because of the above proposition, Ψ is called *asymptotically stationary* if one (hence both) of $\boldsymbol{P}^0$, $\boldsymbol{P}^*$ exist with $0 < \lambda < \infty$.

Proposition 8.2

Suppose that Ψ is asymptotically stationary (and ergodic). Then the two definitions of the arrival rate λ coincide; $\lambda = E[N^*(1)] = [E(T^0)]^{-1}$. Moreover, the ergodic limits in (8.4) and (8.6) hold for all three MPPs, Ψ, Ψ^0, Ψ^* with the right-hand sides replaced by $E[f(\Psi^0)]$ and $E[f(\Psi^*)]$ respectively.

It turns out that, in fact, all three MPPs, Ψ, Ψ^0, Ψ^* *shift couple*, and that is the key to understanding the above two propositions ($\stackrel{\text{d}}{\sim}$ denotes "is distributed as"):

Proposition 8.3

If Ψ is asymptotically stationary, then there exist versions of $\Psi \stackrel{\text{d}}{\sim} \boldsymbol{P}$, $\Psi^0 \stackrel{\text{d}}{\sim} \boldsymbol{P}^0$, $\Psi^* \stackrel{\text{d}}{\sim} \boldsymbol{P}^*$ all on a common probability space together with three random times, S_1, S_2, S_2 such that $\Psi_{S_1} = \Psi^0_{S_2} = \Psi^*_{S_3}$. In other words, they share the same sample paths modulo some time shifts.

Given an asymptotically stationary MPP Ψ, the superscripts ^{0} and * are used to denote point- and time-stationary versions of all associated processes of Ψ. $\Psi^0 = \{(t_n^0, k_n^0)\}$, and $\Psi^* = \{(t_n^*, k_n^*)\}$ denote the two versions, and, for example, $\{(T_n^0, k_n^0)\}$ denotes the stationary sequence of interevent times and marks for Ψ^0, and T^0 denotes such a generic interevent time with F being its distribution; $F(x) = P(T^0 \leq x),\ x \geq 0$. $\{A^*(t)\}$ denotes the forward recurrence time process for Ψ^*, etc.

To illustrate the consequences of Proposition 8.8.2, suppose that $f(\psi) = t_0$. Then $f(\psi_s) = t_0(s) = A(s)$, forward recurrence time, and it holds that

$$\lim_{t\to\infty} \frac{1}{t} \int_0^t A^*(s)\,\mathrm{d}s = E(t_0^*),\ \text{wp1}\,,$$

$$\lim_{t\to\infty} \frac{1}{t} \int_0^t A(s)\,\mathrm{d}s = E(t_0^*),\ \text{wp1}\,,$$

$$\lim_{t\to\infty}\frac{1}{t}\int_0^t A^0(s)\,\mathrm{d}s = E(t_0^*),\ \text{wp1}\,.$$

8.1.8 Examples

Some simple examples are presented. In some of these examples, marks are left out for simplicity and to illustrate the ideas of stationarity better.

1. *Poisson process:* A (time-homogenous) Poisson process with rate λ has independent and identically distributed (iid) interarrival times $T_n,\ n \geq 0$ with an exponential distribution, $P(T \leq x) = 1 - \mathrm{e}^{-\lambda x},\ x \geq 0$. Its famous defining feature is that $\{N(t)\}$ has both stationary and independent increments, and that these increments have a Poisson distribution; $N(t)$ is Poisson-distributed with mean $E[N(t)] = \lambda t,\ t \geq 0$; $P[N(t) = n] = \left[\mathrm{e}^{-\lambda t}(\lambda t)^n\right]/n!,\ n \in \mathbb{Z}_+$.
   If we place t_0 at the origin, $t_0 = 0$, then the Poisson process is point-stationary, whereas if we (independently) choose t_0 distributed as exponential at rate λ, then the Poisson process becomes time-stationary. Thus, for a Poisson process, removing the point at the origin from Ψ^0 yields Ψ^*, while placing a point at the origin for Ψ^* yields Ψ^0. Observe that, by the memoryless property of the exponential distribution, $A(t)$ is distributed as exponential with rate λ for all $t \geq 0$.
   A two-sided time-stationary version is obtained as follows: Choose both $|t_0^*| = B^*(0)$ and $t_1^* = A^*(0)$ as iid with an exponential λ distribution. All interarrival times $T_n^*,\ -\infty < n < \infty$ are iid exponential at rate λ except for $T_0^* = t_1^* - t_0^* = B^*(0) + A^*(0) = S^*(0)$, the spread, which has an Erlang distribution (mean $2/\lambda$). That the distribution of T_0^* is different (larger) than T results from the *inspection paradox*: Randomly choosing the origin in time, we are more likely to land in a larger than usual interarrival time because larger intervals cover a larger proportion of the time line. $S^*(t)$ is distributed as Erlang (mean $2/\lambda$) for all $t \in \mathbb{R}$, by stationarity.
   The Poisson process is the unique simple point process with a counting process that possesses both stationary and independent increments.
2. *Renewal process*: Interarrival times $\{T_n : n \geq 0\}$, are iid with a general distribution $F(x) = P(T \leq x)$ and mean $\lambda^{-1} = E(T)$. If $t_0 = 0$ then the renewal process is point-stationary, and is called a non-delayed version of the renewal process. If instead, independently, $t_0 = A(0) > 0$ and has the *stationary excess* distribution, F_e, defined by

$$F_\mathrm{e}(x) = \lambda\int_0^x \bar{F}(y)\,\mathrm{d}y,\ x \geq 0\,, \tag{8.9}$$

   then the renewal process is time-stationary and $A^*(t)$ is distributed as F_e for all $t \geq 0$. (In the Poisson process case $F_\mathrm{e} = F$.) In general, when $t_0 > 0$ the renewal process is said to be *delayed*. For any renewal process (delayed or not) $\Psi_{(j)}$ always yields a point-stationary version Ψ^0 (for any $j \geq 0$), while Ψ_s always yields a delayed version with delay $t_0(s) = A(s)$. Only when this delay is distributed as F_e is the version time-stationary. As $s \to \infty$, the distribution of $A(s)$ converges (in a Cesàro total variation sense) to F_e; this explains why the distribution of Ψ_s converges (in a Cesàro total variation sense) to the time-stationary version we just described.
   A two-sided time-stationary version Ψ^* is obtained when $T_n^*,\ n \neq 0$ are iid distributed as F, and independently $[B^*(0), A^*(0)] = (|t_0^*|, t_1^*)$ has the joint distribution $P(|t_0^*| > x, t_1^* > y) = \bar{F}_\mathrm{e}(x+y),\ x \geq 0,\ y \geq 0$. Here, as for the Poisson process, $T_0^* = S^*(0)$ has, due to the inspection paradox, a distribution that is stochastically larger than F, $P(T_0^* > x) \geq P(T > x),\ x \geq 0$; this is called the *spread* distribution of F and has tail

$$P(T_0^* > x) = \lambda x\bar{F}(x) + \bar{F}_\mathrm{e}(x)\,; \tag{8.10}$$

   while $E(T_0^*) = E(T^2)/E(T)$. If F has a density $f(x)$, then the spread has a density $\lambda x f(x)$, which expresses the length biasing contained in the spread. F_e always has a density, $f_\mathrm{e}(x) = \frac{\mathrm{d}}{\mathrm{d}x}F_\mathrm{e}(x) = \lambda\bar{F}(x)$, whether or not F does.
3. *Compound renewal process*: Given the counting process $\{N(t)\}$ for a renewal process, and independently an iid sequence of RVs $\{X_n\}$ (called the jumps), with jump distribution $G(x) = P(X \leq x),\ x \in \mathbb{R}$, the process

$$X(t) = \sum_{j=1}^{N(t)} X_j,\ t \geq 0$$

   is called a compound renewal process with jump distribution G. A widely used special case is when the renewal process is a Poisson process, called a *compound Poisson process*.
   This can elegantly be modeled as the MPP $\Psi = \{(t_n, k_n)\}$, where $\{t_n\}$ are the points and $k_n = X_n$. Because it is assumed that $\{X_n\}$ is

independent of $\{t_n\}$, obtaining point and time-stationary versions merely amounts to joining in the iid marks to Example 2's renewal constructions: $k_n^0 = X_n = k_n^*$.

4. *Renewal process with marks depending on interarrival times*: Consider a two-sided renewal process and define the marks as $k_n = T_{n-1}$, the length of the preceding interarrival time. The interesting case is to construct a time-stationary version. This can be done by using the two-sided time-stationary version of the point process, $\{t_n^*\}$, from Example 2. Note that, for $n \neq 1$, the k_n^* are iid distributed as F, defined by $k_n^* = T_{n-1}^*$; only k_1^* is different (biased via the inspection paradox). $k_1^* = T_0^*$ and has the spread distribution.
5. *Cyclic deterministic*: Starting with interarrival time sequence $\{T_n\} = \{1, 2, 3, 1, 2, 3, 1, 2, 3 \dots\}$, Ψ^0 is given by defining $t_0^0 = 0$ and

$$\{T_n^0 : n \geq 0\} = \begin{cases} \{1, 2, 3, 1, 2, 3, \dots\}, \text{ wp} = 1/3\,; \\ \{2, 3, 1, 2, 3, 1, \dots\}, \text{ wp} = 1/3\,; \\ \{3, 1, 2, 3, 1, 2, \dots\}, \text{ wp} = 1/3\,. \end{cases} \tag{8.11}$$

(By randomly selecting a j and choosing t_j as the origin, we are equally likely to select a T_j with length 1, 2, or 3; $P(T^0 = i) = 1/3,\ i = 1, 2, 3.$) The two-sided extension is given by defining $t_0^0 = 0$ and

$$\{\dots, T_{-1}^0, T_0^0, T_1^0, \dots\} = \begin{cases} \{\dots, 3, 1, 2, \dots\}, \text{ wp} = 1/3; \\ \{\dots, 1, 2, 3, \dots\}, \text{ wp} = 1/3\,; \\ \{\dots, 2, 3, 1, \dots\}, \text{ wp} = 1/3\,. \end{cases}$$

A construction of Ψ^* is given as follows. Let U denote a random variable having a continuous uniform distribution over (0, 1). Then

$$\{t_0^*,\ \{T_n^* : n \geq 0\}\} = \begin{cases} U,\ \{2, 3, 1, 2, 3, 1 \dots\}, \text{ wp} = 1/6\,; \\ 2U,\ \{3, 1, 2, 3, 1, 2 \dots\}, \text{ wp} = 1/3\,; \\ 3U,\ \{1, 2, 3, 1, 2, 3 \dots\}, \text{ wp} = 1/2\,. \end{cases} \tag{8.12}$$

By randomly selecting a time s as the origin, we would land inside an interarrival time of length 1, 2, or 3 with probability 1/6, 1/3 and 1/2 respectively (they are proportions of time). Given that we land inside one of length i, $t_0(s)$ would be distributed as $iU,\ i = 1, 2, 3$ (e.g., uniform on $(0, i)$). Unlike $\{T_n^0 : n \geq 0\}$, $\{T_n^* : n \geq 0\}$ is not a stationary sequence because of the unequal probabilities in the mixture.

This illustrates the general fact that t_0^* has the stationary excess distribution $F_e(x)$ of the point-stationary distribution $F(x) = P(T^0 \leq x)$ [recall (8.9)]. In a two-sided extension, the distribution of $T_0^* = |t_0^*| + t_1^* = S^*(0)$ is the spread distribution of F; in this case $P(T_0^* = i) = i/6,\ i = 1, 2, 3$, and the joint distribution of $(|t_0^*|, t_1^*)$ is of the mixture form $(1-U, U), (2-2U, 2U), (3-3U, 3U)$ with probabilities $1/6,\ 1/3,\ 1/2$ respectively.

This example also illustrates the general fact that the time reversal of an MPP Ψ has a different distribution from Ψ; the sequence $\{T_n^0 : n \geq 0\}$ has a different distribution from that of the sequence $\{T_n^0 : n \leq 0\}$.

6. *Single-server queue*: t_n denotes the arrival time of the n-th customer, denoted by C_n, to a system (such as a bank with one clerk) that has one server behind which customers wait in queue (line) in a first-in-first-out manner (FIFO). Upon entering service, C_n spends an amount of time S_n with the server and then departs. D_n denotes the length of time that C_n waits in line before entering service and is called the *delay* of C_n in queue. Thus C_n enters service at time $t_n + D_n$ and departs at time $t_n + D_n + S_n$; $W_n = D_n + S_n$ is called the *sojourn time*. The total number of customers in the system at time t, is denoted by $L(t)$ and can be constructed from $\{W_n\}$;

$$L(t) = \sum_{j=1}^{N(t)} I(W_j > t - t_j), \tag{8.13}$$

because C_j is in the system at time t if $t_j \leq t$ and $W_j > t - t_j$.

Letting $\Psi = [(t_n, S_n)]$ yields an MPP, with marks $k_n = S_n$, called the *input* to the queueing model; from it the queueing processes of interest can be constructed. It is known that D_n satisfies the recursion $D_{n+1} = (D_n + S_n - T_n)_+,\ n \geq 0$, where $x_+ \stackrel{\text{def}}{=} \max(x, 0)$ denotes the positive part of x, and yet another MPP of interest is $\Psi = \{[t_n, (S_n, D_n)]\}$, where now $k_n = (S_n, D_n)$. Letting $\boldsymbol{D}_{(n)} = (D_{n+m} : m \geq 0)$, another important MPP with an infinite-dimensional mark space is $\Psi = \{[t_n, (S_n, \boldsymbol{D}_{(n)})]\}$, where $k_n = (S_n, \boldsymbol{D}_{(n)})$. The *workload* $V(t)$ is defined by $V(t) = D_n + S_n - (t - t_n),\ t \in [t_n, t_{n+1}),\ n \geq 0$, and $D_n = V(t_n-)$; it rep-

resents the sum of all remaining service times in the system at time t. It can also model the water level of a reservoir into which the amounts S_n are inserted at the times t_n while water is continuously drained out at rate 1.

A point-stationary version $\Psi^0 = \{[t_n^0, (S_n^0, D_n^0)]\}$ yields a stationary version of the delay sequence $\{D_n^0\}$ with stationary delay distribution $P(D \le x) = P(D_0^0 \le x)$, which is an important measure of congestion from the point of view of customers, as is its mean, $d \stackrel{\text{def}}{=} E(D)$, the average delay.

A time-stationary version $\Psi^* = \{[t_n^*, (S_n^*, D_n^*)]\}$ yields a time-stationary version of workload $\{V^*(t)\}$ and corresponding stationary distribution $P(V \le x) = P(V^*(0) \le x)$, which is an important measure of congestion from the point of view of the system, as is its mean, $E(V)$, is the average workload.

If the input MPP is asymptotically stationary (ergodic) with $0 < \lambda E(S^0) < 1$, then it is known that $\Psi = \{[t_n, (S_n, D_n)]\}$ is asymptotically stationary, e.g., the stationary versions and distributions for such things as delay and workload exist.

8.2 Inversion Formulas

Inversion formulas allow one to derive $\boldsymbol{P}^0$ from $\boldsymbol{P}^*$, and visa versa.

Theorem 8.2 (Inversion formulas)
Suppose that Ψ is asymptotically stationary (and ergodic) and $0 < \lambda < \infty$. Then

$$P(\Psi^* \in \cdot) = \lambda E\left[\int_0^{T_0^0} I(\Psi_s^0 \in \cdot)\,\mathrm{d}s\right], \tag{8.14}$$

$$P(\Psi^0 \in \cdot) = \lambda^{-1} E\left[\sum_{j=0}^{N^*(1)} I(\Psi_{(j)}^* \in \cdot)\right], \tag{8.15}$$

which, in functional form, become

$$E(f(\Psi^*)) = \lambda E\left[\int_0^{T_0^0} f(\Psi_s^0)\,\mathrm{d}s\right], \tag{8.16}$$

$$E(f(\Psi^0)) = \lambda^{-1} E\left[\sum_{j=0}^{N^*(1)} f(\Psi_{(j)}^*)\right]. \tag{8.17}$$

Recalling (8.6) and Proposition 8.8.2, it is apparent that (8.14) and (8.16) are generalizations (to a stationary ergodic setting) of the renewal reward theorem from renewal theory:

The time average equals the expected value over a cycle divided by the expected cycle length.

Here a cycle length is (by point stationarity) represented by any interarrival time, so the first one, $T_0^0 = t_1^0$, is chosen for simplicity. Equations (8.15) and (8.17) are the inverse [recalling (8.4)]:

The point average equals the expected value over a unit of time divided by the expected number of points during a unit of time.

Here a unit of time is (by time stationarity) represented by any such unit, so the first one, (0, 1], is chosen for simplicity.

8.2.1 Examples

The following examples illustrate how some well-known results that hold for renewal processes, involving the stationary excess distribution (8.9) and the inspection paradox and spread distribution (8.10) also hold in general. Throughout, assume that Ψ is asymptotically stationary (and ergodic).

1. *Stationary forward recurrence time*: $P(t_0^* \le x) = P[A^*(t) \le x] = F_e(x)$ where $F(x) = P(T^0 \le x)$. This is derived by applying (8.17) with $f(\psi) = I(t_0 > x)$: $f(\psi_s^0) = I[t_0^0(s) > x]$ and $t_0^0(s) = A^0(s) = t_1^0 - s, \quad s \in [0, t_1^0)$; $\int_0^{T_0^0} f(\Psi_s^0)\,\mathrm{d}s = \int_0^{T_0^0} I\{s < T_0^0 - x\}\,\mathrm{d}s = (T_0^0 - x)_+$. $\lambda E[(T_0^0 - x)_+] = \lambda \int_x^\infty \bar{F}(y)\mathrm{d}y = \bar{F}_e(x)$.
2. *Stationary backwards recurrence time*: $P[B(0)^* \le x] = F_e(x)$. Here, a two-sided framework must be assumed so that $B(0) = |t_0|$. Applying (8.17) with $f(\psi) = I[B(0) > x]$: $f(\Psi_s^0) = I[B^0(s) > x]$ where $B^0(s) = s, \ s \in [0, t_1^0)$; $\int_0^{T_0^0} f(\Psi_s^0)\,\mathrm{d}s = \int_0^{T_0^0} I(s > x)\,\mathrm{d}s = (T_0^0 - x)_+$. $\lambda E[(T_0^0 - x)_+] = \bar{F}_e(x)$.
3. *Stationary spread*: $P(T_0^* > x) = \lambda x \bar{F}(x) + \bar{F}_e(x)$. Here again, a two-sided framework must be assumed so that $S(0) = |t_0| + t_1$. Applying (8.17)

with $f(\psi) = I(T_0 > x)$: $f(\psi_s) = I[S(s) > x]$ and $S^0(s) = T_0^0, s \in [0, t_1^0)$; $\int_0^{T_0^0} f(\Psi_s^0)\,\mathrm{d}s = \int_0^{T_0^0} I(T_0^0 > x)\,\mathrm{d}s = T_0^0 I(T_0^0 > x)$. $\lambda E(T_0^0 I(T_0^0 > x)) = \lambda x \times \bar{F}(x) + \bar{F}_e(x)$ by carrying out the integration $E[T_0^0 I(T_0^0 > x)] = \int_0^\infty P(T_0^0 > y, T_0^0 > x)\,\mathrm{d}y$.

8.2.2 The Canonical Framework

In the canonical framework $\boldsymbol{E}$ denotes expectation under $\boldsymbol{P}$, $\boldsymbol{E^0}$ denotes expectation under $\boldsymbol{P}^0$ and $\boldsymbol{E}^*$ denotes expectation under $\boldsymbol{P}^*$ and $\Psi : \mathbb{M} \to \mathbb{M}$ is the identity map; $\Psi(\psi) = \psi$. This makes for some elegance and simplicity in notation. For example, the inversion formulas in functional form become

$$\boldsymbol{E}^*[f(\Psi)] = \lambda \boldsymbol{E^0}\left[\int_0^{T_0} f(\Psi_s)\,\mathrm{d}s\right],$$
$$\boldsymbol{E^0}[f(\Psi)] = \lambda^{-1}\boldsymbol{E}^*\left[\sum_{j=0}^{N(1)} f(\Psi_{(j)})\right]. \tag{8.18}$$

8.3 Campbell's Theorem for Stationary MPPs

Suppose that $\Psi = \Psi^*$ is time-stationary (and ergodic), with point-stationary version Ψ^0. From the inversion formula (8.15), $P(k^0 \in K) = \lambda^{-1} E\{\Psi^*[(0,1] \times K]\}$, yielding $E\{\Psi^*[(0,1] \times K]\} = \lambda P(k^0 \in K)$. This implies that the intensity measure from Campbell's theorem becomes $\nu(A \times K) = E[\Psi^*(A \times K)] = \lambda l(A) P(k^0 \in K)$, where $l(A)$ denotes Lebesgue measure {e.g., $E[\Psi^*(\mathrm{d}t \times \mathrm{d}k)] = \lambda\,\mathrm{d}t P(k^0 \in \mathrm{d}k)$}. This can be rewritten as $\nu(A \times K) = \lambda l(A) E[I(k_0^0 \in K)]$, in terms of the mark at the origin k_0^0 of Ψ^0. This yields

Theorem 8.3 [Campbell's theorem under stationarity (and ergodicity)]
For any non-negative measurable function $g = g(t, k)$,

$$E[\Psi^*(g)] = \lambda E\left[\int_{\mathbb{R}} g\big(t, k_0^0\big)\,\mathrm{d}t\right].$$

8.3.1 Little's Law

A classic application of Campbell's theorem in queueing theory is when $\Psi^* = [(t_n^*, W_n^*)]$ (two-sided) represents a time-stationary queueing model, where t_n^* is the arrival time of the n-th customer, and W_n^* their sojourn time. Using $g(t, w) = 0$, $t > 0$ and $g(t, w) = I(w > |t|)$, $t \le 0$ yields $\Psi^*(g) = \sum_{j \le 0} I(W_j^* > |t_j^*|) = L^*(0)$, denoting the time-stationary number of customers in the system at time $t = 0$ [recall (8.13)]. Campbell's theorem then yields $E[L^*(0)] = \lambda E(W^0)$, known as *Little's Law* or $L = \lambda w$.

8.3.2 The Palm–Khintchine Formula

Another application of interest for Campbell's theorem is the *Palm–Khintchine formula*: for all $n \ge 0$ and $t > 0$,

$$P[N^*(t) > n] = \lambda \int_0^t P[N^0(s) = n]\,\mathrm{d}s\,. \tag{8.19}$$

Proof: Since this result does not involve any marks, the marks can be replaced by new ones: define $k_j = \psi_{(j)}$. With these new marks Ψ^* remains stationary (and ergodic). For fixed $t > 0$ and $n \ge 0$, define $g(s, \psi) = I[0 \le s \le t,\ N(t-s) = n]$. Then

$$\Psi^*(g) = \sum_{j=1}^{N^*(t)} I\big(N^*(t_j, t] = n\big) = I[N^*(t) > n]\,,$$

where the last equality is obtained by observing that $N(t) > n$ if and only if there exists a j (unique) such that $t_j < t$ and there are exactly n more arrivals during $(t_j, t]$. Campbell's theorem then yields

$$P[N^*(t) > n] = \lambda E \int_0^t I[N^0(t-s) = n]\,\mathrm{d}s = \lambda \int_0^t P[N^0(t-s) = n]\,\mathrm{d}s\,, = \lambda \int_0^t P[N^0(s) = n]\,\mathrm{d}s\,.$$

■

8.4 The Palm Distribution: Conditioning in a Point at the Origin

Given any time-stationary MPP Ψ, its *Palm* distribution (named after C. Palm) is defined by

$$\boldsymbol{Q}(\cdot) = \lambda^{-1} E\left[\sum_{j=0}^{N(1)} I(\Psi_{(j)} \in \cdot)\right] ,$$

and the mapping taking $P(\Psi \in \cdot)$ to $\boldsymbol{Q}(\cdot)$ is called the *Palm transformation*. From (8.15), it follows that, if Ψ is also ergodic, then $\boldsymbol{Q}$ is the same as the point-stationary distribution $\boldsymbol{P}^0$ [as defined in (8.5)]. If ergodicity does not hold, however, then $\boldsymbol{Q}$ and $\boldsymbol{P}^0$ are different (in general), but the Palm distribution still yields a point-stationary distribution and any version distributed as $\boldsymbol{Q}$ is called a *Palm version* of Ψ.

Similarly, if we start with any point-stationary MPP Ψ, we can define a time-stationary distribution by

$$\boldsymbol{H}(\cdot) = \lambda E\left[\int_0^{T_0} I(\Psi_s \in \cdot)\mathrm{d}s\right] ,$$

which under ergodicity agrees with $\boldsymbol{P}^*$, but otherwise does not (in general). This mapping is called the *Palm inverse transformation* because applying it to $\boldsymbol{Q}$ yields back the original time-stationary distribution $P(\Psi \in \cdot)$. Together the two formulas are called the *Palm inversion formulas*. It should be emphasized that only in the non-ergodic case does the distinction between $\boldsymbol{Q}$ and $\boldsymbol{P}^0$ (or $\boldsymbol{H}$ and $\boldsymbol{P}^*$) become an issue because only when ergodicity holds can $\boldsymbol{Q}$ be interpreted as a point average [as defined in (8.5)], so one might ask if there is some other intuitive way to interpret $\boldsymbol{Q}$. The answer is yes: if Ψ is time-stationary, then its Palm distribution $\boldsymbol{Q}$ can be interpreted as *the conditional distribution of Ψ given a point at the origin*:

Theorem 8.4

If Ψ is time-stationary, then the Palm distribution Q can be obtained as the limiting distribution

$$\boldsymbol{Q}(\cdot) = \lim_{t\to 0} P(\Psi \in \cdot \mid t_0 \le t) ,$$

in the sense of weak convergence. Total variation convergence is obtained if Ψ is first shifted to t_0:

$$\boldsymbol{Q}(\cdot) = \lim_{t\to 0} P(\Psi_{(0)} \in \cdot \mid t_0 \le t) ,$$

in total variation.

As an immediate consequence, we conclude that (under ergodicity)

$$P(\Psi^0 \in \cdot) = \lim_{t\to 0} P(\Psi^* \in \cdot \mid t_0^* \le t)$$

(weak convergence) ,

$$P(\Psi^0 \in \cdot) = \lim_{t\to 0} P(\Psi^*_{(0)} \in \cdot \mid t_0 \le t)$$

(total variation convergence) .

Under ergodicity $\boldsymbol{P}^0$ can be viewed as the conditional distribution of $\boldsymbol{P}^*$ given a point at the origin.

A proof of such results can be carried out using inversion formulas and Khintchine–Korolyuk's Theorem 8.8.1 given in the next section which asserts that $P[N^*(t) > 0] \approx \lambda t$ as $t \to 0$.

Putting the one-sided renewal process aside, it is not true in general that $\Psi^*_{(0)}$ has a point-stationary distribution: shifting a time-stationary MPP to its initial point does not in general make it point-stationary; conditioning on $\{t_0^* \le t\}$ and taking the limit as $t \to 0$ is needed. [Recall the cyclic deterministic example in (8.12), for example.]

8.5 The Theorems of Khintchine, Korolyuk, and Dobrushin

For a Poisson process with rate λ, $P[N(t) = n] = \frac{\mathrm{e}^{-\lambda t}(\lambda t)^n}{n!}$, $n \in \mathbb{Z}_+$; thus $P[N(t) > 0] = 1 - \mathrm{e}^{-\lambda t}$ yielding (by L'Hospital's rule for example)

$$\lim_{t\to 0} \frac{P[N(t) > 0]}{t} = \lambda . \tag{8.20}$$

Similarly, $P[N(t) > 1] = 1 - \mathrm{e}^{-\lambda t}(1 + \lambda t)$ yielding

$$\lim_{t\to 0} \frac{P[N(t) > 1]}{t} = 0 . \tag{8.21}$$

Both (8.20) and (8.21) remain valid for any simple time-stationary point process, and the results are attributed to A. Y. Khintchine, V. S. Korolyuk, and R. L. Dobrushin. Any point process satisfying (8.21) is said to be *orderly*.

Theorem 8.5 (Khintchine–Korolyuk)
If Ψ is time stationary (and simple), then (8.20) holds.

Theorem 8.6 (Dobrushin)
If Ψ is time stationary (and simple), then (8.21) holds.

Proofs can easily be established using inversion formulas. For example, assume ergodicity and let $\Psi^* = \Psi$ with Ψ^0 being a point-stationary version with $F(x) = P(T^0 \le x)$ and $F_e(x) = \lambda \int_0^x [1 - F(y)]\,dy$. Then $P[N^*(t) > 0] = P(t_0^* \le t) = F_e(t)$, from the inversion formula (8.14). L'Hospital's rule then reduces the limit in (8.20) to $\lim_{t\to 0} \lambda[1 - F(t)] = \lambda$ [$F(0) = 0$ by simplicity]. Equation (8.21) can be proved from the Palm–Khintchine formula (8.19) for $n = 1$:

$$\begin{aligned} P[N^*(t) > 1] &= \lambda \int_0^t P[N^0(s) = 1]\,ds \\ &= \lambda \int_0^t P\left(t_1^0 \le s, t_2^0 > s\right) ds \\ &= \lambda \int_0^t P\left(t_1^0 \le s, t_2^0 > s\right) ds \\ &\le \lambda \int_0^t P\left(t_1^0 \le s\right) ds \le \lambda t F(t)\,; \end{aligned}$$

the result then follows since $F(0) = 0$ by simplicity.

8.6 An MPP Jointly with a Stochastic Process

In many applications an MPP Ψ is part of or interacts with some stochastic process $\boldsymbol{X} = [X(t) : t \ge 0]$, forming a joint process $(\boldsymbol{X}, \Psi)$. For example, Ψ might be the arrival times and service times to a queueing model, and $X(t)$ the state of the queue at time t. To accommodate this it is standard to assume that the sample paths of $\boldsymbol{X}$ are functions $x : \boldsymbol{R}_+ \to \boldsymbol{S}$ in the space

$$\mathcal{D}_S[0,\infty) \stackrel{\text{def}}{=} \{x :\ x \text{ is continuous from the right and has left-hand limits}\}\,,$$

endowed with the *Skorohod* topology. The state-space $\boldsymbol{S}$ can be a general complete separable metric space, but in many applications $\boldsymbol{S} = \boldsymbol{R}$, or a higher-dimensional Euclidean space. $\mathcal{D}_S[0,\infty)$ is denoted by $\mathcal{D}$ for simplicity.

Continuous from the right means thats for each $t \ge 0$: $x(t+) \stackrel{\text{def}}{=} \lim_{h\downarrow 0} x(t+h) = x(t)$, while *has left-hand limits* means that for each $t > 0$: $x(t-) \stackrel{\text{def}}{=} \lim_{h\downarrow 0} x(t-h)$ exits (and is finite). Such functions are also called *cadlag* (continue à droit, limits à gauchee) from the French.

It can be shown that such a function has, at most, countably many discontinuities, and is bounded on any finite interval $[a, b]$: $\sup_{t\in[a,b]} |x(t)| < \infty$. If t is a discontinuity, then the *jump* of X at t is defined by $x(t+) - x(t-)$.

Jointly the sample paths are pairs $(x, \psi) \in \mathcal{D} \times \boldsymbol{M}$ and this canonical space is endowed with the product topology and corresponding Borel sets. $(\boldsymbol{X}, \Psi) : \Omega \to \mathcal{D} \times \boldsymbol{M}$ formally is a mapping into the canonical space under some probability P; its distribution is denoted by $\boldsymbol{P}(\cdot) = P[(\boldsymbol{X}, \Psi) \in \cdot]$. The shifts θ_s and $\theta_{(j)}$ extend to this framework in a natural way by defining $\boldsymbol{X}_s = \theta_s \boldsymbol{X} = [X(s+t) : t \ge 0]$; $\theta_s(\boldsymbol{X}, \Psi) = (\boldsymbol{X}_s, \Psi_s)$. The notions of point and time stationarity (and ergodicity) go right through as does the notion of asymptotic stationarity, and the inversion formulas also go through. For example, the functional form of the inversion formulas in the canonical framework are:

$$\boldsymbol{E}^0[f(\boldsymbol{X}, \Psi)] = \lambda^{-1} \boldsymbol{E}^* \left[\sum_{j=0}^{N(t)} f(\boldsymbol{X}_{(j)}, \Psi_{(j)}) \right], \tag{8.22}$$

$$\boldsymbol{E}^*[f(\boldsymbol{X}, \Psi)] = \lambda \boldsymbol{E}^0 \left[\int_0^{T_0} f(\boldsymbol{X}_s, \Psi_s)\,ds \right]. \tag{8.23}$$

A point-stationary version is denoted by $(\boldsymbol{X}^0, \Psi^0)$, and has the property that $\boldsymbol{X}^0$ can be broken up into a stationary sequence of cycles $\mathcal{C}_n = [X^0(t_n^0 + t) : 0 \le t < T_n^0]$, $n \in \boldsymbol{Z}_+$, with cycle lengths being the interevent times $\{T_n\}$.

A time-stationary version is denoted by $(\boldsymbol{X}^*, \Psi^*)$, and $\boldsymbol{X}^*$ is a stationary stochastic process.

The two-sided framework goes through by letting $x : \boldsymbol{R} \to \boldsymbol{S}$ and using the extended space $\mathcal{D}(-\infty, +\infty)$.

8.6.1 Rate Conservation Law

Given a asymptotically stationary (and ergodic) pair $(\boldsymbol{X}, \Psi)$, with $\boldsymbol{X}$ real-valued, assume also that the sample paths of $\boldsymbol{X}$ are right differentiable, $x'(t) = \lim_{h \downarrow 0}[X(t+h) - x(t)]/x(t)$ exists for each t. Further assume that the points t_n of Ψ include all the discontinuity points (jumps) of $\boldsymbol{X}$ (if any); if for some t it holds that $X(t-) \neq X(t+)$, then $t = t_n$ for some n. Noting that (wp1) $\boldsymbol{E}^*[X'(0)] = \lim_{t\to\infty} \frac{1}{t}\int_0^t X'(s)\,\mathrm{d}s$ and $\boldsymbol{E}^0[X(0+) - X(0-)] = \lim_{n\to\infty} \frac{1}{n}\sum_{j=1}^n [X(t_j+) - X(t_j-)]$, average jump size, the following is known as *Miyazawa's rate conservation law* (RCL):

Theorem 8.7

If $\boldsymbol{E}^*|X'(0)| < \infty$ and $\boldsymbol{E}^0|X(0-) - X(0+)| < \infty$, then

$$\boldsymbol{E}^*(X'(0)) = \lambda \boldsymbol{E}^0[X(0-) - X(0+)]\,.$$

The time-average right derivative equals the arrival rate of jumps multiplied by the (negative of) the average jump size.

As an easy example, for $x \geq 0$ let $X(t) = [A(t) - x]_+$, where $A(t)$ is the forward recurrence time for Ψ. Then $A'(t) = -1$ and $X'(t) = -I[A(t) > x]$. Jumps are of the form $X(t_n+) - X(t_n-) = (T_n - x)_+$. The RCL then yields $P[A^*(0) > x] = \lambda E(T_0^0 - x)_+ = 1 - F_e(x)$. The RCL has many applications in queueing theory. For example consider Example 6 from Sect. 8.1.8 and let $X(t) = V^2(t)$. Then $V'(t) = -I[V(t) > 0]$ so $X'(t) = -2V(t)$ and $X(t_n+) - X(t_n-) = 2S_n D_n + S_n^2$; the RCL thus yields *Brumelle's formula*, $E(V) = \lambda E(SD) + \lambda E(S^2)/2$. (Here $SD = S_0^0 D_0^0$.) A sample-path version of the RCL can be found in [8.1].

8.7 The Conditional Intensity Approach

Motivated by the fact that $\{N(t) - \lambda t : t \geq 0\}$ forms a mean-zero martingale for a time-homogenous Poisson process with rate λ, the *conditional intensity* $\lambda(t)$ of a point process (when it exists) satisfies the property that $\{N(t) - \int_0^t \lambda(s)\,\mathrm{d}s\}$ forms a mean-zero martingale. The framework requires a history $\mathcal{F}_t$ supporting $N(t)$ and a heuristic definition is then $\lambda(t)\,\mathrm{d}t = E(N(\mathrm{d}t) \mid \mathcal{F}_t)$ which asserts that for each t the conditional expected number of new arrivals in the next $\mathrm{d}t$ time units, conditional on the history up to time t, is equal to $\lambda(t)\,\mathrm{d}t$. For a time-homogenous Poisson process at rate λ, $\lambda(t) = \lambda$; $E[N(\mathrm{d}t) \mid \mathcal{F}_t] = \lambda\,\mathrm{d}t$ due to stationary and independent increments; but for general point processes, $\lambda(t)$ (if it exists) depends on the past evolution (before time t).

A *non-stationary* Poisson process is a simple and very useful example, where the arrival rate λ changes over time, but $N(t)$ still has a Poisson distribution. A common example of this is when $\lambda(t)$ is a deterministic alternating function [e.g., $\lambda(t) = 2$ during the first 12 hours of each day, and $\lambda(t) = 1$ during the second 12 hours]. Intuitively then, a point process with an intensity is a generalization of a non-stationary Poisson process allowing for more complicated correlations over time.

Given any MPP Ψ, if $E[N(t)] < \infty$, $t \geq 0$, then $\{N(t)\}$ is always a non-negative right-continuous submartingale (with respect to its internal history), so the *Doob–Meyer decomposition* yields a right-continuous (and predictable) increasing process $\Lambda(t)$ (called the *compensator*) for which $\{N(t) - \Lambda(t)\}$ forms a mean-zero martingale. If $\Lambda(t)$ is of the form $\Lambda(t) = \int_0^t \lambda(s)\,\mathrm{d}s$, $t \geq 0$, where $\lambda(t)$ satisfies the regularity conditions of being non-negative, measurable, adapted to $\mathcal{F}_t$ and locally integrable [$\int_A \lambda(s)\,\mathrm{d}s < \infty$ for all bounded sets A], then $\lambda(t)$ is called the conditional intensity of the point process, or the *intensity* for short. (A predictable version of the intensity can always be chosen; this is done so by convention.) By the martingale property, an intensity can equivalently be defined as a stochastic process $\{\lambda(t)\}$ that satisfies the aforementioned regularity conditions and satisfies for all $s \leq t$

$$E[N(s,t] \mid \mathcal{F}_s] = E\left[\int_s^t \lambda(u)\,\mathrm{d}u \mid \mathcal{F}_s\right]\,.$$

Not all point processes admit an intensity. For example, a deterministic renewal process does not admit an intensity. The only part of $\mathcal{F}_t$ that is relevant for predicting the future of a renewal process is the backwards recurrence time $B(t)$, and if the interarrival time distribution F has a density f, then the renewal process admits an intensity $\lambda(t) = f[B(t-)]/\bar{F}[B(t-)]$, the hazard rate function of F evaluated at $B(t-)$. The fact that a density is needed illustrates the general fact that the existence of

an intensity requires some smoothness in the distribution of points over time.

Incorporating marks into an intensity amounts to making rigorous the heuristic $\lambda(t, \mathrm{d}k)\mathrm{d}t = E[\Psi(\mathrm{d}t \times \mathrm{d}k)|\mathcal{F}_t]$, for some *intensity kernal* $\lambda(t, \mathrm{d}k)$ which in integral form becomes

$$E\Big[\int H(t,k)\Psi(\mathrm{d}t \times \mathrm{d}k)\Big] = E\Big[\int H(t,k)\lambda(t, \mathrm{d}k)\Big],$$

for non-negative and predictable H.

Here $\lambda(t, \mathrm{d}k)$ is a measure on the mark space for each t. Equivalently such an intensity kernel must have the properties that, for each mark set K, the process $\{\lambda(t, K) : t \geq 0\}$ is adapted to $\{\mathcal{F}_t\}$ and serves as an intensity for the thinned point process (defined by its counting process) $N_K(t) = \Psi[(0, t] \times K]$.

An elementary example is given by the compound Poisson process at rate λ with (independent of its points) iid jumps $k_n = X_n$ with some distribution $\mu(\mathrm{d}x) = P(X \in \mathrm{d}x)$. Then $\lambda(t, \mathrm{d}x) = \lambda\mu(\mathrm{d}x)$.

8.7.1 Time Changing to a Poisson Process

In some applications, it is desirable to construct (or simulate) a point process with a given intensity or corresponding compensator $\Lambda(t) = \int_0^t \lambda(s)\mathrm{d}s$. This can generally be accomplished by defining $N(t) = M[\Lambda(t)]$, where $M(t)$ is the counting process for an appropriate time-homogenous Poisson process at rate $\lambda = 1$. Conversely, the Poisson process can be retrieved by inverting the time change; $M(t) = N[\Lambda^{-1}(t)]$.

Theorem 8.8

Consider the counting process $\{N(t)\}$ of a (simple) MPP with intensity $\{\lambda(t)\}$ that is strictly positive and bounded. [Also assume that $\Lambda(t) \to \infty$, as $t \to \infty$, wp1.] Then $M(t) \stackrel{\text{def}}{=} N[\Lambda^{-1}(t)]$ defines a time-homogenous Poisson process at rate $\lambda = 1$.

There are some extensions of this result that incorporates the marks, in which case the time-homogenous Poisson process is replaced by a compound Poisson process.

8.7.2 Papangelou's Formula

Suppose that Ψ is asymptotically stationary (and ergodic), and that Ψ^* (two-sided) admits a conditional intensity $\lambda(t)$ with respect to a history $\mathcal{F}_t$.

Proposition 8.4 (Papangelou's formula)

For all non-negative random variables $X \in \mathcal{F}_{0-} \stackrel{\text{def}}{=} \cup_{t<0} \mathcal{F}_t$

$$\boldsymbol{E}^*[\lambda(0)X] = \lambda \boldsymbol{E}^0(X)\,.$$

In other words, conditional on $\mathcal{F}_{0-}$, $\boldsymbol{P}^0$ is absolutely continuous with respect to $\boldsymbol{P}^*$, $\boldsymbol{P}^0 \ll \boldsymbol{P}^*$, having Radon–Nikodým derivative

$$\frac{\mathrm{d}\boldsymbol{P}^0}{\mathrm{d}\boldsymbol{P}^*}\,|\mathcal{F}_{0-} = \frac{\lambda(0)}{\lambda}\,.$$

Note that, when $X = 1$, the basic fact that $\boldsymbol{E}^*(\lambda(t)) = \lambda$ is retrieved. In many applications, $\mathcal{F}_t$ supports a stochastic process $\boldsymbol{X}$ jointly with Ψ in which case, letting $X = X(0-)$, Papangelou's formula yields $\boldsymbol{E}^*[\lambda(0)X(0-)] = \lambda \boldsymbol{E}^0[X(0-)]$. For example in the single-server queue Example 6 from Sect. 8.1.8, letting $X(t) = I[V(t) \leq x]$ yields $\boldsymbol{E}^*\{\lambda(0)I[V(0-) \leq x]\} = \lambda \boldsymbol{P}^0[V(0-) \leq x] = \lambda P(D \leq x)$. If arrivals are Poisson $[\lambda(t) = \lambda]$, this reduces to $P(V \leq x) = P(D \leq x)$ illustrating *Poisson arrivals see time averages* (PASTA), which asserts that when arrival times are Poisson for a queueing process $\{X(t)\}$ and satisfy a lack of anticipation condition (LAC), then the distribution of $X(0-)$ is the same under $\boldsymbol{P}^0$ and $\boldsymbol{P}^*$. LAC is defined as: for each $t \geq 0$ the future increments $\{N(t+s) - N(t) : s \geq 0\}$ are independent of the joint past $\{\{X(s) : s \leq t\}, \{N(s) : s \leq t\}\}$. Recalling the definition of $\boldsymbol{P}^0$ and $\boldsymbol{P}^*$ as Cesàro averages, PASTA says that if arrivals are Poisson then

the proportion of arrivals who find the queueing process in a given state is equal to the proportion of time the system is in that state;

$$\lim_{n\to\infty} \frac{1}{n} \sum_{j=1}^{n} I[X(t_j-) \in A] = \lim_{t\to\infty} \frac{1}{t} \int_0^t I[X(s) \in A]\mathrm{d}s\,.$$

Although its origins and primary applications are in queueing theory, PASTA can be applied to any joint pair $(\boldsymbol{X}, \Psi)$ for which the points of Ψ form a Poisson process satisfying LAC.

8.8 The Non-Ergodic Case

The assumption of ergodicity can be relaxed to allow for a stationary but non-ergodic framework. The key is in conditioning first on the *invariant σ-field* of $\mathbb{M}$,

$$\Im \stackrel{\text{def}}{=} \{\mathcal{E} \subset \mathbb{M} : \theta_t^{-1}\mathcal{E} = \mathcal{E},\ t \geq 0\}\,,$$

where $\theta_t^{-1}\mathcal{E} = \{\psi \in \mathbb{M} : \psi_t \in \mathcal{E}\}$ and the $\mathcal{E}$ are restricted to be Borel sets. Ergodicity is the case when $\boldsymbol{P}(\mathcal{E}) = 0$ or 1 for all $\mathcal{E} \in \Im$. Conditional expectation is denoted by $\boldsymbol{E}_{\Im}(X) \stackrel{\text{def}}{=} \boldsymbol{E}(X|\ \Im)$, and so on. A typical example of an invariant set is $\mathcal{E}_2 = \{\psi \in \mathbb{M} :\ \lim_{t\to\infty} N(t)/t = 2\}$, the set of all ψ with arrival rate exactly 2; it follows immediately that $\theta_t^{-1}\mathcal{E}_2 = \mathcal{E}_2$ because shifting a point process does not effect its long-term arrival rate.

A typical example of a stationary but non-ergodic MPP is a mixture of two Poisson processes, one at rate 1 and one at rate 2: flip a fair coin once. If it lands heads, then choose Ψ as a Poisson process at rate 1; if it lands tails, then choose Ψ as a Poisson process at rate 2. In this case $\boldsymbol{P}(\mathcal{E}_2) = 0.5$, Ψ is non-ergodic.

Inversion formulas still hold between Ψ^* and Ψ^0 if one conditions on $\Im$ first. For example, letting $\lambda_{\Im} \stackrel{\text{def}}{=} \boldsymbol{E}^*_{\Im}[N(1)]$, it holds that

$$P(t_0^* > x) = \boldsymbol{E}^0\{\lambda_{\mathrm{i}} \boldsymbol{E}^0_{\Im}(T_0 - x)_+\}\,. \tag{8.24}$$

In the above Poisson process case, $\lambda_{\Im} = 1$ if the coin lands heads, or 2 if it lands tails, and (8.24) reduces to

$$P(t_0^* > x) = \frac{(\mathrm{e}^{-x} + \mathrm{e}^{-2x})}{2}\,.$$

If the mixture was for two renewal processes with interarrival time distributions F_1 and F_2 respectively, then (8.24) reduces to

$$P(t_0^* > x) = \frac{[\overline{F}_{1,e}(x) + \overline{F}_{2,e}(x)]}{2}\,,$$

involving the two stationary excess distributions. The general inversion formula from $\boldsymbol{P}^0$ to $\boldsymbol{P}^*$ in functional form becomes

$$\boldsymbol{E}^*[f(\Psi)] = \boldsymbol{E}^0\left\{\lambda_{\mathrm{i}} \boldsymbol{E}^0_{\Im}\left[\int_0^{T_0} f(\Psi_s)\,\mathrm{d}s\right]\right\}\,.$$

8.9 MPPs in $\mathbb{R}^d$

When a point process has points in a higher-dimensional space such as $\mathbb{R}^d$, then the theory becomes more complicated. The main reason for this is that there is no longer a natural ordering for the points, e.g., there is no "next" point as is the case on $\mathbb{R}$. So "shifting to the j-th point" to obtain $\Psi_{(j)}$ is no longer well-defined. To make matters worse, point Cesàro limits as in (8.5) depend upon the ordering of the points. Whereas when $d = 1$ there is a one-to-one correspondence between stationary sequences of non-negative RVs (interarrival times) and point-stationary point processes, in higher dimensions such a simple correspondence is elusive. A good example to keep in mind is mobile phone usage, where the points (in $\mathbb{R}^2$ for simplicity) denote the locations of mobile phone users at some given time, and for each user the marks might represent whether a phone call is in progress or not. As in one dimension, it would be useful to consider analyzing this MPP from two perspectives: from the perspective of a "typical" user, and from the perspective of a "typical" spatial position in $\mathbb{R}^2$. For example, one might wish to estimate the average distance from a typical user to a base station, or the average distance from a typical position to a user with a call in progress. A mobile phone company trying to decide where to place some new base stations would benefit by such an analysis.

Some of the multidimensional complications can be handled, and initially it is best to use the measure approach from Sect. 8.1.5 to define an MPP. Starting with $\psi = \{(x_j, k_j)\}$, where $x_j \in \mathbb{R}^d$, it can equivalently be viewed as a σ-finite $\mathbb{Z}_+$-valued measure

$$\psi = \sum_j \delta_{(x_j,k_j)}\,,$$

on (the Borel sets of) $\mathbb{R}^d \times \mathbb{K}$.

The counting process is replaced by the counting measure $N(A) =$ the number of points that fall in the Borel set $A \subset \mathbb{R}^d$, and it is assumed that $N(A) < \infty$ for all bounded A. Simple means that the points x_j are distinct; $N(\{x\}) \leq 1$ for all $x \in \mathbb{R}^d$.

For any x, the shift mapping $\theta_x\psi = \psi_x$ is well defined via $\psi_x(A \times K) = \psi(A + x,\, K)$, where $A + x = \{y + x : y \in A\}$.

8.9.1 Spatial Stationarity in $\mathbb{R}^d$

Analogous to time stationarity in $\mathbb{R}$, the definition of *spatial stationarity* is that Ψ_x has the same distribution for all $x \in \mathbb{R}^d$, and as in (8.8) such MPPs can be viewed as arising as a Cesàro average over space, as follows.

Let B_r denote the d-dimensional ball of radius r centered at 0. Then (with l denoting Lebesgue measure in $\mathbb{R}^d$) a spatially stationary MPP is obtained via

$$P(\Psi^* \in \cdot) \stackrel{\text{def}}{=} \lim_{r\to\infty} \frac{1}{l(B_r)} \int_{B_r} P(\Psi_x \in \cdot)\,\mathrm{d}x \,.$$

In essence, we have randomly chosen our origin from over all of space.

Ergodicity means that the flow of shifts $\{\theta_x\}$ is ergodic. Stationarity implies that $E[N(A)] = \lambda l(A)$ for some λ, called the *mean density*; it can be computed by choosing (say) A as the unit hypercube $H = [0,1]^d$; $\lambda = E[N(H)]$, the expected number of points in any set of volume 1.

An important example in applications is the Poisson process in $\mathbb{R}^d$. $N(A)$ has a Poisson distribution with mean $\lambda l(A)$ for all bounded Borel sets A, and $N(A_1)$ and $N(A_2)$ are independent if $A_1 \cap A_2 = \emptyset$.

8.9.2 Point Stationarity in $\mathbb{R}^d$

Coming up with a definition of point stationarity, however, is not clear, for what do we mean by "randomly selecting a point as the origin", and even if we could do just that what stationarity property would the resulting MPP have? (For example, even for a spatially stationary two-dimensional Poisson process, if a point is placed at the origin, it is not clear in what sense such a point process is stationary.) One would like to be able to preserve the distribution under a point shift, but which point can be chosen as the one to shift to as the new origin? Under ergodicity, one could define $P(\Psi^0 \in \cdot)$ as a sample-path average

$$P(\Psi^0 \in \cdot) \stackrel{\text{def}}{=} \lim_{r\to\infty} \frac{1}{N(B_r)} \sum_{x\in B_r} I(\Psi_x \in \cdot), \ \text{wp1} \,.$$

It turns out that this can be improved to be more like (8.5) as follows. Let p_n denote the n-th point hit by B_r as $r \to \infty$ (if there are ties just order lexicographically). For each sample path of Ψ, $\{p_n\}$ is a permutation of $\{x_n\}$. Define

$$P(\Psi^0 \in \cdot) \stackrel{\text{def}}{=} \lim_{n\to\infty} \frac{1}{n} \sum_{j=1}^{n} P(\Psi_{p_j} \in \cdot) \,.$$

Another approach involves starting with the spatially stationary MPP Ψ^* and defining $P(\Psi^0 \in \cdot)$ by inversion in the spirit of (8.15) and the Palm transformation, replacing a "unit of time" by any set A with volume 1, such as the unit hypercube $H = (0,1]^d$:

$$P(\Psi^0 \in \cdot) = \lambda^{-1} E\left[\sum_{x\in H} I(\Psi_x^* \in \cdot)\right] \,. \tag{8.25}$$

Under ergodicity all these methods yield the same distribution. Ψ^0 has the property that there is a point at the origin, and its distribution is invariant under a two-step procedure involving an external randomization followed by a random point shift as follows (see Chapt. 9 of *Thorisson* [8.2]):

> *First, randomly place a ball B_r of any fixed radius $r > 0$ over the origin, e.g., take U distributed uniformly over the open ball B_r and consider the region $R = B_r + U$. There is at least one point in R, the point at the origin, but in any case let $n = N(R)$ denote the total number. Second, randomly choose one of the n points (e.g., according to the discrete uniform distribution) and shift to that point as the new origin. This shifted* MPP *has the same distribution $P(\Psi^0 \in \cdot)$ as it started with.*

A recent active area of research is to determine whether or not one can achieve this invariance without any randomization. In other words is there an algorithm for choosing the "next point" to move to only using the sample paths of Ψ^0? In one dimension we know this is possible; always choose (for example) the point to the right (or left) of the current point. It turns out that in general this can be done (*Heveling* and *Last* [8.3]), but what is still not known is whether it can be done in such a way that all the points of the point process are exhaustively visited if the algorithm is repeated (as is the case in one dimension). For the Poisson process with $d = 2$ or 3 simple algorithms have indeed been found (*Ferrari* et al. [8.4]).

8.9.3 Inversion and Voronoi Sets

There is an analogue for the inverse part of the formula (8.25) in the spirit of (8.14), but now there is no "cycle" to average over so it is not clear what to do. It turns out that a random *Voronoi cell* is needed. For an MPP ψ with points $\{x_j\}$, for each point x_i define the

Voronoi cell about x_i by

$$V_{x_i}(\psi) = \{x \in \boldsymbol{R}^d : ||x - x_i|| < ||x - x_j|| \text{ , for all points } x_j \neq x_i\} ,$$

the set of elements in $\boldsymbol{R}^d$ that are closer to the point x_i than they are to any other point of ψ. For an MPP, this set is a random set containing x_i and of particular interest is when $\Psi = \Psi^0$ and $x_i = 0$, the point at the origin. We denote this Voronoi cell by V_0. It turns out that $E[l(V_0)] = \lambda^{-1}$, and

$$P(\Psi^* \in \cdot) = \lambda E\left[\int_{V_0} I\left(\Psi_x^0 \in \cdot\right) \mathrm{d}x\right] . \tag{8.26}$$

The Voronoi cell V_0 plays the role that the interarrival time $T_0^0 = t_1^0$ does when $d = 1$. But, even when $d = 1$, V_0 is not the same as an interarrival time; instead it is given by the random interval $V_0 = (-T_{-1}^0/2, T_0^0/2) = (t_{-1}^0/2, t_1^0/2)$ which has length $l(V_0) = (t_1^0 + |t_{-1}^0|)/2$ and hence mean λ^{-1}. It is instructive to look closer at this for a Poisson process at rate λ, for then $l(V_0)$ has an Erlang distribution with mean λ^{-1}.

In the mobile phone context, if the points x_i are now the location of base stations (instead of phones) then V_{x_i} denotes the service zone for the base station, the region about x_i for which x_i is the closest base station. Any mobile user in that region would be best served (e.g., minimal distance) by being connected to the base at x_i. Thus all of space can be broken up into a collection of disjoint service zones corresponding to the Voronoi cells.

Finally, analogous to the $d = 1$ case, starting with a spatially stationary MPP it remains valid (in a limiting sense as in Theorem 8.8.4) that the distribution of Ψ^0 can be obtained as the conditional distribution of Ψ^* given a point at the origin. For example, placing a point at the origin for a spatially stationary Poisson process Ψ^* in $\mathbb{R}^d$ yields Ψ^0.

9. Modeling and Analyzing Yield, Burn-In and Reliability for Semiconductor Manufacturing: Overview

The demand for proactive techniques to model yield and reliability and to deal with various infant mortality issues are growing with increased integrated circuit (IC) complexity and new technologies toward the nanoscale. This chapter provides an overview of modeling and analysis of yield and reliability with an additional burn-in step as a fundamental means for yield and reliability enhancement.

After the introduction, the second section reviews yield modeling. The notions of various yield components are introduced. The existing models, such as the Poisson model, compound Poisson models and other approaches for yield modeling, are introduced. In addition to the critical area and defect size distributions on the wafers, key factors for accurate yield modeling are also examined. This section addresses the issues in improving semiconductor yield including how clustering may affect yield.

The third section reviews reliability aspects of semiconductors such as the properties of failure mechanisms and the typical bathtub failure rate curve with an emphasis on the high rate of early failures. The issues for reliability improvement are addressed.

The fourth section discusses several issues related to burn-in. The necessity for and effects of burn-in are examined. Strategies for the level and type of burn-in are examined. The literature on optimal burn-in policy is reviewed. Often percentile residual life can be a good measure of performance in addition to the failure rate or reliability commonly used.

The fifth section introduces proactive methods of estimating semiconductor reliability from yield information using yield–reliability relation models. Time-dependent and -independent models are discussed.

The last section concludes this chapter and addresses topics for future research and development.

Since Jack Kilby of Texas Instruments invented the first integrated circuit (IC) in 1958, the semiconductor industry has consistently developed more complex chips at ever decreasing cost. Feature size has shrunk by 30% and die area has grown by 12% every three years [9.1]. The number of transistors per chip has grown exponentially while semiconductor cost per function has been reduced at the historical rate of 25% per year. As shown in Table 9.1, the semiconductor market will reach $213 billion in 2004, which represents 28.5% growth over

Table 9.1 Industry sales expectations for IC devices [9.2]

Device type	Billion dollars				Percent growth			
	2003	2004	2005	2006	03/02	04/03	05/04	06/05
Discretes	13.3	16.0	17.0	16.7	8.1	20.2	6.2	−2.0

Total	166.4	213.6	231.7	230.0	18.3	28.5	8.5	−0.7

[a] A growth rate is not meaningful to show since WSTS included actuators from 2003

2003. Growth of 8.5% is forecasted for 2005, followed by virtually zero growth in 2006. In 2007, however, another recovery cycle is expected to begin with market growth in the 10% range.

Clearly, yield and reliability are two of the cornerstones of successful IC manufacturing as they measure semiconductor facility profitability and post-manufacturing device failures. Yield and reliability have played a key role in many aspects of semiconductor operations such as determining the cost of new chips under development, forecasting time-to-market, defining the maximum level of integration possible and estimating the number of wafers to start with. Traditionally, reactive techniques have been used to analyze yield and reliability, and an investigation was launched to determine the cause of yield loss once a low yield was observed during production. Stress testing and failure analysis were commonly performed at the end of the manufacturing line [9.3, 4]. However, as the rapid increase in IC complexity has resulted in multi-billion-dollar semiconductor fabrication facilities, IC manufacturers struggle to obtain a better return on their investment by introducing new process technologies and materials at an accelerated rate to satisfy narrowing market windows. Given this trend, the demand for proactive techniques has strengthened in order to achieve the desired yield and reliability goals early in the process or even before production begins. The demand for these proactive techniques will be even bigger in emerging nanotechnology, which is known to have low yield and reliability [9.5, 6].

Yield and reliability modeling and analysis is a means of achieving proactive yield and reliability management. The purpose of this paper is to review the modeling and analysis of yield and reliability with an additional burn-in step. The importance of yield modeling is emphasized for obtaining better yields quickly after new technologies are introduced. In particular, the relationship between yield, burn-in and reliability will be thoroughly addressed. The relation model between yield and reliability can aid in design for manufacturability (DFM) by improving device layouts for better manufacturing yield and reliability during their early development prior to manufacturing.

9.1 Semiconductor Yield

Yield in semiconductor technology is the most important index for measuring success in the IC business. In general, yield is defined as the fraction of manufactured devices that meet all performance and functionality specifications. Higher yield tends to produce more chips at the same cost, thus allowing prices to decrease.

In this section, we first decompose overall yield into several components. Then, the literature on yield models is reviewed, focusing mainly on the random defect yield model. Traditional Poisson and compound Poisson yield models are thoroughly reviewed as well as some more recent yield models. Finally, issues related to proactive

yield improvement are discussed from the viewpoint of yield modeling.

9.1.1 Components of Semiconductor Yield

The overall yield Y_{overall} of a semiconductor facility can be broken down into several components: wafer process yield Y_{process}, wafer probe yield Y_{probe}, assembly yield Y_{assembly} and final test yield $Y_{\text{final test}}$ [9.7]. Wafer process yield, which is synonymous with line or wafer yield, is the fraction of wafers that complete wafer fabrication. Wafer probe yield is the fraction of chips on yielding wafers that pass the wafer probe test. The terms die yield, chip yield or wafer sort yield are used interchangeably with wafer probe yield. Overall yield is the product of these components, written as

$$Y_{\text{overall}} = Y_{\text{process}} Y_{\text{probe}} Y_{\text{assembly}} Y_{\text{final test}} .$$

9.1.2 Components of Wafer Probe Yield

Most semiconductor industries focus on improving the wafer probe yield, which is the bottleneck of overall yield. The importance of wafer probe yield to financial success is discussed in [9.8, 9]. Wafer probe yield is decomposed into functional yield $Y_{\text{functional}}$ and parametric yield $Y_{\text{parametric}}$ such that

$$Y_{\text{probe}} = Y_{\text{functional}} Y_{\text{parametric}} .$$

Parametric yield refers to the quantification of IC performance that is caused by process parameter variations. The designer attempts to increase parametric yield using several tools to check the design for process and parameter variations. Commonly used methods include corner analysis, Monte Carlo analysis, and the response surface methodology [9.10]. Corner analysis is the most widely used method due to its simplicity. The designer determines the worst-case corner under which the design can be expected to function. Then, each corner is simulated and the output is examined to ascertain whether or not the design performs as required. The disadvantages of corner analysis include the possibility that a design may function well at the corners but fail in between or that the designer may not know what the corners are. In Monte Carlo analysis, samples are generated to estimate yield based on the distributions of the process parameters. A disadvantage of Monte Carlo analysis is that the designer may not know if an increased yield is due to a change in the design parameters or is due to Monte Carlo sampling error. Another disadvantage is that a complete rerun of the analysis is required if the design variables are changed. With the response surface methodology, a set of polynomial models are created from the design of experiments that approximate the original design. These models are run so many times that the sampling error is reduced to nearly zero. A disadvantage of the response surface methodology arises from errors existing as a result of differences between the polynomial models and the original design.

Functional yield is related to manufacturing problems such as particulate matter, mechanical damage, and crystalline defects which cause dice not to function. Therefore, functional yield is a reflection of the quality of the manufacturing process and is often called the manufacturing yield [9.7, 11] or the catastrophic yield [9.12, 13]. In general, functional yield can be further partitioned into three categories: repeating yield $Y_{\text{repeating}}$, systematic yield $Y_{\text{systematic}}$ and random-defect-limited yield Y_{random} [9.14]:

$$Y_{\text{functional}} = Y_{\text{repeating}} Y_{\text{systematic}} Y_{\text{random}} .$$

Repeating yield is limited to reticle defects that occur when there are multiple dies on a reticle. Once reticle defects are identified using a pattern-recognition algorithm, repeating yield is calculated by the ratio of the number of dies without repeating defects to the total number of dies per wafer [9.9]. Then, repeating yield is extracted from functional yield, and tile yield is defined by

$$Y_{\text{tile}} = \frac{Y_{\text{functional}}}{Y_{\text{repeating}}} = Y_{\text{systematic}} Y_{\text{random}} .$$

Systematic yield is limited to nonrandom defects affecting every die in some region of the wafer. To decompose Y_{tile} into $Y_{\text{systematic}}$ and Y_{random}, $Y_{\text{systematic}}$ is assumed to be constant regardless of die size since, in a mature process, $Y_{\text{systematic}}$ is known and controllable and is often equal to one. Then, a model is selected to relate Y_{random} to the die area and the density of the random defects, and curve fitting is used with

$$\ln Y_{\text{tile}} = \ln Y_{\text{systematic}} + \ln Y_{\text{random}}$$

to estimate $Y_{\text{systematic}}$ and the parameters of a model for Y_{random} [9.9].

9.1.3 Modeling Random Defect Yield

Since the early 1960s, researchers have devoted extensive work to developing yield models that relate the mean number of random defects in a device to the device yield.

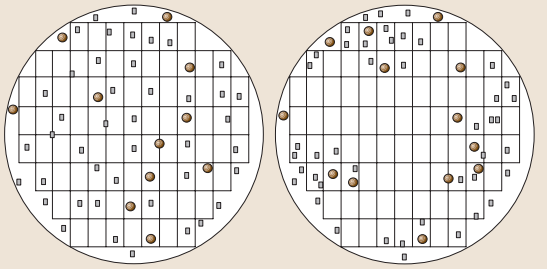

Fig. 9.1 Comparison of defect clustering for the same defect density [9.15]

The basic assumption is that yield is a function of the device area and the average number of yield defects per unit area.

During the manufacturing process, random defects can be introduced at any one of hundreds of process steps. Not all defects necessarily cause device failures. A defect that is of sufficient size and/or occurs in a place that results in an immediate device failure is called a fatal defect [9.16, 17], killer defect [9.18–22] or yield defect [9.23–27]. On the other hand, a defect that is either too small or located in a position that does not cause an immediate failure is called a latent defect, nonfatal defect or reliability defect. In this chapter, we will use the terms yield defect and reliability defect.

Poisson Model

For the purpose of yield modeling, the only yield defects that are of interest are those that can be detected by a manufacturing yield test. Let N_y be the number of yield defects introduced during fabrication on a device of area A. Assuming that the defects are randomly distributed and the occurrence of a defect at any location is independent of the occurrence of any other defect, the probability of a device having k yield defects is calculated by the Poisson probability distribution:

$$P_{\text{Poisson}}(k) = P(N_y = k) = \frac{\mathrm{e}^{-\lambda_y}\lambda_y^k}{k!}\,, \quad k = 0, 1, 2\,, \tag{9.1}$$

where λ_y is the average number of yield defects with $\lambda_y = E(N_y)$. Then, the corresponding Poisson yield is obtained by

$$Y_{\text{Poisson}} = P_{\text{Poisson}}(0) = \mathrm{e}^{-\lambda_y}\,, \tag{9.2}$$

where $\lambda_y = AD_y$, and D_y is the average number of yield defects per unit area.

Compound Poisson Model

Often defects on ICs are not uniformly distributed but tend to cluster. When defects are clustered in certain areas, the Poisson distribution is too pessimistic and the compound Poisson process is used, given by

$$P_{\text{compound}}(k) = P(N_y = k) = \int \frac{\mathrm{e}^{-AD}(AD)^k}{k!} f(D)\mathrm{d}D\,, \quad k = 0, 1, 2\,,$$

where $f(D)$ is the distribution of the defect density. The corresponding yield expression is

$$Y_{\text{compound}} = P_{\text{compound}}(0) = \int \mathrm{e}^{-AD} f(D)\mathrm{d}D\,.$$

Figure 9.1 compares two different degrees of defect clustering for the same average defect density. The left one, with low clustering, belongs more to the Poisson model and the right one, with high clustering, belongs more to the compound Poisson model.

Several distributions such as the symmetric triangle, exponential, uniform, gamma, Weibull and inverse Gaussian have been suggested for $f(D)$ [9.7, 16, 28, 29]. If D follows a uniform distribution in $[0, 2D_y]$, then the corresponding yield can be obtained by

$$Y_{\text{uniform}} = \int_0^{2D_y} \mathrm{e}^{-AD}\frac{1}{2D_y}\mathrm{d}D = \frac{1-\mathrm{e}^{-2\lambda_y}}{2\lambda_y}\,.$$

In the case where D follows a triangle distribution that approximates a normal distribution, the resulting model is called the Murphy's yield and is derived by

$$\begin{aligned} Y_{\text{Murphy's}} &= \int_0^{D_y} \mathrm{e}^{-AD}\frac{D}{D_y^2}\mathrm{d}D \\ &\quad + \int_{D_y}^{2D_y} \mathrm{e}^{-AD}\left(2-\frac{D}{D_y}\right)\frac{1}{D_y}\mathrm{d}D \\ &= \left(\frac{1-\mathrm{e}^{-\lambda_y}}{\lambda_y}\right)^2\,. \end{aligned}$$

For an exponential distribution of D, the model is called the Seed's yield and is given by

$$Y_{\text{Seed's}} = \int_0^{\infty} \mathrm{e}^{-AD}\frac{\mathrm{e}^{-D/D_y}}{D_y}\mathrm{d}D = \frac{1}{1+\lambda_y}\,.$$

For the case of the Weibull distribution, the corresponding yield is [9.29]

$$Y_{\text{Weibull}} = \int_0^\infty \mathrm{e}^{-AD}\frac{\alpha}{\beta^\alpha}D^{\alpha-1}\mathrm{e}^{-(D/\beta)^\alpha}\,\mathrm{d}D = \sum_{k=0}^{\infty}(-1)^k\frac{(AD_y)^k}{k!}\frac{\Gamma(1+k/\alpha)}{\Gamma^k(1+1/\alpha)}\,.$$

Also, if $f(D)$ is the inverse Gaussian distribution, then the yield is [9.29]

$$Y_{\text{inverse-Gaussian}} = \int_0^\infty \mathrm{e}^{-AD}\sqrt{\frac{\phi}{2\pi}}x^{-3/2}\exp\left(-\frac{\phi(D-D_y)^2}{2D_y^2D}\right)\mathrm{d}D = \exp\left\{\phi\left[1-\left(1+\frac{2AD_y}{\phi}\right)^{1/2}\right]\right\}\,.$$

When D follows a gamma distribution, the resulting model is called the negative binomial yield, which is derived as

$$Y_{\text{nb}} = \int_0^\infty \mathrm{e}^{-AD}\frac{1}{\Gamma(\alpha)\beta^\alpha}D^{\alpha-1}\mathrm{e}^{-D/\beta}\,\mathrm{d}D = \left(1+\frac{\lambda_y}{\alpha}\right)^{-\alpha}\,, \tag{9.3}$$

where α is referred to as the clustering factor. A smaller value of α means a higher degree of clustering and greater variation in defect density across the wafer. If $\alpha = 1$, then the negative binomial yield is equivalent to Seed's yield. In the case where $\alpha \to \infty$, the negative binomial yield approaches the Poisson yield. By varying the value of α, the negative binomial yield covers the whole range of yield estimations. *Cunningham* [9.28] reported methods to determine the clustering factor. *Langford* and *Liou* [9.30] presented a new technique to calculate an exact solution of α from wafer probe bin map data.

Critical Area and Defect Size Distribution in Yield Model

The random-defect-limited yield can be more accurately evaluated if the concepts of critical area and defect size distribution are incorporated.

Let $s(x)$ be the probability density function of the defect size. Although the form of $s(x)$ depends on process lines, process time, learning experience gained and other variables, it generally peaks at a critical size and then decreases on either side of the peak [9.31]. Let x_0 be the critical size of the defect that is most likely to occur. The defect size distribution is given by [9.7, 15, 23, 28]

$$s(x) = \begin{cases} cx_0^{-q-1}x^q, & 0 \le x \le x_0 \\ cx_0^{p-1}x^{-p}, & x_0 < x < \infty\,, \end{cases} \tag{9.4}$$

where $p \neq 1, q > 0$ and $c = (q+1)(p-1)/(p+q)$. While p, q and x_0 are process-dependent constants, $q = 1$ and $p = 3$ agree well with the experimental data, and x_0 must be smaller than the minimum width or spacing of the defect monitor [9.7, 23]. A gamma distribution is also used for $s(x)$ in some applications [9.32, 33].

The critical area defines the region of the layout where a defect must fall to cause device failure. Therefore, if a defect occurs in the critical area, then it becomes a yield defect. Given $s(x)$, the yield critical area is expressed by

$$A_y = \int_0^\infty A_y(x)s(x)\,\mathrm{d}x\,,$$

where $A_y(x)$ is a critical area of defect size x. Then $\lambda_y = A_yD_0$ is used in yield models where D_0 is the average defect density of all sizes. The geometric method [9.34], the Monte Carlo method [9.35] and the pattern-oriented method [9.36] have been used for critical area extraction. Critical area analysis can be used to quantify the sensitivity of a design to defects based on the layout [9.37] and can aid DFM by improving layouts for better yield [9.38].

Other Models

Sato et al. [9.39] used a discrete exponential distribution for the number of yield defects for each type of defect:

$$P_{\text{discrete expo}}(k) = (1-\mathrm{e}^{-h})\mathrm{e}^{-hk}\,, \tag{9.5}$$

where h is the parameter. Once the probability density function for m types of defects is derived by m convolution of (9.5), the yield is derived by

$$Y_{\text{discrete expo}} = (1-\mathrm{e}^{-h})^m = (1+A_yD_0/m)^{-m}\,. \tag{9.6}$$

Park and *Jun* [9.40] presented another yield model based on a generalized Poisson distribution. Assuming that the number of defect clusters in a chip and the number of defects in each cluster follows a Poisson distribution, the total number of defects in a chip follows a generalized Poisson distribution. Then yield is calculated using the

fact that the total number of yield defects in a chip is the sum of the yield defects in each cluster if the probability of each defect in the cluster becoming a yield defect is the same.

Jun et al. [9.41] developed a yield model through regression analysis in which the mean number of defects per chip and a new cluster index obtained from the defect location are used as independent variables. Simulation results showed that yield is higher for the higher index, but the rate of yield growth decreases as the cluster index increases.

Carrasco and *Suñé* [9.42] presented a methodology for estimating yield for fault-tolerant systems-on-chip, assuming that the system fails with probability $1 - C_i$ if component i fails. The system failure probability is independent of the subsets of components which failed before. For each component, an upper bound on the yield loss is obtained, which can be formalized as the probability that a Boolean function of certain independent integer-valued random variables is equal to one. The reduced-order multiple-valued decision diagram is used to compute the probability.

Noting that interconnect substrates face low yield and high cost, *Scheffler* et al. [9.43] presented a yield estimation approach to assess the impact on overall substrate cost of changing design rules. Given a defect size distribution, if a design rule is relaxed, for instance, if the line width and line spacing are widened, the total number of yield defects decreases and the critical area increases. From the limitation of applications to interconnect substrates, the critical area can be obtained by the union of the critical area for line shorts and the critical area for line opens. Then, the Poisson yield is expressed as a function of line width, and trade-offs of the design rule change can be studied. If an increase in the design rule has minimal impact on the overall substrate area, then yield improvement by increasing the design rules can lead to a more cost-effective substrate.

Cunningham et al. [9.44] presented a common-yield model to analyze and compare the yield of products from different facilities using a linear regression model. *Berglund* [9.45] developed a variable defect size yield model. *Milchalka* [9.17] presented a yield model that considers the repair capability in a part of the die area. *Stapper* and *Rosner* [9.37] presented a yield model using the number of circuits and average number of yield defects per circuit. *Dance* and *Jarvis* [9.46] explained the application of yield models to accelerate yield learning and to develop a performance–price improvement strategy.

Choosing a yield model is basically an experiential process. IC manufacturers compare data from a specific process for yield versus die size using various models and select the best fit. Depending on the distribution of die sizes of a given product and the distribution pattern of the defects, different yield models will best fit the data [9.47].

9.1.4 Issues for Yield Improvement

Achieving high-yield devices is a very challenging task due to reduced process margins and increased IC design complexity. Recent research has emphasized the role of parametric yield loss as well as that of functional yield loss in proactive yield management. Although random yield loss typically dominates in high-volume production, systematic and parametric yield losses become more important when a fabrication process is newly defined and is being tuned to achieve the necessary processes and device parameters [9.48]. Considerable attention has been paid thus far to improving random yield, but relatively little attention has been paid to systematic and parametric yield problems. With new technologies, a process may never be stabilized and statistical device-parameter variations will be a big headache. Traditionally, parametric yield problems were addressed after a design was manufactured. Low-yielding wafers were investigated to identify what process variations caused the yield loss. Then, simulations were used to see where the design should be changed to improve the yield. The traditional redesign approach is very costly compared to handling design at the front-end of the design process using design for yield (DFY) techniques. The use of DFY techniques accelerates the design flow, reduces cycle times and provides higher yield.

Before a high-volume chip comes to market, it must be manufacturable at an acceptable yield. Although traditionally yield issues have been in the domain of manufacturing teams, a new approach to bridge the gap between design and manufacture is necessary as chip geometry shrinks. *Peters* [9.49] emphasized the increasing role of DFY approaches in leading-edge device manufacturability to allow for tuning of all test programs and models so that design, manufacturing and testing provide high-yielding devices.

Li et al. [9.48] presented a holistic yield-improvement methodology that integrates process recipe and design information with in-line manufacturing data to solve the process and design architecture issues that

affect yield and performance. The approach suggests improving yield not just by eliminating defects but also by resolving parametric problems.

Nardi and *Sangiovanni-Vincentelli* [9.12] observed that for complex nanodesigns functional yield might depend more on the design attributes than on the total chip area. Given that the current yield-aware flow optimizes yield at the layout level after optimizing speed and area, a synthesis-for-manufacturability approach is suggested in which manufacturability replaces area in the cost function.

Segal [9.38] claimed that each new technology generation will see lower and lower yields if the defect level of well-running processes is not reduced. A strategy to reduce the defect level is to encompass techniques for responding quickly to defect excursion using in-line wafer scanners and wafer position tracking. The defect excursion strategy eliminates wafers and lots with very high defect densities.

9.2 Semiconductor Reliability

Once an IC device is released to the user, an important and standard measure of device performance is reliability, which is defined as the probability of a device conforming to its specifications over a specified period of time under specified conditions. A failure rate function is usually used to describe device reliability, which is defined for a population of nonrepairable devices as the instantaneous rate of failure for the surviving devices during the next instant of time. If $h(x)$ denotes a failure rate function, the corresponding reliability function is expressed by

$$R(t) = \mathrm{e}^{-\int_0^t h(x)\,\mathrm{d}x} .$$

In this section, the failure rate in semiconductor device reliability is explained. Then, we discuss where each semiconductor failure mechanism occurs in the bathtub failure rate. Finally, techniques used for reliability improvement are reviewed.

9.2.1 Bathtub Failure Rate

When engineers have calculated the failure rate of a semiconductor population over many years, they have commonly observed that the failure rate is described by a bathtub shape.

Initially, semiconductor devices show a high failure rate, resulting in an infant mortality period. The infant mortality period results from weak devices that have shorter lifetimes than the normal stronger devices, implying that infant mortality period applies to a whole population rather than a single device. The operating period that follows the infant mortality period has a lower, and almost constant, failure rate and is called the useful life period. Infant mortality and useful life failures are due to defects introduced during the manufacturing process, such as particle defects, etch defects, scratches and package assembly defects.

A device that has reached the end of its useful life enters the final phase called the aging period. Failures during the aging period are typically due to aging or cumulative damage, and these can be avoided by careful technology development and product design. These failures are inherent process limitations and are generally well-characterized.

The semiconductor manufacturing process requires hundreds of sequential steps and thus hundreds, or even thousands, of process variables must be strictly controlled to maintain the device reliability. Despite the exponential scaling of semiconductor size and chip complexity, IC reliability has increased at an even faster rate as reliability engineers reduce infant mortality and useful life failure rate and push the aging period beyond the typical usage period through a variety of reliability improvement techniques.

9.2.2 Occurrence of Failure Mechanisms in the Bathtub Failure Rate

Failure mechanisms of semiconductor devices can be classified into three groups: electrical stress failures, intrinsic failures and extrinsic failures [9.7, 50].

Electrical stress failures are user-related, and the major causes are electrical-over-stress (EOS) and electrostatic discharge (ESD) due to improper handling. ESD and EOS problems are thoroughly discussed in *Vinson* and *Liou* [9.51]. Because this failure mechanism is event-related, it can occur anywhere in the infant mortality period, the useful life period or the aging period.

The intrinsic failure mechanism results from all crystal-related defects, and thus it occurs predominantly in the infant mortality period but rarely in the aging period.

On the other hand, extrinsic failures are the result of device packaging, metallization and radiation and they can occur any time over the device's lifetime. Extrinsic failures that are due to process deficiencies, such as migration and microcracks, occur during the infant mortality period. The extrinsic failure mechanisms related to packaging deficiency, such as bond looping and metal degradation, occur in the aging period. The radiation-related extrinsic failure mechanisms, such as bit flips due to external radiation, occur continuously over the device lifetime [9.50].

The terms extrinsic and intrinsic failure have also been used in different contexts. First, intrinsic failure is used to describe those failures that are due to internal causes of a device, while failures due to forces external to the product, such as mishandling or accidents, are called extrinsic failures [9.52]. In this case, intrinsic failures occur in the infant mortality period or in the aging period, while extrinsic failures occur in the useful life period. Secondly, the terms intrinsic and extrinsic failure are used to classify oxide failures [9.53]. In this case, intrinsic failures are due to the breakdown of oxide which is free of manufacturing defects, and thus is usually caused by an inherent imperfection in the dielectric material. These failures occur in the aging period at an increasing failure rate. On the other hand, extrinsic failures that result from process defects in the oxide or problems in the oxide fabrication occur in the infant mortality period.

9.2.3 Issues for Reliability Improvement

As reliability engineers have recognized that it is no longer affordable to handle reliability assurance as a back-end process in IC product development, the reliability emphasis has been shifted from end-of-line statistical-based stress testing to new proactive techniques such as design for reliability (DFR), built-in reliability (BIR), wafer-level reliability (WLR), qualified manufacturing line (QML), and physics-of-failure (POF) approaches [9.54, 55].

DFR means building reliability into the design rather than incorporating it after development [9.56]. The importance of DFR increases as stress testing becomes increasingly difficult as the allowable stress is decreased.

The effectiveness of BIR has been outlined in [9.57, 58] for manufacturing highly reliable ICs through the elimination of all possible defects in the design stage.

WLR represents a transition from the end-of-line concept toward the concept of BIR, because the testing is performed at the wafer level reducing the time and expense of packaging. Examples of WLR implementation into a production line or a testing method are given in [9.59–62].

QML is another evolutionary step devised for the purpose of developing new technologies where the manufacturing line is characterized by running test circuits and standard circuit types [9.63]. Understanding failure mechanisms and performing failure analysis are critical elements in implementing the BIR and QML concept.

In cases where the fundamental mechanical, electrical, chemical, and thermal mechanisms related to failures are known, it is possible to prevent failures in new products before they occur. This is the basic idea of POF, which is the process of focusing on the root causes of failure during product design and development in order to provide timely feedback.

9.3 Burn-In

Burn-in is a production process that operates devices, often under accelerated environments, so as to detect and remove weak devices containing manufacturing defects before they are sold or incorporated into assemblies. Because the design rules change so quickly, burn-in today is an essential part of the assembly and testing of virtually all semiconductor devices. To burn-in or not to burn-in and how long the burn-in should be continued are perennial questions.

In this section, we discuss several issues related to burn-in, such as key questions for burn-in effectiveness, burn-in level and burn-in types. Then, the previous burn-in literature is reviewed based on the level of burn-in application.

9.3.1 The Need for Burn-In

Since most semiconductor devices ordinarily have an infant mortality period, the reliability problem during this period becomes extremely important. Manufacturers use burn-in tests to remove infant mortality failures for most circuits, especially where high reliability is a must. Burn-in ensures that a circuit at assembly has moved to the

useful life period of the bathtub curve. During burn-in, elevated voltage and temperature are often combined to activate the voltage- and temperature-dependent failure mechanisms for a particular device in a short time. Careful attention to design of stress burn-in is necessary to ensure that the defect mechanism responsible for infant mortality failures is accelerated while normal strong devices remain unaffected.

Although burn-in is beneficial for screening in the infant mortality period, the burn-in cost ranges from 5–40% of the total device cost depending on the burn-in time, quantities of ICs and device complexity [9.64], and it might introduce additional failures due to EOS, ESD or handling problems. Solutions to the key questions posed by *Kuo* and *Kuo* [9.65] will continue to be found with new technologies for exercising burn-in effectively:

1. How much should infant mortality be reduced by burn-in?
2. Under what environmental conditions should burn-in be performed?
3. Should burn-in be accomplished at the system, subsystem, or component level?
4. Who should be in charge of burn-in, the vender, the buyer, or a third party?
5. Are there any side-effects of burn-in?
6. How will the industry benefit from burn-in data?
7. What physics laws should be followed to conduct burn-in?

9.3.2 Levels of Burn-In

There are three burn-in types based on levels of a device: package-level burn-in (PLBI), die-level burn-in (DLBI), and wafer-level burn-in (WLBI) [9.66–68].

PLBI is the conventional burn-in technology where dies are packed into the final packages and then subjected to burn-in. Although PLBI has the advantage of assuring the reliability of the final product, repairing or discarding a product after PLBI is far too costly.

The strong demand for known good dies (KGD) has motivated the development of more efficient burn-in technology. Generally, KGD is defined as a bare unpacked die that has been tested and verified as fully functional to meet the full range of device specifications at a certain level of reliability [9.68, 69]. KGD enables manufacturers to guarantee a given quality and reliability level per die before integration and assembly. Optimizing burn-in is a key aspect of KGD [9.69].

In DLBI, dies are placed in temporary carriers before being packed into their final form to reduce the cost of added packaging. DLBI and testing of the individual die before packaging ensures that only KGD are packaged and thus produces a quality product at a reduced cost.

Considerations of how to reduce burn-in cost and solve KGD issues have led to the concept of WLBI. WLBI achieves burn-in on the wafer as soon as it leaves the fab. Though WLBI can result in less-reliable final products than PLBI, the trend in industry is to do more testing at the wafer level due to the cost and KGD issues [9.70].

Recently, the line between burn-in and testing has begun to blur as far as reducing testing costs and cycle times. For example, some test functions have moved to the burn-in stage and multi-temperature environments have moved to final testing. DLBI and WLBI that have evolved from burn-in to include testing are called die-level burn-in and testing (DLBT) and wafer-level burn-in and testing (WLBT), respectively. It is reported that DLBT is an expensive step in memory production and the transfer to WLBT can reduce the overall back-end cost by 50% [9.71].

9.3.3 Types of Burn-In

A basic burn-in system includes burn-in sockets to provide a temporary electrical connection between the burn-in board (BIB) and the device under test (DUT) package. Each BIB might accommodate 50 or more sockets, and a burn-in system might hold 32 BIBs. To develop a successful burn-in strategy, detailed knowledge is necessary about temperature distributions across a DUT package, across a BIB, and throughout the burn-in oven [9.72].

Three burn-in types are known to be effective for semiconductor devices: steady-state or static burn-in (SBI), dynamic burn-in (DBI) and test during burn-in (TDBI) [9.7, 73].

In SBI, DUTs are loaded into the burn-in boards (BIB) sockets, the BIBs are put in the burn-in ovens and the burn-in system applies power and an elevated temperature condition (125–150 °C) to the devices for a period ranging from 12 to 24 h. Once the devices cool down, the BIBs are extracted from the boards. These devices are placed in handling tubes and mounted on a single-device tester. Functional tests are then applied on the devices to sort them according to failure types. Because the DUT is powered but not exercised electrically, SBI may not be useful for complex devices because external biases and loads may not stress internal nodes.

In DBI, the DUT is stimulated at a maximum rate determined by the burn-in oven electronics, which can

propagate to internal nodes. Neither SBI not DBI monitors the DUT response during the stress, and thus dies that fail burn-in cannot be detected until a subsequent functional test.

Beyond static and dynamic burn-in is so-called intelligent burn-in [9.72]. Intelligent burn-in systems not only apply power and signals to DUTs, they also monitor DUT outputs. Therefore, they can guarantee that devices undergoing burn-in are indeed powered up and that input test vectors are being applied. In addition, they can perform some test functions. TDBI is a technique for applying test vectors to devices while they are being subjected to stresses as part of the burn-in process. Though function testing is not possible due to the burn-in stress, idle time can be used advantageously to verify circuit integrity, permitting abbreviated functional testing after burn-in.

9.3.4 Review of Optimal Burn-In Literature

While a considerable number of papers have dealt with burn-in at one level, recent research has been directed to the study of burn-in at multiple levels. In this section, we will review the burn-in literature based on the burn-in level being analyzed.

One-Level Burn-In

To fix burn-in at one level, previous work has taken two different approaches: the black-box approach and the white-box approach. In the black-box approach, each device is treated as a black box and a specific failure rate distribution is assumed for the device. In the white-box approach, the device is decomposed into smaller components and a failure rate distribution is assumed for each component. Then the whole-device failure rate is obtained from the structure function and component failure rate.

Many papers have taken the black-box approach and determined the optimal burn-in time to minimize a cost function. *Mi* [9.74, 75] showed that optimal burn-in times that minimize various cost functions occur in the infant mortality period. *Sheu* and *Chien* [9.76] showed the same result for two different types of failures. Assuming that the device lifetime follows a Weibull distribution, *Drapella* and *Kosznik* [9.77] obtained optimal burn-in and preventive replacement periods using Mathcad code. *Cha* [9.78–80] considered a minimally repaired device and derived the properties of optimal burn-in time and block replacement policy. *Tseng* and *Tang* [9.81] developed a decision rule for classifying a component as strong or weak and an economical model to determine burn-in parameters based on a Wiener process. Assuming a mixed Weibull distribution, *Kim* [9.82] determined optimal burn-in time with multiple objectives of minimizing cost and maximizing reliability. A nonparametric approach [9.83] and a nonparametric Bayesian approach [9.84] have been used to estimate the optimal system burn-in time that minimizes a cost function.

The first report that takes a white-box approach appears in *Kuo* [9.85]. The optimal component burn-in time was determined to minimize a cost function subject to a reliability constraint, assuming that the failure of each component follows a Weibull distribution. *Chi* and *Kuo* [9.86] extended it to include a burn-in capacity constraint. *Kar* and *Nachlas* [9.87] consider a series structure, assuming that each component has a Weibull distribution. Given that each component that fails system burn-in is replaced, the optimal system burn-in time was determined to maximize a net-profit function that balances revenue and cost. For the case where percentile residual life is the performance measure of burn-in, *Kim* and *Kuo* [9.88] studied the relationship between burn-in and percentile residual life.

Multi-level Burn-in

For studying burn-in at various levels, the white-box approach must be asked to characterize the failure time distribution of the whole device. Because system burn-in is never necessary after component burn-in if assembly is perfect [9.89, 90], modeling of burn-in at multiple levels must focus on the quantification of assembly quality. *Whitbeck* and *Leemis* [9.91] added a pseudo-component in series to model the degradation of a parallel system during assembly. Their simulation result showed that system burn-in is necessary after component burn-in to maximize the mean residual life. *Reddy* and *Dietrich* [9.92] added several connections to explain an assembly process and assumed that each of components and connections followed a mixed exponential distribution. The optimal burn-in time at the component and system levels were determined numerically to minimize the cost functions, given that the components were replaced and the connections minimally repaired upon failure. *Pohl* and *Dietrich* [9.93] considered the same problem for mixed Weibull distributions. *Kuo* [9.94] used the term *incompatibility* for reliability reduction realized during assembly process. The incompatibility factor exists not only at the component level but also at the subsystem and the system levels due to poor manufacturability, workmanship, and design strategy. *Chien* and *Kuo* [9.95] proposed a nonlinear model

to estimate the optimal burn-in times for all levels as well as to determine the number of redundancies in each subsystem when incompatibility exists. To quantify the incompatibility factor, *Chien* and *Kuo* [9.96] added a uniform random variable to the reliability function. Optimal burn-in times at different levels were determined to maximize the system reliability, subject to a cost constraint via simulation, assuming that the component followed a Weibull distribution. A conceptual model has been developed [9.97] that considers PLBI and WLBI for minimizing a cost function subject to the reliability requirement. *Kim* and *Kuo* [9.98, 99] analytically derived the conditions for system burn-in to be performed after component burn-in using a general system distribution to which the component burn-in information and assembly problems were transferred. *Kim* and *Kuo* [9.100] presented another model for quantifying the incompatibility factor when the assembly adversely affected the components that were replaced at failure. Optimal component and system burn-in times were determined using nonlinear programming for various criteria.

9.4 Relationships Between Yield, Burn-In and Reliability

As semiconductor technology advances, burn-in is becoming more expensive, time-consuming and less capable of identifying the failure causes. Previous research has focused on the determination of burn-in time based on a reliability function estimated from the time-to-first-failure distribution. However, newer proactive methods to determine the burn-in period in the early production stage are of great interest to the semiconductor industry.

One such approach is based on the relation model of yield, burn-in and reliability, which we will review in this section.

9.4.1 Background

Observing that high yield tends to go with high reliability, it was conjectured that defects created on IC devices during manufacturing processes determine yield as well as reliability [9.31]. Subsequent experiments confirmed that each defect in a device affects either yield or reliability, depending on its size and location. This is illustrated in Fig. 9.2 for oxide defects. Therefore, reliability can be estimated based on yield if the relationship between yield and reliability is identified. A model that relates yield and reliability has many applications, such as in yield and reliability predictions for future devices, device architecture design, process control and specification of allowable defect density in new processes for achieving future yield and reliability goals. As a result, the start-up time of new fabrication facilities and cycle times can be shortened by reducing the amount of traditional stress testing required to qualify new processes and products.

Developing a relation model of yield and reliability has been an active research area in the past decade. Three different definitions have been used for reliability in previous research. First, reliability is defined by the probability of a device having no reliability defects, where a reliability defect is defined not as a function of the operating time but as a fixed defect size. Secondly,

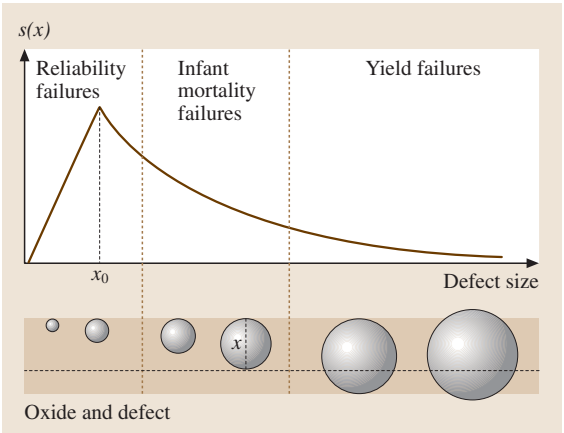

Fig. 9.2 Defect size distribution and oxide problems [9.15]

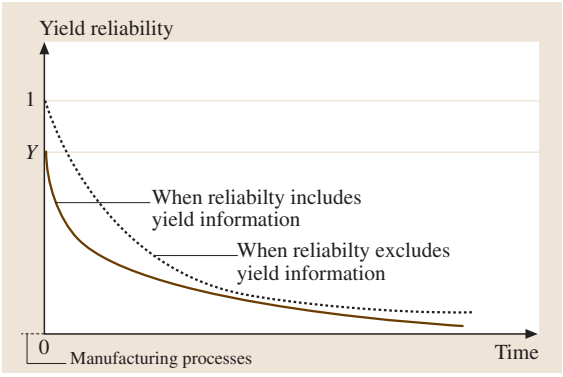

Fig. 9.3 Yield-reliability relationship depending on the definition of reliability [9.24]

reliability denotes the probability of a device having no reliability defects given that there are no yield defects. This reliability is equivalent to yield at time zero, as depicted in Fig. 9.3. This definition of reliability is useful from the designer's point-of-view as it incorporates yield information, but it is not consistent with the traditional definition. Thirdly, reliability is defined as the probability of a device having no reliability defects by time t. In this case, reliability is defined as a function of the operating time without incorporating the yield defects, after assuming that any device that is released to field operation has passed a manufacturing yield test, implying that no yield defects exist. Such a reliability is always 1 at time zero.

9.4.2 Time-Independent Reliability without Yield Information

The first model that related yield and reliability was reported by *Huston* and *Clarke* [9.23]. Let N_y be the number of yield defects and N_r be the number of reliability defects in a device. Reliability defects were defined as a specific defect size rather than as a function of time. Assume that N_y and N_r are independent and each follows a Poisson distribution. Thus, the distribution of N_y is given in (9.1) and the distribution of N_r is given by

$$P^*_{\text{Poisson}}(k) = P(N_r = k) = \frac{e^{-\lambda_r}\lambda_r^k}{k!}, \quad k = 0, 1, 2,$$

where λ_r is the average number of reliability defects per chip. Then, for a device without reliability defects, the Poisson reliability model is obtained by

$$R_{\text{Poisson}} = P^*_{\text{Poisson}}(0) = e^{-\lambda_r}. \tag{9.7}$$

The Poisson yield–reliability relation is obtained from (9.2) and (9.7) by

$$R_{\text{Poisson}} = Y^{\gamma}_{\text{Poisson}} \tag{9.8}$$

where

$$\gamma = \frac{\lambda_r}{\lambda_y}. \tag{9.9}$$

Next, they expressed $\lambda_y = A_y D_0$ and $\lambda_r = A_r D_0$ where D_0 is the common defect density for the yield and reliability defects, and A_y and A_r are the yield and reliability critical areas, respectively.

Subsequently, *Kuper* et al. [9.101] used a similar model given by

$$R_{\text{Poisson}} = (Y_{\text{Poisson}}/M)^{\gamma} \tag{9.10}$$

where M is the maximum possible yield fraction considering clustering effects and edge exclusions. The value of γ depends on the technology and process and on the conditions under which the product is used. They assumed that $\lambda_y = AD_y$ and $\lambda_r = AD_r$ where A is the device area and D_y and D_r are the yield and reliability defect density, respectively. The model was verified with high-volume ICs manufactured by several processes.

Riordan et al. [9.27] verified that (9.10) agrees well for yields based on the lot, the wafer, the region of the wafer and the die in a one-million-unit sample of microprocessors. *Van der Pol* et al. [9.102] used (9.10) to study the IC yield and reliability relationship further for 50 million high-volume products in bipolar CMOS and BICMOS technologies from different wafer fabrication facilities. Experiments showed that a clear correlation exists among functional yield, burn-in failures and field failures.

Zhao et al. [9.103] used a discrete exponential yield model given in (9.6) for yield and (9.7) for reliability. Then, the relation model is obtained by

$$R = \exp\left(-\frac{m\left(1 - Y^{1/m}_{\text{discrete expo}}\right)}{Y^{1/m}_{\text{discrete expo}}}\gamma\right).$$

9.4.3 Time-Independent Reliability with Yield Information

Barnett et al. [9.19] developed a relation model for the negative binomial model, rather than for the Poisson model, assuming that the number of reliability defects is proportional to the number of yield defects in a device. Let N be the total number of defects, where $N = N_y + N_r$. Then

$$P(N_y = m, N_r = n | N = q) = \binom{q}{m} p_y^m p_r^n, \tag{9.11}$$

where p_y is the probability of a defect being a yield defect, and $p_r = 1 - p_y$) is the probability of a defect being a reliability defect. Let $\lambda = E(N)$. If N is assumed to follow a negative binomial distribution

$$P(N = q) = \frac{\Gamma(\alpha + q)}{q!\Gamma(\alpha)} \frac{\left(\frac{\lambda}{\alpha}\right)^q}{(1 + \frac{\lambda}{\alpha})^{\alpha+q}},$$

then the wafer probe yield can be obtained by

$$Y_{\text{nb}} = P(N_y = 0) = \left(1 + \frac{\lambda_y}{\alpha}\right)^{-\alpha}, \tag{9.12}$$

where $\lambda_y = \lambda p_y$ is the average number of yield defects. Let R be the conditional probability that there are no

reliability defects given that there are no yield defects. Then,

$$R = P(N_r = 0 | N_y = 0) = \left(1 + \frac{\lambda_r(0)}{\alpha}\right)^{-\alpha} , \quad (9.13)$$

where

$$\lambda_r(0) = \frac{\lambda p_r}{1 + \lambda p_y / \alpha}$$

is the average number of reliability defects given that there are no yield defects. Using (9.12) and (9.13), the relation model is derived as

$$R = \left[1 + \gamma \left(1 - Y^{1/\alpha}\right)\right]^{-\alpha} ,$$

where $\gamma = \lambda_r / \lambda_y = p_r / p_y$. Numerical examples were used to show that the number of reliability failures predicted by the negative binomial model can differ from the prediction by the Poisson model because of clustering effects. *Barnett* et al. [9.18] modified the model in order to consider the possibility of repair in a certain area of a chip and experimentally verified that the reliability of an IC with a given number of repairs can be accurately quantified with the model. *Barnett* et al. [9.21] and [9.20] validated the yield–reliability relation model using yield and stress test data from a 36-Mbit static random-access memory (SRAM) memory chip and an 8-Mbit embedded dynamic random-access memory (DRAM) chip and from 77 000 microprocessor units manufactured by IBM microelectronics, respectively.

9.4.4 Time-Dependent Reliability

Van der Pol et al. [9.104] added the time aspect of reliability to their previous model [9.102] to suggest detailed burn-in. From an experiment, a combination of two Weibull distributions was employed for the time-to-failure distribution by which $1 - R_{\text{Poisson}}$ in (9.8) is replaced. Similarly, *Barnett* and *Singh* [9.22] introduced the time aspect of reliability in (9.13) using a Weibull distribution. *Forbes* and *Arguello* [9.105] expressed the reliability by time t by

$$\begin{aligned} R(t) &= 1 - e^{-\lambda_r(t)} \simeq 1 - \lambda_r(t) \\ &= 1 - A D_r(t) = 1 - A D_y \gamma(t) , \end{aligned} \quad (9.14)$$

where $\gamma(t) = \frac{D_r(t)}{D_y}$. Then, the Weibull distribution reliability replaces the left-hand side of (9.14) and the corresponding relationship of yield and reliability is used to optimize the burn-in period. All of these models are based on the assumption that the device time-dependent reliability is available in advance from experiments or field failure data.

Kim and *Kuo* [9.26] suggested using $\lambda_r(t) = A_r(t) D_0$ in (9.8), where $\lambda_r(t)$ denotes the mean number of reliability defects realized by time t, and $A_r(t)$ is the reliability critical area by time t. Assuming that the defect growth for operation time t is a known increasing function of time, they calculated $\lambda_r(t)$ and derived a relation model of oxide yield and time-dependent reliability. This is the first model in which time-dependent reliability is estimated from yield and critical area analysis, rather than from field failure data. Because of the properties of the assumed defect growth function, the resulting reliability function has an increasing failure rate. The effect of burn-in on yield, using yield and reliability critical area, was studied by *Kim* et al. [9.106]. *Kim* et al. [9.24] presented another model to tie oxide yield to time-dependent reliability by combining the oxide time to a breakdown model with the defect size distribution given in (9.4). This reliability model predicted from the yield has an infant mortality period such that the optimal burn-in policy for burn-in temperature, burn-in voltage and burn-in time can be determined based on the model.

To handle the dependence between the numbers of yield and reliability defects, *Kim* and *Kuo* [9.25, 107] used a multinomial distribution for the number of yield defects, the number of reliability defects that fail during burn-in and the number of reliability defects that are eventually released to field operation. The distribution of the number of defects is arbitrary. From a feature of multinomial distribution, the number of yield defects

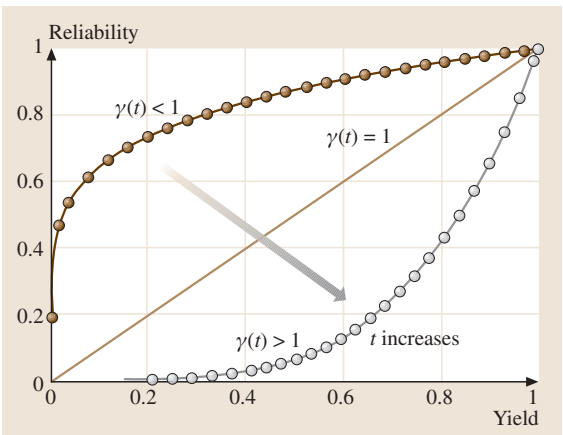

Fig. 9.4 Relation between yield and time-dependent reliability [9.25]

and the number of reliability defects are negatively correlated if the total number of defects in a device is fixed. An analytical result showed that two events, the number of yield defects being zero and the number of reliability defects that fail during burn-in being zero, are positively correlated. This explains the correlated improvement between yield and burn-in fallout. It was also shown that burn-in may be useful if device-to-device variability in the number of defects passing yield tests is greater than a threshold, where the threshold depends on the failure rate of a defect occurrence distribution and the number of defects remaining after the test. Let $\gamma(t)$ be the scaling factor from yield to reliability such that

$$\gamma(t) = \frac{\lambda_r(t)}{\lambda_y} ,$$

where $\lambda_r(t)$ is the number of reliability defects failed by time t. Figure 9.4 shows that a larger value of the scaling factor gives a smaller value of reliability for a given yield value. Clearly, burn-in, reliability and warranty cost can be controlled in an actual process by considering yield and the scaling factor. One can conjecture that burn-in should be performed if the scaling factor is large.

9.5 Conclusions and Future Research

In this chapter, we reviewed semiconductor yield, burn-in and reliability modeling and analysis as a fundamental means of proactive yield and reliability management. It was emphasized that with new technologies the consideration of parametric and systematic yield loss is increasingly important in addition to the consideration of yield defects. Therefore, developing a robust design methodology that can be used to improve parametric and systematic yield becomes a promising research area. Statistical softwares for easily implementing the response surface methodology and Monte Carlo simulation are necessary to overcome the limitations of the current corner analysis method that is widely used in parametric yield analysis.

As design rules tend to change quickly, whether or not to perform burn-in is a perennial question. Previously, a considerable number of papers have studied ways to determine optimal burn-in times based on time-to-first-failure distributions, such as the Weibull distribution or the mixed Weibull distribution. Since burn-in is expensive and time-consuming, more proactive approaches are necessary for determining optimal burn-in time, for example POF analysis.

As correlated improvements in yield, burn-in failures and reliability have occurred, the development of a model relating them has been an active research area in the last decade. Such a model is a prerequisite to predict and control burn-in and reliability based on the device layout in the design stage. Through the model, cycle times and testing costs can be reduced significantly. Currently, experiments are validating the relationship between yield and time-independent reliability. Experiments are necessary to confirm the time-dependent relationship as well. Validation of the time-dependent behavior of reliability defects using IC devices is necessary to determine optimal burn-in periods through the relation model. To do this, physical models must be available to characterize defect growth during operation for various device types, which will enable the estimation of reliability defects as a function of operation time. Also, some future research should be conducted to generalize the yield–reliability relation model to other defect density distributions besides the Poisson and negative binomial models.

Part B Process Mo

Part B Process Monitoring and Improvement

Part B focuses on process monitoring, control and improvement. Chapter 10 describes in detail numerous important statistical methodologies for quality and productivity improvement, including statistical process control, robust design, signal-to-noise ratio, experimental design, and Taguchi methods. Chapter 11 deals with Six Sigma design and methodology. The chapter also discusses decision-making optimization strategies for product and process improvement, including design of experiments and the response-surface methodology. Chapter 12 describes the two widely used parameter-optimization techniques, the response-surface methodology and the Taguchi method, and discusses how to enhance existing methods by developing robust optimization approaches that better maximize the process and product performance. Chapter 13 introduces the concept of uniform design and its applications in the pharmaceutical industry and accelerated stress testing. It also discusses the methods of construction of uniform designs for experiments with mixtures in multidimensional cubes and some relationships between uniform designs and other related designs, while Chapt. 14 focuses on the development and applications of cumulative score statistics and describes the generalized theoretical development from traditional process-monitoring charts as well as how can they be applied to the monitoring of autocorrelated data. Chapter 15 provides a comprehensive review of various chain sampling plans such as acceptance sampling two-stage chains, dependent sampling, and chain sampling with variable inspection, and discusses several interesting extensions of chain sampling, including chain sampling for mixed attribute/variable inspection and deferred sampling plans. Chapter 16 surveys several major models and techniques, such as control charts based on the zero-inflated Poisson distribution, the generalized Poisson distribution and the time-between-event monitoring process, that can be used to monitor high quality processes. Chapter 17 introduces the basic concept and the use of the exponentially weighted moving-average statistic as a process-monitoring scheme commonly used for processes and maintenance in industrial plants. The chapter also discusses some recent innovative types of control charts. Chapter 18 provides a brief review of major univariate quality-monitoring procedures including Crosier's cumulative sum and exponentially weighted moving-average schemes and discusses various multivariate monitoring schemes for detecting a change in the level of a multivariate process.

10. Statistical Methods for Quality and Productivity Improvement

The first section of this chapter introduces statistical process control SPC and robust design RD, two important statistical methodologies for quality and productivity improvement. Section 10.1 describes in-depth SPC theory and tools for monitoring independent and autocorrelated data with a single quality characteristic. The relationship between SPC methods and automatic process control methods is discussed and differences in their philosophies, techniques, efficiencies, and design are contrasted. SPC methods for monitoring multivariate quality characteristics are also briefly reviewed.

Section 10.2 considers univariate RD, with emphasis on experimental design, performance measures and modeling of the latter. Combined and product arrays are featured and performance measures examined, include signal-to-noise ratios SNR, PerMIAs, process response, process variance and desirability functions. Of central importance is the decomposition of the expected value of squared-error loss into variance and off-target components which sometimes allows the dimensionality of the optimization problem to be reduced.

Section 10.3 deals with multivariate RD and demonstrates that the objective function for the multiple characteristic case is typically formed by additive or multiplicative combination of the univariate objective functions. Some alternative objective functions are examined as well as strategies for solving the optimization problem.

Section 10.4 defines dynamic RD and summarizes related publications in the statistics literature, including some very recent entries. Section 10.5 lists RD case studies originating from applications in manufacturing, reliability and tolerance design.

In the current international marketplace, continuous quality improvement is pivotal for maintaining a competitive advantage. Although quality improvement activities are most efficient and cost-effective when implemented as part of the design and development stage (off-line), on-line activities such as statistical process control (SPC) are vital for maintaining quality during manufacturing processes.

Statistical process control (SPC) is an effective tool for achieving process stability and improving process capability through variation reduction. Primarily, SPC is used to classify sources of process variation as either

common cause or assignable cause. Common cause variations are inherent to a process and can be described implicitly or explicitly by stochastic models. Assignable cause variations are unexpected and difficult to predict beforehand. The basic idea of SPC is to quickly detect and correct assignable cause variation before quality deteriorates and defective units are produced. The primary SPC tool was developed in the 1920s by Walter Shewhart of Bell Telephone Laboratories and has been tremendously successful in manufacturing applications [10.1–3].

Robust design is a systematic methodology that uses statistical experimental design to improve the design of products and processes. By making product and process performance insensitive (robust) to hard-to-control disturbances (noise), robust design simultaneously improves product quality, the manufacturing process, and reliability. The RD method was originally developed by the Japanese quality consultant, *Genichi Taguchi* [10.4]. Taguchi's 1980 introduction of robust parameter design to several major American industries resulted in significant quality improvements in product and process design [10.5]. Since then, a great deal of research on RD has improved related statistical techniques and clarified underlying principles.

In addition, many RD case studies have demonstrated phenomenal cost savings. In the electronics industry, *Kackar* and *Shoemaker* [10.6] reported a 60% process variance reduction; *Phadke* [10.5] reported a fourfold reduction in process variance and a twofold reduction in processing time – both from running simple RD experiments. In other industries, the American Supplier Institute (1983–1990) reported a large number of successful case studies in robust design.

Although most data is multivariate in nature, research in both areas has largely focused on normally distributed univariate characteristics (responses). *Montgomery* and *Woodall* [10.2] present a comprehensive panel discussion on SPC (see also *Woodall* and *Montgomery* [10.7]) and multivariate methods are reviewed by *Lowry* and *Montgomery* [10.8] and *Mason* [10.9]. Seminal research papers on RD include *Kackar* [10.10], *Leon* et al. [10.11], *Box* [10.12], *Nair* [10.13] and *Tsui* [10.14]. RD problems with multiple characteristics are investigated by *Logothetis* and *Haigh* [10.15], *Pignatiello* [10.16], *Elsayed* and *Chen* [10.17] and *Tsui* [10.18]. This research has yielded techniques allowing engineers to effectively implement SPC and RD in a host of applications.

This paper briefly revisits the major developments in both SPC and RD that have occurred over the last twenty years and suggests future research directions while highlighting multivariate approaches. Section 10.1 covers SPC of univariate and multivariate random variables for both Shewhart (including $\bar{x}$ and s charts) and non-Shewhart approaches (CUSUM and EWMA) while assessing the effects of autocorrelation and automatic process control. Section 10.2 considers univariate RD, emphasizing performance measures and modeling for loss functions, dual responses and desirability functions. Sections 10.3 and 10.4 deal respectively with multivariate and dynamic RD. Finally, Sect. 10.5 recaps RD case studies from the statistics literature in manufacturing, process control and tolerance design.

10.1 Statistical Process Control for Single Characteristics

The basic idea in statistical process control is a binary view of the state of a process; in other words, it is either running satisfactorily or not. *Shewhart* [10.19] asserted that the process state is related the type of variation manifesting itself in the process. There are two types of variation, called common cause and assignable or special cause variation. Common cause variation refers to the assumption that "future behavior can be predicted within probability limits determined by the common cause system" [10.20]. Special cause variation refers to "something special, not part of the system of common causes" [10.21]. A process that is subject only to common cause variation is "statistically" in control, since the variation is inherent to the process and therefore eliminated only with great difficulty. The objective of statistical process control is to identify and remove special cause variation as quickly as possible.

SPC charts essentially mimic a sequential hypothesis test to distinguish assignable cause variation from common cause variation. For example, a basic mathematical model behind SPC methods for detecting change in the mean is

$$X_t = \eta_t + Y_t \,,$$

where X_t is the measurement of the process variable at time t, and η_t is the process mean at that time. Here Y_t represents variation from the common cause system. In some applications, Y_t can be treated as an independently and identically distributed (iid) process. With few exceptions, the mean of the process is constant except

for abrupt changes, so

$$\eta_t = \eta + \mu_t \,,$$

where η is the mean target and μ_t is zero for $t < t_0$ and has nonzero values for $t \geq t_0$. For analytical simplicity step changes are often assumed; in other words μ_t remains at a new constant level μ for $t \geq t_0$.

10.1.1 SPC for i.i.d. Processes

The statistical goal of SPC control charts is to detect the change point t_0 as quickly as possible and trigger corrective action to bring the process back to the quality target. Among many others, the Shewhart chart, the EWMA chart, and the CUSUM chart are three important and widely used control charts.

Shewhart Chart

The Shewhart control chart monitors the process observations directly,

$$W_t = X_t - \eta \,.$$

Assuming that the standard deviation of W_t is σ_W, the stopping rule of the Shewhart chart is defined as $|W_t| > L\sigma_W$, where L is prespecified to maintain particular probability properties.

EWMA Chart

Roberts [10.22] introduces a control charting algorithm based on the exponentially weighted moving average of the observations,

$$W_t = \sum_{i=0}^{\infty} w_i (X_{t-i} - \eta) \,,$$

where $w_i = \lambda(1-\lambda)^i, (0 < \lambda \leq 1)$. It can be rewritten as

$$W_t = (1-\lambda) W_{t-1} + \lambda (X_t - \eta) \,, \qquad (10.1)$$

where $W_0 = 0$ or the process mean. The stopping rule of the EWMA chart is $|W_t| > L\sigma_W$ where $\sigma_W = \sqrt{\lambda/(2-\lambda)}\sigma_X$. The Shewhart chart is a special case of the EWMA chart with $\lambda = 1$. When the underlying process is i.i.d, the EWMA chart with small λ values is sensitive to the detection of small and medium shifts in mean [10.23].

CUSUM Chart

Page [10.24] introduces the CUSUM chart as a sequential probability test. It can be simply obtained by letting λ approach zero in (10.1). The CUSUM algorithm assigns equal weights to past observations, and its tabular form consists of two quantities,

$$W_t^+ = \max[0,\, W_{t-1}^+ + (X_t - \eta) - k\sigma_X] \,,$$
$$W_t^- = \min[0,\, W_{t-1}^- + (X_t - \eta) + k\sigma_X] \,,$$

where $W_0^+ = W_0^- = 0$. It can be shown that the CUSUM chart with $k = \mu/2$ is optimal for detecting a mean change in μ when the observations are i.i.d.

Because of the randomness of the observations, these control charts may trigger false alarms – out-of-control signals issued when the process is still in control. The expected number of units measured between two successive false alarms is called the *in-control* average run length $(\mathrm{ARL})_0$. When a special cause presents itself, the expected period before a signal is triggered is called the *out-of-control* average run length (ARL_1). The ideal control chart has a long ARL_0 and a short ARL_1. The Shewhart chart typically uses the constant $L = 3$ so that the in-control ARL is 370 when the underlying process is i.i.d. with normal distribution.

These SPC charts are very effective for monitoring the process mean when the process data is i.i.d. It has been shown that the Shewhart chart is sensitive for detecting large shifts while the EWMA and CUSUM charts are sensitive to small shifts [10.23]. However, a fundamental assumption behind these SPC charts is that the common cause variation is free of serial correlation. Due to the prevalence of advanced sensing and measurement technology in manufacturing processes, the assumption of independence is often invalid. For example, measuring critical in-process dimensions is now possible on every unit in the production of discrete parts. In continuous process production systems, the presence of inertial elements such as tanks, reactors, and recycle streams often result in significant serial correlation in the measured variables. Serial correlation creates many challenges and opportunities for SPC methodologies.

10.1.2 SPC for Autocorrelated Processes

Traditional SPC charts have been shown to function poorly while monitoring and controlling serially correlated processes [10.25, 26]. To accommodate autocorrelation, the following time series methods have been proposed.

Modifications of Traditional Methods

One common SPC strategy is to plot the autocorrelated data on traditional charts whose limits have been modified to account for the correlation. *Johnson* and

Bagshaw [10.27] and *Bagshaw* and *Johnson* [10.28] consider the effects of autocorrelation on CUSUM charts using the weak convergence of cumulative sums to a Wiener process. Another alternative is the exponentially weighted moving average chart for stationary processes (EWMAST) studied by *Zhang* [10.29]. *Jiang* et al. [10.30] extend this to a general class of control charts based on autoregressive moving average (ARMA) charts. The monitoring statistic of an ARMA chart is defined to be the result of a *generalized* ARMA(1, 1) process applied to the underlying process $\{X_t\}$,

$$\begin{aligned} W_t &= \theta_0 X_t - \theta X_{t-1} + \phi W_{t-1} \\ &= \theta_0 (X_t - \beta X_{t-1}) + \phi W_{t-1} \,, \end{aligned} \tag{10.2}$$

where $\beta = \theta/\theta_0$ and θ_0 is chosen so that the sum of the coefficients is unity when W_t is expressed in terms of the X_t's, so $\theta_0 = 1 + \theta - \phi$. The authors show that these charts exhibit good performance when the chart parameters are chosen appropriately.

Forecast-Based Monitoring Methods

Forecast-based charts started with the special-cause charts (SCC) proposed by *Alwan* and *Roberts* [10.31]. The general idea is to first apply a one-step-ahead predictor to the observation $\{X_t\}$ and then monitor the corresponding prediction error,

$$W_t = e_t \,, \tag{10.3}$$

where $e_t = X_t - \hat{X}_t$ is the forecast error of predictor $\hat{X}_t$. The SCC method is the first example that uses minimum mean squared error (MMSE) predictors and monitors the MMSE residuals. When the model is accurate, the MMSE prediction errors are approximately uncorrelated. This removal of correlation means that control limits for the SCC can be easily calculated from traditional Shewhart charts, EWMA charts, and CUSUM charts. Another advantage of the SCC method is that its performance can be analytically approximated.

The SCC method has attracted considerable attention and has been extended by many authors. Among them, *Harris* and *Ross* [10.25] and *Superville* and *Adams* [10.32] investigate process monitoring based on the MMSE prediction errors for simple autoregressive [AR(1)] models; *Wardell* et al. [10.33, 34] discuss the performance of SCC for ARMA(1, 1) models; and *Vander Wiel* [10.35] studies the performance of SCC for integrated moving average [IMA(0, 1, 1)] models. SCC methods perform poorly when detecting small shifts since a constant mean shift always results in a dynamic shift pattern in the error term.

In general this approach can be applied to any predictor. *Montgomery* and *Mastrangelo* [10.36] recommend the use of EWMA predictors in the SCC method (hereafter called the M–M chart). *Jiang* et al. [10.37] propose the use of proportional-integral-derivative (PID) predictors

$$\begin{aligned} \hat{X}_t = \hat{X}_{t-1} &+ (k_\mathrm{P} + k_\mathrm{I} + k_\mathrm{D}) e_{t-1} \\ &- (k_\mathrm{P} + 2k_\mathrm{D}) e_{t-2} + k_\mathrm{D} e_{t-3} \,, \end{aligned} \tag{10.4}$$

where k_P, k_I, and k_D are parameters of the PID controller defined in Sect. 10.1.3. The family of PID-based charts includes the SCC, EWMA, and M–M charts as special cases. *Jiang* et al. [10.37] show that the predictors of the EWMA chart and M–M chart may sometimes be inefficient and the SCC over-sensitive to model deviation. They also show that the performance of the PID-based chart is affected by the choice of chart parameters. For any given underlying process, one can therefore tune the parameters of the PID-based chart to optimize its performance.

GLRT-Based Multivariate Methods

Since forecast-based residual methods monitor a single statistic e_t, they often suffer from the problem of a narrow "window of opportunity" when the underlying process is positively correlated [10.35]. If the shift occurrence time is known, the problem can be alleviated by including more historical observations/residuals in the test. This idea was first proposed by *Vander Wiel* [10.35] using a generalized likelihood ratio test (GLRT) procedure. Assuming residual signatures $\{\delta_i\}$ when a shift occurs, the GLRT procedure based on residuals is

$$W_t = \max_{0 \le k \le p-1} \left| \sum_{i=0}^{k} \delta_i e_{t-k+i} \right| \Big/ \sqrt{\sum_{i=0}^{k} \delta_i^2} \,, \tag{10.5}$$

where p is the prespecified size of the test window. *Apley* and *Shi* [10.38] show that this procedure is very efficient in detecting mean shifts when p is sufficiently large. Similar to the SCC methods, this is model-based and the accuracy of signature strongly depends on the window length p. If p is too small and a shift is not detected within the test window, the signature in (10.5) might no longer be valid and the test statistic no longer efficient.

Note that a step mean shift at time $t-k+1$ results in a signature

$$d_k = (0, \cdots, 0, \overbrace{1, \cdots, 1}^{k})' \quad (1 \le k \le p)$$

and

$$d_k = (1, 1, \cdots, 1)' \quad (k > p)$$

on $U_t = (X_{t-p+1}, X_{t-p+2}, \cdots, X_t)'$. To test these signatures, the GLRT procedure based on observation vector W_t is defined as

$$W_t = \max_{0 \le k \le p-1} |d_k' \Sigma_U^{-1} U_t| / \sqrt{d_k' \Sigma_U^{-1} d_k} \,, \qquad (10.6)$$

where Σ_U is the covariance matrix of U_t. *Jiang* [10.39] points out that this GLRT procedure is essentially model-free and always matches the true signature of U_t regardless of the timing of the change point. If a non-step shift in the mean occurs, multivariate charts such as Hotelling's T^2 charts can be developed accordingly [10.40].

Monitoring Batch Means

One of the difficulties with monitoring autocorrelated data is accounting for the underlying autocorrelation. In simulation studies, it is well known that batch means reduce autocorrelation within data. Motivated by this idea, *Runger* and *Willemain* [10.41, 42] use a weighted batch mean (WBM) and a unified batch mean (UBM) to monitor autocorrelated data. The WBM method weighs the mean of observations, defines batch size so that autocorrelation among batches is reduced to zero and requires knowledge of the underlying process model [10.43]. The UBM method determines batch size so that autocorrelation remains below a certain level and is "model-free". Runger and Willemain show that the UBM method is simple and often more cost-effective in practice.

Batch-means methods not only develop statistics based on batch-means, but also provide variance estimation of these statistics for some commonly used SPC charts. *Alexopoulos* et al. [10.44] discuss promising methods for dealing with correlated observations including nonoverlapping batch means (NBM), overlapping batch means (OBM) and standardized time series (STS).

10.1.3 SPC versus APC

Automatic process control (APC) complements SPC as a variation reduction tool for manufacturing industries. While SPC techniques are used to reduce unexpected process variation by detecting and removing the cause of variation, APC techniques are used to reduce systematic variation by employing feedforward and feedback control schemes. The relationships between SPC and APC are important to both control engineers and quality engineers.

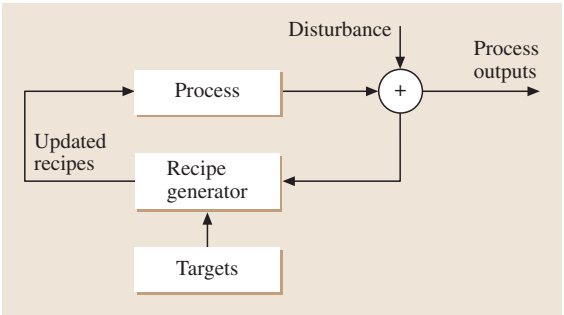

Fig. 10.1 Automatic process control

Feedback Control versus Prediction

The feedback control scheme is a popular APC strategy that uses the deviation of output from target (set-point) to signal a disturbance of the process. This deviation or error is then used to compensate for the disturbance. Consider a pure-gain dynamic feedback-controlled process, as shown in Fig. 10.1. The process output can be expressed as

$$e_t = X_t - Z_{t-1} \,. \qquad (10.7)$$

Suppose $\hat{X}_t$ is an estimator (a predictor) of X_t that can be obtained at time $t-1$. A realizable form of control can be obtained by setting

$$Z_{t-1} = -\hat{X}_t \qquad (10.8)$$

so that the output error at time $t+1$ becomes

$$e_t = X_t - \hat{X}_t \,, \qquad (10.9)$$

which is equal to the "prediction error". Control and prediction can therefore have a one-to-one corresponding relationship via (10.8) and (10.9).

As shown in *Box* and *Jenkins* [10.45], when the process can be described by an ARIMA model, the MMSE control and the MMSE predictor have exactly the same form. Serving as an alternative to the MMSE predictor, the EWMA predictor corresponds to the integral (I) control [10.46] and is one of the most frequently used prediction methods due to its simplicity and efficiency. In general, the EWMA predictor is robust against nonstationarity due to the fact that the I control can continuously adjust the process whenever there is an offset.

An extension of the I control is the widely used PID control scheme,

$$Z_t = -k_P e_t - k_I \frac{1}{1-B} e_t - k_D (1-B) e_t \,, \qquad (10.10)$$

where k_P, k_I, and k_D are constants that, respectively, determine the amount of proportional, integral, and derivative control action. The corresponding PID predictor (10.4) can be obtained from (10.8) and (10.10). When $\lambda_3 = 0$, in other words when $k_D = 0$ (and thus $\lambda_1 = k_P + k_I$ and $\lambda_2 = -k_P$), we have a PI predictor corresponding to the proportional-integral control scheme commonly used in industry.

Process Prediction versus Forecast-Based Monitoring Methods

As discussed in Sect. 10.1.2, one class of SPC methods for autocorrelated processes starts from the idea of "whitening" the process and then monitoring the "whitened" process with time series prediction models. The SCC method monitors MMSE prediction errors and the M–M chart monitors the EWMA prediction error. Although the EWMA predictor is optimal for an IMA(0, 1, 1) process, the prediction error is no longer i.i.d. for predicting other processes. Most importantly, the EWMA prediction error that originated from the I control can compensate for mean shifts in steady state which makes the M–M chart very problematic for detecting small shifts in mean.

Since PID control is very efficient and robust, PID-based charts motivated by PID predictors outperform SCC and M–M charts. APC-based knowledge of the process can moreover clarify the performance of PID-based charts. In summary, the P term ensures that process output is close to the set point and thus sensitive in SPC monitoring, whereas the I term always yields control action regardless of error size which leads to a zero level of steady-state error. This implies that the I term is dominant in SPC monitoring. The purpose of derivative action in PID control is to improve closed-loop stability by making the D term in SPC monitoring less sensitive. Although there is no connection between the EWMA predictor and the EWMA chart, it is important to note that the I control leads to the EWMA predictor and the EWMA prediction-based chart is the M–M chart. As shown in *Jiang* et al. [10.37], the EWMA chart is the same as the P-based chart.

10.1.4 SPC for Automatically Controlled Processes

Although APC and SPC techniques share the objective of reducing process variation, their advocates have quarrelled for decades. It has recently been recognized that the two techniques can be integrated to produce more efficient tools for process variation reduction [10.47–52].

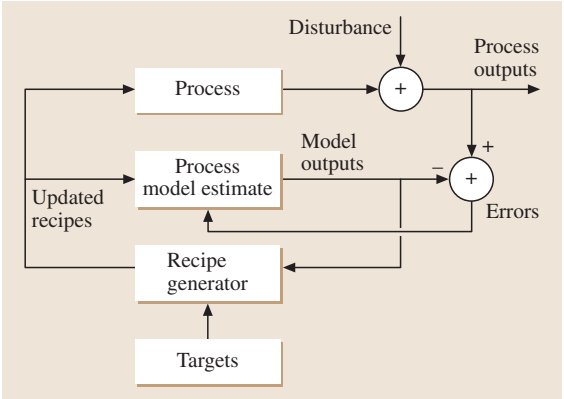

Fig. 10.2 APC/SPC integration

This APC/SPC integration employs an APC rule to regulate the system and superimposes SPC charts on the APC-controlled system to detect process departures from the system model. Using Deming's terminology, the APC scheme is responsible for reducing common cause variation while the SPC charts are responsible for reducing assignable cause variation. From the statistical point of view, the former part resembles a parameter estimation problem for forecasting and adjusting the process and the latter part emulates a hypothesis test of process location. Figure 10.2 pictures a conceptual integration of SPC charts into the framework of a feedback control scheme. To avoid confusion, *Box* and *Luceno* [10.46] refer to APC activities as process adjustment and to SPC activities as process monitoring. Since this chapter emphasizes SPC methods for quality improvement, we discuss only the monitoring component of APC/SPC integration.

As discussed in Sect. 10.1.3, control charts developed for monitoring autocorrelated observations shed light on the monitoring of integrated APC/SPC systems. Fundamentally, the output of an automatically controlled process is recommended for SPC monitoring. This is equivalent to forecast-based control charts of the corresponding predictor. For example, if the process is controlled by an MMSE controller, monitoring the output is exactly the same as the SCC method. Similar to forecast-based methods, assignable causes have an effect that is always contaminated by the APC control action which results in a limited "window of opportunity" for detection [10.35]. As an alternative, some authors suggest that monitoring the APC control action may improve the probability of detection [10.20]. *Jiang* and *Tsui* [10.53] compare the performance of monitoring the output vs. the control action of an APC process and

show that for some autocorrelated processes monitoring the control action may be more efficient than monitoring the output of the APC system.

In general, the performance achieved by SPC monitoring an APC process depends on the data stream (the output or the control action) being measured, the APC control scheme employed, and the underlying autocorrelation of the process. If information from process output and control action can be combined, a universal monitor with higher SPC efficiency [10.51] can be developed. *Kourti* et al. [10.54] propose a method of monitoring process outputs conditional on the inputs or other changing process parameters. *Tsung* et al. [10.55] propose multivariate control charts such as Hotelling's T^2 chart and the Bonferroni approach to monitor output and control action simultaneously. Defining the vector of outputs and control actions as $V_t = (e_t, \cdots, e_{t-p+1}, X_t, \cdots, X_{t-p+1})'$, a dynamic T^2 chart with window size p monitors statistic

$$W_t = V_t' \Sigma_V^{-1} V_t \,,$$

where Σ_V is the covariance matrix of V_t [10.56]. W_t follows a χ^2 distribution during each period given known process parameters. However, strong serial correlation exists so that the χ^2 quantiles cannot be used for control limits. By recognizing the mean shift patterns of V_t, *Jiang* [10.57] develops a GLRT procedure based on V_t. This GLRT procedure is basically univariate and more efficient than the T^2 chart.

10.1.5 Design of SPC Methods: Efficiency versus Robustness

Among many others, the minimization of mean squared error/prediction error is one of the important criteria for prediction/control scheme design. Although the special cause chart is motivated by MMSE prediction/control, many previously mentioned SPC charts such as the PID chart have fundamentally different criteria from those of the corresponding APC controllers. When selecting SPC charts, the desired goal is maximization of the probability of shift detection.

For autocorrelated processes, *Jiang* [10.37] propose an ad hoc design procedure using PID charts. They demonstrate how two capability indices defined by signal-to-noise ratios (SNR) play a critical role in the evaluation of SPC charts. They denote σ_W as the standard deviation of charting statistic W_t and μ_T ($/\mu_S$) as the shift levels of W_t at the first step (/long enough) after the shift takes place. The transient state ratio is defined as $C_T = \mu_T/\sigma_W$, which measures the capability of the control chart to detect a shift in its first few steps. The steady state ratio is defined as $C_S = \mu_S/\sigma_W$, which measures the ability of the control chart to detect a shift in its steady state. These two signal-to-noise ratios determine the efficiency of the SPC chart and can be manipulated by selecting control chart parameters.

For a particular mean shift level, if the transient state ratio/capability can be tuned to a high value (say 4 to 5) by choosing appropriate chart parameters, the corresponding chart will detect the shift very quickly. Otherwise the shift will likely be missed during the transient state and will need to be detected in later runs. Since a high steady state ratio/capability heralds efficient shift detection at steady state, a high steady state ratio/capability is also desired. However, the steady state ratio/capability should not be tuned so high that it results in an extremely small transient ratio/capability, indicative of low probability of detection during the transient state. To endow the chart with efficient detection at both states, a tradeoff is needed when choosing the charting parameters. An approximate C_S value of 3 is generally appropriate for balancing the values of C_T and C_S.

One of the considerations when choosing an SPC method is its robustness to autocorrelated and automatically controlled processes. Robustness of a control chart refers to how insensitive its statistical properties are to model mis-specification. Reliable estimates of process variation are of vital importance for the proper functioning of all SPC methods [10.58]. For process X_t with positive first-lag autocorrelation, the standard deviation derived from moving range is often underestimated because

$$E(\hat{\sigma}_{MR}) = E(\overline{MR}/d_2) = \sigma_X \sqrt{1-\rho_1} \,,$$

where ρ_1 is the first-lag correlation coefficient of X_t [10.59].

A more serious problem with higher sensitivity control charts such as the PID chart is that they may be less robust than lower sensitivity control charts such as the SCC. *Tsung* et al. [10.60] and *Luceno* [10.61] conclude that PID controllers are generally more robust than MMSE controllers against model specification error. However *Jiang* [10.37] shows that PID charts tend to have a shorter "in-control" ARL when the process model is mis-specified since model errors can be viewed as a kind of "shift" from the "true" process model. This seems to be a discouraging result for higher sensitivity control charts. In practice, a trade-off is necessary between sensitivity and robustness when selecting control charts for autocorrelated processes. *Apley* and *Lee* [10.62] recommend using

a conservative control limit for EWMA charts when monitoring MMSE residuals. By using the worst-case estimation of residual variance, the EWMA chart can be robustly designed for the in-control state with a slight efficiency loss in the out-of-control state. This design strategy can be easily generalized to other SPC methods for autocorrelated or automatically controlled processes.

10.1.6 SPC for Multivariate Characteristics

Through modern sensing technology that allows frequent measurement of key quality characteristics during manufacturing, many in-process measurements are strongly correlated to each other. This is especially true for measurements related to safety, fault detection and diagnosis, quality control and process control. In an automatically controlled process for example, process outputs are often strongly related to process control actions. Joint monitoring of these correlated characteristics ensures appropriate control of the overall process. Multivariate SPC techniques have recently been applied to novel fields such as environmental monitoring and detection of computer intrusion.

The purpose of multivariate on-line techniques is to investigate whether measured characteristics are simultaneously in statistical control. A specific multivariate quality control problem is to consider whether an observed vector of measurements $\boldsymbol{x} = (x_1, \ldots, x_k)$ exhibits a shift from a set of "standard" parameters $\boldsymbol{\mu}^0 = (\mu_1^0, \ldots, \mu_k^0)'$. The individual measurements will frequently be correlated, meaning that their covariance matrix Σ will not be diagonal.

Versions of the univariate Shewhart, EWMA and CUSUM charts have been developed for the case of multivariate normality.

Multivariate T^2 Chart

To monitor a multivariate vector, *Hotelling* [10.63] suggested an aggregated statistic equivalent to the Shewhart control chart in the univariate case,

$$T^2 = (\boldsymbol{x} - \boldsymbol{\mu}^0)' \, \hat{\Sigma}_{\boldsymbol{x}}^{-1} \, (\boldsymbol{x} - \boldsymbol{\mu}^0) \,, \tag{10.11}$$

where $\hat{\Sigma}_{\boldsymbol{x}}$ is an estimate of the population covariance matrix Σ. If the population covariance matrix is known, Hotelling's T^2 statistic follows a χ^2 distribution with k degrees of freedom when the process is in-control. A signal is triggered when $\chi^2 > \chi^2_{k,\alpha}$. One of the important features of the T^2 charts is that its out-of-control performance depends solely on the noncentrality parameter $\delta = \sqrt{(\boldsymbol{\mu} - \boldsymbol{\mu}^0)' \Sigma_{\boldsymbol{x}}^{-1} (\boldsymbol{\mu} - \boldsymbol{\mu}^0)}$, where $\boldsymbol{\mu}$ is the actual mean vector. This means that its detectional performance is invariant along the contours of the multivariate normal distribution.

Multivariate EWMA Chart

Hotelling's T^2 chart essentially utilizes only current process information. To incorporate recent historical information, *Lowry* [10.64] develop a similar multivariate EWMA chart

$$W_t^2 = \boldsymbol{w}_t' \Sigma_{\boldsymbol{w}}^{-1} \boldsymbol{w}_t \,,$$

where $\boldsymbol{w}_t = \Lambda(\boldsymbol{x}_t - \boldsymbol{\mu}^0) + (\boldsymbol{I} - \Lambda)\boldsymbol{w}_{t-1}$ and $\Lambda = \mathrm{diag}(\lambda_1, \lambda_2, \cdots, \lambda_k)$. For simplicity, $\lambda_i = \lambda \; (1 \le i \le k)$ is generally adopted and $\Sigma_{\boldsymbol{w}} = \lambda/(2-\lambda)\Sigma_{\boldsymbol{x}}$.

Multivariate CUSUM Chart

There are many CUSUM procedures for multivariate data. *Crosier* [10.65] proposes two multivariate CUSUM procedures, cumulative sum of T (COT) and MCUSUM. The MCUSUM chart is based on the statistics

$$\boldsymbol{s}_t = \begin{cases} \boldsymbol{0} & \text{if } C_t \le k_1 \\ (\boldsymbol{s}_{t-1} + \boldsymbol{x}_t)(1 - k_1/C_t) & \text{if } C_t > k_1 \,, \end{cases} \tag{10.12}$$

where $\boldsymbol{s}_0 = \boldsymbol{0}$, $C_t = \sqrt{(\boldsymbol{s}_{t-1} + \boldsymbol{x}_t)' \Sigma_{\boldsymbol{x}}^{-1} (\boldsymbol{s}_{t-1} + \boldsymbol{x}_t)}$, and $k_1 > 0$. The MCUSUM chart signals when $W_t = \boldsymbol{s}_t' \Sigma_{\boldsymbol{x}}^{-1} \boldsymbol{s}_t > h_1$. *Pignatiello* and *Runger* [10.66] propose another multivariate CUSUM chart (MC1) based on the vector of cumulative sums,

$$W_t = \max\left(0, \sqrt{D_t' \Sigma_{\boldsymbol{x}}^{-1} D_t} - k_2 l_t\right) \,, \tag{10.13}$$

where $k_2 > 0$, $D_t = \sum_{i=t-l_t+1}^{t} \boldsymbol{x}_i$, and

$$l_t = \begin{cases} l_{t-1} + 1 & \text{if } W_{t-1} > 0 \\ 1 & \text{otherwise} \,. \end{cases}$$

Once an out-of-control signal is triggered from a multivariate control chart, it is important to track the cause of the signal so that the process can be improved. Fault diagnosis can be implemented by T^2 decompositions following the signal and large components are suspected to be faulty. Orthogonal decompositions such as principal component analysis [10.67] are popular tools. *Mason* et al. [10.68], *Hawkins* [10.69] and *Hayter* and *Tsui* [10.70] propose other alternatives which integrate process monitoring and fault diagnosis. *Jiang* and *Tsui* [10.71] provide a thorough review of these methods.

10.2 Robust Design for Single Responses

Taguchi [10.4] introduced parameter design, a method for designing processes that are robust (insensitive) to uncontrollable variation, to a number of American corporations. The objective of this methodology is to find the settings of design variables that minimize the expected value of squared-error loss defined as

$$L(Y,t) = (Y-t)^2 \,, \tag{10.14}$$

where Y represents the actual process response and t the targeted value. A loss occurs if the response Y deviates from its target t. This loss function originally became popular in estimation problems considering unbiased estimators of unknown parameters. The expected value of $(Y-t)^2$ can be easily expressed as

$$\begin{aligned} E(L) &= A_0 E(Y-t)^2 \\ &= A_0\left[\mathrm{Var}(Y) + (E(Y)-t)^2\right] , \end{aligned} \tag{10.15}$$

where $\mathrm{Var}(Y)$ and $E(Y)$ are the mean and variance of the process response and A_0 is a proportional constant representing the economic costs of the squared error loss. If $E(Y)$ is on target then the squared-error loss function reduces to the process variance. Its similarity to the criterion of least squares in estimation problems makes the squared-error loss function easy for statisticians and engineers to grasp. Furthermore the calculations for most decision analyses based on squared-error loss are straightforward and easily seen as a trade-off between variance and the square of the off-target factor.

Robust design (RD) assumes that the appropriate performance measure can be modeled as a transfer function of the fixed control variables and the random noise variables of the process as follows:

$$Y = f(\boldsymbol{x}, \boldsymbol{N}, \boldsymbol{\theta}) + \epsilon \,, \tag{10.16}$$

where $\boldsymbol{x} = (x_1, \ldots, x_p)^T$ is the vector of control factors, $\boldsymbol{N} = (N_1, \ldots, N_q)^T$ is the vector of noise factors, $\boldsymbol{\theta}$ is the vector of unknown response model parameters, and f is the transfer function for Y. The control factors are assumed to be fixed and represent the fixed design variables. The noise factors $\boldsymbol{N}$ are assumed to be random and represent the uncontrolled sources of variability in production. The pure error ϵ represents the remaining variability that is not captured by the noise factors, and is assumed to be normally distributed with zero mean and finite variance.

Taguchi divides the design variables into two subsets, $\boldsymbol{x} = (\boldsymbol{x}_\mathrm{a}, \boldsymbol{x}_\mathrm{d})$, where $\boldsymbol{x}_\mathrm{a}$ and $\boldsymbol{x}_\mathrm{d}$ are called respectively the adjustment and nonadjustment design factors. An adjustment factor influences process location while remaining effectively independent of process variation. A nonadjustment factor influences process variation.

10.2.1 Experimental Designs for Parameter Design

Taguchi's Product Arrays and Combined Arrays

Taguchi's experimental design takes an orthogonal array for the controllable design parameters (an inner array of control factors) and crosses it with another orthogonal array for the factors beyond reasonable control (an outer array of noise factors). At each test combination of control factor levels, the entire noise array is run and a performance measure is calculated. Hereafter we refer to this design as the product array. These designs have been criticized by *Box* [10.12] and others for being unnecessarily large.

Welch [10.72] combined columns representing the control and noise variables within the same orthogonal array. These combined arrays typically have a shorter number of test runs and do not replicate the design. The lack of replication prevents unbiased estimation of random error but we will later discuss research addressing this limitation.

Which to Use: Product Array or Combined Array. There is a wide variety of expert opinion regarding choice of experimental design in *Nair* [10.13]. The following references complement Nair's comprehensive discussion. *Ghosh* and *Derderian* [10.73] derive robustness measures for both product and combined arrays, allowing the experimenter to objectively decide which array provides a more robust option. *Miller* et al. [10.74] consider the use of a product array on gear pinion data. *Lucas* [10.75] concludes that the use of classical, statistically designed experiments can achieve the same or better results than Taguchi's product arrays. *Rosenbaum* [10.76] reinforces the efficiency claims of the combined array by giving a number of combined array designs which are smaller for a given orthogonal array strength or stronger for a given size. Finally, *Wu* and *Hamada* [10.77] provide an intuitive approach to choosing between product and combined array based on an effect-ordering principle.

They list the most important class of effects as those containing control–noise interactions, control main effects and noise main effects. The second highest class contains the control–control interactions and the control–control–noise interactions while the third and

least important class contains the noise–noise interactions. That array producing the highest number of clear effect estimates in the most important class is considered the best design.

Noting that the combined array is often touted as being more cost-effective due to an implied smaller number of runs, Wu and Hamada place the cost comparison on a more objective basis by factoring in both cost per control setting and cost per noise replicate. They conclude that the experimenter must prioritize the effects to be estimated and the realistic costs involved before deciding which type of array is optimal.

Choosing the Right Orthogonal Array for RD

Whether the experimenter chooses a combined or product array, selecting the best orthogonal array is an important consideration. The traditional practice in classical design of experiments is to pick a Resolution IV or higher design so that individual factors are aliased with three factor interactions, of which there are relatively few known physical examples.

However, the estimation of main effects is not necessarily the best way to judge the value of a test design for RD. The control–noise interactions are generally regarded as having equal importance as the control effects for fine tuning the final control factor settings for minimal product variation. Hence evaluation of an experimental design for RD purposes must take into account the design's ability to estimate the control–noise interactions deemed most likely to affect product performance.

Kackar and *Tsui* [10.78] feature a graphical technique for showing the confounding pattern of effects within a two-level fractional factorial. *Kackar* et al. [10.79] define orthogonal arrays and describe how Taguchi's fixed element arrays are related to well known fractional factorial designs. Other pieces related to this decision are *Hou* and *Wu* [10.80], *Berube* and *Nair* [10.60] and *Bingham* and *Sitter* [10.81].

D-Optimal Designs

In this section several authors show how D-optimal designs can be exploited in RD experiments. A D-optimal design minimizes the area of the confidence ellipsoids for parameters being estimated from an assumed model. Their key strength is their invariance to linear transformation of model terms and their characteristic weakness is a dependence on the accuracy of the assumed model. By using a proper prior distribution to attack the singular design problem and make the design less model-dependent, *Dumouchel* and *Jones* [10.82] provide a Bayesian D-optimal design needing little modification of existing D-optimal search algorithms.

Atkinson and *Cook* [10.83] extend the existing theory of D-optimal design to linear models with nonconstant variance. With a Bayesian approach they create a compromise design that approximates preposterior loss. *Vining* and *Schaub* [10.84] use D-optimality to evaluate separate linear models for process mean and variance. Their comparison of the designs indicates that replicated fractional factorials of assumed constant variance best estimate variance while semi-Bayesian designs better estimate process response.

Chang [10.85] proposes an algorithm for generating near D-optimal designs for multiple response surface models. This algorithm differs from existing approaches in that it does not require prior knowledge or data based estimates of the covariance matrix to generate its designs. *Mays* [10.86] extends the quadratic model methodology of RSM to the case of heterogeneous variance by using the optimality criteria D (maximal determinant) and I (minimal integrated prediction variance) to allocate test runs to locations within a central composite design.

Other Designs

The remaining references discuss types of designs used in RD which are not easily classified under the more common categories previously discussed.

Pledger [10.87] divides noise variables into observable and unobservable and argues that one's ability to observe selected noise variables in production should translate into better choices of optimal control settings. *Rosenbaum* [10.88] uses blocking to separate the control and noise variables in combined arrays, which were shown in *Rosenbaum* [10.76] to be stronger for a given size than the corresponding product array designs. *Li* and *Nachtsheim* [10.89] present experimental designs which don't depend on the experimenter's prior determination of which interactions are most likely significant.

10.2.2 Performance Measures in RD

In Sect. 10.2.1 we compared some of the experimental designs used in parameter design. Of equal importance is choosing which performance measure will best achieve the desired optimization goal.

Taguchi's Signal-to-Noise Ratios

Taguchi introduced a family of performance measures called signal-to-noise ratios whose specific form depends on the desired response outcome. The case where

the response has a fixed nonzero target is called the nominal-the-best case (NTB). Likewise, the cases where the response has a smaller-the-better target or a larger-the-better target are, respectively, called the STB and LTB cases.

To accomplish the objective of minimal expected squared-error loss for the NTB case, Taguchi proposed the following two-step optimization procedure: (i) Calculate and model the SNRs and find the nonadjustment factor settings which maximize the SNR. (ii) Shift mean response to the target by changing the adjustment factor(s).

For the STB and LTB cases, Taguchi recommends directly searching for the values of the design vector $\boldsymbol{x}$ which maximize the respective SNR. Alternatives for these cases are provided by *Tsui* and *Li* [10.90] and *Berube* and *Wu* [10.91].

Performance Measure Independent of Adjustment (PerMIAs)

Taguchi did not demonstrate how minimizing the SNR would achieve the stated goal of minimal average squared-error loss. *Leon* et al. [10.11] defined a function called the performance measure independent of adjustment (PerMIA) which justified the use of a two-step optimization procedure. They also showed that Taguchi's SNR for the NTB case is a PerMIA when both an adjustment factor exists and the process response transfer function is of a specific multiplicative form. When Taguchi's SNR complies with the properties of a PerMIA, his two-step procedure minimizes the squared-error loss.

Leon et al. [10.11] also emphasized two major advantages of the two-step procedure:

- It reduces the dimension of the original optimization problem.
- It does not require reoptimization for future changes of the target value.

Box [10.12] agrees with *Leon* et al. [10.11] that the SNR is only appropriately used in concert with models where process sigma is proportional to process mean. *Maghsoodloo* [10.92] derives and tabulates exact mathematical relationships between Taguchi's STB and LTB measures and his quality loss function.

Leon and *Wu* [10.93] extend the PerMIA of *Leon* et al. [10.11] to a maximal PerMIA which can solve constrained minimization problems in a two-step procedure similar to that of Taguchi. For nonquadratic loss functions, they introduce general dispersion, location and off-target measures while developing a two-step process. They apply these new techniques in a number of examples featuring additive and multiplicative models with nonquadratic loss functions. *Tsui* and *Li* [10.90] establish a multistep procedure for the STB and LTB problem based on the response model approach under certain conditions.

Process Response and Variance as Performance Measures

The dual response approach is a way of finding the optimal design settings for a univariate response without the need to use a loss function. Its name comes from its treatment of mean and variance as responses of interest which are individually modeled. It optimizes a primary response while holding the secondary response at some acceptable value.

Nair and *Pregibon* [10.94] suggest using outlier-robust measures of location and dispersion such as median (location) and interquartile range (dispersion). *Vining* and *Myers* [10.95] applied the dual response approach to Taguchi's three SNRs while restricting the search area to a spherical region of limited radius. *Copeland* and *Nelson* [10.96] solve the dual response optimization problem with the technique of direct function minimization. They use the Nelder-Mead simplex procedure and apply it to the LTB, STB and NTB cases. Other noteworthy papers on the dual response method include *Del Castillo* and *Montgomery* [10.97] and *Lin* and *Tu* [10.98].

Desirability as a Performance Measure

The direct conceptual opposite of a loss function, a utility function maps a specific set of design variable settings to an expected utility value (value or worth of a process response). Once the utility function is established, nonlinear direct search methods are used to find the vector of design variable settings that maximizes utility.

Harrington [10.99] introduced a univariate utility function called the desirability function, which gives a quality value between zero (unacceptable quality) and one (further improvement would be of no value) of a quality characteristic of a product or process. He defined the two-sided desirability function as follows:

$$d_i = \mathrm{e}^{-|Y_i'|^c} , \tag{10.17}$$

where e is the natural logarithm constant, c is a positive number subjectively chosen for curve scaling, and Y_i' is a linear transformation of the univariate response Y_i whose properties link the desirability values to product specifications. It is of special interest to note that for $c = 2$, a mid-specification target and response values

within the specification limits, this desirability function is simply the natural logarithm constant raised to the squared-error loss function.

Other Performance Measures

Ng and *Tsui* [10.100] derive a measure called q-yield which accounts for variation from target among passed units as well as nonconforming units. It does this by penalizing yield commensurate with the amount of variation measured within the passed units. *Moorhead* and *Wu* [10.91] develop modeling and analysis strategies for a general loss function where the quality characteristic follows a location-scale model. Their three-step procedure includes an adjustment step which moves the mean to the side of the target with lower cost. Additional performance measures are introduced in *Joseph* and *Wu* [10.101] and *Joseph* and *Wu* [10.102].

10.2.3 Modeling the Performance Measure

The third important decision the experimenter must grapple with is how to model the chosen performance measure. Linear models are by far the most common way to approximate loss functions, SNR's and product responses. This section covers response surface models, the generalized linear model and Bayesian modeling.

Response Surface Models

Response surface models (RSM) are typically second-order linear models with interactions between the first-order model terms. While many phenomena cannot be accurately represented by a quadratic model, the second-order approximation of the response in specific regions of optimal performance may be very insightful to the product designer.

Myers et al. [10.103] make the case for implementing Taguchi's philosophy within a well established, sequential body of empirical experimentation, RSM. The combined array is compared to the product array and the modeling of SNR compared to separate models for mean and variance. In addition, RSM lends itself to the use of mixed models for random noise variables and fixed control variables. *Myers* et al. [10.104] incorporate noise variables and show how mean and variance response surfaces can be combined to create prediction limits on future response.

Analysis of Unreplicated Experiments. The most commonly cited advantage of modeling process responses rather than SNR is the use of more efficient combined arrays. However the gain in efficiency usually assumes there is no replication for estimating random error. Here we review references for analyzing the data from unreplicated fractional factorial designs.

Box and *Meyer* [10.105] present an analysis technique which complements normal probability plots for identifying significant effects from an unreplicated design. Their Bayesian approach assesses the size of contrasts by computing a posterior probability that each contrast is active. They start with a prior probability of activity and assume normality of the significant effects and deliver a nonzero posterior probability for each effect.

Lenth [10.106] introduces a computationally simple and intuitively pleasing technique for measuring the size of contrasts in unreplicated fractional factorials. The Lenth method uses standard T statistics and contrast plots to indicate the size and significance of the contrast. Because of its elegant simplicity, the method of Lenth is commonly cited in RD case studies.

Pan [10.107] shows how failure to identify even small and moderate location effects can subsequently impair the correct identification of dispersion effects when analyzing data from unreplicated fractional factorials. *Ye* and *Hamada* [10.77] propose a simple simulation method for estimating the critical values employed by Lenth in his method for testing significance of effects in unreplicated fractional factorial designs.

McGrath and *Lin* [10.108] show that a model that does not include all active location effects raises the probability of falsely identifying significant dispersion factors. They show analytically that without replication it is impossible to deconfound a dispersion effect from two location effects.

Generalized Linear Model

The linear modeling discussed in this paper assumes normality and constant variance. When the data does not demonstrate these properties, the most common approach is to model a compliant, transformed response. In many cases this is hard or impossible. The general linear model (GLM) was developed by *Nelder* and *Wedderburn* [10.109] as a way of modeling data whose probability distribution is any member of the single parameter exponential family.

The GLM is fitted by obtaining the maximum likelihood estimates for the coefficients to the terms in the linear predictor, which may contain continuous, categorical, interaction and polynomial terms. *Nelder* and *Lee* [10.110] argue that the GLM can extend the class of useful models for RD experiments to data-sets wherein a simple transformation cannot necessarily satisfy the

important criteria of normality, separation and parsimony. Several examples illustrate how the link functions are chosen.

Engel and *Huele* [10.111] integrate the GLM within the RSM approach to RD. Nonconstant variance is assumed and models for process mean and variance are obtained from a heteroscedastic linear model of the conditional process response. The authors claim that nonlinear models and tolerances can also be studied with this approach. *Hamada* and *Nelder* [10.112] apply the techniques described in *Nelder* and *Lee* [10.110] to three quality improvement examples to emphasize the utility of the GLM in RD problems over its wider class of distributions.

Bayesian Modeling

Bayesian methods of analysis are steadily finding wider employment in the statistical world as useful alternatives to frequentist methods. In this section we mention several references on Bayesian modeling of the data.

Using a Bayesian GLM, *Chipman* and *Hamada* [10.113] overcome the GLM's potentially infinite likelihood estimates from categorical data taken from fractional factorial designs. *Chipman* [10.114] uses the model selection methodology of *Box* and *Meyer* [10.115] in conjunction with priors for variable selection with related predictors. For optimal choice of control factor settings he finds posterior distributions to assess the effect of model and parameter uncertainty.

10.3 Robust Design for Multiple Responses

Earlier we discussed loss and utility functions and showed how the relation between off-target and variance components underlies the loss function optimization strategies for single responses. Multi-response optimization typically combines the loss or utility functions of individual responses into a multivariate function to evaluate the sets of responses created by a particular set of design variable settings. This section is divided into two subsections which, respectively, deal with the additive and multiplicative combination of loss and utility functions, respectively.

10.3.1 Additive Combination of Univariate Loss, Utility and SNR

The majority of multiple response approaches additively combine the univariate loss or SNR performance measures discussed. In this section we review how these performance measures are additively combined and their relative advantages and disadvantages as multivariate objective functions.

Multivariate Quadratic Loss

For univariate responses, expected squared-error loss is a convenient way to evaluate the loss caused by deviation from target because of its decomposition into squared off-target and variance terms. A natural extension of this loss function to multiple correlated responses is the multivariate quadratic function of the deviation vector $(\boldsymbol{Y}-\tau)$ where $\boldsymbol{Y}=(Y_1,\ldots,Y_r)^{\mathrm{T}}$ and $\tau=(t_1,\ldots,t_r)^{\mathrm{T}}$, i. e.,

$$\mathrm{MQL}(\boldsymbol{Y},\tau)=(\boldsymbol{Y}-\tau)^{\mathrm{T}}\boldsymbol{A}(\boldsymbol{Y}-\tau)\,, \tag{10.18}$$

where $\boldsymbol{A}$ is a positive definite constant matrix. The values of the constants in $\boldsymbol{A}$ are related to the costs of nonoptimal design, such as the costs related to repairing and/or scrapping noncompliant product. In general, the diagonal elements of $\boldsymbol{A}$ represent the weights of the r characteristics and the off-diagonal elements represent the costs related to pairs of responses being simultaneously off-target.

It can be shown that, if $\boldsymbol{Y}$ follows a multivariate normal distribution with mean vector $E(\boldsymbol{Y})$ and covariance matrix $\boldsymbol{\Sigma_Y}$, the average (expected) loss can be written as:

$$\begin{aligned} E(\mathrm{MQL}) &= E(\boldsymbol{Y}-\tau)^{\mathrm{T}}\boldsymbol{A}(\boldsymbol{Y}-\tau) \\ &= \mathrm{Tr}(\boldsymbol{A}\boldsymbol{\Sigma_Y}) \\ &\quad +[E(\boldsymbol{Y})-\tau]^{\mathrm{T}}\boldsymbol{A}[E(\boldsymbol{Y})-\tau]. \end{aligned} \tag{10.19}$$

The simplest approach to solving the RD problem is to apply algorithms to directly minimize the average loss function in (10.19). Since the mean vector and covariance matrix are usually unknown, they can be estimated by the sample mean vector and sample covariance matrix or a fitted model based on a sample of observations of the multivariate responses. The off-target vector product $[E(\boldsymbol{Y})-\tau]^{\mathrm{T}}\boldsymbol{A}[E(\boldsymbol{Y})-\tau]$ and $\mathrm{Tr}(\boldsymbol{A}\boldsymbol{\Sigma_Y})$ are multivariate analogs to the squared off-target component and variance of the univariate squared-error loss function. This decomposition shows how moving all response means to target simplifies the expected multivariate loss to the $\mathrm{Tr}(\boldsymbol{A}\boldsymbol{\Sigma_Y})$ term. The trace-covariance term shows how the values of $\boldsymbol{A}$ and the covariance matrix $\boldsymbol{\Sigma_Y}$ directly affect the expected multivariate loss.

Optimization of Multivariate Loss Functions

For the expected multivariate quadratic loss of (10.19), *Pignatiello* [10.16] introduced a two-step procedure for finding the design variable settings that minimize this composite cost of poor quality. *Tsui* [10.18] extended Pignatiello's two-step procedure to situations where responses may be NTB, STB or LTB.

To this point we have examined squared-error loss functions whose expected value is decomposed into off-target and variance components. *Ribeiro* and *Elsayed* [10.116] introduced a multivariate loss function which additionally considers fluctuation in the supposedly fixed design variable settings. *Ribeiro* et al. [10.117] add a term for manufacturing cost to the gradient loss function of Ribeiro and Elsayed.

Additive Formation of Multivariate Utility Functions

Kumar et al. [10.118] suggest creating a multiresponse utility function as the additive combination of utility functions from the individual responses where the goal is to find the set of design variable settings that maximizes overall utility. Additional papers related to this technique include *Artiles-Leon* [10.119] and *Ames* et al. [10.120].

Quality Loss Functions for Nonnegative Variables

Joseph [10.121] argues that, in general, processes should not be optimized with respect to a single STB or LTB characteristic, rather to a combination of them. He introduces a new class of loss functions for nonnegative variables which accommodates the cases of unknown target and asymmetric loss and which can be additively combined for the multiresponse case.

10.3.2 Multivariate Utility Functions from Multiplicative Combination

In this section, a multivariate desirability function is constructed from the geometric average of the individual desirability functions of each response.

The geometric average of r components $(d_1, \ldots, d_r)$ is the rth root of their products:

$$\mathrm{GA}(d_1, \ldots, d_r) = \left(\prod_{i=1}^{r} d_i \right)^{\frac{1}{r}} . \qquad (10.20)$$

The GA is then a multiplicative combination of the individuals. When combining individual utility functions whose values are scaled between zero and one, the GA yields a value less than or equal to the lowest individual utility value. When rating the composite quality of a product, this prevents any single response from reaching an unacceptable value, since a very low value on any crucial characteristic (such as safety features or cost) will render the entire product worthless to the end user.

Modifications of the Desirability Function

In order to allow the DM to place the ideal target value anywhere within the specifications, *Derringer* and *Suich* [10.122] introduced a modified version of the desirability functions of *Harrington* [10.99] which encompassed both one-sided and two-sided response specifications. Additional extensions of the multivariate desirability function were made by *Kim* and *Lin* [10.123].

10.3.3 Alternative Performance Measures for Multiple Responses

Duffy et al. [10.124] propose using a reasonably precise estimate of multivariate yield, obtained via Beta distribution discrete point estimation, as an efficient alternative to Monte Carlo simulation. This approach is limited to independently distributed design variables. *Fogliatto* and *Albin* [10.125] propose using predictor variance as a multiresponse optimization criterion. They measure predictive variance as the coefficient of variance (CV) of prediction since it represents a normalized measure of prediction variance. *Plante* [10.126] considers the use of maximal process capability as the criterion for choosing control variable settings in multiple response RD situations. He uses the concepts of process capability and desirability to develop process capability measures for multiple response systems.

10.4 Dynamic Robust Design

10.4.1 Taguchi's Dynamic Robust Design

Up to this point, we've discussed only static RD, where the targeted response is a given, fixed level and is only affected by control and noise variables. In dynamic robust design (DRD) a third type of variable exists, the signal variable M whose magnitude directly affects the mean value of the response. The experimental design

recommended by Taguchi for DRD is the product array consisting of an inner control array crossed with an outer array consisting of the sensitivity factors and a compound noise factor.

A common choice of dynamic loss function is the quadratic loss function popularized by Taguchi,

$$L[Y, t(M)] = A_0[Y - t(M)]^2 , \tag{10.21}$$

where A_0 is a constant. This loss function provides a good approximation to many realistic loss functions. It follows that the average loss becomes

$$\begin{aligned} R(\boldsymbol{x}) &= A_0 E_M E_{N,\epsilon}[Y - t(M)]^2 \\ &= A_0 E_M \left\{ \mathrm{Var}_{N,\epsilon}(Y) + [E_{N,\epsilon}(Y) - t(M)]^2 \right\} . \end{aligned} \tag{10.22}$$

Taguchi identifies dispersion and sensitivity effects by modeling SNR respectively as a function of control factors and sensitivity factors. His two-step procedure for DRD finds control factor settings to minimize SNR and sets other, non-SNR related control variables to adjust the process to the targeted sensitivity level.

10.4.2 References on Dynamic Robust Design

Ghosh and *Derderian* [10.127] introduce the concept of robustness of the experimental plan itself to the noise factors present when conducting DRD. For combined arrays they consider blocked and split-plot designs and for product arrays they consider univariate and multivariate models. In product arrays they do this by choosing settings which minimize the noise factor effects on process variability and for the combined array they attempt to minimize the interaction effects between control and noise factors.

Wasserman [10.128] clarifies the use of the SNR for the dynamic case by explaining it in terms of linear modeling of process response. He expresses the dynamic response as a linear model consisting of a signal factor, the true sensitivity (β) at specific control variable settings, and an error term. *Miller* and *Wu* [10.129] prefer the term signal-response system to dynamic robust design for its intuitive appeal and identify two distinct types of signal-response systems. They call them measurement systems and multiple target systems, where this distinction determines the performance measure used to find the optimal control variable settings.

Lunani, *Nair* and *Wasserman* [10.130] present two new graphical procedures for identifying suitable measures of location and dispersion in RD situations with dynamic experimental designs. *McCaskey* and *Tsui* [10.131] show that Taguchi's two-step procedure for dynamic systems is only appropriate for multiplicative models and develop a procedure for dynamic systems under an additive model. For a dynamic system this equates to minimizing the sum of process variance and bias squared over the range of signal values.

Tsui [10.132] compares the effect estimates obtained using the response model approach and Taguchi's approach for dynamic robust design problems. Recent publications on DRD include *Joseph* and *Wu* [10.133], *Joseph* and *Wu* [10.134] and *Joseph* [10.135].

10.5 Applications of Robust Design

10.5.1 Manufacturing Case Studies

Mesenbrink [10.136] applied the techniques of RD to optimize three performance measurements of a high volume wave soldering process. They achieved significant quality improvement using a mixed-level fractional factorial design to collect ordered categorical data regarding the soldering quality of component leads in printed circuit boards. *Lin* and *Wen* [10.137] apply RD to improve the uniformity of a zinc coating process.

Chhajed and *Lowe* [10.138] apply the techniques of RD to the problem of structured tool management. For the cases of tool selection and tool design they use Taguchi's quadratic loss function to find the most cost effective way to accomplish the processing of a fixed number of punched holes in sheet metal products.

10.5.2 Reliability

Reliability is the study of how to make products and processes function for longer periods of time with minimal interruption. It is a natural area for RD application and the Japanese auto industry has made huge strides in this area compared to its American counterpart. In this section several authors comment on the application of RD to reliability.

Hamada [10.139] demonstrates the relevance of RD to reliability improvement. He recommends the response model approach for the additional information it provides on control–noise interactions and suggests alternative performance criteria for maximizing reliability. *Kuhn* et al. [10.140] extend the methods of *Myers* et al. [10.103] for linear models and normally

distributed data to achieve a robust process when time to an event is the response.

10.5.3 Tolerance Design

This paper has focused on RD, which is synonymous with Taguchi's methods of parameter design. Taguchi has also made significant contributions in the area of tolerance design. This section reviews articles which examine developments in the techniques of tolerance design.

D'errico and *Zaino* [10.141] propose a modification of Taguchi's approach to tolerance design based on a product Gaussian quadrature which provides better estimates of high-order moments and outperforms the basic Taguchi method in most cases. *Bisgaard* [10.142] proposes using factorial experimentation as a more scientific alternative to trial and error to design tolerance limits when mating components of assembled products.

Zhang and *Wang* [10.143] formulate the robust tolerance problem as a mixed nonlinear optimization model and solve it using a simulated annealing algorithm. The optimal solution allocates assembly and machining tolerances so as to maximize the product's insensitivity to environmental factors. *Li* and *Wu* [10.55] combined parameter design with tolerance design.

Maghsoodloo and *Li* [10.144] consider linear and quadratic loss functions for determining an optimal process mean which minimizes the expected value of the quality loss function for asymmetric tolerances of quality characteristics. *Moskowitz* et al. [10.145] develop parametric and nonparametric methods for finding economically optimal tolerance allocations for a multivariable set of performance measures based on a common set of design parameters.

11. Statistical Methods for Product and Process Improvement

The first part of this chapter describes a process model and the importance of product and process improvement in industry. Six Sigma methodology is introduced as one of most successful integrated statistical tool.

Then the second section describes the basic ideas for Six Sigma methodology and the (D)MAIC(T) process for better understanding of this integrated process improvement methodology.

In the third section, "Product Specification Optimization", optimization models are developed to determine optimal specifications that minimize the total cost to both the producer and the consumer, based on the present technology and the existing process capability. The total cost consists of expected quality loss due to the variability to the consumer, and the scrap or rework cost and inspection or measurement cost to the producer. We set up the specifications and use them as a counter measure for the inspection or product disposition, only if it reduces the total cost compared with the expected quality loss without inspection. Several models are presented for various process distributions and quality loss functions.

The fourth part, "Process Optimization", demonstrates that the process can be improved during the design phase by reducing the bias or variance of the system output, that is, by changing the mean and variance of the quality characteristic of the output. Statistical methods for process optimization, such as experimental design, response surface methods, and Chebyshev's orthogonal polynomials are reviewed. Then the integrated optimization models are developed to minimize the total cost to the system of producers and customers by determining the means and variances of the controllable factors. Finally, a short summary is given to conclude this chapter.

Improving manufacturing or service processes is very important for a business to stay competitive in today's marketplace. Companies have been forced to improve their business processes because customers are always demanding better products and services. During the last 20 years, industrial organizations have become more and more interested in process improvement. Statistical methods contribute much to this activity, including design of experiments, regression analysis, response surface methodology, and their integration with optimization methods.

A process is a collection of activities that takes one or more kinds of inputs and creates a set of outputs that are of value to the customer. Everyone may be involved in various processes in their daily life, for example, ordering books from an Internet retailer, checking out in a grocery store, remodeling a home, or developing new products. A process can be graphed as shown in Fig. 11.1. The purpose of this model is to define the supplier, process inputs, the process, associated outputs, and the customer. The loops for the feedback information for continuous improvement are also shown.

As mentioned above, a process consists of many input variables and one or multiple output variables. The input variables include both controllable and uncontrollable or noise factors. For instance, for an electric circuit designed to obtain a target output voltage, the designer can specify the nominal values of resistors or capacitor, but he cannot control the variability of resistors or capacitors at any point in time or over the life cycle of the product. A typical process with one output variable is given in Fig. 11.2, where $X_1, X_2, \ldots, X_n$ are controllable variables and y is the realization of the random output variable Y.

Many companies have implemented continuous process improvement with Six Sigma methodology, such as Motorola [11.1] and GE [11.2]. Six Sigma is a customer-focused, data-driven, and robust methodology that is well rooted in mathematics and statistics. A typical process for Six Sigma quality improvement has six phases: define, measure, analyze, improve, control, and technology transfer, denoted by (D)MAIC(T). The section "Six Sigma Methodology and the (D)MAIC(T) Process" introduces the basic ideas behind Six Sigma methodology and the (D)MAIC(T) process for a better understanding of this integrated process-improvement methodology.

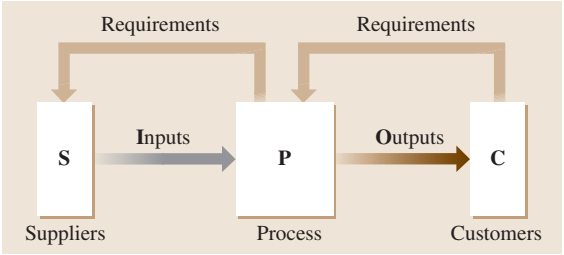

Fig. 11.1 Process model

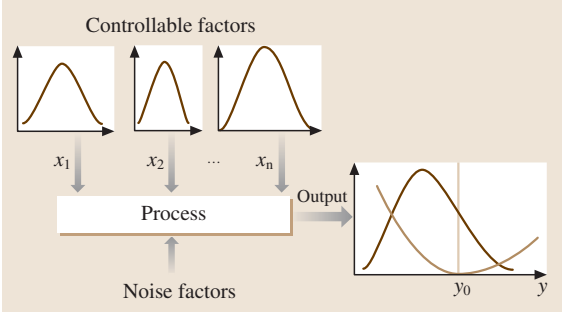

Fig. 11.2 General process with one output variable

In the section "Product Specification Optimization," we create optimization models to develop specifications that minimize the total cost to both the producer and the consumer, based on present technology and existing process capabilities. The total cost consists of expected quality loss due to the variability to the consumer and the scrap or rework cost and inspection or measurement cost to the producer. We set up the specifications and use them as a countermeasure for inspection or product disposition only if it reduces the total cost compared with the expected quality loss without inspection. Several models are presented for various process distributions and quality-loss functions.

In the section "Process Optimization," we assume that the process can be improved during the design phase by reducing the bias or variance of the system output, that is, by changing the mean and variance of the quality characteristic of the output. Statistical methods for process optimization, such as experimental design, response surface methods, and Chebyshev's orthogonal polynomials, are reviewed. Then the integrated optimization models are developed to minimize the total cost to the system of producers and customers by determining the means and variances of the controllable factors.

11.1 Six Sigma Methodology and the (D)MAIC(T) Process

The traditional evaluation of quality is based on average measures of a process/product. But customers judge the quality of process/product not only on the average, but also by the variance in each transaction or use of the product. Customers value consistent, predictable processes that deliver best-in-class levels of quality. This is what Six Sigma process strives to produce. Six Sigma methodology focuses first on reducing process variation and thus on improving the process capability.

The typical definition of a process capability index, C_{pk}, is $C_{pk} = \min((\mathrm{USL} - \hat{\mu})/(3\hat{\sigma}), (\hat{\mu} - \mathrm{LSL})/(3\hat{\sigma}))$, where USL is the upper specification limit, LSL is the lower specification limit, $\hat{\mu}$ is the point estimator of the mean, and $\hat{\sigma}$ is the point estimator of the standard deviation. If the process is centered at the middle of the specifications, which is also interpreted as the target value, i.e., $\hat{\mu} = (\mathrm{USL} + \mathrm{LSL})/(2) = y_0$, then the Six Sigma process means that $C_{pk} = 2$. In the literature, it is typically mentioned that the Six Sigma process results in 3.4 defects per million opportunities (DPMO). For this statement, we assume that the process shifts by 1.5σ over time from the target (which is assumed to be the middle point of the specifications). It implies that the realized C_{pk} is 1.5 for the Six Sigma process over time. Thus, it is obvious that 6σ requirements or C_{pk} of 1.5 is not the goal; the ideal objective is to continuously improve the process based on some economic or other higher-level objectives for the system.

At the strategic level, the goal of Six Sigma is to align an organization to its marketplace and deliver real improvement to the bottom line. At the operational level, Six Sigma strives to move product or process characteristics within the specifications required by customers, shrink process variation to the six sigma level, and reduce the cause of defects that negatively affect quality [11.3].

Six Sigma continuous improvement is a rigorous, data-driven, decision-making approach to analyzing the root causes of problems and improve the process capability to the six sigma level. It utilizes a systematic six-phase, problem-solving process called (D)MAIC(T): define, measure, analyze, improve, control, and technology transfer. Traditionally, a four-step process, MAIC, is often referred to as a general process for Six Sigma process improvement in the literature. We extend it to the six-step process, (D)MAIC(T). We want to emphasize the importance of the define (D) phase as the first phase for the problem definition and project selection, and we want to highlight technology transfer (T) as the never-ending phase for continuous applications of Six Sigma technology to other parts of the organization. The process of (D)MAIC(T) stays on track by establishing deliverables for each phase, by creating engineering models over time to reduce process variation, and by continuously improving the predictability of system performance. Each of the six phases in the (D)MAIC(T) process is critical to achieving success.

11.1.1 Define: What Problem Needs to Be Solved?

It is important to define the scope, expectations, resources, and timelines for the selected project. The definition phase for the Six Sigma approach identifies the specific scope of the project, defines the customer and critical-to-quality (CTQ) issues from the viewpoint of the customer, and develops the core processes.

11.1.2 Measure: What Is the Current Capability of the Process?

Design for Six Sigma is a data-driven approach that requires quantifying and benchmarking the process using actual data. In this phase, the performance or process capability of the process for the CTQ characteristics are evaluated.

11.1.3 Analyze: What Are the Root Causes of Process Variability?

Once the project is understood and the baseline performance documented, it is time to do an analysis of the process. In this phase, the Six Sigma approach applies statistical tools to determine the root causes of problems. The objective is to understand the process at a level sufficient to be able to formulate options for improvement. We should be able to compare the various options with each other to determine the most promising alternatives. In general, during the process of analysis, we analyze the data collected and use process maps to determine root causes of defects and prioritize opportunities for improvement.

11.1.4 Improve: Improving the Process Capability

During the improvement phase of the Six Sigma approach, ideas and solutions are incorporated to initialize

the change. Based on the root causes discovered and validated for the existing opportunity, the target process is improved by designing creative solutions to fix and prevent problems. Some experiments and trials may be implemented in order to find the best solution. If a mathematical model is developed, then optimization methods are utilized to determine the optimum solution.

11.1.5 Control: What Controls Can Be Put in Place to Sustain the Improvement?

The key to the overall success of the Six Sigma methodology is its sustainability, which seeks to make everything incrementally better on a continuous basis. The sum of all these incremental improvements can be quite large. Without continuous sustenance, over time things will get worse until finally it is time for another attempt at improvement. As part of the Six Sigma approach, performance-tracking mechanisms and measurements are put in place to assure that the gains made in the project are not lost over time and the process remains on the new course.

11.1.6 Technology Transfer: Where Else Can These Improvements Be Applied?

Ideas and knowledge developed in one part of an organization can be transferred to other parts of the organization. In addition, the methods and solutions developed for one product or process can be applied to other similar products or processes. Numbering by infinity, we keep on transferring technology, which is a never-ending phase for achieving Six Sigma quality. With technology transfer, the Six Sigma approach starts to create phenomenal returns.

There are many optimization problems in the six phases of this methodology. In the following sections, several statistical methods and optimization models are reviewed or developed to improve the quality of product or process to the six sigma level, utilizing the tools of probabilistic design, robust design, design of experiments, multivariable optimization, and simulation techniques. The goal is to investigate and explore the engineering, mathematical, and statistical bases of (D)MAIC(T) process.

11.2 Product Specification Optimization

For any process, strategic decisions have to be made in terms of the disposition of the output of the process, which may be some form of inspection or other countermeasures such as scrapping or reworking the output product. We may do zero inspection, 100% inspection, or use sampling inspection. Some of the problems with acceptance sampling were articulated by *Deming* [11.4], who pointed out that this procedure, while minimizing the inspection cost, does not minimize the total cost to the producer. *Orsini* [11.5] in her doctoral thesis explained how this results in a process of suboptimization.

Deming's inspection criterion indicates that inspection should be performed either 100% or not at all, depending on the total cost to the producer, which includes the cost of inspection, k_1, and the detrimental cost of letting a nonconforming item go further down into production, k_2. The criterion involves k_1, k_2, and p, the proportion of incoming nonconforming items. The break-even point is given by $k_1/k_2 = p$. If $k_1/k_2 < p$, then 100% inspection is called for; if $k_1/k_2 > p$, then no inspection is done under the assumption that the process is in a state of statistical control. The practicality and usefulness of Deming's criterion for a manufacturing company was illustrated by *Papadakis* [11.6], who formulated models to decide if we should do either 100% inspection or zero inspection based on the total cost to the producer.

Deming [11.4] also concludes that k_1 and k_2 are not the only costs to consider. As manufacturers try hard to meet or exceed customer expectations, the cost to the customers should be considered when planning for the inspection strategy. To meet the requirements of the current competitive global markets, we consider the cost to both consumers and producers, thus the total cost to the whole system in the general inspection model. If we decide to do 100% inspection, we should also know what specification limits are for the purpose of inspection, so that we can make decisions about the disposition of the output. The work done by Deming and others does not explicitly consider the specification limits for inspection and how to determine them.

In the following discussion, several economic models are proposed that not only explain when to do 100% inspection but also develop the specifications for the inspection. A general optimization model is developed to minimize the total cost to the system, including both the producer and the customer, utilizing the quality loss function based on some of the contribution of *Taguchi*'s

work [11.7, 8]. In particular, the optimization models with the symmetric and asymmetric quadratic quality loss function are presented to determine the optimal process mean and specification limits for inspection.

11.2.1 Quality Loss Function

The traditional concept of conformance to specifications is a binary evaluation system (Fig. 11.3). Units that meet the specification limits are labeled "good" or "conforming," and units out of specification limits are "bad" or "nonconforming." In the traditional quality concept, quality evaluation systems focus only on the nonconforming units and cost of quality is defined as cost of nonconformance. We can easily recognize the simplicity of this binary (go/no go) evaluation system, as the quality may not differ very much between a "good" item that is just within specifications and a "bad" item that is just outside specifications.

A better evaluation system should measure the quality of all the items, both within and outside specifications. As shown in Fig. 11.4, the concept of quality loss function provides a quantitative evaluation of loss caused by functional variation. We describe the derivation of the quadratic quality loss function in what follows.

Let $L_1(y)$ be a measure of losses, disutility, failure rate, or degradation associated with the quality characteristic y. $L_1(y)$ is a differentiable function in the neighborhood of the target y_0. Using Taylor's series expansion, we have

$$L_1(y) = L_1(y_0) + L_1'(y_0)(y - y_0) + L_1''(y_0)\frac{(y-y_0)^2}{2!} + \cdots .$$

The minimum quality loss should be obtained at y_0, and hence $L_1'(y_0) = 0$. Since $L_1(y_0)$ is a constant quality loss at y_0, we define the deviation loss of y from y_0 as

$$L(y) = L_1(y) - L_1(y_0) = L_1''(y_0)\frac{(y-y_0)^2}{2!} + \cdots .$$

By ignoring the higher-order terms, $L(y)$ can be approximated using a quadratic function:

$$L(y) \approx k(y - y_0)^2 ,$$

where

$$k = \frac{L_1''(y_0)}{2} .$$

If the actual quality loss function $L(y)$ is known, we should use it instead of the approximated loss function.

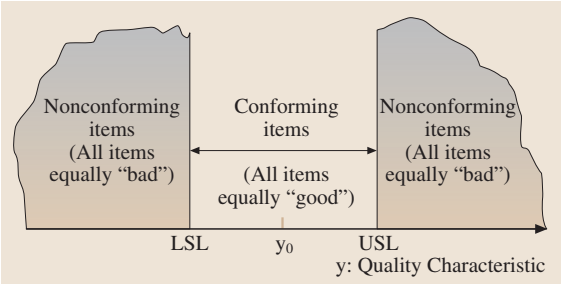

Fig. 11.3 Conformance to specifications concept of quality

Let $f(y)$ be the probability density function (pdf) of the random variable Y; then the expected loss for any given $L(y)$ is

$$\mathcal{L} = E[L(y)] = \int_{\text{all } y} L(y) f(y)\,\mathrm{d}y .$$

From this equation we can see that the expected loss depends heavily on the distribution of Y. To reduce the expected quality loss, we need to improve the distribution of Y, not just reduce the number of items outside specification limits. It is quite different from the traditional evaluation policy, which only measures the cost incurred by nonconforming quality characteristics. In the following sections, different quality loss functions are discussed for different types of quality characteristics.

"The Smaller the Better" Quality Characteristics

The objective is to reduce the value of the quality characteristic. Usually the smallest possible value for such characteristics is zero, and thus $y_0 = 0$ is the "ideal" or target value, as shown in Fig. 11.5. Some examples are wear, degradation, deterioration, shrinkage, noise

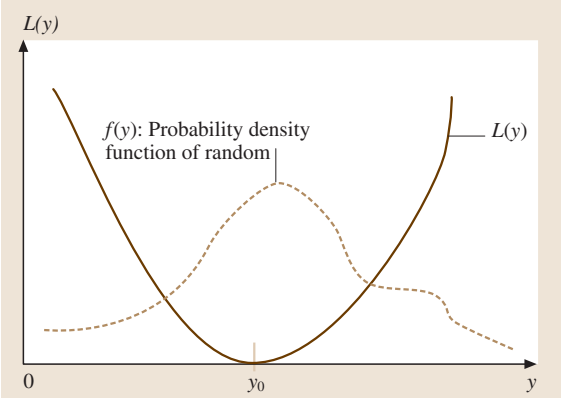

Fig. 11.4 Quality loss function $L(y)$

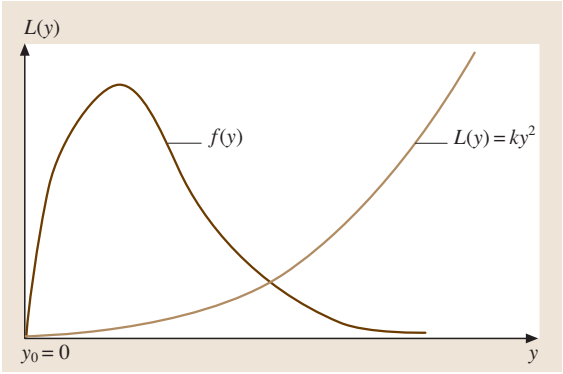

Fig. 11.5 "The smaller the better" quality characteristics

level, harmful effects, level of pollutants, etc. For such characteristics, engineers generally have an upper specification limit (USL). A good approximation of $L(y)$ is $L(y) = ky^2$, $y \geq 0$.

The expected quality loss is calculated as

$$\begin{aligned}\mathcal{L} &= E[L(y)] \\ &= \int_{\text{all } y} L(y) f(y)\,\mathrm{d}y \\ &= \int_{\text{all } y} ky^2 f(y)\,\mathrm{d}y \\ &= \int_{\text{all } y} k\left[(y-\mu)^2 + 2(y-\mu)\mu + \mu^2\right] f(y)\,\mathrm{d}y \\ &= k\left(\sigma^2 + \mu^2\right) .\end{aligned}$$

To reduce the loss, we must reduce the mean μ and the variance σ^2 simultaneously.

"The Larger the Better" Quality Characteristics

For such quality characteristics, we want to increase their value as much as possible (within a given frame of reference), as shown in Fig. 11.6. Some examples are strength, life of a system (a measure of reliability), fuel efficiency, etc. An ideal value may be infinity, though impossible to achieve. For such characteristics, engineers generally have a lower specification limit (LSL). A good approximation of $L(y)$ is

$$L(y) = \frac{k}{y^2}, \quad y \geq 0 .$$

The expected quality loss is given by

$$\mathcal{L} = E[L(y)] = \int_{\text{all } y} L(y) f(y)\,\mathrm{d}y = \int_{\text{all } y} \frac{k}{y^2} f(y)\,\mathrm{d}y .$$

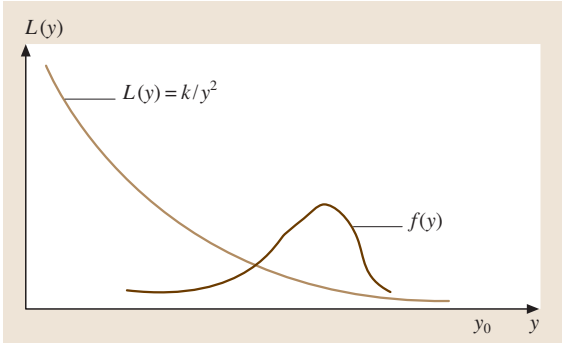

Fig. 11.6 "The larger the better" quality characteristics

Using Taylor's series expansion for $1/y^2$ around μ, we have

$$\begin{aligned}\frac{1}{y^2} &= \mu^{-2} \\ &\quad + \left(-2y^{-3}\,|_{\mu}\right)(y-\mu) \\ &\quad + 6y^{-4}\,|_{\mu}\,\frac{(y-\mu)^2}{2!} \\ &\quad + \cdots .\end{aligned}$$

By ignoring higher-order terms, we have

$$\frac{1}{y^2} \approx \frac{1}{\mu^2} + \frac{2}{\mu^3}(y-\mu) + \frac{3}{\mu^4}(y-\mu)^2 .$$

Finally, we have

$$\begin{aligned}E[L(y)] &\approx k \int_{\text{all } y} \left[\frac{1}{\mu^2} + \frac{2}{\mu^3}(y-\mu) \right. \\ &\qquad \left. + \frac{3}{\mu^4}(y-\mu)^2\right] f(y)\,\mathrm{d}y \\ &\approx k\left(\frac{1}{\mu^2} + \frac{3\sigma^2}{\mu^4}\right) .\end{aligned}$$

To reduce quality losses for the "larger the better" quality characteristics, we must increase the mean μ and reduce the variance σ^2 of Y simultaneously.

"Nominal the Best" Quality Characteristics

For such quality characteristics, we have an ideal or nominal value, as shown in Fig. 11.7. The performance of the product deteriorates as we move from each side of the nominal value. Some examples are dimensional characteristics, voltage, viscosity of a fluid, shift pressure, clearance, and so on. For such characteristics, engineers generally have both LSL and USL. An approximation of quality loss function for "nominal the best" quality characteristics is $L(y) = k(y - y_0)^2$.

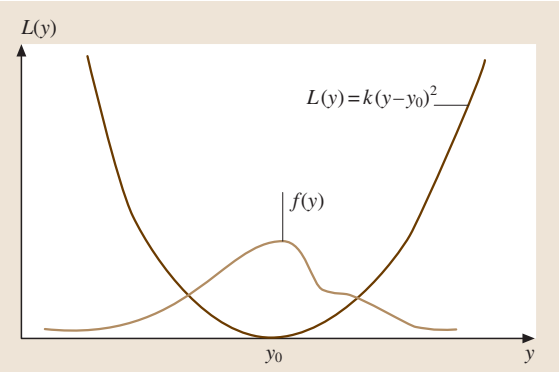

Fig. 11.7 "Nominal the best" quality characteristics

The expected quality loss is calculated as

$$\mathcal{L} = E[L(y)] = \int_{\text{all } y} L(y) f(y)\,\mathrm{d}y$$
$$= \int_{\text{all } y} k(y-y_0)^2 f(y)\,\mathrm{d}y$$
$$= k\left[\sigma^2 + (\mu - y_0)^2\right] .$$

Given the constant k, we must reduce bias $|\mu - y_0|$ and variance σ^2 to reduce the losses.

11.2.2 General Product Specification Optimization Model

Quality loss relates to cost or "loss" in dollars, not just to the manufacturer at the time of production, but also to the next consumer. The intangible losses (customer dissatisfaction, loss of customer loyalty, and eventual loss of market share), along with other tangible losses (rework, defects, down time, etc.), make up some of the components of the quality loss. Quality loss function is a way to measure losses due to variability from the target values and transform them to economic values. The greater the deviation from target, the greater the economic loss.

Variability means some kind of waste, but it is impossible to have zero variability. The common response has been to set not only a target level for performance but also a range of tolerance about that target, or specification limits, which represents "acceptable" performance. Thus if a quality characteristic falls anywhere within the specifications, it is regarded as acceptable, while if it falls outside that specifications, it is not acceptable. If the inspection has to be done to decide what is acceptable, we must know the specification limits. We consider the specifications not just from the viewpoint of the customer or the producer but from the viewpoint of the whole system. The issue is not only to decide when to do inspection, but also to decide what specifications will be applied for the inspection.

Suppose a process has been improved to its optimal capability using the present technology; then we consider the following two questions:

Question 1: Should we perform 100% inspection or zero inspection before shipping the output to the next or downstream customers?

Question 2: If 100% inspection is to be performed, how do we determine the optimal specification limits that minimize the total cost to the system, which includes both producers and consumers?

To answer the above two questions, the decision maker has to choose between the following two decisions:

Decision 1: No inspection is done, and thus we ship the whole distribution of the output to the next customer. One economic interpretation of cost to the downstream customers is the expected quality loss.

Decision 2: Do 100% inspection. It is clear that we will do the inspection and truncate the tails of the distribution only if it reduces total cost to both the producer and the consumer. If we have some arbitrary specification limits, we may very well increase the total cost by doing inspection. When we truncate the distribution by using certain specification limits, some additional costs will be incurred, such as the measurement or inspection cost (to evaluate if units meet the specifications), the rework cost, and the scrap cost. The general optimization model is

$$\text{Minimize ETC} = \text{EQL} + \text{ESC} + \text{IC} ,$$

where

ETC = Expected total cost per produced unit

EQL = Expected quality loss per unit

ESC = Expected scrap cost per unit

IC = Inspection cost per unit

and where the specification limits are the decision variables in the optimization model. Based on this general optimization model, models have been formulated under the following assumptions:

- The nature of the quality characteristics:
  - "The smaller the better"
  - "The larger the better"
  - "Target the best"

- The nature of the underlying distributions of the output:
  - Normal distribution
  - Lognormal distribution
  - Weibull distribution
- The relationship between the process mean and the target value:
  - The process mean is centered at the target: $\mu = y_0$
  - The process mean is not centered at the target: $\mu \neq y_0$
- The shape of the quality loss function:
  - Symmetric
  - Asymmetric
- The number of quality characteristics:
  - Single quality characteristic
  - Multiple quality characteristics

Kapur [11.9], *Kapur* and *Wang* [11.10], *Kapur* and *Cho* [11.11], and *Kapur* and *Cho* [11.12] have developed several models for various quality characteristics and illustrated the models with several numerical problems. *Kapur* and *Wang* [11.10] and *Kapur* [11.13] considered the normal distribution for the "target the best" single quality characteristic to develop the specification limits based on the symmetric quality loss function and also used the lognormal distribution to develop the model for the "smaller the better" single quality characteristic. For the "smaller or larger the better" single quality characteristic, *Kapur* and *Cho* [11.11] used the Weibull distribution to approximate the underlying skewed distribution of the process, because a Weibull distribution can model various shapes of the distribution by changing the shape parameter β. *Kapur* and *Cho* [11.12] proposed an optimization model for multiple quality characteristics with the multivariate normal distribution based on the multivariate quality loss function.

In the next two subsections, two optimization models are described to determine the optimal specification limits. The first model is developed for a normal distributed quality characteristic with a symmetric quality loss function, published by *Kapur* and *Wang* [11.10] and *Kapur* [11.13]. The second model is formulated for a normal distributed quality characteristic with an asymmetric quality loss function, proposed by *Kapur* and *Feng* [11.14].

11.2.3 Optimization Model with Symmetric Loss Function

We summarize the basic assumptions presented in *Kapur* and *Wang* [11.10] and *Kapur* [11.13] as below:

- The single quality characteristic is "target the best," and the target is y_0.
- The process follows a normal distribution: $Y \propto N(\mu, \sigma^2)$.
- The process mean is centered at the target: $\mu = y_0$.
- The quality loss function is symmetric about the target y_0 and given as $L(y) = k(y - y_0)^2$.

Based on these assumptions, the expected quality loss without inspection is calculated as:

$$\begin{aligned}\mathcal{L} = E[L(Y)] &= \int_{-\infty}^{\infty} k(y - y_0)^2 f(y)\,\mathrm{d}y \\ &= k\left\{[E(Y) - y_0]^2 + Var(Y)\right\} \\ &= k\left[\sigma^2 + (y_0 - \mu)^2\right] .\end{aligned}$$

After setting the process mean at the target, $\mu = y_0$, the expected loss only has the variance term, which is $\mathcal{L} = k\sigma^2$.

If we do 100% inspection, we will truncate the tails of the distribution at specification limits, which should be symmetric about the target:

$$\begin{aligned}\mathrm{LSL} &= \mu - n\sigma , \\ \mathrm{USL} &= \mu + n\sigma .\end{aligned}$$

In order to optimize the model, we need to determine the variance of the truncated normal distribution (the distribution of the units shipped to the customer), which is $\mathrm{V}(Y_\mathrm{T})$. Let $f_\mathrm{T}(y_\mathrm{T})$ be the probability density function for the truncated random variable Y_T; then we have

$$f_\mathrm{T}(y_\mathrm{T}) = \frac{1}{q} f(y_\mathrm{T}) = \frac{1}{q\sigma\sqrt{2\pi}} \mathrm{e}^{-\frac{(y_\mathrm{T}-\mu)^2}{2\sigma^2}} ,$$

where

$$\begin{aligned}q &= 2\Phi(n) - 1 \\ &= \text{fraction of units shipped to customers} \\ &\quad \text{or area under normal distribution within} \\ &\quad \text{specification limits}\end{aligned}$$

and

$$\mu - n\sigma \leq y_\mathrm{T} \leq \mu + n\sigma ,$$

where $\phi(\cdot)$ is the pdf for the standard normal variable and $\Phi(\cdot)$ is the cdf for the standard normal variable. From the probability density function (pdf) we can derive the mean and variance of the truncated normal distribution as

$$E(Y_T) = \mu \,,$$
$$V(Y_T) = \sigma^2 \left[1 - \frac{2n}{2\Phi(n)-1}\phi(n)\right] .$$

It is clear that the quantity of $V(Y_T)$ is less than σ^2, which means that we reduce the variance of units shipped to the customer (Y_T). Then the expected quality loss, $\mathcal{L}_T$, for the truncated distribution is

$$\mathcal{L}_T = k\left\{[E(Y_T) - y_0]^2 + V(Y_T)\right\} = kV(Y_T) \,.$$

Then the expected quality loss per unit EQL is $q\mathcal{L}_T$, because the fraction of units shipped to customers is q. Given k, SC, and IC, we have the optimization model with only one decision variable n as

$$\begin{aligned} &\text{Minimize ETC} = q\mathcal{L}_T + (1-q)\text{SC} + \text{IC} \,, \\ &\text{subject to } \mathcal{L}_T = k\sigma^2\left[1 - \frac{2n}{2\Phi(n)-1}\phi(n)\right] , \\ &\qquad q = 2\Phi(n) - 1 \,, \\ &\qquad n \geq 0 \,. \end{aligned}$$

The above objective function is unimodal and differentiable, and hence the optimal solution can be found by differentiating the objective function with respect to n and setting it equal to zero. Thus we solve $(\partial \text{ETC}/\partial n) = 0$, and the solution is $n^* = \sqrt{\text{SC}/(k\sigma^2)}$.

Let us now consider an example for a normal process with $\mu = 10$, $\sigma = 0.50$, $y_0 = 10$, $k = 5$, IC = \$0.10, and SC = \$2.00.

Decision 1: If we do not conduct any inspection, the total expected quality loss per unit is calculated as $\text{TC} = \mathcal{L} = k\sigma^2 = 5 \times 0.50^2 = \$1.25$.

Decision 2: Let us determine the specification limits that will minimize the total expected cost by using the following optimization model:

$$\begin{aligned} &\text{Minimize ETC} = q\mathcal{L}_T + (1-q)\text{SC} + \text{IC} \\ &\qquad = 5 \times 0.5^2\,[2\Phi(n) - 1 - 2n\phi(n)] \\ &\qquad\quad + [2 - 2\Phi(n)] \times 2.00 + 0.10 \\ &\text{subject to } n \geq 0 \,. \end{aligned}$$

The optimal solution is given by $n^* = \sqrt{\text{SC}/(k\sigma^2)} = 1.26$, and $\text{ETC}^* = \$0.94 < \$1.25$. Thus, the optimal strategy is to have LSL = 9.37 and USL = 10.63, and do 100% inspection to screen the nonconforming units. The above model presents a way to develop optimum specification limits by minimizing the total cost. Also, Fig. 11.8 gives the relationship between the expected total cost ETC and n, where we can easily observe that the minimum is when $n = 1.26$.

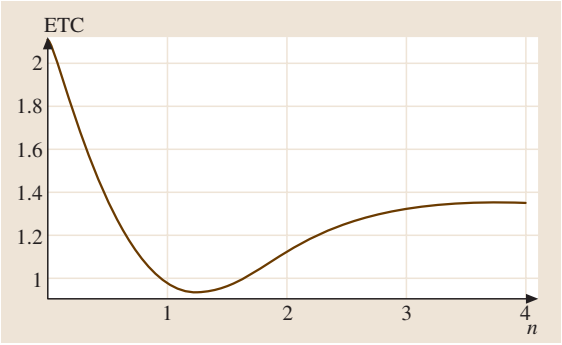

Fig. 11.8 Expected total cost vs. n

In addition to the above model for the "target the best" quality characteristic, *Kapur* and *Wang* [11.10] used the lognormal distribution to develop a model for the "smaller the better" quality characteristic. For the "smaller or larger the better" quality characteristic, *Kapur* and *Cho* [11.11] used the Weibull distribution to approximate the underlying skewed distribution of the process because a Weibull distribution can model various shapes of the distribution by changing the shape parameter β.

11.2.4 Optimization Model with Asymmetric Loss Function

The following assumptions are presented to formulate this optimization model [11.14]:

- The single quality characteristic is "target the best," and the target is y_0.
- The process follows a normal distribution: $Y \approx N(\mu, \sigma^2)$, and the probability density function of Y is $f(y) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(y-\mu)^2}{2\sigma^2}}$.
- The mean of the process can be easily adjusted, but the variance is given based on the present technology or the inherent capability of the process.
- The process mean may not be centered at the target: $\mu \neq y_0$, which is a possible consequence of an asymmetric loss function.
- The quality loss function is asymmetric about the target y_0, which means that the performance of the product deteriorates in the different ways as the

quality characteristic deviates to either side of the target value. An asymmetric quality loss function is given as:

$$\begin{cases} k_1(y-y_0)^2, & y \le y_0\,, \\ k_2(y-y_0)^2, & y > y_0\,. \end{cases}$$

Based on these assumptions, if we ship the whole distribution of the output to the next customer as for Decision 1, the total cost is just the expected quality loss to the customer. We can prove that the expected quality loss without truncating the distribution is:

$$\begin{aligned} \mathrm{ETC}_1 = \mathcal{L} = & \int_{-\infty}^{y_0} k_1(y-y_0)^2 f(y)\,\mathrm{d}y \\ & + \int_{y_0}^{\infty} k_2(y-y_0)^2 f(y)\,\mathrm{d}y \\ = & (k_1-k_2)\sigma(y_0-\mu)\phi\left(\frac{y_0-\mu}{\sigma}\right) \\ & + \left[\sigma^2+(y_0-\mu)^2\right] \\ & \times\left[(k_1-k_2)\Phi\left(\frac{y_0-\mu}{\sigma}\right)+k_2\right], \end{aligned}$$

where $\phi(\cdot)$ is the pdf for the standard normal variable and $\Phi(\cdot)$ is the cdf for the standard normal variable. Given k_1, k_2, and y_0 and the standard deviation σ, the total cost or the expected quality loss to the customer in this case should be minimized by finding the optimal process mean μ^*. The optimization model for Decision 1 is:

$$\begin{aligned} \text{Minimize } \mathrm{ETC}_1 = & (k_1-k_2)\sigma(y_0-\mu)\phi\left(\frac{y_0-\mu}{\sigma}\right) \\ & + \left[\sigma^2+(y_0-\mu)^2\right] \\ & \times\left[(k_1-k_2)\Phi\left(\frac{y_0-\mu}{\sigma}\right)+k_2\right] \\ \text{subject to } & \mu \in \mathbb{R}\,. \end{aligned}$$

Given k_1, k_2, y_0, and σ, ETC_1 or $\mathcal{L}$ is a convex differential function of μ, because the second derivative $\frac{\mathrm{d}^2\mathcal{L}}{\mathrm{d}\mu^2} > 0$. We know that a convex differential function obtains its global minimum at $\frac{\mathrm{d}\mathcal{L}}{\mathrm{d}\mu} = 0$, which is given by

$$\begin{aligned} \frac{\mathrm{d}\mathcal{L}}{\mathrm{d}\mu} = & 2(k_2-k_1)\left[\sigma^2 f(y_0)+(\mu-y_0)\int_{y_0}^{\mu} f(y)\,\mathrm{d}y\right] \\ & + (k_1+k_2)(\mu-y_0) \\ = & 0\,. \end{aligned} \tag{11.1}$$

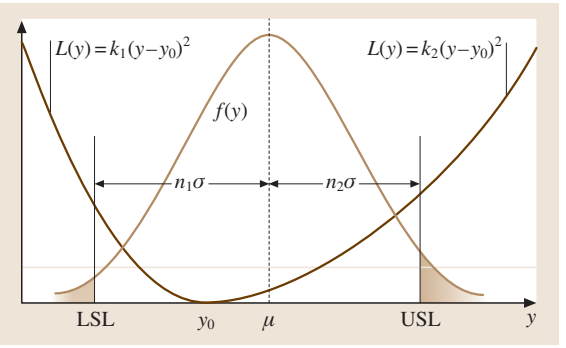

Fig. 11.9 Optimization model with asymmetric loss function

Thus, the optimal value of the process mean μ^* is obtained by solving the above equation of μ. Since the root of (11.1) cannot be found explicitly, we can use Newton's method to search the numerical solution by Mathematica.

If we do the 100% inspection as for Decision 2, we should truncate the tails of the distribution at asymmetric specification limits as shown in Fig. 11.9, where

$$\begin{aligned} \mathrm{LSL} &= \mu - n_1\sigma\,, \\ \mathrm{USL} &= \mu + n_2\sigma\,. \end{aligned}$$

Let $f_\mathrm{T}(y_\mathrm{T})$ be the probability density function for the truncated random variable Y_T; then we have

$$\begin{aligned} & f_\mathrm{T}(y_\mathrm{T}) = \frac{1}{q} f(y_\mathrm{T}) = \frac{1}{q\sigma\sqrt{2\pi}}\,\mathrm{e}^{-\frac{(y_\mathrm{T}-\mu)^2}{2\sigma^2}}\,, \\ & \text{where} \quad q = \Phi(n_1)+\Phi(n_2)-1\,, \\ & \text{and} \quad \mu - n_1\sigma \le y_\mathrm{T} \le \mu + n_2\sigma\,. \end{aligned}$$

Using the above information, we can prove that the expected quality loss for the truncation distribution is:

$$\begin{aligned} \mathcal{L}_\mathrm{T} = & \frac{1}{q}\left\{k_1\sigma\left[2(\mu-y_0)-n_1\sigma\right]\phi(n_1)\right. \\ & \left. + k_2\sigma\left[2(y_0-\mu)-n_2\sigma\right]\phi(n_2)\right\} \\ & + \frac{1}{q}\left\{\sigma(y_0-\mu)(k_1-k_2)\phi\left(\frac{y_0-\mu}{\sigma}\right)\right. \\ & \left. + (k_1-k_2)\left[\sigma^2+(y_0-\mu)^2\right]\Phi\left(\frac{y_0-\mu}{\sigma}\right)\right\} \\ & + \frac{1}{q}\left\{\left[\sigma^2+(y_0-\mu)^2\right]\right. \\ & \left. \times\left[k_1\Phi(n_1)+k_2\Phi(n_2)-k_1\right]\right\}. \end{aligned}$$

Then the expected quality loss per unit EQL is $q\mathcal{L}_T$, because the fraction of units shipped to customers is q. If k_1, k_2, y_0, ESC, and IC are given, we can minimize ETC_2 to find the optimal value of n_1, n_2, and the process mean value μ. The optimization model for Decision 2 is

$$\begin{aligned}\text{Min ETC}_2 &= q\mathcal{L}_T + (1-q)\text{SC} + \text{IC}\\ &= \Big\{ k_1\sigma[2(\mu - y_0) - n_1\sigma]\phi(n_1)\\ &\quad + k_2\sigma[2(y_0-\mu) - n_2\sigma]\phi(n_2)\\ &\quad + \sigma(y_0-\mu)(k_1-k_2)\phi\left(\frac{y_0-\mu}{\sigma}\right)\\ &\quad + (k_1-k_2)\left[\sigma^2 + (y_0-\mu)^2\right]\\ &\quad \times \Phi\left(\frac{y_0-\mu}{\sigma}\right)\\ &\quad + \left[\sigma^2 + (y_0-\mu)^2\right]\\ &\quad \times [k_1\Phi(n_1) + k_2\Phi(n_2) - k_1]\Big\}\\ &\quad + [2 - \Phi(n_1) - \Phi(n_2)]\,\text{SC} + \text{IC}\,.\end{aligned}$$

To choose from the alternative decisions, we should optimize the model for Decision 1 with zero inspection first and have the minimum expected total cost ETC_1^*. Then we optimize the model for Decision 2 with 100% inspection and have the optimal expected total cost ETC_2^*. If $ETC_1^* < ETC_2^*$, we should adjust the process mean to the optimal mean value given by the solutions and then ship all the output to the next or downstream customers without any inspection because the total cost to the system will be minimized in this way. Otherwise, we should take Decision 2, adjust the process mean, and do 100% inspection at the optimal specification limits given by the solutions of the optimization model.

For example, we need to make decisions in terms of the disposition of the output of a process that has the following parameters: the output of the process has a target value $y_0 = 10$; the quality loss function is asymmetrical about the target with $k_1 = 10$ and $k_2 = 5$, based on the input from the customer; the distribution of the process follows a normal distribution with $\sigma = 1.0$; the inspection cost per unit is IC = \$0.10, and the scrap cost per unit is SC = \$4.00. Should we do 100% inspection or zero inspection? If 100% inspection is to be done, what specification limits should be used?

First, we minimize the optimization model for Decision 1:

$$\begin{aligned}\text{Min ETC}_1 &= (k_1-k_2)\sigma(y_0-\mu)\phi\left(\frac{y_0-\mu}{\sigma}\right)\\ &\quad + \left[\sigma^2 + (y_0-\mu)^2\right]\\ &\quad \times \left[(k_1-k_2)\Phi\left(\frac{y_0-\mu}{\sigma}\right) + k_2\right]\\ &= 5(10-\mu)\phi\,(10-\mu)\\ &\quad + \left[1 + (10-\mu)^2\right]\\ &\quad \times [5\Phi\,(10-\mu) + 5]\end{aligned}$$

subject to $\mu \geq 0$.

Using Mathematica to solve the equation with the given set of parameters, we have the optimal solution $\mu^* = 10.28$, and $ETC_1^* = \$6.96$. Also, Genetic Algorithm by *Houck* et al. [11.15] gives us the same optimal solution.

Then, we optimize the model for Decision 2 given by

$$\begin{aligned}\text{Min ETC}_2 &= \Big\{(20\mu - 10n_1 - 200)\phi(n_1)\\ &\quad + (100 - 10\mu - 5n_2)\phi(n_2)\\ &\quad + (50 - 5\mu)\phi\,(10-\mu)\\ &\quad + \left[5 + 5(10-\mu)^2\right]\Phi\,(10-\mu)\\ &\quad + \left[1 + (10-\mu)^2\right]\\ &\quad \times [10\Phi(n_1) + 5\Phi(n_2) - 10]\Big\}\\ &\quad + 4\,[2 - \Phi(n_1) - \Phi(n_2)] + 0.1\end{aligned}$$

subject to $n_1 \geq 0,\ n_2 \geq 0$.

This can be minimized using Genetic Algorithm provided by *Houck* et al. [11.15], which gives us $n_1^* = 0.72$, $n_2^* = 0.82$, $\mu^* = 10.08$, and $TC^* = \$2.57 < \$6.96$.

Since $ETC_1^* > ETC_2^*$, we should adjust the process mean to 10.08 given by the optimal solution from Decision 2 and do 100% inspection with respect to LSL = 9.36 and USL = 10.90 to screen the nonconforming units. In this way, the expected total cost to the whole system will result in a reduction of \$4.39, or 63% decrease in ETC. This example presents a way to determine the optimal process mean value and specification limits by minimizing the total cost to both producer and consumer.

11.3 Process Optimization

In the previous section, it is assumed that it is difficult to improve the process because of the constraint of the current technology, cost, or capability. To improve the performance of the output, we screen or inspect the product before shipping to the customer by setting up optimal specification limits on the distribution of the output. Thus the focus is on inspection of the product. To further optimize the performance of the system, it is supposed that the process can be improved during the design phase, which is also called offline quality engineering. Then the process should be designed and optimized with any effort to meet the requirements of customers economically. During offline quality engineering, three design phases need to be taken [11.7]:

- ***System design***: The process is selected from knowledge of the pertinent technology. After system design, it is often the case that the exact functional relationship between the output variables and input variables cannot be expressed analytically. One needs to explore the functional relationship of the system empirically. Design of experiments is an important tool to derive this system transfer function. Orthogonal polynomial expansion also provides an effective means of evaluating the influences of input variables on the output response.
- ***Parameter design***: The optimal settings of input variables are determined to optimize the output variable by reducing the influence of noise factors. This phase of design makes effective use of experimental design and response surface methods.
- ***Tolerance design***: The tolerances or variances of the input variables are set to minimize the variance of output response by directly removing the variation causes. It is usually true that a narrower tolerance corresponds to higher cost. Thus cost and loss due to variability should be carefully evaluated to determine the variances of input variables. Experimental design and response surface methods can be used in this phase.

In the following sections, the statistical methods involved in the three design phases are reviewed, including experimental design method, orthogonal polynomial expansion, and response surface method. Since the ultimate goal is to minimize the total cost to both producers and consumers, or the whole system, some integrated optimization models are developed from the system point of view.

11.3.1 Design of Experiments

Introduction to Design of Experiments

Experiments are typically operations on natural entities and processes to discover their structure, functioning, or relationships. They are an important part of the scientific method, which entails observation, hypothesis, and sequential experimentation. In fact, experimental design methods provide us the tools to test the hypothesis, and thus to learn how systems or processes work.

In general, experiments are designed to study the performance of processes or systems. The process or system model can be illustrated by Fig. 11.2 as given in the introduction of this chapter. The process consists of many input variables and one or multiple output variables. The input variables include both controllable factors and uncontrollable or noise factors.

Experimental design methods have broad applications in many disciplines such as agriculture, biological and physical sciences, and design and analysis of engineering systems. They can be used to improve the performance of existing processes or systems and also to develop new ones. The applications of experimental design techniques can be found in:

- Improving process yields
- Reducing variability including both bias from target value and variance
- Evaluating the raw material or component alternatives
- Selecting of component-level settings to make the output variables robust
- Reducing the total cost to the organization and/or the customer

Procedures of Experimental Design

To use statistical methods in designing and analyzing an experiment, it is necessary for experimenters to have a clear outline of procedures as given below.

Problem Statement or Definition. A clear statement of the problem contributes substantially to better understanding the background, scope, and objective of the problem. It is usually helpful to list the specific problems that are to be solved by the experiment. Also, the physical, technological, and economic constraints should be stated to define the problem.

Selection of Response Variable. After the statement of the problem, the response variable y should be selected. Usually, the response variable is a key performance measurement of the process, or the critical-to-quality (CTQ) characteristic. It is important to have precise measures of the response variable. If at all possible, it should be a quantitative (variable) quality characteristic, which would make data analysis easier and meaningful.

Choice of Factors, Levels, and Ranges. Cause and effect diagrams should be developed by a team or panels of experts in the area. The team should represent all points of view and should also include people necessary for implementation. A brainstorming approach can be used to develop theories for the construction of cause and effect diagrams.

From the cause and effect diagrams a list of factors that affect the response variables is developed, including both qualitative and quantitative variables. Then the factors are decomposed into control factors and noise factors. Control factors are factors that are economical to control. Noise factors are uncontrollable or uneconomical to control. Three types of noise factors are outer noise, inner noise, and production noise.

The list of factors is generally very large, and the group may have to prioritize the list. The number of factors to include in the study depends on the priorities, difficulty of experimentation, and budget. The final list should include as many control factors as possible and some noise factors that tend to give high or low values of the response variable.

Once the factors have been selected, the experimenter must choose the number of levels and the range for each factor. It also depends on resource and cost considerations. Usually, factors that are expected to have a linear effect can be assigned two levels, while factors that may have a nonlinear effect should have three or more levels. The range over which the factors are varied should also be chosen carefully.

Selection of Experimental Design. The selection of experimental design depends on the number of factors, the number of levels for each factor, and the number of replicates that provides the data to estimate the experimental error variance. Also, the determination of randomization restrictions is involved, such as blocking or not. Randomization justifies the statistical inference methods of estimation and tests of hypotheses. In selecting the design, it is important to keep the experimental objectives in mind. Several books review and discuss the types of experimental designs and how to choose an appropriate experimental design for a wide variety of problems [11.16–18].

Conduction of the Experiment. Before performing the experiment, it is vital to make plans for special training if required, design data sheets, and schedule for experimentation etc. In the case of product design experimentation, sometimes the data can be collected through the use of simulation programs rather than experiments with actual hardware. Then the computer simulation models need to be developed before conducting the experiment.

When running the experiment in the laboratory or a full-scale environment, the experimenter should monitor the process on the right track, collect all the raw data, and record unexpected events.

Analysis and Interpretation of the Data. Statistical methods are involved in data analysis and interpretation to obtain objective conclusions from the experiment. There are many software packages designed to assist in data analysis, such as SAS, S-Plus, etc. The statistical data analysis can provide us with the following information:

- Which factors and interactions have significant influences on the response variable?
- What are the rankings of relative importance of main effects and interactions?
- What are the optimal factor level settings so that the response is near the target value? (parameter design)
- What are the optimal factor level settings so that the effects of the noise factors are minimized? (robust design)
- What are the best factor level settings so that the variability of the response is reduced?
- What is the functional relationship between the controllable factors and response, or what is the empirical mathematical model relating the output to the input factors?

Statistical methods lend objectivity to the decision-making process and attach a level of confidence to a statement. Usually, statistical techniques will lead to solid conclusions with engineering knowledge and common sense.

Conclusions and Recommendations. After data analysis, the experimenter should draw some conclusions and recommend an action plan. Usually, a confirmation experiment is run to verify the reproducibility of the optimum recommendation. If the result is not confirmed

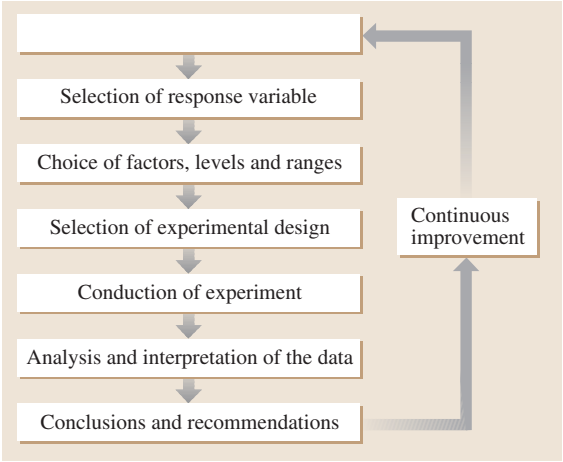

Fig. 11.10 Iterative procedures of experimental design

or is unsatisfactory, additional experimentation may be required.

Based on the results of the confirmation experiment and the previous analysis, the experimenter can develop sound conclusions and recommendations.

Continuous Improvement. The entire process is actually a learning process, where hypotheses about a problem are tentatively formulated, experiments are conducted to investigate these hypotheses, and new hypotheses are then formulated based on the experimental results. By continuous improvement, this iterative process moves us closer to the "truth" as we learn more about the system at each stage (Fig. 11.10). Statistical methods enter this process at two points: (1) selection of experimental design and (2) analysis and interpretation of the data [11.16].

11.3.2 Orthogonal Polynomials

Most research in engineering is concerned with the derivation of the unknown functional relationship between input variables and output response. In many cases, the model is often easily and elegantly constructed as a series of orthogonal polynomials [11.19–21]. Compared with other orthogonal functions, the orthogonal polynomials are particularly convenient for at least two reasons. First, polynomials are easier to work with than irrational or transcendental functions; second, the terms in orthogonal polynomials are statistically independent, which facilitates both their generation and processing. One of the other advantages of orthogonal polynomials is that users can simply develop their own system of functions in accordance with the particular problem. More often, a problem can be transformed to one of the standard families of polynomials, for which all significant relations have already been worked out.

Orthogonal polynomials can be used whether the values of controllable factors Xs are equally or unequally spaced [11.22]. However, the computation is relatively easy when the values of factor levels are in equal steps. For a system with only one equal-step input variable X, the general orthogonal polynomial model of the functional relationship between response variable Y and X is given as

$$y = \mu + \alpha_1 P_1(x) + \alpha_2 P_2(x) + \alpha_3 P_3(x) + \cdots + \alpha_n P_n(x) + \varepsilon \,, \tag{11.2}$$

where x is the value of factor level, y is the measured response [11.17], μ is the grand mean of all responses, and $P_k(x)$ is the kth-order orthogonal polynomial of factor X. The transformations for the powers of x into orthogonal polynomials $P_k(x)$ up to the cubic degree are given below:

$$P_1(x) = \lambda_1 \left(\frac{x-\bar{x}}{d}\right) ,$$

$$P_2(x) = \lambda_2 \left[\left(\frac{x-\bar{x}}{d}\right)^2 - \left(\frac{t^2-1}{12}\right)\right] ,$$

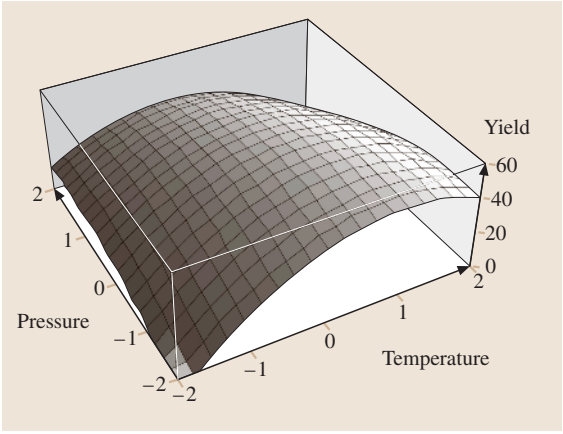
$$P_3(x) = \lambda_3 \left[\left(\frac{x-\bar{x}}{d}\right)^3 - \left(\frac{x-\bar{x}}{d}\right)\left(\frac{3t^2-7}{20}\right)\right] , \tag{11.3}$$

where $\bar{x}$ is the average value of factor levels, t is the number of levels of the factor, d is the distance between factor levels, and the constant λ_k makes $P_k(x)$ an integral value for each x.

Since t, d, $\bar{x}$, and x are known, $P_k(x)$ can be calculated for each x. For example, a four-level factor X ($t = 4$) can fit a third-degree equation in x. The orthogonal polynomials can be tabulated based on the calculation of (11.3) as below:

	$P_1(x)$	$P_2(x)$	$P_3(x)$
x_1	−3	1	−1
x_2	−1	−1	3
x_3	1	−1	−3
x_4	3	1	1

The values of the orthogonal polynomials $P_k(x)$ have been tabulated up to $t = 104$ [11.21].



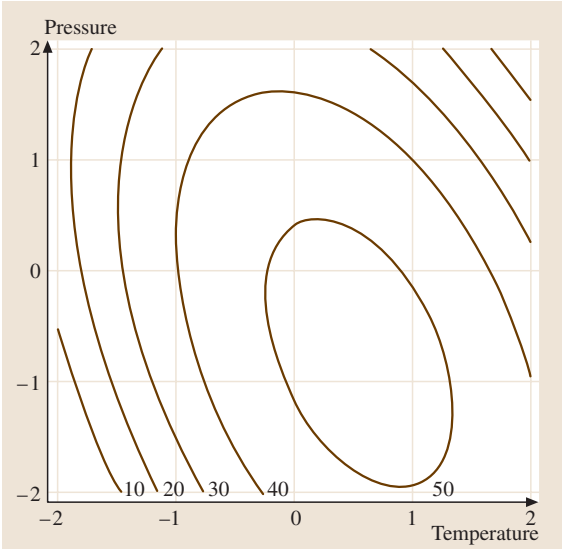


Fig. 11.11a,b Response surface **(a)** and contour plot **(b)** for a chemical process

Given the response y_i for the ith level of X, x_i, $i = 1, 2, \ldots, t$, the estimates of the α_k coefficients for the orthogonal polynomial (11.2) are calculated as

$$\alpha_k = \sum_{i=1}^{t} y_i P_k(x_i) \Big/ \sum_{i=1}^{t} P_k(x_i)^2$$

for $k = 1, 2, \ldots, n$. The estimated orthogonal polynomial equation is found by substituting the estimates of $\mu, \alpha_1, \alpha_2, \cdots, \alpha_n$ into (11.2).

It is desirable to find the degree of polynomials that adequately represents the functional relationship between the response variable and the input variables. One strategy to determine the polynomial equation is to test the significance of the terms in the sequence: linear, quadratic, cubic, and so forth. Beginning with the simplest polynomial, a more complex polynomial is constructed as the data require for adequate description. The sequence of hypotheses is $H_0 : \alpha_1 = 0$, $H_0 : \alpha_2 = 0$, $H_0 : \alpha_3 = 0$, and so forth. These hypotheses about the orthogonal polynomials are each tested with the F test ($F = \mathrm{MSC}/\mathrm{MSE}$) for the respective polynomial. The sum of square for each polynomial needs to be calculated for the F test, which is

$$SS_{P_k} = \left(\sum_{i=1}^{t} y_i P_k(x_i) \right)^2 \Big/ \sum_{i=1}^{t} P_k(x_i)^2$$

for $k = 1, 2, \ldots, n$. The system function relationship can be developed by including the statistically significant terms in the orthogonal polynomial model.

For the multiple equal-step input variables $X_1, X_2, \ldots, X_n$, the orthogonal polynomial equation is found in a similar manner as for the single input variable. *Kuel* [11.17] gives an example of water uptake by barley plants to illustrate procedures to formulate the functional relationship between the amount of water uptake and two controllable factors: salinity of medium and age of plant.

11.3.3 Response Surface Methodology

Response surface methodology (RSM) is a specialized experimental design technique for developing, improving, and optimizing products and processes. The method can be used in the analysis and improvement phases of the (D)MAIC(T) process. As a collection of statistical and mathematical methods, RSM consists of an experimental strategy for exploring the settings of input variables, empirical statistical modeling to develop an appropriate approximating relationship between the response and the input variables, and optimization methods for finding the levels or values of the input variables that produce desirable response values.

Figure 11.11 illustrates the graphical plot of response surface and the corresponding contour plot for a chemical process, which shows the relationship between the response variable yield and the two process variables: temperature and pressure. Thus, when the response surface is developed by the design of experiments and constructed graphically, optimization of the process becomes easy using the response surface.

The process model given in Fig. 11.2 is also very useful for RSM. Through the response surface methodology, it is desirable to make the process box "transparent" by obtaining the functional relationship between the output response and the input factors. In fact, successful use of RSM is critically dependent upon the development of a suitable response function. Usually, either a first-order or second-order model is appropriate in a relatively small region of the variable space.

In general, a first-order response model can be written as

$$Y = b_0 + b_1 X_1 + b_2 X_2 + \cdots + b_n X_n + \varepsilon \, .$$

For a system with nonlinear behavior, a second-order response model is used as given below:

$$Y = b_0 + \sum_i b_i X_i + \sum_i b_{ii} X_i^2 + \sum_i \sum_j d_{ij} X_i X_j + \varepsilon \, .$$

The method of least squares estimation is used to estimate the coefficients in the above polynomials. The second-order model is widely used in response surface methodology.

As an extended branch of experimental design, RSM has important applications in the design, development, and formulation of new products, as well as in the improvement of existing product designs. The applications of RSM can be found in many industrial settings where several variables influence the desired outcome (e.g., minimum fraction defective or maximum yield), including the semiconductor, electronic, automotive, chemical, and pharmaceutical industries.

Sequential Procedures of RSM

The applications of RSM are sequential in nature [11.23]. That is, at first we perform a screening experiment to reduce the list of candidate variables to a relatively few, so that subsequent experiments will be more efficient and require few tests. Once the important independent variables are identified, the next objective is to determine if the current levels or settings of the independent variables result in a value of the response that is near the optimum. If they are not consistent with optimum performance, a new set of adjustments to input variables should be determined to move the process toward the optimum. When the process is near the optimum, a model is needed to accurately approximate the true response function within a relatively small region around the optimum. Then, the model can be analyzed to identify the optimum conditions for the process. We can list the sequential procedures as follows [11.24]:

Step 0: *Screening experiment.* Usually the list of input variables is rather long, and it is desirable to start with a screening experiment to identify the subset of important variables. After the screening experiment, the subsequent experiments will be more efficient and require fewer runs or tests.

Step 1: *Determine if the optimal solution is located inside the current experimental region.* Once the important variables are identified through screening experiments, the experimenter's objective is to determine if the current settings of the input variables result in a value of response that is near optimum. If the current settings are not consistent with optimum performance, then go to step 2; otherwise, go to step 3.

Step 2: *Search the region that contains the optimal solution.* The experimenter must determine a set of adjustments to the process variables that will move the process toward the optimum. This phase of response surface methodology makes considerable use of the first-order model with two-level factorial experiment, and an optimization technique called the method of steepest ascent. Once the region containing the optimum solution is determined, go to step 3.

Step 3: *Establish an empirical model to approximate the true response function within a relatively small region around the optimum.* The experimenter should design and conduct a response surface experiment and then collect the experimental data to fit an empirical model. Because the true response surface usually exhibits curvature near the optimum, a nonlinear empirical model (often a second-order polynomial model) will be developed.

Step 4: *Identify the optimum solution for the process.* Optimization methods will be used to determine the optimum conditions. The techniques for the analysis of the second-order model are presented by *Myers* [11.23].

The sequential nature of response surface methodology allows the experimenter to learn about the process or system as the investigation proceeds. The investigation procedures involve several important topics/methods, including two-level factorial designs, method of steepest ascent, building an empirical model, analysis of second-order response surface, and response surface experimental designs, etc. For more detailed information, please refer to *Myers* [11.23] and *Yang* and *El-Haik* [11.24].

11.3.4 Integrated Optimization Models

The ultimate objective of Six Sigma strategy is to minimize the total cost to both producer and consumer, or the whole system. The cost to the consumer is related to the expected quality loss of the output variable, and it is caused by the deviation from the target value. The cost to the producer is associated with changing probability distributions of input variables. If the system transfer function and the variance transmission equation are available, and the cost functions for different grades of input factors are given, the general optimization model to reflect the optimization strategy is given in Fig. 11.12.

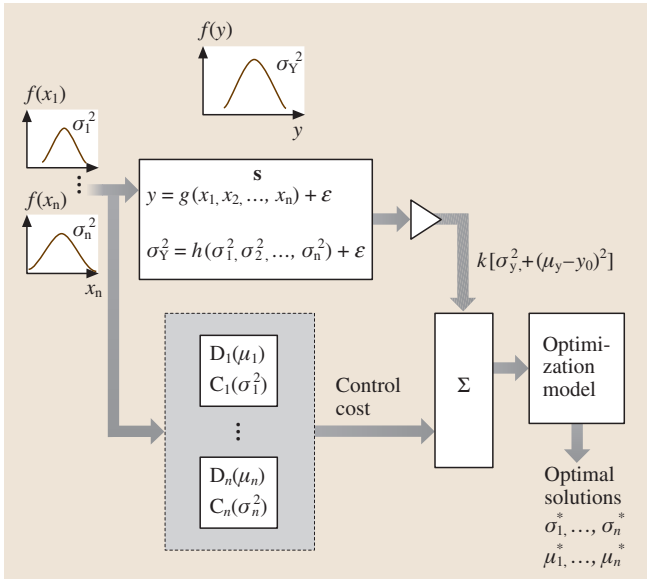

Fig. 11.12 General optimization model for system

General Optimization Problem

We usually consider the first two moments of the probability distributions of input variables, and then the optimization models will focus on the mean and variance values. Therefore, the expected quality loss to the consumer consists of two parts: the bias of the process and the variance of the process. The strategy to reduce bias is to find adjustment factors that do not affect variance and thus are used to bring the mean closer to the target value. Design of experiments can be used to find these adjustment factors. It will incur certain costs to the producer. To reduce the variance of Y, the designer should reduce the variances of the input variables, which will also increase costs. The problem is to balance the reduced expected quality loss with the increased cost for the reduction of the bias and variances of the input variables. Typically, the variance control cost for the ith input variable X_i is denoted by $C_i(\sigma_i^2)$, and the mean control cost for the ith input variable X_i is denoted by $D_i(\mu_i)$. By focusing on the first two moments of the probability distributions of $X_1, X_2, \ldots, X_n$, the general optimization model is formulated as

$$\begin{aligned}\text{Minimize TC} = &\sum_{i=1}^{n} C_i\left(\sigma_i^2\right) + \sum_{i=1}^{n} D_i(\mu_i) \\ &+ k\left[\sigma_Y^2 + (\mu_Y - y_0)^2\right] , \\ \text{subject to } &\mu_Y \approx m(\mu_1, \mu_2, \cdots, \mu_n) , \\ &\sigma_Y^2 \approx h\left(\sigma_1^2, \sigma_2^2, \cdots, \sigma_n^2\right) . \end{aligned} \tag{11.4}$$

In this objective function, the first two terms,

$$\sum_{i=1}^{n} C_i\left(\sigma_i^2\right) \text{ and } \sum_{i=1}^{n} D_i(\mu_i) ,$$

are the control costs on the variances and means of input variables, or the cost to the producer; the last term, $k\left[\sigma_Y^2 + (\mu_Y - y_0)^2\right]$, is the expected quality loss to the customer, where k is a constant in the quality loss function. The first constraint, $\mu_Y \approx m(\mu_1, \mu_2, \cdots, \mu_n)$, is the model for the mean of the system, which can be obtained through the system transfer function. The second constraint, $\sigma_Y^2 \approx h(\sigma_1^2, \sigma_2^2, \cdots, \sigma_n^2)$, is the variance transmission equation. A future research problem is to solve this optimization problem in such a way as to consider together both the mean and the variance.

Tolerance Design Problem

If we assume that the bias reduction has been accomplished, the general optimization problem given by (11.4) can be simplified as a tolerance design problem, which is given below:

$$\begin{aligned}\text{Minimize TC} = &\sum_{i=1}^{n} C_i\left(\sigma_i^2\right) + k\sigma_Y^2 \\ \text{subject to } &\sigma_Y^2 \approx h\left(\sigma_1^2, \sigma_2^2, \cdots, \sigma_n^2\right) . \end{aligned} \tag{11.5}$$

The objective of the tolerance design is to determine the tolerances (which are related to variances) of the input variables to minimize the total cost, which consists of the expected quality loss due to variation $k\sigma_Y^2$ and the control cost on the tolerances of the input variables

$$\sum_{i=1}^{n} C_i\left(\sigma_i^2\right) .$$

Typically, $C_i(\sigma_i^2)$ is a nonincreasing function of each σ_i^2.

For this tolerance design problem, a RLC circuit example is given by *Chen* [11.25] to minimize the total cost to both the manufacturer and the consumer. Taguchi's method is used to construct the variance transmission equation as the constraint in Chen's example. *Bare* et al. [11.26] propose another optimization model to minimize the total variance control cost by finding the optimum standard deviations of input variables. Taylor's series expansion is used to develop the variance transmission equation in their model.

Case Study: Wheatstone Bridge Circuit Design

We use the Wheatstone bridge circuit design problem [11.7] as a case study to illustrate models described above [11.27]. The system transfer function is known for this example, and thus we will illustrate the development of variance transmission equation and optimization design models.

The Wheatstone bridge in Fig. 11.13 is used to determine an unknown resistance Y by adjusting a known resistance so that the measured current is zero. The resistor B is adjusted until the current X registered by the galvanometer is zero, at which point the resistance value B is read and Y is calculated from the formula $Y = BD/C$. Due to the measurement error, the current is not exactly zero, and it is assumed to be a positive or negative value of about 0.2 mA. In this case the resistance is given by the following system transfer function:

$$Y = \frac{BD}{C} - \frac{X}{C^2 E}[A(C+D)+D(B+C)] \times [B(C+D)+F(B+C)] \ .$$

The noise factors in the problem are variability of the bridge components, resistors A, C, D, F, and input voltage E. This is the case where control factors and noise factors are related to the same variables. Another noise factor is the error in reading the galvanometer X. Assuming that when the galvanometer is read as zero, there may actually be a current about 0.2 mA. Taguchi did the parameter design using L_{36} orthogonal arrays for the design of the experiment. When the parameter design cannot sufficiently reduce the effect of internal and external noises, it becomes necessary to develop the variance transmission equation and then control the variation of the major noise factors by reducing their tolerances, even though this increases the cost.

Let the nominal values or mean of control factors be the second level and the deviations due to the noise factors be the first and third level. The three levels of noise factors for the optimum combination based on parameter design are given in Table 11.1.

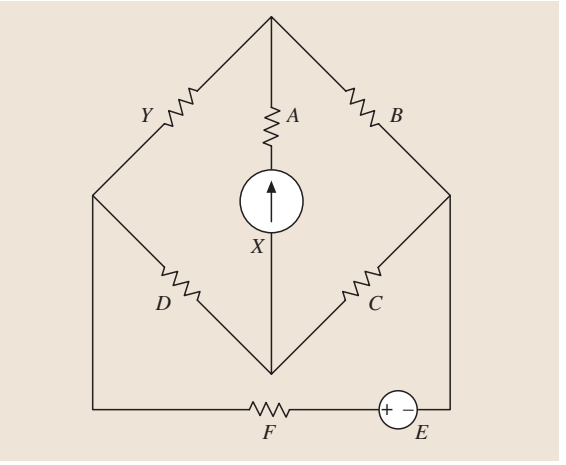

Fig. 11.13 Wheatstone bridge and parameter symbols

We use three methods to develop the variance transmission equation: Taylor series approximation, response surface method, and experimental design method. The results for various approaches are given in Table 11.2. RSM (L_{36}) and DOE (L_{36}) have the same L_{36} orthogonal array design layout for comparison purposes. Improved RSM and improved DOE use the complete design with $N = 3^7 = 2187$ design points for the unequal-mass three-level noise factors. For comparison purposes, we also perform the complete design with 2187 data points for the equal-mass three-level noise factors, which are denoted as RSM (2187) and DOE (2187) in Table 11.2. Without considering the different design layouts, it seems that the improved method gives better approximation of variance. We can see that the improved DOE's VTE does not differ much from the original one in its ability to approximate the variance of the response. Because the improved DOE method requires the complete evaluation at all combinations of levels, it is costly in terms of time and resources. If

Table 11.1 Noise factor levels for optimum combination

Factor	Level 1	Level 2	Level 3
$A(\Omega)$	19.94	20	20.06
$B(\Omega)$	9.97	10	10.03
$C(\Omega)$	49.85	50	50.15
$D(\Omega)$	9.97	10	10.03
$E(\mathrm{V})$	28.5	30	31.5
$F(\Omega)$	1.994	2	2.006
$X(\mathrm{A})$	−0.0002	0	0.0002

Methods	VTE	σ_Y^2
Linear Taylor	$\sigma_Y^2 = 0.040\,00\sigma_B^2 + 0.001\,60\sigma_C^2 + 0.040\,00\sigma_D^2 + 276.002\,84\sigma_X^2 + O(\sigma^3)$	$7.939\,01 \times 10^{-5}$
Nonlinear Taylor	$\sigma_Y^2 = 0.040\,00\sigma_B^2 + 0.001\,60\sigma_C^2 + 0.040\,00\sigma_D^2 + 276.002\,84\sigma_X^2 + 3.84 \times 10^{-6}\sigma_C^4 + O(\sigma^5)$	$7.939\,10 \times 10^{-5}$
RSM (L_{36})	$\sigma_Y^2 = 0.040\,04\sigma_B^2 + 0.001\,62\sigma_C^2 + 0.040\,36\sigma_D^2 + 300.373\,96\sigma_X^2 + 1.42 \times 10^{-8}$	$8.045\,28 \times 10^{-5}$
RSM (2187)	$\sigma_Y^2 = 0.040\,00\sigma_B^2 + 0.001\,60\sigma_C^2 + 0.040\,00\sigma_D^2 + 299.598\,75\sigma_X^2 + 1.00 \times 10^{-8}$	$8.000\,03 \times 10^{-5}$
IPV RSM	$\sigma_Y^2 = 0.040\,00\sigma_B^2 + 0.001\,60\sigma_C^2 + 0.040\,00\sigma_D^2 + 299.601\,30\sigma_X^2 + 1.43 \times 10^{-8}$	$8.000\,51 \times 10^{-5}$
DOE (L_{36})	$\sigma_Y^2 = 0.041\,18\sigma_B^2 + 0.001\,66\sigma_C^2 + 0.041\,50\sigma_D^2 + 308.939\,35\sigma_X^2 + 1.42 \times 10^{-8}$	$8.274\,94 \times 10^{-5}$
DOE (2187)	$\sigma_Y^2 = 0.040\,02\sigma_B^2 + 0.001\,60\sigma_C^2 + 0.040\,02\sigma_D^2 + 299.735\,65\sigma_X^2 + 1.00 \times 10^{-8}$	$8.004\,08 \times 10^{-5}$
IPV DOE	$\sigma_Y^2 = 0.040\,00\sigma_B^2 + 0.001\,60\sigma_C^2 + 0.040\,00\sigma_D^2 + 299.768\,00\sigma_X^2 + 1.43 \times 10^{-8}$	$8.000\,95 \times 10^{-5}$
Monte Carlo	1 000 000 observations	$7.998\,60 \times 10^{-5}$

Note: The calculation of σ_Y^2 is for $\sigma_B = 0.024\,49$, $\sigma_C = 0.122\,47$, $\sigma_D = 0.024\,49$, $\sigma_X = 0.000\,16$; RSM (2187) is the response surface method applied on the same data set as Taguchi's VTE (2187); improved (IPV) RSM is the response surface method applied on the same data set as the improved (IPV) Taguchi VTE

the high cost of the complete design is a concern, the original DOE's equal-mass three-level method using orthogonal array is preferred. If the complete evaluation can be accomplished by simulation without much difficulty, the improved DOE method should be applied to ensure high accuracy. Thus, the variance transmission equation for this Wheatstone bridge circuit is determined as

$$\sigma_Y^2 = 0.040\,00\sigma_B^2 + 0.001\,60\sigma_C^2 + 0.040\,00\sigma_D^2 + 299.768\,00\sigma_X^2 + 1.43 \times 10^{-8}\,.$$

For such a problem, we can easily develop the mean model and use it with the above VTE to develop the general optimization model. It is well understood that the tolerances or variances on resistors, voltage, and current impact the cost of the design, i. e., tighter tolerances result in higher cost. Thus we can develop the variance control cost functions $C_i(\sigma_i^2)$ for each component. Similarly, the mean control cost functions $D_i(\mu_i)$ for any problem can be developed. For this problem, if the cost associated with changing the mean values is relatively small or insignificant, then we can just focus on the tolerance design problem given by (11.5), which is

$$\begin{aligned}\text{Minimize TC} &= C_B(\sigma_B^2) + C_C(\sigma_C^2) + C_D(\sigma_D^2) \\ &\quad + C_X(\sigma_X^2) + k\sigma_Y^2\,, \\ \text{subject to } \sigma_Y^2 &= 0.040\,00\sigma_B^2 + 0.001\,60\sigma_C^2 \\ &\quad + 0.040\,00\sigma_D^2 + 299.768\,00\sigma_X^2 \\ &\quad + 1.43 \times 10^{-8}\,.\end{aligned}$$

Based on the complexity of the cost functions $C_i(\sigma_i^2)$ and $D_i(\mu_i)$ and the constraint, such optimization problems can be solved by many optimization methods including software available for global search algorithms such as genetic algorithm optimization toolbox (GAOT) for Matlab 5 (http://www.ie.ncsu.edu/mirage/GAToolBox/gaot/).

11.4 Summary

In this chapter, we first introduce the Six Sigma quality and design for Six Sigma process. By focusing on the analysis and improvement phases of the (D)MAIC(T) process, we discuss the statistical and optimization strategies for product and process optimization, respectively. Specifically, for product optimization, we review the quality loss function and various optimization models for specification limits development. For process optimization, we discuss design of experiments, orthogonal polynomials, response surface methodology, and integrated optimization models. Those statistical methods play very important roles in the activities for process and product improvement.

12. Robust Optimization in Quality Engineering

Quality engineers often face the job of identifying process or product design parameters that optimize performance response. The first step is to construct a model, using historical or experimental data, that relates the design parameters to the response measures. The next step is to identify the best design parameters based on the model. Clearly, the model itself is only an approximation of the true relationship between the design parameters and the responses. The advances in optimization theory and computer technology have enabled quality engineers to obtain a good solution more efficiently by taking into account the inherent uncertainty in these empirically based models.

Two widely used techniques for parameter optimization, described with examples in this chapter, are the response surface methodology (RSM) and Taguchi loss function. In both methods, the response model is assumed to be fully correct at each step. In this chapter we show how to enhance both methods by using robust optimization tools that acknowledge the uncertainty in the models to find even better solutions. We develop a family of models from the confidence region of the model parameters and show how to use sophistical optimization techniques to find better design parameters over the entire family of approximate models.

Section 12.1 of the chapter gives an introduction to the design parameter selection problem and motivates the need for robust optimization. Section 12.2 presents the robust optimization approach to address the problem of optimizing empirically based response functions by developing a family of models from the confidence region of the model parameters. In Sect. 12.2 robust optimization is compared to traditional optimization approaches where the empirical model is assumed to be true and the optimization is conducted without considering the uncertainty in the parameter estimates. Simulation is used to make the comparison in the context of response surface methodology, a widely used method to optimize products and processes that is briefly described in the section. Section 12.3 introduces a refined technique, called weighted robust optimization, where more-likely points in the confidence region of the empirically determined parameters are given heavier weight than less-likely points. We show that this method provides even more effective solutions compared to robust optimization without weights. Section 12.4 discusses Taguchi's loss function and how to leverage robust optimization methods to obtain better solutions when the loss function is estimated from empirical experimental data.

One of the central themes in quality engineering is the identification of optimal values for the design parameters to make a process or product function in the best possible way to maximize its performance. The advances in optimization theory and computing technology in the last half century have greatly stimulated the progress in quality improvement—optimization methodology has provided a systematic framework to guide today's quality engineers to identify optimal levels in design parameters efficiently, while the same task would have taken many iterations of experiments for engineers one generation ago without the aid of modern optimization techniques.

Many quality engineering problems arising in today's complex manufacturing processes can be reduced to some optimization problem. For example, in process control problems, we are interested in selecting a best possible set of values for process settings to maximize the output of the final products that satisfy the specifications in the shortest amount of time. In the context of product design problems, the purpose is to choose an optimal mix of design parameters to maximize the performance measures of the new products.

The iteration process in applying optimization techniques to solve quality improvement problems includes the following steps:

1. Convert the quality requirements and specifications to an optimization model; (12.1)
2. Solve the optimization problems and identify the optimal values for the decision variables, i. e., the process settings or design parameters;
3. Apply the optimal solution identified in step 2 to the actual process control or product design environment, validate the effectiveness of the optimal solution and revise the optimization model if necessary.

There exists a large volume of literature advocating the use of optimization techniques to improve process and product quality; see *Box* et al. [12.1], *Box* and *Draper* [12.2], *Myers* and *Montgomery* [12.3], *Khuri* and *Cornell* [12.4], among many others.

The most critical step in the above procedure is to construct the optimization model using the historical or experimental data collected in the process control or product design stage. Usually we tend to regard a model constructed on empirical data as a true physical law. Thus we assume that the model accurately describes the underlying process or product and that the optimal solution to the model is better than any other choice.

However there is much uncertainty involved in the model construction process. First, the most common uncertainty comes from the measurement error and noise effect. The devices used to capture the readings are more or less subject to measurement errors. Noise factors, such as environmental conditions and material properties, will sometimes severely distort the values of the true performance measure. Second, the failure to identify and record every possible main factor that contributes to the final performance measure will certainly degrade the quality of the model since it cannot incorporate all of the major predictors. Finally the model selection process adds another layer of uncertainty in the final model we will reach. There are numerous forms of models we can choose from. For example, should we develop a linear model or a nonlinear one? If it is a nonlinear model, should we try a higher-order polynomial function or a logistic function, or something else?

The uncertainty in the model construction process poses huge challenges to the statistical sciences, which have provided numerous methods to identify effective models to represent the true relationship between the design parameters and process/product performance as closely as possible. However, although statistics is highly useful in reducing the uncertainty in a response model, it does not eliminate all of the sources of the uncertainty. Therefore the resulting optimization model, constructed from the empirical data through careful adjustment and calibration using statistical methods, is not a perfect mirror of the true relationship; it is an approximation of the true mechanism in the underlying process or product. We have an opportunity in the optimization stage to address the uncertainty inherent to the statistical model to enhance the optimal solution.

In the context of quality engineering, response surface methodology (RSM) is a set of statistical and optimization techniques that are used sequentially to identify the optimal solution to a quality improvement problem. The iterative procedure in RSM includes performing an experiment in the region of the best known solution, fitting a response model to the experimental data, and optimizing the estimated response model. RSM has been widely used in quality engineering since the seminal work of George Box in the 1950s; for more details see *Box* and *Wilson* [12.5]. We give a brief introduction to RSM in Sect. 12.2 of this chapter.

In RSM, the optimization procedure is performed directly on the estimated response model, so it does not deliver a solution that minimizes the uncertainty in the model estimation process. This chapter is motivated by the work in *Xu* and *Albin* [12.6] and provides

an introduction into how we can use robust optimization methods to identify good solutions that maximize the performance of a process or product and, in the meantime, address the uncertainty inherent to a response model that is an approximation of the true relationship between the design parameters and the process/product performance. To make this idea clearer, consider the following function $y = f(\boldsymbol{x}, \boldsymbol{\beta})$, where y is the true process/product performance, $\boldsymbol{x}$ includes a set of design parameters and the function $f(x, \cdot)$ describes the true relationship between the design parameters in x and the process/product performance y. The vector $\boldsymbol{\beta}$ captures the important parameters in the function $f(x, \cdot)$.

If the function is a first-order polynomial

$$y = \sum_{i=1}^{n} \beta_i x_i \ ,$$

then $\boldsymbol{\beta}$ is a vector including all the coefficients $(\beta_1, \beta_2, \cdots \beta_n)'$. If the function is a second-order polynomial

$$y = \sum_{1 \le i \le j \le n} \beta_{ij} x_i x_j + \sum_{i=1}^{n} \beta_i x_i \ ,$$

then the vector $\boldsymbol{\beta}$ can be written as

$$(\beta_{11}, \beta_{12}, \cdots \beta_{nn}, \beta_1, \beta_2, \cdots \beta_n)' \ .$$

We note that the function $f(\boldsymbol{x}, \boldsymbol{\beta})$ is linear in the coefficients in $\boldsymbol{\beta}$ when $f(\boldsymbol{x}, \boldsymbol{\beta})$ is a polynomial of x. This property plays an important role in the robust method introduced in this chapter.

The parameters in $\boldsymbol{\beta}$ are important in that they characterize how a process or product behaves. For example, let us consider a mixture design problem on glass/epoxy composites. We are interested in choosing the optimal mix of glass and epoxy to maximize the strength of the composites. Assume the relationship between the strength y and the fraction of glass (x_1) and epoxy (x_2) can be described by the response function $y = \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_1 x_2$. The parameter β_1 (β_2) measures how the composite strength changes in response to the change in the fraction of glass (epoxy) while the parameter β_3 measures the glass–epoxy interaction effect on the composite strength.

Although the parameters in $\boldsymbol{\beta}$ are crucial in determining the behavior of a process or product, the true values for $\boldsymbol{\beta}$ are usually unknown to quality engineers. The only way to derive the values for $\boldsymbol{\beta}$ is by fitting a statistical model to the experimental data. Since the coefficients in $\boldsymbol{\beta}$ are estimated values, instead of writing $y = f(\boldsymbol{x}, \boldsymbol{\beta})$, we will use the notation $y = f(\boldsymbol{x}, \hat{\boldsymbol{\beta}})$, where $\hat{\boldsymbol{\beta}}$ is estimated from historical or experimental data.

In quality engineering problems, we usually use the canonical optimization approach to determine the optimal solution. We first estimate the model $f(\boldsymbol{x}, \hat{\boldsymbol{\beta}})$ from the experimental data and treat it as a true characterization of the underlying model. Then we solve for the optimal solution to the model $f(\boldsymbol{x}, \hat{\boldsymbol{\beta}})$. In the canonical approach, the point estimates in $\hat{\boldsymbol{\beta}}$ are regarded as a single representation of the true parameters in $\boldsymbol{\beta}$ and thus the optimization steps do not take into account the uncertainty about the estimate $\hat{\boldsymbol{\beta}}$. Although the canonical approach provides a simple, practical way to optimize the process/product performance, the solution obtained from the canonical approach may be far from optimal under the true performance response model.

Figure 12.1 illustrates the potential danger of the canonical approach when the performance response model is a second-order model. The dashed curve on the right represents the true, but unknown, model and the solid curve on the left the fitted model. If the goal is to minimize the performance response, the optimal value of the design variable is D_0 and the optimal performance response is 0. The canonical approach selects the value D_1 for the design variable, which results in the performance response P_1, well above the true optimal. Thus, even a slight deviation of the fitted model from the true model might result in unacceptable performance.

Section 12.2 in this chapter presents the robust optimization approach to address the pitfall illustrated in the above example. In contrast to the canonical approach, where uncertainty about the estimates $\hat{\boldsymbol{\beta}}$ is not explicitly addressed and only a single model $f(\boldsymbol{x}, \hat{\boldsymbol{\beta}})$ is optimized, the robust approach considers a family of models and each model in the family is a possible representation of the true model. Robust and canonical optimization

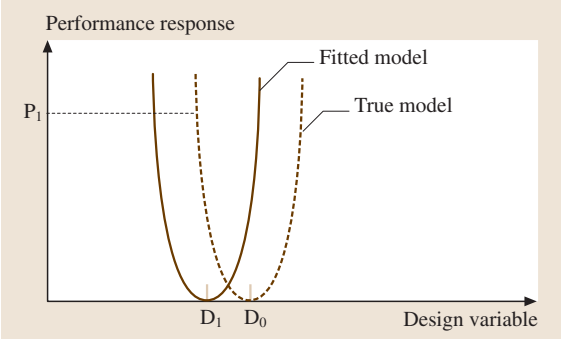

Fig. 12.1 Optimizing the estimated model yields performance response P_1, significantly higher than the true minimum 0

are compared using a Monte Carlo simulation example in Sect. 12.2, in the context of response surface methodology (RSM), a widely used method to optimize product/process.

The single estimated model $f(\boldsymbol{x}, \hat{\boldsymbol{\beta}})$ in the canonical approach is the most likely representation of the true model $f(\boldsymbol{x}, \boldsymbol{\beta})$, while the robust approach incorporates more information by considering a family of models. Section 12.3 takes this a step further by combining each individual model in this family with a likelihood measure of how close it is to the true $f(\boldsymbol{x}, \boldsymbol{\beta})$. The improved approach presented in Sect. 12.3 is called the weighted robust optimization method and we prove that it provides a more effective solution to the estimated optimization model.

One of the greatest achievements in quality engineering in the last century is the robust design method that Taguchi proposed to minimize the expectation of Taguchi's loss function. The loss function is a measure of the deviation of the product performance from the desired target. The quality of a product can be measured by the loss function so a robust design problem can be reduced to an optimization problem whose objective is to minimize the expectation of the loss function by choosing optimal levels in design parameters.

To obtain the objective function in the robust design problem, designed experiments must be conducted, experimental data be collected and the loss function be fitted from the data. We are confronted with the same problems as discussed earlier on the uncertainty associated with the inference from the experimental data. Therefore robust optimization approach can be applied to identify a robust set of values for the design parameters. Section 12.4 discusses how we can leverage the robust optimization methods to better address Taguchi's robust design problems.

12.1 An Introduction to Response Surface Methodology

Response surface methodology (RSM) is a sequential approach and comprises iterative steps to conduct designed experiments, estimate the response model and derive the optimal solution in sequence. This section introduces the most essential steps in RSM and we refer the reader to *Box* and *Draper* [12.2], *Myers* and *Montgomery* [12.3], *Khuri* and *Cornell* [12.4] for a more comprehensive introduction to RSM.

We assume that, prior to running RSM, we have selected a list of significant factors that are the most important contributors to the response. Screening experiments such as fractional factorial designs and Plackett–Burman designs can be used to identify the important factors; see *Wu* and *Hamada* [12.7].

Let $\boldsymbol{x} = (x_1, x_2, \cdots x_k)$ denote the factors we have selected. We first run a first-order experiment such as 2^k factorial designs and fit a linear model to the experimental data. The next step is to choose the path of steepest ascent or steepest descent, run several experiments along the path and choose the one with the best performance response. We move the experimental region to the new location identified on the steepest ascent (descent) path and run the first-order experiments using the same steps above. We continue this process until no improvement is possible using first-order experiments. A second-order experiment, such as central composite designs, is conducted in order to describe the response surface better. We then solve a quadratic optimization model, obtain the solution and run confirmatory experiments to validate the optimal solution.

We use a paper helicopter example to illustrate the steps described above. The purpose of this exercise is to design a paper helicopter by choosing the optimal levels for rotor length/width, body length/width and other factors to maximize the flight time of the helicopter. Due to the convenience of the design, this exercise has been used in several institutions to teach design of experiments and RSM. We use the results presented in *Erhardt* and *Mai* [12.8] to demonstrate the basic steps in RSM. Another good source for the design of paper helicopter using RSM can be found in *Box* and *Liu* [12.9].

In *Erhardt* and *Mai* [12.8], there are eight factors that are likely to contribute to the flight time of the paper helicopter: rotor length, rotor width, body length, foot length, fold length, fold width, paper weight, and direction of fold. Screening experiments were conducted and the investigators found that two of the eight variables, rotor length and rotor width, are important in determining the flight time.

Erhardt and *Mai* [12.8] conducted a 2^2 factorial experiment with replicated runs and center points. The experimental data is shown in Table 12.1. The coded level 1 and -1 for rotor length stands for 11.5 and 5.5 cm, respectively. The coded level 1 and -1 for rotor width stands for 5 and 3 cm, respectively.

The first-order model fitted to the data in Table 12.1 is

$$\text{Flight time} = 11.1163 + 1.2881 \times \text{Rotor length} - 1.5081 \times \text{Rotor width}\,.$$

Therefore the path of steepest ascent is (1.2881, −1.5081) in coded level; in other words, for every one centimeter of increase in rotor length, rotor width should be decreased by

$$\frac{1.5081}{1.2881} \times \frac{1}{3} = 0.39\,\text{cm}\,.$$

The investigators conducted five experiments along the steepest ascent path and the experimental data is recorded in Table 12.2. The combination of rotor length and width that gives the longest flight time is 11.5 and 2.83 cm.

The investigators then conduct a central composite design (CCD) by adding experimental runs at axial points. Table 12.3 below contains the data from the CCD experiment. The center point of the CCD design is (11.5, 2.83), which is the solution obtained from the experimental runs on the steepest ascent path. One coded unit stands for 1 cm for rotor length and 0.39 cm for rotor width.

Table 12.1 2^2 factorial design for paper helicopter example

Coded level		Actual level (cm)		Flight time (seconds)			
Rotor length	Rotor width	Rotor length	Rotor width	Replicate 1	Replicate 2	Replicate 3	Replicate 4
1	1	11.5	5	10.02	9.94	9.95	9.93

The second-order model fitted to the data in Table 12.3 is given below:

$$\text{Flight time} = 16.713 - 0.702x_1 + 0.735x_2 - 1.311x_1^2 - 0.510x_1x_2 - 1.554x_2^2 ,$$

where x_1 stands for rotor length and $x_2$stands for rotor width. The optimal solution by maximizing this quadratic model is $(-0.32,\ 0.29)$ in coded units, or 11.18 cm for rotor length and 2.94 cm for rotor width.

The paper helicopter example presented in this section is a simplified version of how response surface methodology works to address quality improvement. A complicated real-world problem may require many more iterations in order to find an optimal solution and many of the technical details can be found in the references given in the beginning of this section.

12.2 Minimax Deviation Method to Derive Robust Optimal Solution

As we discussed in the introduction, the estimated model $f(\boldsymbol{x}, \hat{\boldsymbol{\beta}})$ is a single representation of the true relationship between the response y and the predictor variables in $\boldsymbol{x}$, where $\hat{\boldsymbol{\beta}}$ is a point estimate and is derived from the sample data. The solution obtained by optimizing a single estimated model $f(\boldsymbol{x}, \hat{\boldsymbol{\beta}})$ may not work well for the true model $f(\boldsymbol{x}, \boldsymbol{\beta})$. This section introduces the minimax deviation method to derive the robust solution when the experimental or historical data is available to estimate the optimization model.

One assumption we make here is that the vector $\boldsymbol{\beta}$ in $f(\boldsymbol{x}, \boldsymbol{\beta})$ contains the coefficients in the model and we assume that $f(\boldsymbol{x}, \boldsymbol{\beta})$ is linear in the coefficients in $\boldsymbol{\beta}$. This assumption covers a wide range of applications since most of the models considered in quality engineering are derived using regression and the hypothetical model $f(\boldsymbol{x}, \boldsymbol{\beta})$ is always linear in regression coefficients even if the model itself is nonlinear in $\boldsymbol{x}$. For example, consider $f(\boldsymbol{x}, \boldsymbol{\beta}) = \beta_1 x^2 + \beta_2 x + \beta_3 \frac{1}{x}$, clearly $f(\boldsymbol{x}, \boldsymbol{\beta})$ is linear in $(\beta_1, \beta_2, \beta_3)$, although it is not linear in $\boldsymbol{x}$.

12.2.1 Motivation of the Minimax Deviation Method

Consider two models in Fig. 12.2 where model 1 is $y = f(\boldsymbol{x}, \boldsymbol{\beta}^{(1)})$ and model 2 is $y = f(\boldsymbol{x}, \boldsymbol{\beta}^{(12.1)})$. If we assume that model 1 and model 2 are equally likely to be the true one, then how do we choose the value for x to minimize the response y in the true model? If the value at point A is chosen, there is a 50% chance that the response value y reaches its minimum if model 1 is the true model, while we are facing another 50% chance that the response value y is much worse when model 2 is the true model. A similar conclusion can be made if point B is chosen. Thus a rational decision maker will probably

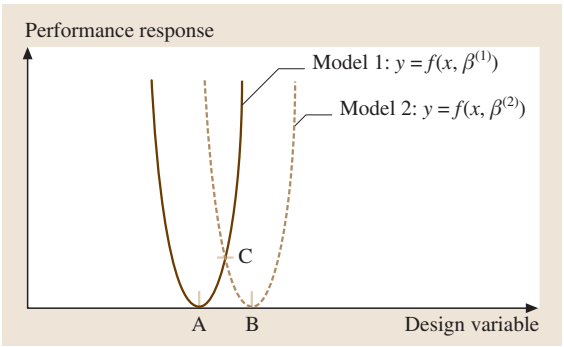

Fig. 12.2 Point C makes the response value close to the minimum whether model 1 or model 2 is the true model

choose point C such that the response value y will not be too far off from the minimum 0 whether model 1 or model 2 is the true one.

To formalize the reasoning, we use the following notation: let g_1 be the minimum value of $f(\boldsymbol{x}, \boldsymbol{\beta}^{(1)})$, and g_2 be the minimum value of $f(\boldsymbol{x}, \boldsymbol{\beta}^{(12.1)})$. For the example in Fig. 12.2, $g_1$and g_2 are both zeros. Given that model 1 and model 2 are equally likely to be the true model, a rational decision maker wants to find an x such that, when the true model is model 1, the response value at $\boldsymbol{x}$, or $f(\boldsymbol{x}, \boldsymbol{\beta}^{(1)})$, is not too far from g_1; and when the true model is model 2, the response value at x, or $f(\boldsymbol{x}, \boldsymbol{\beta}^{(12.1)})$, is not too far from g_2. In other words, we want to select x such that both $f(\boldsymbol{x}, \boldsymbol{\beta}^{(1)}) - g_1$ and $f(\boldsymbol{x}, \boldsymbol{\beta}^{(12.1)}) - g_2$ are as small as possible. Mathematically this is equivalent to the following problem.

Choose $\boldsymbol{x}$ to minimize

$$\text{Max}\left[f(\boldsymbol{x}, \boldsymbol{\beta}^{(1)}) - g_1,\ f(\boldsymbol{x}, \boldsymbol{\beta}^{(2)}) - g_2 \right] . \qquad (12.1)$$

The difference $f(\boldsymbol{x}, \boldsymbol{\beta}^{(1)}) - g_1$ can be understood as the *regret* a rational decision maker will have if he

chooses this particular x when the true model is model 1, since g_1 is the minimum value the response can reach under model 1. Similarly the difference $f(\boldsymbol{x}, \boldsymbol{\beta}^{(2)}) - g_2$ is the *regret* a rational decision maker will have when the true model is model 2. Thus the aim of (12.1) is to choose an $\boldsymbol{x}$ to minimize the maximum regret over the two likely models.

12.2.2 Minimax Deviation Method when the Response Model Is Estimated from Data

Given the motivation in the previous section where the true model has two likely forms, we now consider the case where the response model is estimated from sample data; thus there are infinitely many forms that are likely the true model. Let the experimental data be $(\boldsymbol{x}_1, y_1), (\boldsymbol{x}_2, y_2) \cdots (\boldsymbol{x}_n, y_n)$, where $\boldsymbol{x}_i$ contains predictor variables for the i^{th} observation and y_i is the corresponding response value. Suppose the true model is $y = f(\boldsymbol{x}, \boldsymbol{\beta})$where $\boldsymbol{\beta}$ contains the parameters we will fit using the experimental data. The estimate for $\boldsymbol{\beta}$, denoted by $\hat{\boldsymbol{\beta}}$, can be derived using the MLE or LSapproach. The estimated model using the point estimate $\hat{\boldsymbol{\beta}}$, or $f(\boldsymbol{x}, \hat{\boldsymbol{\beta}})$, is only one of the many possible forms for the true model $f(\boldsymbol{x}, \boldsymbol{\beta})$. Statistical inference provides ways to construct a confidence region, rather than a single-point estimate, to cover the possible value for the true $\boldsymbol{\beta}$. Let us denote a confidence region for $\boldsymbol{\beta}$ by B; thus any model $f(\boldsymbol{x}, \boldsymbol{\beta})$, where $\boldsymbol{\beta} \in B$, represents a likely true model.

Figure 12.3 illustrates how robust optimization works by incorporating all of the estimates in the confidence region. The rectangle in Fig. 12.3 is the confidence region for $\boldsymbol{\beta}$ derived from the sample data, and the center point of the rectangle is the point estimate $\hat{\boldsymbol{\beta}}$. The usual canonical approach optimizes only a single model corresponding to the point estimate, or $f(\boldsymbol{x}, \hat{\boldsymbol{\beta}})$. In contrast, robust optimization considers all of the possible estimates in the confidence region, so it optimizes all of the likely models $f(\boldsymbol{x}, \boldsymbol{\beta})$ whose $\boldsymbol{\beta}$ is in the rectangle.

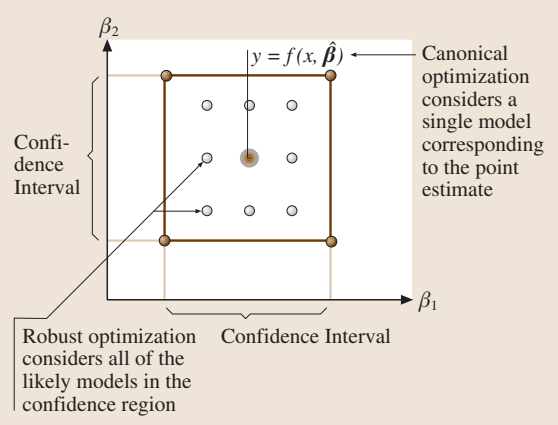

Fig. 12.3 Canonical optimization considers a single model while robust optimization considers all of the models with estimates in the confidence region

We now use the minimax deviation method in Sect. 12.2.1 to derive the robust solution where all of the likely models with estimates in the confidence region are considered. Suppose our goal is to minimize $f(\boldsymbol{x}, \boldsymbol{\beta})$ and the confidence region for $\boldsymbol{\beta}$ is B. The minimax deviation method can be formulated in the following equations:

$$\text{Min}_{\boldsymbol{x}} \text{Max}_{\boldsymbol{\beta} \in B} \left[f(\boldsymbol{x}, \boldsymbol{\beta}) - g(\boldsymbol{\beta}) \right] , \tag{12.2}$$

where

$$g(\boldsymbol{\beta}) = \text{Min}_{\boldsymbol{x}} f(\boldsymbol{x}, \boldsymbol{\beta}), \text{ for any} \boldsymbol{\beta} \in B .$$

The interpretation of the minimax deviation method in (12.2) is similar to that given in Sect. 12.2.1. The difference $f(\boldsymbol{x}, \boldsymbol{\beta}) - g(\boldsymbol{\beta})$ is the regret incurred by choosing a particular $\boldsymbol{x}$ if the true coefficients in the model are $\boldsymbol{\beta}$. However the true values for $\boldsymbol{\beta}$ are unknown and they are likely at any point in the confidence region B. So $\text{Max}_{\boldsymbol{\beta} \in B} [f(\boldsymbol{x}, \boldsymbol{\beta}) - g(\boldsymbol{\beta})]$ stands for the maximum regret over the confidence region. We solve for the robust solution for $\boldsymbol{x}$ by minimizing the maximum regret over B.

The minimax deviation model in (12.2) is equivalent to the following mathematical program as in reference [12.10]

$$\begin{aligned} &\text{Min}(z) , \\ &f(\boldsymbol{x}, \boldsymbol{\beta}) - g(\boldsymbol{\beta}) \le z, \quad \forall \boldsymbol{\beta} \in B , \\ &g(\boldsymbol{\beta}) = \text{Min}_{\boldsymbol{x}} \left[f(\boldsymbol{x}, \boldsymbol{\beta}) \right] . \end{aligned} \tag{12.3}$$

The number of decision variables in this statement is finite while the number of constraints is infinite because every constraint corresponds to a point in the confidence region, or the rectangle in Fig. 12.3. Therefore the program in (12.3) is semi-infinite.

As illustrated in Fig. 12.3, we assume the confidence region can be constructed as a polytope. With this assumption, we have the following reduction theorem.

Reduction theorem. If B is a polytope and $f(\boldsymbol{x}, \boldsymbol{\beta})$ is linear in $\boldsymbol{\beta}$ then

$$\begin{aligned} &\text{Min}_{\boldsymbol{x}} \text{Max}_{\boldsymbol{\beta} \in B} \left[f(\boldsymbol{x}, \boldsymbol{\beta}) - g(\boldsymbol{\beta}) \right] \\ &= \text{Min}_{\boldsymbol{x}} \text{Max}_i \left[f(\boldsymbol{x}, \boldsymbol{\beta}^{\text{i}}) - g(\boldsymbol{\beta}^{\text{i}}) \right] , \end{aligned}$$

where $\boldsymbol{\beta}^1, \boldsymbol{\beta}^2 \cdots \boldsymbol{\beta}^m$ are the extreme points of B.

The reduction theorem says that the minimization of the maximum regret over the entire confidence region is equivalent to the minimization of the maximum regret over the extreme points of the confidence region. Figure 12.4 illustrates the use of the reduction theorem that reduces the original semi-infinite program in (12.3) to a finite program. The proof of the reduction theorem can be found in *Xu* and *Albin* [12.6].

12.2.3 Construction of the Confidence Region

One of the assumptions of the reduction theorem is that the confidence region for $\boldsymbol{\beta}$ is a polytope. This section introduces how we can construct a confidence region as a polytope.

A simple and straightforward way to construct a confidence polytope is to use simultaneous confidence intervals (*Miller* [12.11]). Suppose $\boldsymbol{\beta} = (\boldsymbol{\beta}_1, \boldsymbol{\beta}_2, \cdots, \boldsymbol{\beta}_p)$ and we want to construct a confidence polytope with a confidence level of $(1-\alpha)\times 100\%$ or more. First we construct a $(1-\alpha/p)\times 100\%$ confidence interval for each of the p coefficients in $\boldsymbol{\beta}$. Specifically, let I_i be the $(1-\alpha/p)\times 100\%$ confidence interval for $\boldsymbol{\beta}_i$, or equivalently, $P(\boldsymbol{\beta}_i \in I_i) = 1-\alpha/p$. Thus the simultaneous confidence intervals is the Cartesian product $B = I_1 \times I_2 \times \cdots \times I_p$. Using Bonferroni's inequality, we have

$$\begin{aligned} P(\boldsymbol{\beta} \in B) &= P\left(\boldsymbol{\beta}_1 \in I_1, \boldsymbol{\beta}_2 \in I_2, \cdots \boldsymbol{\beta}_p \in I_p\right) \\ &\geq 1 - \sum_{i=1}^{p} P(\boldsymbol{\beta}_i \notin I_i) \\ &= 1 - p\times\alpha/p = 1-\alpha\,. \end{aligned}$$

Therefore the confidence level of the simultaneous confidence intervals B is at least $(1-\alpha)\times 100\%$. Figure 12.5 illustrates the simultaneous confidence intervals in a two-dimensional space. Suppose the ellipsoid in the left panel of Fig. 12.5 is a 90% confidence region for $(\boldsymbol{\beta}_1, \boldsymbol{\beta}_2)$. To construct simultaneous confidence intervals, we first identify the 95% confidence interval I_1 for $\boldsymbol{\beta}_1$, and the 95% confidence interval I_2 for $\boldsymbol{\beta}_2$; thus the rectangle $I_1 \times I_2$ is a confidence polytope for $(\boldsymbol{\beta}_1, \boldsymbol{\beta}_2)$ with a confidence level of at least 90%. However, we know from Fig. 12.5 that the rectangle does not cover the 90% confidence ellipsoid very tightly, so the simultaneous confidence intervals are not the smallest confidence polytope at a certain confidence level. Clearly a better way to construct a more efficient confidence polytope is to find a rectangle that circumscribes the ellipsoid, such as that in the right panel of Fig. 12.5.

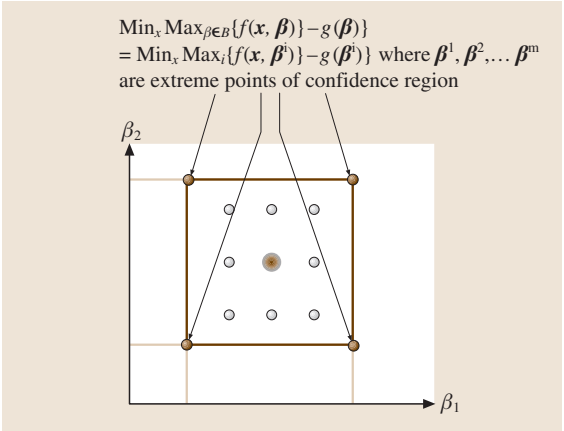

Fig. 12.4 The reduction theorem reduces the semi-infinite program over the entire confidence region to a finite program over the set of extreme points of the confidence region

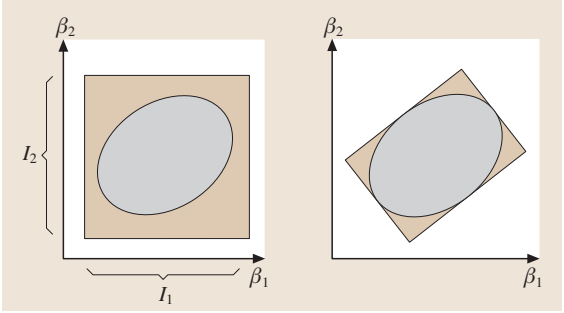

Fig. 12.5 Simultaneous confidence intervals are not the most efficient confidence polytope

We now present a transformation method to construct a tighter confidence polytope, which proves very effective to enhance robust optimization performance. Let $\boldsymbol{X}$ be a matrix with each row representing the observed values for the predictor variables in $\boldsymbol{x}$, and let $\boldsymbol{Y}$ be a vector with each element being the observed response value y.

From regression analysis, the $(1-\alpha)\times 100\%$ confidence region for $\boldsymbol{\beta}$ is an ellipsoid described as

$$\begin{aligned} &(1-\alpha)\times 100\% \text{ confidence region} \\ &= \left(\boldsymbol{\beta} \middle| \frac{(\boldsymbol{\beta}-\hat{\boldsymbol{\beta}})'(\mathbf{X}'\mathbf{X})(\boldsymbol{\beta}-\hat{\boldsymbol{\beta}})}{p\mathrm{MSE}} \leq F_{p,n-p,\alpha}\right), \end{aligned} \quad (12.4)$$

where $\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y}$ is the point estimator, p is the number of parameters we need to estimate in the response model, n is the total number of observations

we have in the sample data, $\text{MSE} = (\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}})'(\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}})/n - p$ is the mean squared error, and $F_{p,n-p,\alpha}$ is the $(1-\alpha)\times 100$ percentile point for the F distribution with p and $(n-p)$ degrees of freedom. Details about (12.4) can be found in *Myers* [12.12].

We use Fig. 12.6 to illustrate the motivation for the transformation method to construct the confidence polytope in two dimensions. The ellipsoid in the left-hand picture of Fig. 12.6 is the $(1-\alpha)\times 100\%$ confidence region in (12.4). We want to find a polytope to cover the confidence ellipsoid more tightly. One such choice is to identify a rectangle with sides parallel to the major and minor axes of the ellipsoid, such as the one with vertices $\boldsymbol{\beta}^1$, $\boldsymbol{\beta}^2$, $\boldsymbol{\beta}^3$ and $\boldsymbol{\beta}^4$ in Fig. 12.6.

It is hard to identify these extreme points $\boldsymbol{\beta}^1$, $\boldsymbol{\beta}^2$, $\boldsymbol{\beta}^3$ and $\boldsymbol{\beta}^4$ directly in the original coordinate system $(\boldsymbol{\beta}_1, \boldsymbol{\beta}_2)$. However, by choosing appropriate algebraic transformation, the coordinate system $(\boldsymbol{\beta}_1, \boldsymbol{\beta}_2)$ can be transformed into the coordinate system (z_1, z_2), where the ellipsoid is converted to a unit ball in the right-hand picture of Fig. 12.6. In the coordinate system (z_1, z_2), it is easy to find a hypercube, with extreme points z^1, z^2, z^3 and z^4, to cover this ball tightly. We then map these extreme points back to the extreme points in $(\boldsymbol{\beta}_1, \boldsymbol{\beta}_2)$ to obtain $\boldsymbol{\beta}^1$, $\boldsymbol{\beta}^2$, $\boldsymbol{\beta}^3$ and $\boldsymbol{\beta}^4$.

To achieve this idea, we define the following transformation $\boldsymbol{\beta} \mapsto \mathrm{z}$:

$$\mathbf{z} = \boldsymbol{\Gamma}\,(\boldsymbol{\beta} - \hat{\boldsymbol{\beta}})\,, \text{ where } \Gamma = \frac{(\mathbf{X}'\mathbf{X})^{1/2}}{\sqrt{p \times \text{MSE} \times F_{p,n-p,\alpha}}}\,.$$

Through this transformation, the confidence ellipsoid in (12.4) in the coordinate system $\boldsymbol{\beta}$ can be converted into a unit ball in the coordinate system z: $\left(\mathrm{z}|\mathrm{z}'\mathrm{z} \le 1\right)$. It is easy to know that the hypercube covering the unit ball has extreme points $\mathrm{z}^i = (z_1, z_2, \cdots, z_p)$, where $z_j = \pm 1$, $j = 1, 2, \cdots, p$. By mapping these points back to the coordinate system $\boldsymbol{\beta}$, we can construct a confidence polytope with extreme points as follows:

$$\boldsymbol{\beta}^i = \hat{\boldsymbol{\beta}} + \boldsymbol{\Gamma}^{-1}\mathbf{z}^i, \text{ where } \Gamma = \frac{(\mathbf{X}'\mathbf{X})^{1/2}}{\sqrt{p \times \text{MSE} \times F_{p,n-p,\alpha}}}\,. \tag{12.5}$$

Thus the robust optimization model in (12.3) can be written as

$$\begin{aligned} &\text{Min}(z)\,, \\ &f(\boldsymbol{x}, \boldsymbol{\beta}^{\mathrm{i}}) - g(\boldsymbol{\beta}^{\mathrm{i}}) \le z\,, \\ &g(\boldsymbol{\beta}^{\mathrm{i}}) = \text{Min}_{\boldsymbol{x}}\, f(\boldsymbol{x}, \boldsymbol{\beta}^{\mathrm{i}})\,, \end{aligned} \tag{12.6}$$

where $\boldsymbol{\beta}^{\mathrm{i}}$ is given in (12.5)

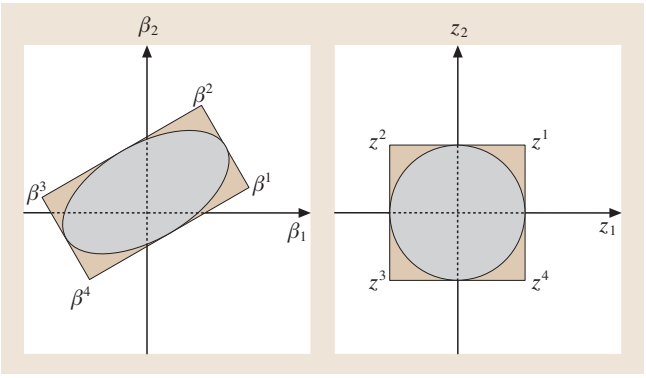

Fig. 12.6 Illustration of the transformation method to construct a confidence polytope

12.2.4 Monte Carlo Simulation to Compare Robust and Canonical Optimization

This section compares the performance of robust optimization and canonical optimization using Monte Carlo simulation on a hypothetical response model. Much of the material is from *Xu* and *Albin* [12.6] and *Xu* [12.13]. Suppose the true function relating performance response $y$and design variables x_1 and x_2 is the quadratic function

$$y = 0.5x_1^2 - x_1x_2 + x_2^2 - 2x_1 - 6x_2\,. \tag{12.7}$$

The objective is to identify x_1 and x_2 to minimize y with the constraints that $x_1 + x_2 \le 6$, $x_1 \ge 0$, and $x_2 \ge 0$. If the response model in (12.7) is known, the true optimal solution can be easily identified: $x_1 = 2.8$, $x_2 = 3.2$, yielding the optimal value $y = -19.6$.

Now suppose that the objective function is not known. We could perform a designed experiment to estimate the performance response function. Since we seek a second-order function we would perform a 3^2 factorial design with three levels for x_1 and three levels for x_2, resulting in a total of nine different combinations of $x_1$and x_2. The possible experimental values are -1, 0 and 1 for $x_1$and -1, 0, and 1 for x_2.

Instead of performing the experiment in a laboratory, we use Monte Carlo simulation, where the response y is produced by generating responses equal to the underlying response function in (12.7) plus noise ε:

$$\begin{aligned} &y = 0.5x_1^2 - x_1x_2 + x_2^2 - 2x_1 - 6x_2 + \varepsilon \\ &\quad \text{and } \varepsilon \sim N(0, \sigma^2)\,. \end{aligned} \tag{12.8}$$

Once the experiment has been run, we fit coefficients to the data by ordinary least-square regression and then optimize using the robust and canonical approaches, respectively.

The solutions obtained from the two approaches are inserted into (12.7) to determine the resulting performance response values and we compare these to determine which is closer to the true optimal.

We perform the above experiment and subsequent optimizations 100 times for each of the following degrees of experimental noise; that is, the noise term ε in (12.8) has standard deviation, σ, equal to 0.5, 1, 2, 3, or 4.

Thus we have 100 objective values for the canonical approach and 100 objective values for the robust approach for each value of σ. Table 12.4 gives the means and standard deviations of these performance responses using the canonical approach, the robust approach with simultaneous confidence intervals, and the robust approach with transformation method.

Table 12.4 shows that, when the experimental noise is small (σ= 0.5), yielding a relatively accurate point estimate of $\boldsymbol{\beta}$, the objective values given by the canonical approach are slightly closer to those given by the robust optimization approach. However, when the experimental noise is large (σ= 1,2,3,4), yielding a relatively inaccurate point estimate of $\boldsymbol{\beta}$, the robust approach yields results much closer to the true optimal than the canonical approach. We also notice that the robust approach using transformation method to construct the confidence polytope gives better results than the method using the simultaneous confidence intervals.

12.3 Weighted Robust Optimization

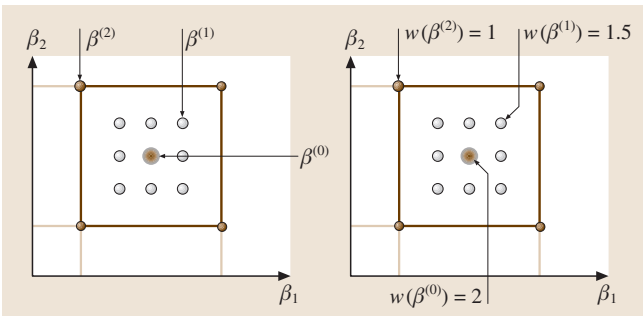

Fig. 12.7 Weighted robust optimization assigns weights to every point in the confidence region to reflect the likelihood of that point being close to the true $\boldsymbol{\beta}$

As we discussed earlier, robust optimization minimizes the maximum regret over a confidence region for the coefficients in the response model. Recall that the robust optimization is written as follows:

$$\mathrm{Min}_{\boldsymbol{x}}\mathrm{Max}_{\boldsymbol{\beta}\in B}\left[f(\boldsymbol{x},\boldsymbol{\beta})-g(\boldsymbol{\beta})\right]\ ,$$

where $g(\boldsymbol{\beta}) = \mathrm{Min}_{\boldsymbol{x}} f(\boldsymbol{x},\boldsymbol{\beta})$, for any $\boldsymbol{\beta}\in B$.

An implicit assumption in the minimax regret equation above is that all of the points in the confidence region B are treated with equal importance. For example, consider the three points $\boldsymbol{\beta}^{(0)}$, $\boldsymbol{\beta}^{(1)}$, and $\boldsymbol{\beta}^{(2)}$ in the left-hand picture of Fig. 12.7, the *regrets* we have at the three points by choosing $\boldsymbol{x}$ are $f(\boldsymbol{x},\boldsymbol{\beta}^{(0)})-g(\boldsymbol{\beta}^{(0)})$, $f(\boldsymbol{x},\boldsymbol{\beta}^{(1)})-g(\boldsymbol{\beta}^{(1)})$ and $f(\boldsymbol{x},\boldsymbol{\beta}^{(2)})-g(\boldsymbol{\beta}^{(2)})$, respectively. However, we know from statistical inference that the center point $\boldsymbol{\beta}^{(0)}$ is more likely close to be the true $\boldsymbol{\beta}$ than $\boldsymbol{\beta}^{(1)}$, and $\boldsymbol{\beta}^{(1)}$ is more likely to be close to the true $\boldsymbol{\beta}$ than$\boldsymbol{\beta}^{(2)}$, so in the *regret* calculation, weights can be assigned to each point in the confidence region to measure how likely that point is to be close to the true $\boldsymbol{\beta}$.

In the right-hand picture of Fig. 12.7, the weights for the three points are $w\left(\boldsymbol{\beta}^{0}\right)=2$, $w\left(\boldsymbol{\beta}^{(1)}\right)=1.5$, and $w\left(\boldsymbol{\beta}^{(2)}\right)=1$, so the *regrets* at these three points can be defined as $2\left[f\left(\boldsymbol{x},\boldsymbol{\beta}^{(0)}\right)-g\left(\boldsymbol{\beta}^{(0)}\right)\right]$, $1.5\left[f\left(\boldsymbol{x},\boldsymbol{\beta}^{(1)}\right)-g\left(\boldsymbol{\beta}^{(1)}\right)\right]$ and $\left[f\left(\boldsymbol{x},\boldsymbol{\beta}^{(2)}\right)-g\left(\boldsymbol{\beta}^{(2)}\right)\right]$. In general, the weighted robust optimization can be written as

$$\mathrm{Min}_{\boldsymbol{x}}\mathrm{Max}_{\boldsymbol{\beta}\in B}\left[f(\boldsymbol{x},\boldsymbol{\beta})-g(\boldsymbol{\beta})\right]w(\boldsymbol{\beta})\ , \qquad (12.9)$$

where $w(\boldsymbol{\beta})$ is the weight assigned to the point $\boldsymbol{\beta}$ in the confidence region. So the aim of the weighted robust optimization in (12.9) is to minimize the maximum weighted regret over the confidence region. The center point of the confidence region should be assigned the largest weight since it is most likely to be close to the true $\boldsymbol{\beta}$. On the other hand, the extreme points of the confidence region should be assigned the smallest weights.

We now consider two choices of the weight function $w(\boldsymbol{\beta})$. Let $\boldsymbol{\beta}^{(0)}$ be the center point of the confidence region; let $\boldsymbol{\beta}^{(+)}$ be an extreme point with the largest distance to $\boldsymbol{\beta}^{(0)}$. In the first version of weight function, we treat the point $\boldsymbol{\beta}^{(0)}$ as twice as important as $\boldsymbol{\beta}^{(+)}$. In other words, we assign weight 1 to the extreme point $\boldsymbol{\beta}^{(+)}$ and the weight for the center point $\boldsymbol{\beta}^{(0)}$ is 2. The weight for any other point $\boldsymbol{\beta}$ is between 1 and 2 and decreases linearly with its distance from the center point $\boldsymbol{\beta}^{(0)}$. This linear-distance-based weight function can be

written in the following way:

$$w(\boldsymbol{\beta}) = 2 - \frac{||\boldsymbol{\beta} - \boldsymbol{\beta}^{(0)}||}{||\boldsymbol{\beta}^{(+)} - \boldsymbol{\beta}^{(0)}||} \,. \tag{12.10}$$

We now discuss the second version of weight function. Let $\boldsymbol{x}^{(\mathrm{i})}$and y_i, i = 1, 2, $\cdots$, n, be the observation for the predictors and response value. For any estimator $\boldsymbol{\beta}$ in the confidence region, the sum of squared errors (SSE) $\sum_{i=1}^{n}[\,\boldsymbol{y}_i - f(\boldsymbol{x}^{(\mathrm{i})}, \boldsymbol{\beta})]^2$ can be viewed as an indirect measure of how close the estimator $\boldsymbol{\beta}$ is to the true coefficients. So we take the reciprocal of the SSE as the weight function, or

$$w(\boldsymbol{\beta}) = \frac{1}{\sum_{i=1}^{n}[\,\boldsymbol{y}_i - f(\boldsymbol{x}^{(\mathrm{i})}, \boldsymbol{\beta})]^2} \,. \tag{12.11}$$

To compare the performance of robust optimization and weighted robust optimization, we use the same underlying response model in (12.7) to generate the experimental data and then apply the two approaches to derive the robust solutions. Table 12.5 contains the means and standard deviations of the performance responses obtained by the canonical, robust and weighted robust optimization approaches.

It is clear that the performance of the weighted robust optimization dominates that of the standard robust optimization. We further note that the weight function in (12.10) performs better than the weight function in (12.11) when the experimental noise is large ($\sigma = 1, 2, 3, 4$).

Although the weighted robust optimization gives better results, computationally it is much harder and more challenging. Unfortunately, weighting the points in the confidence region, using weight functions $w(\boldsymbol{\beta})$ in (12.10) or (12.11), results in an optimization problem in (12.9) with an objective function that is not linear in $\boldsymbol{\beta}$. Consequently, the reduction theorem is no longer applicable to (12.9) to reduce the optimization problem to a finite program. Therefore a numerical algorithm has to be designed to solve the weighted robust optimization problem in (12.9).

For simplicity, let $F(\boldsymbol{x}, \boldsymbol{\beta}) = [\,f(\boldsymbol{x}, \boldsymbol{\beta}) - g(\boldsymbol{\beta})]\, w(\boldsymbol{\beta})$. Thus we can write the weighted robust optimization problem as follows

$$\mathrm{Min}_{\boldsymbol{x}}\mathrm{Max}_{\boldsymbol{\beta}\in B} F(\boldsymbol{x}, \boldsymbol{\beta}) \tag{12.12}$$

or equivalently,

$$\begin{aligned} &\mathrm{Min}_{\boldsymbol{x}}\{\xi\}\,, \\ &\text{s.t. x} \in X\,, \\ &F(\boldsymbol{x}, \boldsymbol{\beta}) \le \xi, \forall \boldsymbol{\beta} \in B\,. \end{aligned} \tag{12.13}$$

We use the Shimizu–Aiyoshi relaxation algorithm to solve (12.13). For a rigorous treatment of this relaxation algorithm, see *Shimizu* and *Aiyoshi* [12.10]. The main steps in this algorithm are given as follows:

Step 1: choose any initial point $\boldsymbol{\beta}^{(1)}$. Set $k = 1$.

Step 2: solve the following relaxed problem of (12.13):

$$\begin{aligned} &\mathrm{Min}_{\boldsymbol{x}}\{\xi\} \\ &\text{s.t.}\, \boldsymbol{x} \in X \\ &F(\boldsymbol{x}, \boldsymbol{\beta}^{(i)}) \le \xi, i = 1, 2, \cdots, k \end{aligned} \tag{12.14}$$

Obtain an optimal solution $(\boldsymbol{x}^{(k)}, \boldsymbol{\xi}^{(k)})$ for (12.14). The $\boldsymbol{\xi}^{(k)}$ is also the optimal value for (12.14). We note that $\boldsymbol{\xi}^{(k)}$ is a lower bound on the optimal value for (12.13).

Step 3: solve the maximization problem:

$$\mathrm{Max}_{\boldsymbol{\beta}\in B} F(\boldsymbol{x}^{(k)}, \boldsymbol{\beta})\,. \tag{12.15}$$

Obtain an optimal solution $\boldsymbol{\beta}^{(k+1)}$ and the maximal value $\phi(\boldsymbol{x}^{(k)}) = F(\boldsymbol{x}^{(k)}, \boldsymbol{\beta}^{(k+1)})$. We note that $\phi(\boldsymbol{x}^{(k)})$ is an upper bound on the optimal value of (12.12) or (12.13).

Step 4: If $\phi(\boldsymbol{x}^{(k)}) - \boldsymbol{\xi}^{(k)} < \varepsilon$, terminate and report the solution $\boldsymbol{x}^{(k)}$; otherwise, set $k = k$+1 and go back to step 2.

We now introduce the method for solving the optimization problems (12.14) and (12.15). First, we address (12.14). If the response model $f(\boldsymbol{x}, \boldsymbol{\beta})$ is linear in $\boldsymbol{x}$, then $F(\boldsymbol{x}, \boldsymbol{\beta})$ is also linear in $\boldsymbol{x}$; thus (12.14) is a linear programming problem if we assume that the feasible region $\boldsymbol{X}$ contains only linear constraints. If the response model $f(\boldsymbol{x}, \boldsymbol{\beta})$ is quadratic in $\boldsymbol{x}$, then $F(\boldsymbol{x}, \boldsymbol{\beta})$ is also quadratic in $\boldsymbol{x}$; thus (12.14) is a quadratically constrained quadratic programming problem.

Quadratically constrained quadratic programming (QCQP) is a very challenging problem. One efficient way to solve QCQP is to approximate it by a semidefinite program (SDP) and the solution for SDP usually provides a very tight bound on the optimal value of the QCQP. There exist very efficient and powerful methods to solve SDP and numerous software packages have been developed. After an approximate solution is obtained from SDP, we then use a randomized algorithm to search for a good solution for the original QCQP. For a comprehensive introduction to SDP, see *Vandenberghe* and *Boyd* [12.14]; for the connection between QCQP and SDP, see *Alizadeh* and *Schmieta* [12.15], and *Frazzoli* [12.16]; for software packages to solve SDP, see *Alizadeh* et al. [12.17], and *Sturm* [12.18].

We finally comment on the optimization problem (12.15). The objective function in (12.15) is

$F(\boldsymbol{x}^k, \boldsymbol{\beta}) = \{f(\boldsymbol{x}^k, \boldsymbol{\beta}) - g(\boldsymbol{\beta})\}w(\boldsymbol{\beta})$. We note that the function $g(\boldsymbol{\beta})$ has no closed-form expression since it is the minimal value of $f(\boldsymbol{x}, \boldsymbol{\beta})$. Here we use a powerful global optimization algorithm, called DIRECT, to solve (12.15). The DIRECT algorithm was proposed by *Jones* et al. [12.19]. There are several advantages of using DIRECT: it is a global optimization algorithm and has a very good balance between global searching and local searching, and it converges quite quickly; it does not need derivative information on the objective function. For software on DIRECT, see *Bjorkman* and *Holmstrom* [12.20].

12.4 The Application of Robust Optimization in Parameter Design

This section applies robust optimization to solve Taguchi's parameter design problem. The aim of parameter design is to choose optimal levels for the control factors to reduce the performance variation as well as to make the response close to the target. Section 12.4.1 introduces both traditional and more recent approaches to handling parameter design problems. Section 12.4.2 discusses how to use robust optimization to identify a robust solution for control factors when the response model is estimated from experimental data. Section 12.4.3 presents the robust optimization method to solve parameter design problem when the experimental data is from a fractional factorial design and some effects are aliased.

12.4.1 Response Model Approach to Parameter Design Problems

Parameter design was promoted by Genichi Taguchi in the 1950s and has since been widely used in quality engineering (*Taguchi* [12.21]). In parameter design, there are two sets of variables: control factors and noise variables. Control factors are those variables that can be set at fixed levels in the production stage; noise variables are those variables that we cannot control such as environmental conditions and material properties, and are hence assumed random in the production stage. The performance response is affected by both control factors and noise variables.

The contribution of Taguchi, among many others, is to recognize that interaction often exists between control factors and noise variables. Hence, appropriate levels of control factors can be selected to reduce the impact of noise variables on the performance response.

Taguchi proposed a set of methodologies, including inner–outer array design and signal-to-noise ratio (SNR), to identify optimal levels of control factors. *Welch* et al. [12.22] and *Shoemaker* et al. [12.23] have proposed the response model formulation, a more statistically sound method, to deal with parameter design problems.

In the response model approach, we first conduct experiments at appropriate levels of control factors and noise variables. Then we can fit the following model to relate the performance response to both control factors and noise variables:

$$\begin{aligned} y &= f(\boldsymbol{x}; \alpha, \gamma, \mu, A, \Delta) \\ &= \mu + \tfrac{1}{2}\mathrm{x}'Ax + \alpha' x + x'\Delta \mathrm{z} + \gamma' z + \varepsilon\,, \end{aligned} \tag{12.16}$$

where $\boldsymbol{x}$ represents the control factors and $\boldsymbol{z}$ the noise variables. Equation (12.16) includes first- and second-order terms in control factors, a first-order term in noise variables and an interaction term between control factors and noise variables. The noise variables $\boldsymbol{z}$ have a normal distribution with mean $\boldsymbol{0}$ and variance Σ_z, or $z \sim N(0, \Sigma_z)$. The ε term incorporates unidentified noise other than $\boldsymbol{z}$.

The difference between the response model in (12.16) and the response model $f(\boldsymbol{x}, \boldsymbol{\beta})$ in the previous sections is that the former divides the noise into $\boldsymbol{z}$ and ε and introduces a first-order term and an interaction term related to $\boldsymbol{z}$ while the latter has the noise only in ε. We further note that the coefficients $(\alpha, \gamma, \mu, A, \Delta)$ in (12.16) are estimated from designed experiments. More details about (12.16) can be found in *Myers* and *Montgomery* [12.3].

From (12.16), it is easy to derive the expected value and standard deviation of the response value y

$$\begin{aligned} E(y) &= \mu + \tfrac{1}{2}x'Ax + \alpha' x\,, \\ \mathrm{Var}(y) &= x'\Delta\Sigma_z\Delta' x + \gamma'\Sigma_z\gamma + \sigma_\varepsilon^2\,. \end{aligned}$$

Suppose our goal is to choose control factors $\boldsymbol{x}$ such that the response y is as close as possible to a target t. In Taguchi's parameter design problem, the criterion to identify optimal levels for control factors $\boldsymbol{x}$ is to minimize the following expected squared loss:

$$\begin{aligned} L(\boldsymbol{x}; \alpha, \gamma, \mu, A, \Delta) &= [E(y) - t]^2 + \mathrm{Var}(y) \\ &= \left(\mu + \tfrac{1}{2}x'Ax + \alpha' x - t\right)^2 \\ &\quad + x'\Delta\Sigma_z\Delta' x + \gamma'\Sigma_z\gamma + \sigma_\varepsilon^2\,. \end{aligned}$$

12.4.2 Identification of Control Factors in Parameter Design by Robust Optimization

Since the true values for the coefficients $(\alpha, \gamma, \mu, A, \Delta)$ in (12.16) are unknown and they are estimated from data, we use robust optimization to derive a robust solution $\boldsymbol{x}$ that is resistant to the estimation error. First we use the same method as in Sect. 12.2.3 to construct a confidence region B for the coefficients $(\alpha, \gamma, \mu, A, \Delta)$ and then we solve the following minimax deviation model:

$$\begin{aligned}
&\mathrm{Min}_{\boldsymbol{x}}\mathrm{Max}_{(\alpha,\gamma,\mu,A,\Delta)\in B} L(\boldsymbol{x};\alpha,\gamma,\mu,A,\Delta)\\
&-g(\alpha,\gamma,\mu,A,\Delta)\,,\\
&g(\alpha,\gamma,\mu,A,\Delta)=\mathrm{Min}_{\boldsymbol{x}}L(\boldsymbol{x};\alpha,\gamma,\mu,A,\Delta)\,,\\
&L(\boldsymbol{x};\alpha,\gamma,\mu,A,\Delta)=\left(\mu+\tfrac{1}{2}x'Ax+\alpha'x-t\right)^2\\
&+x'\Delta\Sigma_z\Delta'x+\gamma'\Sigma_z\gamma+\sigma_\varepsilon^2\,. \qquad (12.17)
\end{aligned}$$

Note that the model (12.17) is not linear in the coefficients $(\alpha, \gamma, \mu, A, \Delta)$, so we have to resort to a numerical optimization algorithm to solve it.

We use the following example from *Xu* [12.13] to show the application of robust optimization to the parameter design problem. Suppose there are two control factors A and B and one noise variable C. The underlying relationship between the performance response $y$and control/noise factors A, B and C is

$$y=3A+2B+0.15C+0.5AC-BC+6+\varepsilon\,, \qquad (12.18)$$

where $\varepsilon\sim N(0,1)$. We further assume that the variance of the noise factor C is $\sigma_C=1$. Our goal is to choose the optimal levels of (A, B) over the feasible region $\{(A, B)|-1\le A, B\le 1\}$ to make the response y close to the target $t=7.5$. We notice that the response values have a minimum squared loss of 1 when the control factors $(A, B)=(0.3, 0.3)$.

Assume we do not know the true model (12.18), so we have first to fit a response model $y=\mu+\alpha_1A+\alpha_2B+\gamma_1C+\delta_1AC+\delta_2BC$, where $(\mu, \alpha_1, \alpha_2, \gamma_1, \delta_1, \delta_2)$ are the coefficients we will estimate. Suppose we perform a full 2^3 factorial design with the design matrix and the observed responses as follows.

Using the experimental data from the factorial design in Table 12.3, we first construct the confidence region B for the coefficients $(\mu, \alpha_1, \alpha_2, \gamma_1, \delta_1, \delta_2)$ in the response model. The squared loss for the response value y is $L=[E(y)-t]^2+\mathrm{Var}(y)=(\mu+\alpha_1A+\alpha_2B-t)^2+(\gamma_1+\delta_1A+\delta_2B)^2\sigma_C^2+\sigma_\varepsilon^2$. By substituting $t=7.5$ and $\sigma_C=\sigma_\varepsilon=1$, we have $L=(\mu+\alpha_1A+\alpha_2B-7.5)^2+(\gamma_1+\delta_1A+\delta_2B)^2+1$. Therefore we can write the robust optimization model as follows:

$$\begin{aligned}
&\mathrm{Min}_{\{-1\le A,B\le 1\}}\mathrm{Max}_{(\mu,\alpha_1,\alpha_2,\gamma_1,\delta_1,\delta_2)\in B}\\
&L(A,B;\mu,\alpha_1,\alpha_2,\gamma_1,\delta_1,\delta_2)\\
&-g(\mu,\alpha_1,\alpha_2,\gamma_1,\delta_1,\delta_2)\,,\\
&g(\mu,\alpha_1,\alpha_2,\gamma_1,\delta_1,\delta_2)\\
&=\mathrm{Min}_{(A,B)}L(A,B;\mu,\alpha_1,\alpha_2,\gamma_1,\delta_1,\delta_2)\,,\\
&L(A,B;\mu,\alpha_1,\alpha_2,\gamma_1,\delta_1,\delta_2)\\
&=(\mu+\alpha_1A+\alpha_2B-7.5)^2\\
&+(\gamma_1+\delta_1A+\delta_2B)^2+1\,. \qquad (12.19)
\end{aligned}$$

By solving the optimization problem in (12.19), we can obtain the robust solution $(A, B) = (0.35, 0.22)$. If this solution is applied to the underlying model (12.18), the response values would have an expected squared loss 1.01, which is quite close to the true minimum 1. To be complete, we also present the results obtained by canonical optimization. The canonical solution is $(A, B) = (0.29, 0.95)$ and if this solution is applied to the true model, the expected squared loss would be 3.08, which is much worse than the true optimum.

12.4.3 Identification of Control Factors when the Response Model Contains Alias Terms

Fractional factorial design is a widely used tool to reduce the number of runs in experimental design. The downside of fractional factorial design is that the main effects and higher-order interactions are confounded. For example, in a fractional factorial design with resolution III, the main effects are aliased with the two-factor interaction in the response model. A usual way to address this question is to assume that the interaction is zero and attribute all effects to the main factors. However if the interaction term is important to determine the process/product performance, the loss of this information may be critical. If in the parameter design we cannot differentiate between the effects from the main factors and those from the interaction terms, there is no easy way to identify the optimal levels for the control factors to minimize the variance in the final performance response.

Fractional factorial design usually is used for factor-screening purposes, however if we can use the data from fractional design to make a preliminary assessment of where the optimal levels for control factors may be located, this can help move the design more quickly to the region where the final performance response is most

likely to be optimal and start the full factorial design or other sophisticated designs sooner. So this poses the challenge of how we can solve a parameter design problem if two effects are aliased due to the nature of the data from a fractional factorial design.

Robust optimization provides a useful methodology to address the above challenge if we can include prior information on the alias terms. For example, the prior information can be that both the main factor and interaction term contribute positively to the response value, etc.. To be clear, let us consider the same response model as in (12.18), but assume that, instead of the full factorial design in Table 12.3, only the data from a fractional factorial design is available. The 2^{3-1} design is shown in Table 12.4 where we retain the observations 1, 4, 6, 7 from Table 12.3. At each design point in Table 12.4, replicate 1 is the response value we observed from the design in Table 12.3, in addition, we perform one more run of the experiments and replicate 2 contains the corresponding response value.

We note that the design in Table 12.4 has the defining relation $ABC = I$, so the effects of the main factor A and the interaction BC cannot be differentiated using the data in Table 12.4; similarly the effects of the main factor B and the interaction AC are confounded too. Hence instead of estimating the response model in (12.18), we can only use the data in Table 12.4 to estimate the following model:

$$y = \mu + \boldsymbol{\beta}_1 \tilde{A} + \boldsymbol{\beta}_2 \tilde{B} + \gamma_1 C \,, \tag{12.20}$$

where $\tilde{A} = A + BC$, $\boldsymbol{\beta}_1$ measures the combined effect of the factors A and BC, $\tilde{B} = B + AC$, $\boldsymbol{\beta}_2$ measures the combined effect of the factors B and AC.

Using the same notation as in Sect. 12.4.2, let

$\alpha_1 =$ denote the effect of the main factor A,
$\alpha_2 =$ denote the effect of the main factor B,
$\delta_1 =$ denote the effect of the interaction term AC,
$\delta_2 =$ denote the effect of the interaction term BC.

Given the values for $\boldsymbol{\beta}_1$ and $\boldsymbol{\beta}_2$, if there is no other information, α_1 and δ_2 can be any values as long as they satisfy $\alpha_1 + \delta_2 = \boldsymbol{\beta}_1$; similarly, α_2 and δ_1 can be any values as long as they satisfy $\alpha_2 + \delta_1 = \boldsymbol{\beta}_2$. However we assume here that quality engineers already know the prior information that: (1) the effects of the main factor A and the interaction BC are in the same direction; and (2) the effects of the main factor B and the interaction AC are in the opposite direction. We can describe the prior information in (1) and (2) in the following constraints:

$$\alpha_1 = \lambda_1 \boldsymbol{\beta}_1, \quad \delta_2 = (1 - \lambda_1)\boldsymbol{\beta}_1, \quad 0 \le \lambda_1 \le 1 \,, \tag{12.21}$$

$$\alpha_2 = \lambda_2 \boldsymbol{\beta}_2, \quad \delta_1 = (1 - \lambda_2)\boldsymbol{\beta}_2, \quad \lambda_2 \ge 1 \,. \tag{12.22}$$

Table 12.4 Comparison of performance responses using canonical and robust optimization approaches (true optimal performance: -19.6)

Dist. of ε	Canonical approach		Robust approach with simultaneous confidence intervals		Robust approach with transformation method	
	Mean	Std. dev.	Mean	Std. dev.	Mean	Std. dev.
$N(0, 0.5)$	-18.7	1.2	-18.2	1.5	-18.4	1.6
$N(0, 1)$	-15.4	6.0	-15.2	3.3	-17.0	3.5
$N(0, 2)$	-9.9	8.7	-10.8	4.9	-15.0	5.4
$N(0, 3)$	-6.3	9.3	-9.0	5.4	-13.2	6.3
$N(0, 4)$	-4.6	9.0	-7.8	5.7	-11.4	6.9

Table 12.5 Comparison of performance responses using canonical, robust, and weighted robust optimization (adapted from [12.13])

ε	Canonical optimization		Robust optimization		Weighted robust opt. with weights (12.10)		Weighted robust opt. with weights (12.11)	
	Mean	Std. dev.	Mean	Std. dev.	Mean	Std. dev.	Mean	Std. dev.
$N(0, 0.5)$	-18.7	1.2	-18.4	1.6	-18.4	1.4	-18.8	1.0
$N(0, 1)$	-15.4	6.0	-17.0	3.5	-18.0	1.9	-17.8	2.1
$N(0, 2)$	-9.9	8.7	-15.0	5.4	-17.4	2.8	-16.4	3.7
$N(0, 3)$	-6.3	9.3	-13.2	6.3	-17.2	3.0	-15.3	4.8
$N(0, 4)$	-4.6	9.0	-11.4	6.9	-17.0	3.7	-14.7	5.4

We first construct the confidence region B for $(\mu, \boldsymbol{\beta}_1, \boldsymbol{\beta}_2, \gamma_1)$, the parameters in the response model (12.20). By substituting (12.21) and (12.22) into the optimization problem in (12.19), we have the following equations:

$$\begin{aligned}
&\mathrm{Min}_{\{-1\le A,B\le 1\}}\mathrm{Max}_{(\mu,\boldsymbol{\beta}_1,\boldsymbol{\beta}_2,\gamma_1)\in B}\\
&L(A,B;\mu,\boldsymbol{\beta}_1,\boldsymbol{\beta}_2,\gamma_1)-g(\mu,\boldsymbol{\beta}_1,\boldsymbol{\beta}_2,\gamma_1)\,,\\
&g(\mu,\boldsymbol{\beta}_1,\boldsymbol{\beta}_2,\gamma_1)\\
&=\mathrm{Min}_{(A,B)}L(A,B;\mu,\boldsymbol{\beta}_1,\boldsymbol{\beta}_2,\gamma_1)\,,\\
&L(A,B;\mu,\boldsymbol{\beta}_1,\boldsymbol{\beta}_2,\gamma_1)\\
&=[\mu+\lambda_1\boldsymbol{\beta}_1A+\lambda_2\boldsymbol{\beta}_2B-7.5]^2\\
&\quad+[\gamma_1+(1-\lambda_2)\boldsymbol{\beta}_2A+(1-\lambda_1)\boldsymbol{\beta}_1B]^2+1\,,\\
&0\le\lambda_1\le 1,\ \lambda_2\ge 1\,. \qquad (12.23)
\end{aligned}$$

By solving the optimization problem in (12.23), we will get the solution $(A, B) = (0.17, 0.36)$ with the expected squared loss 1.089. Although this solution seems a little off from the true optimal solution (0.3, 0.3), it still provides valuable information and can guide the design to move quickly to the region closer to the true optimal solution even in the early stage that only the data from the fractional factorial design is available.

We finally comment on the use of the prior information on the main factor effect and the higher-order interaction effect in the formulation of the robust optimization model in (12.23). This information is usually available based on the qualitative knowledge and reasonable judgment of quality engineers. If this information is not available, that is, the values for λ_1 and λ_2 in (12.23) can take any real numbers, we believe robust optimization will not be able to yield a good solution.

13. Uniform Design and Its Industrial Applications

Uniform design is a kind of space-filling design whose applications in industrial experiments, reliability testing and computer experiments is a novel endeavor. Uniform design is characterized by uniform scattering of the design points over the experimental domain, and hence is particularly suitable for experiments with an unknown underlying model and for experiments in which the entire experimental domain has to be adequately explored. An advantage of uniform design over traditional designs such as factorial design is that, even when the number of factors or the number of levels of the factors are large, the experiment can still be completed in a relatively small number of runs. In this chapter we shall introduce uniform design, the relevant underlying theories, and the methods of constructing uniform designs in the s-dimensional cube and in the $(q-1)$-dimensional simplex for experiments with mixtures. We shall also give application examples of industrial experiments, accelerated stress testing and computer experiments.

Human history shows that performing experiments systemically is a catalyst to speeding up the process of knowledge discovery. Since the 20th century, when design of experiments was first adopted in agriculture, technology has developed more quickly then ever before. In industry, design of experiments now has an important position in product design and process design. In recent decades, a large amount of theoretical work has been done on design of experiments, and many successful examples of industrial applications are available. For a comprehensive review of the different types of designs, readers may refer to *Ghosh* and *Rao* [13.1]. In this chapter, we shall focus on a type of design called the *uniform design*, whose concept was first introduced in 1978 [13.2] and has now gained popularity and proven to be very successful in industrial applications.

A response in an industrial process may depend on a number of contributing factors. A major objective of an industrial experiment is to explore the relationship between the response and the various causes that may be contributing factors, and to find levels for the contributing factors that optimize the response. Examples of responses are the tensile strength of a material produced from different raw ingredients, the mean time to failure of an electrical component manufactured under different settings of the production equipment, or the yield of a product produced from a chemical process under different reaction conditions. To optimize the response, the relationship between the response and the contributing factors has to be established. If it is difficult to derive the theoretical relationship, experiments may be conducted and statistical methods may be used to establish empirical models or metamodels. When the

form of the model is unknown, one may wish to explore the entire design region by choosing a design whose design points are spread uniformly over the region. Such an objective may be achieved by using uniform design, which was formally introduced in *Fang* [13.3] and *Wang* and *Fang* [13.4]. Figure 2 shows some examples of uniform designs constructed in the two-dimensional square. There are many examples of successful applications of uniform designs in science, engineering and industries. A major multinational automobile manufacturer has recently adopted uniform designs as a standard procedure in product design and process design. A review of applications of uniform designs in chemistry and chemical engineering is given in *Liang* et al. [13.5]. An example of application in quality improvement in electronics manufacturing is given in *Chan* and *Huang* [13.6], *Chan* and *Lo* [13.7] and *Li* et al. [13.8]. Investigations have shown that uniform design performs better at estimating nonlinear problems than other designs, and is robust against model assumptions; see *Zhang* et al. [13.9] and *Xu* et al. [13.10].

Uniform design is different from traditional designs (such as orthogonal arrays and Latin square designs) in that it is not defined in terms of combinatorial structure but rather in terms of the spread of the design points over the entire design region. An advantage of uniform designs over traditional designs is that the former can be used for experiments in which the number of factors and the number of levels of the factor are not small, but a large number of runs is not available. In an experiment with 15 factors and 15 levels on each factor, for example, $225 = 15^2$ runs will be required if an orthogonal array is used, but if a uniform design is used it is possible to complete the experiment in 15 runs. In a Taguchi-type parameter design (*Taguchi* [13.11]), the number of runs required is smaller if uniform designs are used instead of orthogonal arrays. For example, if an $L_{36}(2^3 \times 3^{11})$ orthogonal array is used for the inner and outer arrays, a total of 36×36 runs are required, while if $U_{13}(13^8)$ and $U_{12}(12^{10})$ uniform designs are used instead, $13 \times 12 = 156$ runs will be sufficient [13.12]. Sometimes, to limit the number of runs in an experiment, one may choose designs with a small number of levels, say two- or three-level designs. However, when the behavior of the response is unknown, designs with small numbers of levels are generally unsatisfactory. In Fig. 13.1, all of the two-, three-, four- and five-level designs with equally spaced design points in $[-1, 1]$ (including the points ± 1) wrongly indicate that y decreases as x increases in $[-1, 1]$. Only designs with six or more levels with equally spaced designs points will disclose the peak of y.

A uniform design with n runs, q levels on each of the s factors is denoted by $U_n(q^s)$. Similar notation, for example $U_n(q_1^{s_1} \times q_2^{s_2})$, is used for mixed-level designs. Uniform design tables have been constructed and are available from the website www.math.hkbu.edu.hk/UniformDesign for convenient use. Plots of uniform designs constructed for $n = 2, 5, 8, 20$ are shown in Fig. 13.2. Uniform designs, whose designs points are scattered uniformly over the design region, may be constructed by minimizing a discrepancy. Uniform designs can also be used as space-filling designs in numerical integration. In recent years, many theoretical results on uniform designs have been developed. Readers may refer to *Fang* and *Wang* [13.13], *Fang* and *Hickernell* [13.14], *Hickernell* [13.15], *Fang* and *Mukerjee* [13.16], *Xie* and *Fang* [13.17], *Fang* and *Ma* [13.18, 19], *Fang* et al. [13.20], *Fang* [13.21] and *Hickernell* and *Liu* [13.22].

In what follows, we will use "UD" as an abbreviation for " uniform design". This chapter is organized as follows. Section 13.1 gives a general procedure for conducting an industrial experiment, and gives an example of an application of uniform design in a pharmaceutical experiment which has three contributing factors and where each factor has seven levels. No theoretical model is available for the relationship between these contributing factors and the response (the yield of the process). From the results of the experiment conducted according to a uniform design, several empirical models are proposed, and specific levels for the contributing factors are suggested to maximize the yield. Section 13.2 gives an example of the application of uniform design to accelerated stress testing for determining the

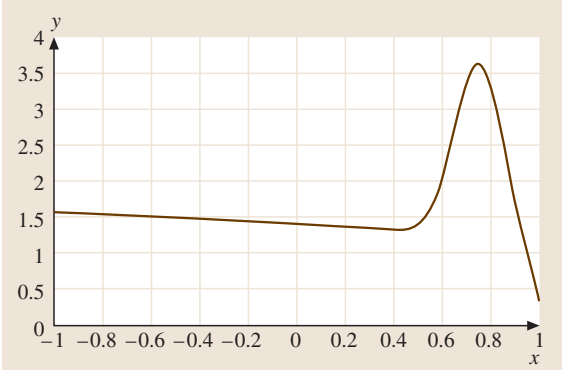

Fig. 13.1 An example of a response curve

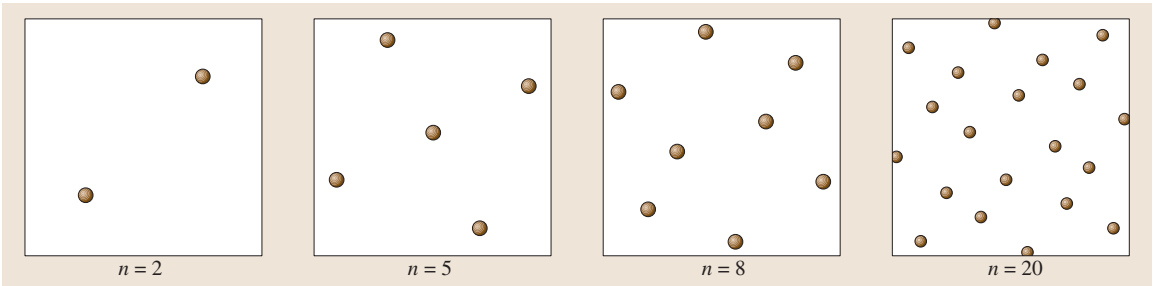

Fig. 13.2 Plots of uniform designs in S^2

median time to failure of an electronics device, with a known theoretical model. The values of the parameters in the theoretical model are determined from the results of accelerated stress testing conducting according to uniform design, and a predicted value for the median time to failure is obtained. Section 13.3 explains when computer experiments can be used for solving practical problems, and illustrates with a simple example on a robot arm how a computer experiment is conducted using uniform design to obtain an approximation of the true theoretical model of the robot arm position. Section 13.4 formally defines uniform design on the s-dimensional cube $[0, 1]^s$ in terms of minimization of the *discrepancy*, and introduces several different discrepancies and their computational formulas. The U-type design, which is used to define a discrete discrepancy, is also introduced. Section 13.5 states that the construction of uniform designs on the s-dimensional cube is an NP-hard problem even when high-power computers are used, and explains how approximate uniform designs can be constructed more easily using U-type designs. Lower bounds for several discrepancies are given, and these lower bounds can be used to indicate how close (in terms of discrepancy) an approximate uniform design is to the theoretical uniform design. Some methods for construction of approximate uniform designs are given. Section 13.6 is devoted to uniform designs for experiments with mixtures in which the contributing factors are proportions of the ingredients in a mixture. It is explained with illustrations how uniform designs can be constructed on the the simplex S^{q-1}, which is the complete design region, and on a subregion of it. Section 13.7 gives the relationships between uniform design and other designs or design criteria, including aberration, orthogonality, supersaturated design, isomorphic design, and equivalent Hadamard matrices. This chapter is concluded briefly in Section 13.8.

13.1 Performing Industrial Experiments with a UD

One purpose of performing industrial experiments is to acquire data to establish quantitative models, if such models cannot be built solely based on theoretical consideration or past experience. Such models can be used to quantify the process, verify a theory or optimize the process. The following steps may be taken as a standard procedure for performing industrial experiments.

1. **Aim.** Specify the aim of the experiment (which may be maximizing the response, defining the operational windows of the contributing and noncontributing factors, etc.), and identify the process response to study.
2. **Factor and domain.** Specify possible contributing factors, and identify the domain of variation of each factor according to experience and practical constraints.
3. **Numbers of levels and runs.** Choose a sufficiently large number of levels for each factor and the total number of runs according to experience, physical consideration and resources available.
4. **Design.** Specify the number of runs and choose a design for the first set of experiment. It is recommended to adopt a UD from the literature or from the website www.math.hkbu.edu.hk/UniformDesign that matches the requirements in Step 3.
5. **Implementation.** Conduct the experiment according to the design chosen in Step 4. Allocate the runs randomly.

6. **Modeling.** Analyze the results using appropriate statistical tools according to the nature of the data. Such tools may include regression methods, ANOVA, Kriging models, neural networks, wavelets, splines, etc. Establish models relating the response to the contributing factors.
7. **Diagnostics.** Make conclusions from the models established in Step 6 to fulfil the aim specified in Step 1.
8. **Further Experiments.** If applicable, perform additional runs of the experiment to verify the results obtained in Steps 6 and 7, or perform subsequent experiments in order to fulfil the aim in Step 1.

The following example illustrates a successful application of UD in an industrial experiment.

Example 13.1: The yield y of an intermediate product in pharmaceutical production depends on the percentages of three materials used: glucose (A), ammonia sulphate (B) and urea (C). The aim of the experiment is to identify the percentages of A, B and C, say x_1, x_2, x_3, which will produce the highest yield. The region for the experiment was defined by the following possible ranges of variation of x_1, x_2, x_3:

$$\text{A: } 8.0 \le x_1 \le 14.0(\%); \quad \text{B: } 2.0 \le x_2 \le 8.0(\%);$$
$$\text{C: } 0.0 \le x_3 \le 0.3(\%). \tag{13.1}$$

It was planned to complete one experiment in not more than eight runs. The levels chosen for the factors are as follows:

x_1: (1)8.0, (2)9.0, (3)10.0, (4)11.0, (5)12.0, (6)13.0, (7)14.0;
x_2: (1)2.0, (2)3.0, (3)4.0, (4)5.0, (5)6.0, (6)7.0, (7)8.0;
x_3: (1)0.00, (2)0.05, (3)0.10, (4)0.15, (5)0.20, (6)0.25, (7)0.30.

Table 13.1 Experiment for the production yield y

No.	$U_7(7^3)$			x_1	x_2	x_3	y
1	1	2	3	8.0	3.0	0.10	7.33
2	2	4	6	9.0	5.0	0.25	5.96
3	3	6	2	10.0	7.0	0.05	6.15
4	4	1	5	11.0	2.0	0.20	9.59
5	5	3	1	12.0	4.0	0.00	8.91
6	6	5	4	13.0	6.0	0.15	6.47
7	7	7	7	14.0	8.0	0.30	4.82

A $U_7(7^3)$ UD was adopted. Table 13.1 shows the $U_7(7^3)$ UD adopted, the layout of the experiment, and the observed response y.

Fitting the data in Table 13.1 with a linear model in x_1, x_2, x_3 gives

$$\hat{y} = 8.1812 + 0.3192x_1 - 0.7780x_2 - 5.1273x_3\,, \tag{13.2}$$

with $R^2 = 0.9444$, $s^2 = 0.3202$, and an F probability of 0.022. The ANOVA is shown in Table 13.2. From (13.2), the maximum value of $\hat{y} = 11.094$ is attained at $x_1 = 14$, $x_2 = 2$ and $x_3 = 0$ within the ranges specified in (13.1).

Fitting the data with a second-degree polynomial by maximizing R^2 gives

$$\hat{y} = 7.0782 + 0.0542x_1^2 - 0.1629x_1x_2 - 0.3914x_1x_3 + 0.1079x_3^2\,, \tag{13.3}$$

with $R^2 = 0.9964$, $s^2 = 0.0309$, and an F probability of 0.007. The ANOVA table is shown in Table 13.3. From (13.3), the maximum value of $\hat{y} = 13.140$ is attained at $(x_1, x_2, x_3) = (14.0, 2.0, 0.0)$, within the ranges specified in (13.1).

On the other hand, fitting the data with a centered second-degree polynomial in the variables $(x_1 - \bar{x}_1)$, $(x_2 - \bar{x}_2)$ and $(x_3 - \bar{x}_3)$ by maximizing R^2 gives

$$\hat{y} = 8.2209 - 0.5652(x_2 - 5) - 4.5966(x_3 - 0.15) - 0.4789(x_1 - 11)^2 + 0.3592(x_1 - 11)(x_2 - 5)\,, \tag{13.4}$$

with $R^2 = 0.9913$, indicating a good fit. The ANOVA table is shown in Table 13.4. From (13.4), the maximum value of $\hat{y} = 11.2212$ is attained at $(x_1, x_2, x_3) = (9.8708, 2.0, 0.0)$, within the ranges specified in (13.1).

The second-degree model (13.2) and the centered second-degree model (13.3) fit the data better than the linear model. The maximum predicted values of $\hat{y}$ given by (13.2–13.4) are between 11.094 and 13.140 when x_1 is between 98.708 and 14, $x_2 = 2$ and $x_3 = 0$ in the design region. These results show that the smaller x_2 and x_3, the larger $\hat{y}$. Zero is the smallest possible value

of x_3, but x_2 may be extended beyond its smallest value of 2, and x_1 can be extended beyond its largest value of 14 from the boundary of the design region. To explore whether any larger values of maximum y can be achieved outside the design region, further investigation can be carried out by fixing x_3 at 0 and performing two factor experiments with x_1 in the range [8, 16] and x_2 in the range [0, 3].

13.2 Application of UD in Accelerated Stress Testing

Accelerated stress testing is an important method in studying the lifetime of systems. As a result of advancement in technology the lifetime of products is increasing, and as new products emerge quickly product cycle is decreasing. Manufacturers need to determine the lifetime of new products quickly and launch them into the market before another new generation of products emerges. In many cases it is not viable to determine the lifetime of products by testing them under normal operating conditions. To estimate their lifetime under normal operating conditions, accelerated stress testing is commonly used, in which products are tested under high-stress physical conditions. The lifetime of the products are extrapolated from the data obtained using some lifetime models. Many different models, such as the Arrhenius model, the inverse-power-rule model, the proportional-hazards model, etc., have been proposed based on physical or statistical considerations. Readers may refer to *Elsayed* [13.23] for an introduction to accelerated stress testing. In this section we shall give an example to illustrate the application of UD to accelerated stress testing.

Example 13.2: The median time to failure t_0 of an electronics device under the normal operating conditions has to be determined under accelerated stress testing. Theoretical consideration shows that, for such a device, a model of the inverse response type should be appropriate. Under such a model, when the device is operating under voltage V (Volts), temperature T (Kelvin) and relative humidity H (%), its median time to failure t is given by

$$t = a\, V^{-b}\, \mathrm{e}^{c/T}\, \mathrm{e}^{-dH}\,,$$

where a, b, c, d are constants to be determined. Under normal operating conditions, the device operates at $V = 1$, $T = 298$, $H = 60$. The ranges for V, T, H determined for this experiment were 2–5, 353–373, and 85–100, respectively. Logarithmic transformation on the above model gives

$$\ln t = \ln a - b \ln V + c/T - dH\,.$$

An experiment with eight runs and four equally spaced levels on each of $\ln V$, $1/T$ and H was planned. These

Table 13.5 The set up and the results of the accelerated stress test

No.	$U_8(4^3)$			$\ln V$	V	$1/T$	T	H	t
1	1	3	2	0.6931	2	0.0027821	359	90	296.5
2	1	1	3	0.6931	2	0.0026809	373	95	304.3
3	4	1	2	1.6094	5	0.0026809	373	90	95.0
4	4	3	3	1.6094	5	0.0027821	359	95	129.6
5	3	4	1	1.3040	3.68	0.0028328	353	85	278.6
6	3	2	4	1.3040	3.68	0.0027315	366	100	186.0
7	2	4	4	0.9985	2.71	0.0028328	353	100	155.4
8	2	2	1	0.9985	2.71	0.0027315	366	85	234.0

levels were as follows.

$\ln V$: (1)0.6931, (2)0.9985, (3)1.3040, (4)1.6094 ;
$1/T$: (1)0.0026809, (2)0.0027315, (3)0.0027821, (4)0.0028328 ;
H: (1)85, (2)90, (3)95, (4)100 .

The corresponding levels of V and T were

V: (1)2, (2)2.71, (3)3.68, (4)5 ;
T: (1)373, (2)366, (3)359, (4)353 .

The test was performed according to a $U_8(3^4)$ UD. The layout of the experiment and the t values observed are shown in Table 13.5.

Table 13.6 ANOVA for an inverse responsive model

Source	SS	df	MS	F	P
Regression	1.14287	3	0.38096	11.70	0.019
Error	0.13024	4	0.03256		
Total	1.27311	7			

Regression analysis gives

$$\hat{\ln t} = 5.492 - 1.0365 \ln V + 1062/T - 0.02104H ,$$

or

$$\hat{t} = 240.327 V^{-1.0365} \, e^{1062/T - 0.02104H} ,$$

with $R^2 = 0.898$ and $s^2 = 0.0325$. The ANOVA table in Table 13.6 shows a significance level of 0.019. The value of t at the normal operating condition $V = 1$, $T = 298$ and $H = 60$ is estimated to be $\hat{t}_0 = 2400.32$ (hours).

13.3 Application of UDs in Computer Experiments

Indeed, UDs were first used by mathematicians as a space-filling design for numerical integration, and application of UDs in experiments was motivated by the need for effective designs in *computer experiments* in the 1970s [13.2].

The computer can play its role as an artificial means for simulating a physical environment so that experiments can be implemented virtually, if such experiments are not performed physically for some reasons. For example, we do not wish to perform an experiment physically if the experiment may cause casualty. It is not practical to perform a hurricane experiment because we cannot generate and control a hurricane, but if a dynamical model can be established the experiment can be performed virtually on the computer. In such a situation, computer experiments, in which computation or simulation is carried out on the computer, may help study the relation between the contributing factors and the outcome. To perform a computer experiment, levels will have to be set for each of the contributing factors, and in order to have a wide coverage of the entire design region with a limited number of runs, a UD is a good recommendation.

Another use of computer experiments is to establish approximations of known theoretical models if such models are too complicated to handle in practice. From the theoretical model, if computation can be carried out using the computer in evaluating the numerical values of the response y at given values of the variants $x_1, \cdots, x_k$, from the numerical results we can establish metamodels that are good approximations to the theoretical model but yet simple enough for practical use. On the other hand, if the theoretical model is so complicated (for example, represented as a large system of partial differential equations) that it is not even practical to solve it using a computer but if it is possible to observe the values of the response y at different values of $x_1, \cdots, x_k$, we can make use of the computer to establish mathematically tractable empirical models to replace the complicated theoretical model.

In computer experiments, UDs can be used for the selection of representative values of $x_1, \cdots, x_k$ that cover the design region uniformly in a limited number of runs. This is illustrated by an example on water flow in *Fang* and *Lin* [13.24]. Another example of the application of UDs in computer experiments is for real-time control of robotic systems in which the kinematics is described by a system of complicated equations containing various angles, lengths and speeds of movement. Control of robotic systems requires the solution of such a system of equations on a real-time basis at a sufficiently fast speed, which sometimes cannot be achieved because of the intensive computation required (which may involve inversion of high-order Jacobian determinants, etc.). For such a case, computer experiments may be employed, in which the system of equations is solved off-line and the results obtained are used to establish statistical models that are mathematically simple enough to be used for real-time computation. To achieve a sufficiently uniform coverage of the design region, UDs can be used. The fol-

lowing Example 3 is a simplified version of a robot arm in two dimensions which illustrates this application.

Example 13.3: A robot arm on the uv-plane consists of s segments. One end of the first segment is connected to the origin by a rotational join, and the other end of the first segment is connected to one end of the second segment by a rotational join. The other end of the second segment is connected to one end of the third segment a by rotational join, and so on. Let L_j represent the length of the j^{th} segment, θ_1 represent the angle of the first segment with the u-axis, θ_j represent the angle between the $(j-1)^{\text{th}}$ and j^{th} segment, where $0 \le \theta_j \le 2\pi (j = 1, \cdots, s)$. The length between the origin and the end point of the last segment of the robot arm is given by

$$y = f(L_1, \cdots, L_s, \theta_1, \cdots, \theta_s) = \sqrt{u^2 + v^2}\,,$$

$$u = \sum_{j=1}^{s} L_j \cos\Big(\sum_{i=1}^{j} \theta_i\Big)\,,$$

$$v = \sum_{j=1}^{s} L_j \sin\Big(\sum_{i=1}^{j} \theta_i\Big)\,.$$

For simplicity, suppose that $s = 2$. We intend to represent y as a generalized linear function in the variables $L_1, L_2, \theta_1, \theta_2$. A computer experiment is performed with a $U_{28}(28^6)$ UD, in which the values of y were evaluated at different values of L_i and θ_i. The results of the computation is shown in the rightmost column of Table 13.7.

Fitting the data in Table 13.7 with a centered generalized linear regression model with variables $(L_i - 0.5)$, $(\theta_i - \pi)$ and $\cos(\theta_i - \pi)$ $(i = 1, 2, 3)$ using

a stepwise procedure in the package SAS gives the model

$$\begin{aligned}\hat{y} = {} & 0.9088 + 0.1760(L_1 - 0.5) + 0.6681(L_2 - 0.5) \\ & + 0.3917(L_3 - 0.5) - 0.2197\cos(\theta_2 - \pi) \\ & - 0.3296\cos(\theta_3 - \pi) \\ & - 0.01919(\theta_1 - \pi)(\theta_2 - \pi) \\ & - 0.5258(L_2 - 0.5)\cos(\theta_3 - \pi) \\ & - 0.0792 L_3 \theta_1 - 0.7622(L_3 - 0.5)\cos(\theta_3 - \pi) \\ & - 0.0114(\theta_1 - \pi)(\theta_3 - \pi) \\ & - 0.0274(\theta_2 - \pi)(\theta_3 - \pi) \\ & + 0.2894\cos(\theta_2 - \pi)\cos(\theta_3 - \pi)\,,\end{aligned}$$

with $R^2 = 0.9868$, $s^2 = 0.0063$, and an F of 0.0000. The ANOVA table is omitted here. Evaluation at different values of L_i and θ_i shows that $\hat{y}$ is a good approximation of y.

13.4 Uniform Designs and Discrepancies

In this section, the formal definition of a UD will be introduced. A UD is, intuitively, a design whose points distribute *uniformly* over the design space. Such uniformity may be achieved by minimizing a discrepancy. There is more than one definition of discrepancy, and different discrepancies may produce different uniform designs.

Without loss of generality, let the design space be the s-dimensional unit cube $C^s = [0, 1]^s$. We represent any point in C^s by $\boldsymbol{x}' = (x_1, \cdots, x_s)$, where $x_1, \cdots, x_s \in [0, 1]$, and the prime denotes the transpose of matrices. For a given positive integer n, a uniform design with n points is a collection of points $\mathcal{P}^* = \{\boldsymbol{x}_1^*, \cdots, \boldsymbol{x}_n^*\} \subset C^s$ such that

$$M(\mathcal{P}^*) = \min M(\mathcal{P})\,,$$

where the minimization is carried out over all $\mathcal{P} = \{\boldsymbol{x}_1, \cdots, \boldsymbol{x}_n\} \subset C^s$ with respect to some measure of uniformity, M. One choice for M is the classical L_p-discrepancy adopted in quasi-Monte-Carlo methods [13.25, 26],

$$D_p(\mathcal{P}) = \left(\int_{C^s} \left| \frac{N(\mathcal{P}, [\boldsymbol{0}, \boldsymbol{x}])}{n} - \mathrm{Vol}\,[\boldsymbol{0}, \boldsymbol{x}] \right|^p \mathrm{d}\boldsymbol{x} \right)^{1/p},$$

where $[\boldsymbol{0}, \boldsymbol{x}]$ denotes the interval $[0, x_1] \times \cdots \times [0, x_s]$, $N(\mathcal{P}, [\boldsymbol{0}, \boldsymbol{x}])$ denotes the number of points of $\mathcal{P}$ falling in $[\boldsymbol{0}, \boldsymbol{x}]$, and $\mathrm{Vol}\,[\boldsymbol{0}, \boldsymbol{x}]$ is the volume of the set $[\boldsymbol{0}, \boldsymbol{x}] \in C^s$, which is the distribution function of the uniform distribution on C^s.

The $D_\infty(\mathcal{P})$ discrepancy

$$\max_{\boldsymbol{x} \in C^s} \left| \frac{N(\mathcal{P}, [\boldsymbol{0}, \boldsymbol{x}])}{n} - \mathrm{Vol}\,[\boldsymbol{0}, \boldsymbol{x}] \right|$$

is called the star discrepancy, which is the Kolmogorov–Smirnov statistic used for the goodness-of-fit test.

The L_p-discrepancy is a measure of uniformity of the distribution of points of $\mathcal{P}$ in C^s. The smaller the value of $D_p(\mathcal{P})$, the more uniform the distribution of points of $\mathcal{P}$. The star discrepancy is not as sensitive as the L_p-discrepancy for finite values of p.

The quantity $D_p(\mathcal{P})$ is in general difficult to compute. Let $\boldsymbol{x}_k = (x_{k1}, \cdots, x_{ks})'$ $(k = 1, \cdots, n)$. For $p = 2$, computation can be carried out more efficiently using the following closed-form analytic formula [13.27]:

$$\begin{aligned} D_2(\mathcal{P})^2 = {} & 3^{-s} - \frac{2^{1-s}}{n} \sum_{k=1}^{n} \prod_{l=1}^{s} (1 - x_{kl}^2) \\ & + \frac{1}{x^2} \sum_{k=1}^{n} \sum_{j=1}^{n} \prod_{i=1}^{s} [1 - \max(x_{ki}, x_{ji})]\,. \end{aligned}$$

As pointed out by *Fang* et al. [13.20], the L_2-discrepancy ignores the discrepancy of $\mathcal{P}$ on lower-dimensional subspaces of C^s. To overcome this drawback, *Hickernell* [13.28] proposed the following modified L_2-discrepancy, which includes L_2-discrepancies of projections of $\mathcal{P}$ in all lower dimensional subspaces of C^s

$$\begin{aligned} & D_{2,\,\mathrm{modified}}(\mathcal{P})^2 \\ & = \sum_u \int_{C^u} \left| \frac{N(\mathcal{P}_u, J_{\boldsymbol{x}_u})}{n} - \mathrm{Vol}(J_{\boldsymbol{x}_u}) \right|^p \mathrm{d}\boldsymbol{x}_u\,, \end{aligned} \qquad (13.5)$$

where u is a non-empty subset of the set of coordinate indices $S = \{1, \cdots, s\}$, C^u is the $|u|$-dimensional cube involving the coordinates in u, $|u|$ is the cardinality of u, $\mathcal{P}_u$ is the projection of $\mathcal{P}$ on C^u, $\boldsymbol{x}_u$ is the projection of $\boldsymbol{x}$ on C^u, and $J_{\boldsymbol{x}_u}$ is the projection of a rectangle $J_{\boldsymbol{x}}$ on C^u, which depends on $\boldsymbol{x}$ and is defined based on some specific geometric consideration. Different choices of $J_{\boldsymbol{x}}$ produce discrepancies with different properties, the centered L_2-discrepancy (CD)

(which contains all L_2-discrepancies each calculated using one of the 2^s vertices of C^s as the origin), the wrap-around L_2-discrepancy (WD) (which is calculated after wrapping around each one-dimensional subspace of C^s into a close loop), and others. Closed-form analytic formulas for CD and WD, the most commonly used discrepancies, are displayed below, and corresponding formulas for other discrepancies can be found in *Fang* et al. [13.20] and *Hickernell* [13.28, 29]

$$[\mathrm{CD}(\mathcal{P})]^2 = \left(\frac{13}{12}\right)^s - \frac{2}{n}\sum_{k=1}^{n}\prod_{j=1}^{s}\left(1+\frac{1}{2}|x_{kj}-0.5| - \frac{1}{2}|x_{kj}-0.5|^2\right) + \frac{1}{n^s}\sum_{k=1}^{n}\sum_{j=1}^{n}\prod_{i=1}^{s}\left(1+\frac{1}{2}|x_{ki}-0.5| + \frac{1}{2}|x_{ji}-0.5| - \frac{1}{2}|x_{ki}-x_{ji}|\right), \quad (13.6)$$

$$[\mathrm{WD}(\mathcal{P})]^2 = \left(\frac{4}{3}\right)^s + \frac{1}{n^2}\sum_{k=1}^{n}\sum_{j=1}^{n}\prod_{i=1}^{s}\left[\frac{3}{2} - |x_{ki}-x_{ji}| \times (1-|x_{ki}-x_{ji}|)\right]. \quad (13.7)$$

The CD is invariant under relabeling of coordinate axes. It is also invariant under reflection of points about any plane passing through the center and parallel to the faces of the unit cube C^s, that is, invariant when the i^{th} coordinate x_i is replaced by $1-x_i$. It follows from the definition that the CD takes into account the uniformity of $\mathcal{P}$ over C^s and also over all projections of $\mathcal{P}$ onto all subspaces of C^s. The uniform designs given in the website www.math.hkbu.edu.hk/UniformDesign are constructed using the CD [13.30].

Another useful discrepancy is called the *discrete discrepancy*, or *categorical discrepancy*. It is defined on the discrete space based on the following U-type designs, and can be used as a vehicle for construction of UDs via U-type designs.

Table 13.8 A design in $\mathcal{U}(6; 3^2\times 2)$

No.	1	2	3
1	1	1	1
2	2	1	2
3	3	2	1
4	1	2	2
5	2	3	1
6	3	3	2

Definition 13.1

A U-type design is an array of n rows and s columns with entries $1, \cdots, q_j$ in the j-th column such that each entry in each column appears the same number of times ($j = 1, \cdots, s$). The collection of all such designs is denoted by $\mathcal{U}(n; q_1\times\cdots\times q_s)$, which is the design space. When all q_j are the same, the design space will be denoted by $\mathcal{U}(n; q^s)$. Designs in $\mathcal{U}(n; q_1\times\cdots\times q_s)$ (where the q_j are distinct) are asymmetric, while designs in $\mathcal{U}(n; q^s)$ are symmetric.

Table 13.8 shows a U-type design in $\mathcal{U}(6; 3^2\times 2)$. Obviously, in a U-type design in $\mathcal{U}(n; q_1\times\cdots\times q_s)$,$n$ must be an integer multiple of q_j for all $j = 1, \cdots, s$.

A discrete discrepancy is defined on $\mathcal{U}(n; q_1\times\cdots\times q_s)$ in terms of two positive numbers $a \neq b$, and is denoted by $D^2(U; a, b)$. The computational formula for $D^2(U; a, b)$ is

$$D^2(U; a, b) = -\prod_{j=1}^{s}\left(\frac{a+(q_j-1)b}{q_j}\right) + \frac{1}{n^2}\sum_{k=1}^{n}\sum_{l=1}^{n}\prod_{j=1}^{s}\widetilde{K}(u_{kj}, u_{lj}), \quad (13.8)$$

where $(u_{k1}, \cdots, u_{ks})$ represents the k-th point in U and

$$\widetilde{K}(u_{kj}, u_{lj}) = \begin{cases} a & \text{if } u_{kj} = u_{lj}, \\ b & \text{if } u_{kj} \neq u_{lj}. \end{cases}$$

13.5 Construction of Uniform Designs in the Cube

In order to construct a uniform design on the continuum $C^s = [0, 1]^s$, we need to search for all possible sets of n points over C^s for a design with minimum discrepancy, which is an NP-hard problem for high-power computers even if n and s are not large. In general, the coordinates of the points in a UD in C^s may be irrational. It can be proved that when $s = 1$, the set $\left\{\frac{1}{2n}, \frac{3}{2n}, \cdots, \frac{2n-1}{2n}\right\}$ with equally spaced points is the n-point uniform design on [0, 1] with CD $= 1/(\sqrt{12}n)$, which is the smallest possible value [13.30]). Since the

design points of a UD distribute *uniformly* over the design region, from the last result on [0, 1] it is natural to expect that values of the coordinates of points in a UD in C^s are either equally spaced or nearly equally spaced on each one-dimensional subspace of C^s. Along this line of thought, while uniform designs defined for the continuum C^s are difficult to find, we can search over the discrete set of U-type designs to construct approximate uniform designs. Computation shows that this approach produces good results. The closeness between the UDs with exactly the minimum discrepancy constructed for C^2 and the approximate UDs constructed from U-type designs for $n = 2, \cdots, 9$ is illustrated in Fig. 13.3 of *Fang* and *Lin* [13.24], and for larger values of n these two types of UDs are practically identical.

Tables of UDs in the website www.math.hkbu.edu.hk/UniformDesign are constructed from U-type designs. Figure 13.2 shows the plots of such designs constructed for $n = 2, 5, 8, 20$ for $s = 2$. An obvious advantage of using U-type designs for construction is that in the UD constructed values of each coordinate of the design are equally spaced. Such designs are much more convenient to use in practice than the exact UDs with irregular values of coordinates constructed for the continuum C^s.

If P is a design consisting of n points $\boldsymbol{x}_1 = (x_{11}, \cdots, x_{1s})', \cdots, \boldsymbol{x}_n = (x_{n1}, \cdots, x_{ns})'$, we shall use the following notations, on different occasions as appropriate, to represent P: $P = \{\boldsymbol{x}_1, \cdots, \boldsymbol{x}_n\}$, $P = \{x_{ij}\}_{i=1,\cdots,n;\ j=1,\cdots,s}$, $P = \{x_{ij}\}$, $P = \begin{pmatrix} x_{11} & \cdots & x_{1s} \\ \vdots & \ddots & \vdots \\ x_{n1} & \cdots & x_{ns} \end{pmatrix}$, $P = \begin{pmatrix} \boldsymbol{x}_1 \\ \vdots \\ \boldsymbol{x}_n \end{pmatrix}$.

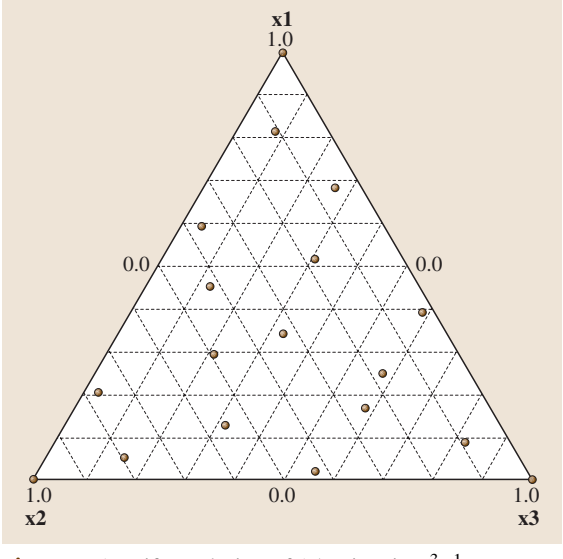

Fig. 13.3 A uniform design of 15 points in S^{3-1}

In the following Definition 13.2, we shall introduce uniform design defined on the discrete set $\mathcal{U}(n; q^s)$.

Definition 13.2

A design $U \in \mathcal{U}(n; q_1 \times \cdots \times q_s)$ is called a uniform design under the measure of discrepancy M if

$$M(U) = \min_{V \in \mathcal{U}(n; q_1 \times \cdots \times q_s)} M(V) .$$

The collection of all such designs is denoted by $U_n(q_1 \times \cdots \times q_s)$. When $q_1 = \cdots = q_s$, U will be called a symmetric design, and $U_n(q_1 \times \cdots \times q_s)$ will be denoted by $U_n(q^s)$.

If $U \in \mathcal{U}(n; q_1 \times \cdots \times q_s)$ is a U-type design consisting of the n points $\boldsymbol{u}_1, \cdots, \boldsymbol{u}_n$, where $\boldsymbol{u}_i = (u_{i1}, \cdots, u_{is})'$ $(i = 1, \cdots, n)$, we define $x_{ij} = (u_{ij} - 0.5)/q_j$, so that $\mathcal{P} = \{x_1, \cdots, x_n\} \in C^s$. If M is a discrepancy on C^s, we define $M(U) = M(\mathcal{P})$. Finding UDs in $U_n(q_1 \times \cdots \times q_s)$ by minimizing discrepancies is still an NP-hard problem because of the amount of computation required, even though it is a more manageable task than finding UDs in the continuum C^s. To get around this difficulty, a variety of methods have been proposed by different authors.

For a given discrepancy, and given n and s, it can be seen from the definition that the discrepancy of all designs of n points has a positive lower bound. Thus, lower bounds of discrepancies are used as a benchmark in the construction of UDs or approximate UDs. A UD is a design whose discrepancy equals the lower bound, and a design whose discrepancy is close to the lower bound is a good design.

13.5.1 Lower Bounds of Categorical, Centered and Wrap-Around Discrepancies

(A) Lower Bounds of the Categorical Discrepancy

Let $c(kl)$ be the coincidence number of a pair of elements between rows k and l of a design. Clearly $c(kk) = s$,

and $s-c(kl)$ is the Hamming distance between rows k and l.

Theorem 13.1
A lower bound of the categorical discrepancy in $\mathcal{U}(n; q_1 \times \cdots \times q_s)$ is given by

$$-\prod_{j=1}^{s}\left(\frac{a+(q_j-1)b}{q_j}\right)+\frac{a^s}{n}+\frac{n-1}{n}b^s\left(\frac{a}{b}\right)^{\psi}, \tag{13.9}$$

where $\psi=(\sum_{j=1}^{s} n/q_j - s)/(n-1)$. This lower bound is attained if and only if ψ is an integer and all $c(kl)$ are equal to ψ. When the design space is $\mathcal{U}(n; q^s)$ the above lower bound becomes

$$-\left(\frac{a+(q-1)b}{q}\right)^{s}+\frac{a^s}{n}+\frac{n-1}{n}b^s\left(\frac{a}{b}\right)^{\psi}, \tag{13.10}$$

where $\psi = s(n/q-1)/(n-1)$.

The above lower bonds can be used in searching for UDs in $\mathcal{U}(n; q_1 \times \cdots \times q_s)$.

It is known that block designs have a very good balance structure. Balanced incomplete block (BIB) designs have appeared in many textbooks. *Liu* and *Fang* [13.31] and *Lu* and *Sun* [13.32] found that there is a link between UDs and resolvable BIB designs, a subclass of BIB. Through this link, many UDs can be generated from the large amount of resolvable BIB designs available in the literature. Reader may refer to *Fang* et al. [13.33], *Fang* et al. [13.34] and *Qin* [13.35] for the details.

(B) Lower Bounds of the Wrap-Around L_2-Discrepancy

Values of the wrap-around discrepancy of a designs in $\mathcal{U}(n; q^s)$ can be calculated by (13.7). Let $\alpha_{ij}^k \equiv |x_{ik}-x_{jk}|(1-|x_{ik}-x_{jk}|)$ $(i, j = 1, \cdots, n, i \neq j$ and $k = 1, \cdots, s)$. For any two rows of a design denote the distribution of values of α_{ij}^k by F_{ij}^{α}. *Fang* et al. [13.36] obtained lower bounds for $q = 2, 3$. Recently, *Fang* et al. [13.37] gave lower bounds of the wrap-around discrepancy for any number of levels q as follows:

Theorem 13.2
Lower bounds of the wrap-around L_2-discrepancy on $\mathcal{U}(n; q^s)$ for even and odd q are given by

$$\mathrm{LB}_{\mathrm{even}} = \Delta + \frac{n-1}{n}\left(\frac{3}{2}\right)^{\frac{s(n-q)}{q(n-1)}}\left(\frac{5}{4}\right)^{\frac{sn}{q(n-1)}} \times\left(\frac{3}{2}-\frac{2(2q-2)}{4q^2}\right)^{\frac{2sn}{q(n-1)}}\cdots \times\left(\frac{3}{2}-\frac{(q-2)(q+2)}{4q^2}\right)^{\frac{2sn}{q(n-1)}},$$

$$\mathrm{LB}_{\mathrm{odd}} = \Delta + \frac{n-1}{n}\left(\frac{3}{2}\right)^{\frac{s(n-q)}{q(n-1)}} \times\left(\frac{3}{2}-\frac{2(2q-2)}{4q^2}\right)^{\frac{2sn}{q(n-1)}}\cdots \times\left(\frac{3}{2}-\frac{(q-1)(q+1)}{4q^2}\right)^{\frac{2sn}{q(n-1)}},$$

respectively, where $\Delta = -\left(\frac{4}{3}\right)^s + \frac{1}{n}\left(\frac{3}{2}\right)^s$. A U-type design in $\mathcal{U}(n; q^s)$ is a uniform design under the wrap-around L_2-discrepancy if all its F_{ij}^{α} distributions, for $i \neq j$, are the same. In this case, the WD_2 value of this design achieves the above lower bound.

Fang et al. [13.37] also proposed a powerful algorithm based on Theorem 13.2 and obtained many new UDs.

(C) Lower Bounds of the Centered L_2-Discrepancy

A tight lower bound for the centered L_2-discrepancy is rather difficult to find. *Fang* and *Mukerjee* [13.16] gave a lower bound for the centered L_2-discrepancy on $\mathcal{U}(n; 2^s)$. *Fang* et al. [13.36] gave some improvement of Fang and Mukerjee's results. Recently, *Fang* et al. [13.38] provided a tight lower bound for the centered L_2-discrepancy for $q = 3, 4$. They also proposed an efficient algorithm for searching for UDs.

13.5.2 Some Methods for Construction

The design space $\mathcal{U}(n; q^s)$ contains many poor designs with large values of discrepancy. Confining our search to subspaces in $\mathcal{U}(n; q^s)$ with good designs will significantly reduce the amount of computation. Methods developed along this direction are the *good lattice point method* (see Sect. 1.3 of *Fang* and *Wang* [13.13]), the *Latin square method* and the *extending orthogonal design method* (see *Fang* and *Hickernell* [13.14]). *Ma* and *Fang* [13.39] proposed the *cutting method* that con-

structs a subdesign from a large uniform design. *Fang* and *Qin* [13.40] suggested merging two uniform designs to generate a larger design. Let $U = \{u_{ij}\}$ be a U-type design in $\mathcal{U}(n; q_1 \times \cdots \times q_s)$ and $V = \{v_{kl}\}$ be one in $\mathcal{U}(m; m^t)$. We can construct a new U-type design $D_{U,V}$ by collapsing U and V as follows:

$$D_{U,V} = (\mathbf{1}_m \otimes U \vdots V \otimes \mathbf{1}_n) ,$$

where $\mathbf{1}_n$ is the column vector of ones and $A \otimes B$ is the Kronecker product of $A = (a_{ij})$ and $B = (b_{kl})$ defining by $A \otimes B = (a_{ij} B)$. For example, if

$$A = \begin{pmatrix} 1 & 2 & 4 \\ 2 & 1 & 3 \\ 3 & 4 & 2 \\ 4 & 3 & 1 \end{pmatrix} , \quad \text{and} \quad B = \begin{pmatrix} 1 & 2 \\ 2 & 1 \end{pmatrix} ,$$

then

$$A \otimes B = \begin{pmatrix} 1 & 2 & 2 & 4 & 4 & 8 \\ 2 & 1 & 4 & 2 & 8 & 4 \\ 2 & 4 & 1 & 2 & 3 & 6 \\ 4 & 2 & 2 & 1 & 6 & 3 \\ 3 & 6 & 4 & 8 & 2 & 4 \\ 6 & 3 & 8 & 4 & 4 & 2 \\ 4 & 8 & 3 & 6 & 1 & 2 \\ 8 & 4 & 6 & 3 & 2 & 1 \end{pmatrix} .$$

If both U and V are uniform designs, *Fang* and *Qin* [13.40] proved that the new design $D_{U,V}$ has the lowest discrepancy in a subclass of $\mathcal{U}(nm; q_1, \times \cdots \times q_s \times m^t)$.

13.6 Construction of UDs for Experiments with Mixtures

Experiments with mixtures are experiments in which the variants are proportions of ingredients in a mixture. An example is an experiment for determining the proportion of ingredients in a polymer mixture that will produce plastics products with the highest tensile strength. Similar experiments are very commonly encountered in industries. A mixture can be represented as $\boldsymbol{x} = (x_1, \cdots, x_q)' \in \{(x_1, \cdots, x_q)' : x_1 + \cdots + x_q = 1; x_1, \cdots, x_q \geq 0\} = S^{q-1}$, where $q \geq 2$ is the number of ingredients in the mixture. The set S^{q-1} is called the $(q-1)$-dimensional simplex. Readers may refer to the monograph by *Cornell* [13.41] and the survey article by *Chan* [13.42] for details of design and modeling in experiments with mixtures. Among the designs for experiments with mixtures, simplex lattice designs have the longest history, followed by simplex centroid designs and axial designs. UDs on S^{q-1}, however, provide a more uniform coverage of the design region than these designs. In this section, we shall explain how UDs on S^{q-1} can be constructed using UDs constructed for C^s.

Suppose that $U = (u_{ki})_{k=1,\cdots,n;i=1,\cdots,q-1}$ is a $U_n(n^{q-1})$ selected from the website. Let $c_{ki} = (u_{ki} - 0.5)/n$ $(k = 1, \cdots, n;\ i = 1, \cdots, q-1)$, and let $\boldsymbol{c}'_k = (c_{k1}, \cdots, c_{k,q-1})$. Then

$$C = \begin{pmatrix} \boldsymbol{c}'_1 \\ \boldsymbol{c}'_2 \\ \vdots \\ \boldsymbol{c}'_n \end{pmatrix}$$

is a UD on $[0, 1]^{q-1}$ from which a UD on S^{q-1} can be constructed. In the construction, special consideration is required because $(x_1, \cdots, x_q)'$ in S^{q-1} is under the constant-sum constraint $x_1 + \cdots + x_q = 1$.

(A) When the Design Region is S^{q-1}

When the design region is the entire simplex S^{q-1}, the variables $x_1, \cdots, x_q$ can take any value in $[0, 1]$ as far as $x_1 + \cdots + x_q = 1$. The following method of constructing UD on S^{q-1} is due to *Wang* and *Fang* [13.43,44] which is also contained in *Fang* and *Wang* [13.13]. For each $\boldsymbol{c}'_k (k = 1, \cdots, n)$ in the above uniform design C, let

$$\begin{aligned} x_{k1} &= 1 - c_{k1}^{1/(q-1)} , \\ x_{k2} &= (1 - c_{k2}^{1/(q-2)}) c_{k1}^{1/(q-1)} , \\ x_{k3} &= (1 - c_{k3}^{1/(q-3)}) c_{k1}^{1/(q-1)} c_{k2}^{1/(q-2)} , \\ &\vdots \\ x_{k,q-1} &= (1 - c_{k,s-1}^{1/1}) c_{k1}^{1/(q-1)} c_{k2}^{1/(q-2)} \cdots c_{k,q-2}^{1/2} , \\ x_{kq} &= c_{k1}^{1/(q-1)} c_{k2}^{1/(q-2)} \cdots c_{k,q-2}^{1/2} c_{k,q-1}^{1/1} . \end{aligned}$$

Let $\boldsymbol{x}'_k = (x_{k1}, \cdots, x_{k,q})$ $(k = 1, \cdots, n)$. Then $\begin{pmatrix} \boldsymbol{x}'_1 \\ \boldsymbol{x}'_2 \\ \vdots \\ \boldsymbol{x}'_n \end{pmatrix}$ is a UD on S^{q-1}. This method of construction is based on the following theory of transformation.

Let $\boldsymbol{x} = (X_1, \cdots, X_s)$ be uniformly distributed on S^{s-1}. Let

$$X_i = C_i^2 \prod_{j=1}^{i-1} S_j^2 (i = 1, \cdots, s-1),$$
$$X_s = \prod_{j=1}^{s-1} S_j^2$$

where

$$S_j = \sin\left(\pi\phi_j/2\right),$$
$$C_j = \cos\left(\pi\phi_j/2\right)$$
$$(j = 1, \cdots, s-1),$$
$$(\phi_1, \cdots, \phi_{s-1}) \in C^{s-1}.$$

Then, we have

(a) $\phi_1, \cdots, \phi_{s-1}$ are mutually independent;
(b) the cumulative distribution function of ϕ_j is

$$F_j(\phi) = \sin^{2(s-j)}(\pi\phi/2),$$
$$(j = 1, \cdots, s-1).$$

With the inverse transformation, the above formulas for $x_{k1}, \cdots, x_{ks}$ follow.

When $q = 3$, this construction is expressed as

$$x_{k1} = 1 - c_{k1}^{1/2},$$
$$x_{k2} = (1 - c_{k2}) c_{k1}^{1/2},$$
$$x_{k3} = c_{k1}^{1/2} c_{k2},$$

and under this transformation a rectangle in S^2 is transformed into a trapezium in S^{3-1}. Figure 13.3 shows a plot of a UD of 15 points on S^{3-1} constructed from the $U_{15}(15^2)$ design

$$\begin{pmatrix} 10 & 15 & 14 & 9 & 6 & 2 & 12 & 13 & 11 & 5 & 1 & 8 & 3 & 4 & 7 \\ 1 & 9 & 3 & 12 & 15 & 13 & 6 & 14 & 17 & 4 & 7 & 5 & 2 & 10 & 8 \end{pmatrix}^{\top}.$$

(B) When There are Restrictions on the Mixture Components

In many cases, lower and upper bounds are imposed on the components in a mixture. For example, in a concrete mixture, the amount of water cannot be less than 10% nor more than 90%. Let $a_i, b_i \in [0, 1]$ $(i = 1, \cdots, q)$, $\boldsymbol{a} = (a_1, \cdots, a_q)'$, $\boldsymbol{b} = (b_1, \cdots, b_q)'$, and let $a = a_1 + \cdots + a_q$ and $b = b_1 + \cdots + b_q$. Define $S_{\boldsymbol{a},\boldsymbol{b}}^{q-1} = \{\boldsymbol{x}' = (x_1, \cdots, x_q) \in S^{q-1} : a_i \le x_i \le b_i (i = 1, \cdots, q)\}$. From $x_1 + \cdots + x_q = 1$ it is not difficult to see that $S_{\boldsymbol{a},\boldsymbol{b}}^{q-1}$ is non-empty if and only if $a \le 1 \le b$, and $S_{\boldsymbol{a},\boldsymbol{b}}^{q-1}$ contains more than one point if and only if $a < 1 < b$. *Fang* and *Yang* [13.45] proposed a method for construction of n-point UDs on $S_{\boldsymbol{a},\boldsymbol{b}}^{q-1}$ using a conditional distribution and the Monte Carlo method. It is more complicated than the method due to *Wang* and *Fang* [13.44], but produces designs with better uniformity. To use this method, the following steps may be followed.

1. Check whether the condition $a < 1 < b$ is satisfied. If this condition is not satisfied, the set $S_{\boldsymbol{a},\boldsymbol{b}}^{q-1}$ is either empty or contains only one point, and in both cases there is no need to construct UDs on $S_{\boldsymbol{a},\boldsymbol{b}}^{q-1}$.
2. Suppose that $a < 1 < b$. Some of the restrictions $a_1 \le x_i \le b_i$ $(i = 1, \cdots, q)$ may be redundant. To remove redundant restrictions, define

$$a_i^0 = \max(a_i, b_i + 1 - b),$$
$$b_i^0 = \min(b_i, a_i + 1 - a)(i = 1, \cdots, q).$$

   The restrictions $a_1^0 \le x_i \le b_i^0$ $(i = 1, \cdots, q)$ do not contains redundant ones, and $a_1 \le x_i \le b_i$ is equivalent to $a_1^0 \le x_i \le b_i^0$ $(i = 1, \cdots, q)$.
3. Reduce the lower bounds to 0 by defining $y_i = \left(x_i - a_i^0\right)/\left[1 - \left(a_1^0 + \cdots + a_q^0\right)\right]$ and $b_i^* = \left(b_i^0 - a_i^0\right)/\left[1 - \left(a_1^0 + \cdots + a_q^0\right)\right](i = 1, \cdots, q)$. Then $a_i^0 \le x_i \le b_i^0$ is equivalent to $0 \le y_i \le b_i^*$ $(i = 1, \cdots, q)$.
4. Define the function $G(c, d, \phi, \Delta, \ell) = \Delta\left(1 - \left[c(1-\phi)^\ell + (1-c)(1-d)^\ell\right]^{1/\ell}\right)$, and follow the steps below to make use the uniform design C on $[0, 1]^{q-1}$ selected above to construct a UD design on the set $S_{\boldsymbol{0},\boldsymbol{b}^*}^{q-1} = \{(y_1, \cdots, y_q)' : 0 \le y_i \le b_i^* (i = 1, \cdots, q)\}$, where $\boldsymbol{b}^* = (b_1^*, \cdots, b_q^*)$. Recall that $\boldsymbol{c}_k' = (c_{k1}, \cdots, c_{k,q-1})$ $(k = 1, \cdots, q-1)$.

Step 1. Let $\Delta_q = 1$,
$d_q = \max\left[0, 1 - (b_1^* + \cdots b_{q-1}^*)/\Delta_q\right]$
$\phi_q = \min\left(1, b_q^*/\Delta_q\right)$.
Let $y_q = G(c_{1,1}, d_q, \phi_q, \Delta_q, q-1)$.

Step 2. Let $\Delta_{q-1} = \Delta_q - y_q$
$d_{q-1} = \max\left[0, 1 - (b_1^* + \cdots b_{q-2}^*)/\Delta_{q-1}\right]$
$\phi_{q-1} = \min\left(1, b_{q-1}^*/\Delta_{q-1}\right)$.
Let $y_{q-1} = G(c_{1,2}, d_{q-1}, \phi_{q-1}, \Delta_{q-1}, q-2)$.
⋮

Step (q−2). Let $\Delta_3 = \Delta_4 - y_4$,
$d_3 = \max\left[0, 1 - \left(b_1^* + b_2^*\right)/\Delta_3\right]$,
$\phi_3 = \min\left(1, b_3^*/\Delta_3\right)$.
Let $y_3 = G(c_{1,q-2}, d_3, \phi_3, \Delta_4, 2)$.

Table 13.9 Construction of UD in $S^{3-1}_{\mathbf{a},\mathbf{b}}$

$\boldsymbol{c}'_1 = (0.625, 0.125)$

(1)°	$\Delta_3 = 1$	$d_3 = 0$	$\phi_3 = 1$	$c_{1,1} = 0.062500$	$y_3 = 0.387628$
(2)°	$\Delta_2 = 0.612372$	$d_2 = 0$	$\phi_2 = 0.816497$	$c_{1,2} = 0.125$	$y_2 = 0.0625$
(3)°	nil	nil	nil	nil	$y_1 = 0.549872$

$(x_1, x_2, x_3) = (0.432577, 0.137500, 0.429923)$.

$\boldsymbol{c}'_2 = (0.125, 0.375)$

(1)°	$\Delta_3 = 1$	$d_3 = 0$	$\phi_3 = 1$	$c_{2,1} = 0.125$	$y_3 = 0.064586$
(2)°	$\Delta_2 = 0.935414$	$d_2 = 0.109129$	$\phi_2 = 0.534522$	$c_{2,2} = 0.375$	$y_2 = 0.25130$
(3)°	nil	nil	nil	nil	$y_1 = 0.684113$

$(x_1, x_2, x_3) = (0.238751, 0.250781, 0.510468)$.

$\boldsymbol{c}'_3 = (0.875, 0.625)$

(1)°	$\Delta_3 = 1$	$d_3 = 0$	$\phi_3 = 1$	$c_{3,1} = 0.875$	$y_3 = 0.646447$
(2)°	$\Delta_2 = 0.853553$	$d_2 = 0$	$\phi_2 = 1$	$c_{3,2} = 0.625$	$y_2 = 0.220971$
(3)°	nil	nil	nil	nil	$y_1 = 0.132583$

$(x_1, x_2, x_3) = (0.587868, 0.232583, 0.179550)$.

$\boldsymbol{c}'_4 = (0.375, 0.875)$

(1)°	$\Delta_3 = 1$	$d_3 = 0$	$\phi_3 = 1$	$c_{4,1} = 0.375$	$y_3 = 0.209431$
(2)°	$\Delta_2 = 0.790569$	$d_2 = 0$	$\phi_2 = 0.632456$	$c_{4,2} = 0.875$	$y_2 = 0.437500$
(3)°	nil	nil	nil	nil	$y_1 = 0.353069$

$(x_1, x_2, x_3) = (0.325659, 0.362500, 0.311841)$.

Step $(q-1)$. Let $\Delta_2 = \Delta_3 - y_3$,
$d_2 = \max(0,\ 1 - b^*_1/\Delta_2)$,

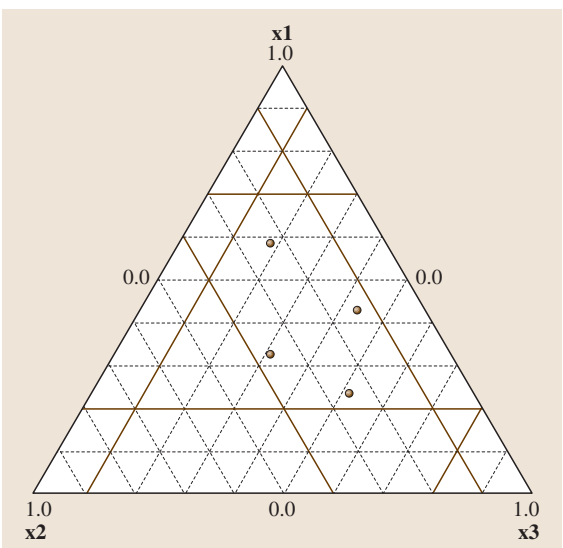

Fig. 13.4 An example of a uniform design with constraints

$\phi_2 = \min\left(1, b^*_2/\Delta_2\right)$.
Let $y_2 = G(c_{1,q-1}, d_2, \phi_2, \Delta_2, 1)$.

Step q. Let $y_1 = 1 - (y_q + \cdots y_2)$.

The point $\boldsymbol{y}'_1 = (y_1, \cdots, y_q)$ is a point for a UD in $S^{q-1}_{\mathbf{0},\boldsymbol{b}^*}$. Let

$$x_1 = \left[1 - \left(a^0_1 + \cdots + a^0_q\right)\right] y_1 + a^0_1 ,$$

$$\vdots$$

$$x_q = \left[1 - \left(a^0_1 + \cdots + a^0_q\right)\right] y_q + a^0_q .$$

The point $\boldsymbol{x}'_1 = (x_1, \cdots, x_q)$ is a point for a UD in $S^{q-1}_{\boldsymbol{a},\boldsymbol{b}}$. Repeat the above with each of $\boldsymbol{c}_2, \cdots, \boldsymbol{c}_{q-1}$ to obtain another $(n-1)$ points $\boldsymbol{y}'_2, \cdots, \boldsymbol{y}'_n$, and thus another $(n-1)$ points $\boldsymbol{x}'_2, \cdots, \boldsymbol{x}'_n$. Let

$$Y = \begin{pmatrix} \boldsymbol{y}'_1 \\ \boldsymbol{y}'_2 \\ \vdots \\ \boldsymbol{y}'_n \} \end{pmatrix} ,$$

and let

$$X = \begin{pmatrix} \boldsymbol{x}_1' \\ \boldsymbol{x}_2' \\ \vdots \\ \boldsymbol{x}_n' \end{pmatrix} .$$

Then Y is a UD on $S^{q-1}_{\boldsymbol{0},\boldsymbol{b}^*}$, and X is a UD on $S^{q-1}_{\boldsymbol{a},\boldsymbol{b}}$.

The following example illustrates construction of a UD of $n = 4$ points on S^{3-1} when there are restrictions on x_1, x_2, x_3.

Example 13.4: Let x_i be subject to the restriction $a_i \le x_i \le b_i$ $(i = 1, 2, 3)$, where $(a_1, a_2, a_3) = (0.2, 0.1, 0.1) = \mathbf{a}'$, $(b_1, b_2, b_3) = (0.7, 0.4, 0.8) = \mathbf{b}'$. Suppose that we want to find a UD with four points on $S^{3-1}_{\boldsymbol{a},\boldsymbol{b}}$. We choose the following $U_4(4^{3-1})$ uniform design U from the website, and from U we construct the following UD, C, on $[0, 1]^{3-1}$ by defining $c_{ki} = (u_{ki} - 0.5)/4$:

$$U = \begin{pmatrix} 3 & 1 \\ 1 & 2 \\ 4 & 3 \\ 2 & 4 \end{pmatrix} , \quad C = \begin{pmatrix} 0.625 & 0.125 \\ 0.125 & 0.375 \\ 0.875 & 0.625 \\ 0.375 & 0.875 \end{pmatrix} .$$

1. We have $a = 0.2 + 0.1 + 0.1 = 0.4$ and $b_1 + b_2 + b_3 = 1.9$. Since the condition $a < 1 < b$ is satisfied, the set $S^{3-1}_{\boldsymbol{a},\boldsymbol{b}}$ contains more than one point and the construction of the UD proceeds.
2. We have

$$\begin{aligned} a_1^0 &= \max(0.2, 0.7 + 1 - 1.9) = 0.2 , \\ b_1^0 &= \min(0.7, 0.2 + 1 - 0.4) = 0.7 , \\ a_2^0 &= \max(0.1, 0.4 + 1 - 1.9) = 0.1 , \\ b_1^0 &= \min(0.4, 0.1 + 1 - 1.9) = 0.4 , \\ a_3^0 &= \max(0.1, 0.8 + 1 - 1.9) = 0.1 , \\ b_1^0 &= \min(0.8, 0.1 + 1 - 0.4) = 0.7 . \end{aligned}$$

3. Define

$$\begin{aligned} y_1 &= (x_1 - 0.2)/0.6 , \\ b_1^* &= (0.7 - 0.2)/0.6 = 5/6 , \\ y_2 &= (x_2 - 0.1)/0.6 , \\ b_2^* &= (0.4 - 0.1)/0.6 = 1/2 , \\ y_3 &= (x_3 - 0.1)/0.6 , \\ b_3^* &= (0.7 - 0.1)/0.6 = 1 . \end{aligned}$$

Then $0.2 \le x_1 \le 0.7$, $0.1 \le x_2 \le 0.4$ and $0.1 \le x_3 \le 0.7$ are equivalent to $0 \le y_1 \le 5/6$, $0 \le y_2 \le 1/2$, $0 \le y_3 \le 1$.

4. Table 13.9 displays the values of Δ_k, d_k, ϕ_k and y_k $(k = 1, 2, 3, 4)$ calculated from the rows c_1', c_2', c_3', c_4' of C.
Hence

$$Y = \begin{pmatrix} 0.387628 & 0.062500 & 0.549872 \\ 0.064586 & 0.251301 & 0.684113 \\ 0.646447 & 0.229071 & 0.132582 \\ 0.209431 & 0.437500 & 0.353069 \end{pmatrix} ,$$

$$X = \begin{pmatrix} 0.432577 & 0.137500 & 0.429923 \\ 0.238751 & 0.250781 & 0.510468 \\ 0.587868 & 0.232583 & 0.179550 \\ 0.325659 & 0.362500 & 0.311841 \end{pmatrix} ,$$

Y is a UD on $S^{3-1}_{\boldsymbol{0},\boldsymbol{b}^*}$, and X is a UD on $S^{q-1}_{\boldsymbol{a},\boldsymbol{b}}$. The plot of the points of X is shown in Fig. 13.4.

13.7 Relationships Between Uniform Design and Other Designs

13.7.1 Uniformity and Aberration

A q^{s-p} factorial design D is uniquely determined by p defining words. A word consists of letters that represent the factors, and the number of letters in a word is called the word-length. The group formed by the p defining words is the defining contrast subgroup of D. Let $A_i(D)$ be the number of words of word-length i in the defining contrast subgroup. If D_1 and D_2 are two regular fractions of a q^{s-p} factorial, and there exists an integer k $(1 \le k \le s)$ such that

$$\begin{aligned} A_1(D_1) = A_1(D_2), \cdots , A_{k-1}(D_1) \\ = A_{k-1}(D_2), A_k(D_1) < A_k(D_2) , \end{aligned}$$

then D_1 is said to have less aberration than D_2. Aberration is a criterion for comparing designs in terms of confounding. The smaller the aberration, the less

confounding the design has, and hence designs with small aberration are preferred. Minimum aberration, as well as maximum resolution, which is also a criterion defined in terms of confounding for comparing designs, are two such commonly used criteria in the literature.

Fang and *Mukerjee* [13.16] proved the following relationship, which connects two seemingly unrelated criteria, CD and aberration, for two-level designs:

$$[\mathrm{CD}(D)]^2 = \left(\frac{13}{12}\right)^s - 2\left(\frac{35}{12}\right)^s + \left(\frac{8}{9}\right)^s \left(1 + \sum_{i=1}^{s} \frac{A_i(D)}{9^i}\right).$$

This relationship shows that minimum CD is essential equivalent to minimum aberration. *Fang* and *Ma* [13.46] extended this result to regular fraction 3^{s-1} designs, and proved the following relationships concerning WD for a regular fractional factorial design q^{s-k} $(q = 2, 3)$:

$$[\mathrm{WD}(D)]^2 = \left(\frac{11}{8}\right)^s - \left(\frac{4}{3}\right)^s + \left(\frac{11}{8}\right) + \sum_{i=1}^{s} \frac{A_i(D)}{11^i} \quad (q = 2),$$

$$[\mathrm{WD}(D)]^2 = -\left(\frac{4}{3}\right)^s + \left(\frac{73}{54}\right)^s \times \left[1 + \sum_{i=1}^{s} \left(\frac{4}{73}\right)^i A_i(D)\right] \quad (q = 3).$$

The last two relationships show that minimum WD and minimum aberration are essentially equivalent.

13.7.2 Uniformity and Orthogonality

An orthogonal array has a balanced structure. In any r columns in an orthogonal array of strength r, combinations of different of $1 \times r$ vectors occur the same number of times. Because of the balanced structure of orthogonal arrays, it is not surprising that an orthogonal array has a small discrepancy and is a uniform design. *Fang* and *Winker* [13.47] showed that many UDs are also orthogonal arrays of strength 2, for example, $U_4(2^3)$, $U_8(2^7)$, $U_{12}(2^{11})$, $U_{12}(2^{11})$, $U_{16}(2^{15})$, $U_9(3^4)$, $U_{12}(3 \times 2^3)$, $U_{16}(4^5)$, $U_{16}(4 \times 2^{12})$, $U_{18}(2 \times 3^7)$ and $U_{25}(25^6)$, and they conjectured that an orthogonal array is a uniform design under a certain discrepancy. *Ma* et al. [13.48] proved this conjecture for complete designs (designs in which all level combinations of the factors appear equally often) and for 2^{s-1} factorials, under L_2-discrepancy.

13.7.3 Uniformity of Supersaturated Designs

A design whose number of runs is equal to the number of effects to estimate is called a *saturated design*. A *supersaturated design* is a design in which the number of runs is less than the number of effects to estimate. In an industrial or scientific experiment, sometimes a large number of possible contributing factors are present, but it is believed that only a few of these factor contribute significantly to the outcome. In this situation of *effect scarcity*, one may use supersaturated designs to identify the major contributing factors. Studies on two- and three-level supersaturated designs are available in the literature [13.49–54].

A supersaturated design can be formed by adding columns to an orthogonal array. Since the number of rows in a supersaturated design is less than the number of columns, a supersaturated design cannot be an orthogonal array. Many criteria have been defined for construction of supersaturated designs that are as close to being orthogonal as possible; they are Ave(s^2), $E(s^2)$, ave(χ^2), and others. *Ma* et al. [13.55] defined a more general criterion, the $D_{\phi,\theta}$ criterion

$$D_{\phi,\theta} = \sum_{1 \le < j \le m} \theta\left(\sum_{u=1}^{q_i} \sum_{v=1}^{q_j} \phi\left|n_{uv}^{(ij)} - \frac{n}{q_i q_j}\right|\right),$$

where $\phi(\cdot)$ and $\theta(\cdot)$ are monotonic increasing functions on $[0, \infty)$, $\phi(0) = \theta(0) = 0$, $n_{uv}^{(ij)}$ is the number of occurrences of the pair (u, v) in the two-column matrix formed by column i and column j of the matrix design. The smaller the value of $D_{\phi,\theta}$, the closer the supersaturated design is to an orthogonal design. Since $n/(q_i q_j)$ is the average number of occurrence of level combinations of the pair (u, v), it is clear that $D_{\phi,\theta} = 0$ for an orthogonal array. *Fang* et al. [13.56] considered a special case of $D_{\phi,\theta}$, denoted by $E(f_{\mathrm{NOD}})$, from which they proposed a way of construction of supersaturated designs. *Fang* et al. [13.56] also proposed a way for constructing supersaturated design with mixed levels. *Fang* et al. [13.57] proposed a way that collapses a uniform design to an orthogonal array for construction of multi-level supersaturated designs. *Fang* et al. [13.33] and *Fang* et al. [13.58] proposed construction of supersaturated designs by a combinatorial approach.

13.7.4 Isomorphic Designs, and Equivalent Hadamard Matrices

Two factorial designs are said to be isomorphic if one can be obtained from the other by exchanging rows and columns and permutating levels of one or more factors. Two isomorphic designs are equivalent in the sense that they produce the same result under the ANOVA model. In the study of factorial designs, a task is to determine whether two designs are isomorphic. To identify two isomorphic designs $d(n, q, s)$ of n runs and s factors each having q levels requires a search over $n!(q!)^s s!$ designs, which is an NP-hard problem even if the values of (n, s, q) are of moderate magnitudes. Some methods have been suggested for reducting the computation load, but such methods are not very satisfactory. The following method using discrepancy suggested by *Ma* et al. [13.59] is a much more efficient alternative.

Given a factorial design $D = d(n, q, s)$ and k $(1 \le k \le s)$, there are $[s!/(k!\,(s-k)!)]$ $d(n, q, s)$ subdesigns. The values of CD of these subdesigns form a distribution $F_k(D)$. It is known that two isomorphic designs $d(n, q, s)$ have the same value of CD and the same distribution $F_k(D)$ for all k, $(1 \le k \le s)$. Based on this, *Ma* et al. [13.59] proposed an algorithm for detecting non-isomorphic designs.

Two Hadamard matrices are said to be equivalent if one can be obtained from the other by some sequence of row and column permutation and negations. To identify whether two Hadamard matrices are equivalent is also an NP-hard problem. A method called the profile method suggested by *Lin* et al. [13.60] can be used, but this method is still not satisfactory. Recently, *Fang* and *Ge* [13.61] proposed a much more efficient algorithm using a symmetric Humming distance and a criterion which has a close relationship with several measures of uniformity. Applying this algorithm, they verified the equivalence of 60 known Hadamard matrices of order 24 and discovered that there are at least 382 pairwise-equivalent Hadamard matrices of order 36.

13.8 Conclusion

In this chapter, we have introduced the *uniform design* (UD) which is a space-filling design characterized by uniform distribution of its design points over the entire experimental domain. Abundant theoretical results on UDs and the relationships between UDs and other well-established design criteria are now available in the literature, as are many successful examples of application of UDs in industry.

Theoretical studies show that UDs are superior, in the sense that establishing uniformity of design by minimizing discrepancies will automatically optimize many other design criteria. An advantage of using UDs in experiments is that, even when the number of factors and the levels of factors are large, the experiment can be conducted in a much smaller number of runs than many other commonly used designs such as factorial designs.

UDs can be used in industrial experiments. Since their design points uniformly cover the design region, UDs are suitable for experiments in which the underlying model is unknown. The UD can be used as a space-filling design for numerical integration and computer experiments, and as a robust design against model specification. For users' convenience, many tables for UDs are documented in the website www.math.hkbu.edu.hk/UniformDesign.

Research in the UD is a new area of study compared with classical areas in experimental designs. Some existing theoretical problems have not yet been solved, and many other problems can be posed. Many successful industrial applications have been recorded, but widespread application of UDs in industries still needs further promotion. We hope that this short chapter can serve as an introduction to the UD, and in the future more researchers and industrial practitioners will join us in studying and applying the UD.

14. Cuscore Statistics: Directed Process Monitoring for Early Problem Detection

This chapter presents the background to the Cuscore statistic, the development of the Cuscore chart, and how it can be used as a tool for directed process monitoring. In Sect. 14.1 an illustrative example shows how it is effective at providing an early signal to detect known types of problems, modeled as mathematical signals embedded in observational data. Section 14.2 provides the theoretical development of the Cuscore and shows how it is related to Fisher's score statistic. Sections 14.3, 14.4, and 14.5 then present the details of using Cuscores to monitor for signals in white noise, autocorrelated data, and seasonal processes, respectively. The capability to home in on a particular signal is certainly an important aspect of Cuscore statistics. however, Sect. 14.6 shows how they can be applied much more broadly to include the process model (i. e., a model of the process dynamics and noise) and process adjustments (i. e., feedback control). Two examples from industrial cases show how Cuscores can be devised and used appropriately in more complex monitoring applications. Section 14.7 concludes the chapter with a discussion and description of future work.

The traditional view of statistical process control is that a process should be monitored to detect any aberrant behavior, or what *Deming* [14.1] called "special causes" that are suggested by significant patterns in the data that point to the existence of systematic signals. The timing, nature, size, and other information about the signals can lead to the identification of the signaling factor(s) so that it can (ideally) be permanently eliminated. Conventional Shewhart charts are designed with exactly this philosophy, where the signal they detect is an unexpected spike change in white noise.

Many situations occur, however, where certain process signals are anticipated because they are characteristic of a system or operation. The cumulative score (Cuscore) chart can be devised to be especially sensitive to deviations or signals of an expected type. In general, after working with a particular process, engineers and operators often know – or at least have a belief – about how a process will potentially falter. (Unfortunately, the problem seldom announces its time and location in advance.) For example, consider a process where a valve is used to maintain pressure in a pipeline. Because the valve will experience wear over time, it must be periodically replaced. However, in addition to the usual wear, engineers are concerned that the value may fatigue or fail more rapidly than normal. The Cuscore chart can be used to incorporate this working knowledge and experience into the statistical monitoring function. This concept often has a lot of intuitive appeal for industry practitioners.

After laying the background and theoretical foundation of Cuscores this chapter progresses through signal detection in white noise, autocorrelated data, and seasonal data. Two examples from actual industry settings show how Cuscores can be devised and used appropriately in more complex monitoring applications. The final section of the chapter provides a discussion on how Cuscores can be extended in a framework to include statistical experiments and process control.

14.1 Background and Evolution of the Cuscore in Control Chart Monitoring

Statistical process control (SPC) has developed into a rich collection of tools to monitor a system. The first control chart proposed by *Shewhart* [14.2] is still the most widely used in industrial systems [14.3]. As observational data from the system are plotted on the chart, the process is declared "in control" as long as the points on the chart stay within the control limits. If a point falls outside those limits an "out of control" situation is declared and a search for a special cause is initiated.

Soon practitioners realized that the ability of the Shewhart chart to detect small changes was not as good as its ability to detect big changes. One approach to improve the sensitivity of the chart was to use several additional rules (e.g., *Western Electric rules* [14.4] that signal for a number of consecutive points above the center line, above the warning limits, and so on). Another approach was to design complementary charts that could be used in conjunction with the Shewhart chart but that were better at detecting small changes. *Page* [14.5] and *Barnard* [14.6] developed the cumulative sum (Cusum) chart where past and present data are used in a cumulative way to detect small shifts in the mean. *Roberts* [14.7] and *Hunter* [14.8] proposed the exponentially weighted moving average (EWMA) as another way to detect small changes. This ability comes from the fact that the EWMA statistic can be written as a moving average of the current and past observations, where the weights of the past observations fall off exponentially.

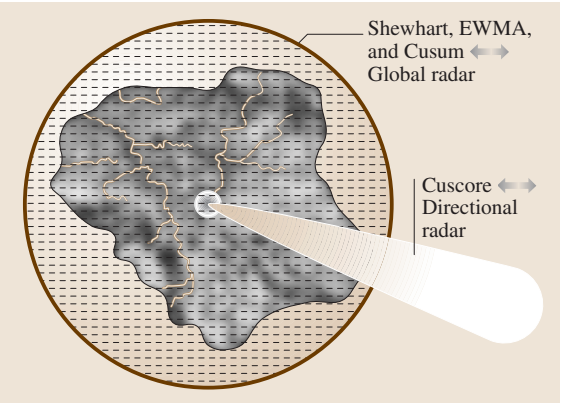

Fig. 14.1 The roles of the Shewhart and Cuscore charts are compared to those of global and directional radar defenses for a small country

Of course the Shewhart, Cusum, and EWMA charts are broadly applicable to many types of process characterizations. Remarkably, the Cuscore chart generalizes the Shewhart, Cusum, and EWMA charts; however, its real benefit is that it can be designed to be a high-powered diagnostic tool for specific types of process characterizations that are not covered by the basic charts. We will develop this result more formally after introducing the Cuscore theory. However, an analogy due to *Box* [14.9] will help to establish the ideas.

Suppose a nation fears aerial attack. As Fig. 14.1 shows, a global radar scanning the full horizon will have a broad coverage of the entire border, but with

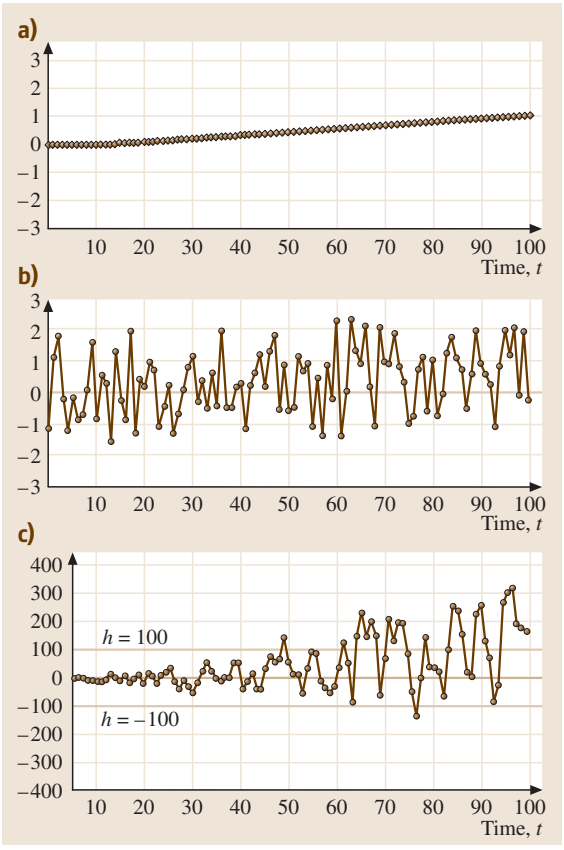

Fig. 14.2a–c Detection of a ramp signal: **(a)** ramp signal beginning at time 10; **(b)** the signal plus white noise consisting of 100 random normal deviates with zero mean and standard deviation $\sigma = 1$; and **(c)** the Cuscore statistic applied to the data of **(b)**

a limited range; this is the analog of the Shewhart, Cusum, and EWMA charts. A directional radar aimed in the direction of likely attack will have a specific zone of the border to cover, but with a long range for early detection; this is the analog of the Cuscore chart.

As a first illustration of the Cuscore chart, let us consider it within the framework of looking for a signal in noise. Suppose we have an industrial process where the objective is to control the output Y_t to a target value T. We may conveniently view the target as the specification and record deviations from the target. Suppose that the process may experience a small drift to a new level over time – a ramp signal. Although corrective actions have been taken to hopefully resolve the process, it is feared that the same problem might reoccur. The components of the process are illustrated in Fig. 14.2 which shows: (a) the ramp signal beginning at time $t = 10$; (b) the signal plus white noise consisting of 100 random normal deviates with zero mean and standard deviation $\sigma = 1$; and (c) the appropriate Cuscore statistic

$$Q_t = \sum_{i=1}^{t} (Y_t - T)t \, .$$

The development of the statistic is also shown in Sect. 14.3. We may note that Fig. 14.2b is equivalent to a Shewhart control chart with upper and lower control limits of $+3\sigma$ and -3σ respectively. The Shewhart chart is relatively insensitive to small shifts in the process, and characteristically, it never detects the ramp signal (Fig. 14.2b). With a decision interval $h = 100$, the Cuscore chart initially detects the signal at time 47 and continues to exceed h at several later time periods (Fig. 14.2c). Although tailored to meet different process monitoring needs, the EWMA and Cusum charts would similarly involve a direct plot of the actual data to look for an unexpected signal in white noise. In this case, since we have some expectation about the signal, i. e., that it is a ramp, we incorporate that information into the Cuscore by multiplying the differences (which are residuals) by t before summing.

Similarly, if demanded by the monitoring needs, the Cuscore can be devised to monitor for a mean shift signal in autocorrelated noise, or for a bump signal in nonstationary noise, or for an exponential signal in correlated noise, or any other combination. Indeed, the Cuscore chart can be designed to look for almost any kind of signal in any kind of noise. The theoretical development of the Cuscore statistic will help illuminate this idea.

14.2 Theoretical Development of the Cuscore Chart

Consider a model of the output of a process determined by adding the process target to an autoregressive integrated moving average (ARIMA) time-series model:

$$Y_t = T + \frac{\theta(B)}{\phi(B)} a_{t0} \, , \qquad (14.1)$$

where B is the backshift operator such that $B^k X_t = X_{t-k}$; $\phi(B)$ and $\theta(B)$ are the autoregressive (AR) and moving average (MA) polynomials parameterized as $\phi(B) = 1 - \phi_1 B - \phi_2 B^2 - \cdots - \phi_p B^p$ and $\theta(B) = 1 - \theta_1 B - \theta_2 B^2 - \cdots - \theta_q B^q$ [$(1 - B)\phi(B)$ can be used to difference the process]; the a_t values are independent and identically distributed $N(0, \sigma_a^2)$(i. e., white noise). However, in the model the zero in a_t is added to indicate that the a_{t0} values are just residuals; they are not white-noise innovations unless the model is true. This model is referred to as the null model: the in-control model assuming that no feared signal occurs.

Now assume that an anticipated signal that could appear at some time where γ is some unknown parameter of the signal, and $f(t)$ indicates the nature of the signal:

$$Y_t = T + \frac{\theta(B)}{\phi(B)} a_t + \gamma f(t) \, . \qquad (14.2)$$

This model is referred to as the discrepancy model and is assumed to be true when the correct value for γ is used.

Box and *Ramírez* [14.10, 11] presented a design for the Cuscore chart to monitor for an anticipated signal. It is based on expressing the statistical model in (14.2) in terms of white noise:

$$a_i = a_i(Y_i, X_i, \gamma) \quad \text{for } i = 1, 2, \ldots, t \, , \qquad (14.3)$$

where X_i are the known levels of the input variables. The concept is that we have properly modeled the system so that only white noise remains when the signal is not present. After the data have actually occurred, for each choice of γ, a set of a_i values can be calculated from (14.3). In particular, let γ_0 be some value, possibly different from the true value γ of the parameter. The sequential probability ratio test for γ_0 against some other

value γ_1 has the likelihood ratio

$$LR_t = \prod_{i=1}^{t} \exp\left\{\frac{1}{2\sigma_a^2}\left[a_i^2(\gamma_0) - a_i^2(\gamma_1)\right]\right\}.$$

After taking the log, this likelihood ratio leads to the cumulative sum

$$S_t = \frac{1}{2\sigma_a^2}\sum_{i=1}^{t}\left[a_i^2(\gamma_0) - a_i^2(\gamma_1)\right].$$

Expanding $a_i^2(\gamma)$ around γ_0, letting $\eta = (\gamma_1 - \gamma_0)$, and $d_i = -\frac{\partial a_i}{\partial \gamma}|_{\gamma=\gamma_0}$ we have

$$S_t = \frac{1}{2\sigma_a^2}\sum_{i=1}^{t}\left[2\eta a_i(\gamma_0)d_i(\gamma_0) - \eta^2 d_i^2(\gamma_0)\right]$$

$$= \frac{\eta}{\sigma_a^2}\sum_{i=1}^{t}\left[a_i(\gamma_0)d_i(\gamma_0) - \frac{\eta}{2}d_i^2(\gamma_0)\right].$$

The quantity

$$Q_t = \sum_{i=1}^{t}\left[a_i(\gamma_0)d_i(\gamma_0) - \frac{\eta}{2}d_i^2(\gamma_0)\right] = \sum_{i=1}^{t} q_i \quad (14.4)$$

is referred to as the Cuscore associated with the parameter value $\gamma = \gamma_0$ and d_i is referred to as the detector. The detector measures the instantaneous rate of change in the discrepancy model when the signal appears. *Box* and *Luceño* [14.12] liken its operation to a radio tuner because it is designed in this way to synchronize with any similar component pattern existing in the residuals. Accordingly, it is usually designed to have the same length as the anticipated signal series. The term $\frac{\eta}{2}d_i^2(\gamma_0)$ can be viewed as a reference value around which $a_i(\gamma_0)d_t(\gamma_0)$ is expected to vary if the parameter does not change. The quantity $a_i(\gamma_0)d_t(\gamma_0)$ is equal to Fisher's score statistic [14.13], which is obtained by differentiating the log likelihood with respect to the parameter γ. Thus

$$\frac{\partial}{\partial\gamma}\left[\ln p\left(a_i|\gamma\right)\right]\Big|_{\gamma=\gamma_0} = \frac{\partial}{\partial\gamma}\left(-\frac{1}{2\sigma^2}\sum_{i=1}^{t}a_i^2\right)\Big|_{\gamma=\gamma_0}$$

$$= \frac{1}{\sigma^2}\sum_{i=1}^{t}a_i(\gamma_0)d_i(\gamma_0),$$

where $p(a_i|\gamma)$ is the likelihood or joint probability density of a_i for any specific choice of γ and the $a_i(\gamma_0)$ values are obtained by setting $\gamma = \gamma_0$ in (14.3). Since the q_is are in this way a function of Fisher's score function, the test procedure is called the Cuscore. The Cuscore statistic then amounts to looking for a specific signal $f(t)$ that is present when $\gamma \neq \gamma_0$.

To use the Cuscore operationally for process monitoring, we can accumulate q_i only when it is relevant for the decision that the parameter has changed and reset it to zero otherwise. Let Q_t denote the value of the Cuscore procedure plotted at time t, i. e., after observation t has been recorded. Let Q_t^+ and Q_t^- denote the one-sided upper and lower Cuscores respectively as follows:

$$Q_t^+ = \max(0,\, Q_{t-1}^+ + q_t), \quad (14.5a)$$

$$Q_t^- = \min(0,\, Q_{t-1}^- + q_t), \quad (14.5b)$$

where the starting values are $Q_0^+ = Q_0^- = 0$. The one-sided Cuscore is preferable when the system has a long period in the in-control state, during which Q_t would drift and thus reduce the effectiveness of the monitoring chart.

If either Q_t^+ or Q_t^- exceed the decision interval h, the process is said to be out of control. *Box* and *Ramírez* [14.10] showed that an approximation to h can be obtained as a function of the type-I error, α, the magnitude of the change in the parameter $\gamma = (\gamma_1 - \gamma_0)$, and the variance of the as:

$$h = \frac{\sigma_a^2 \ln(1/\alpha)}{\gamma}. \quad (14.6)$$

For simpler models, we could also develop control limits for the Cuscore chart by directly estimating the standard deviation of the Cuscore statistic. For more complex models, control limits may be obtained by using simulation to evaluate the average run length associated with a set of out of control conditions.

14.3 Cuscores to Monitor for Signals in White Noise

Let us now consider the Cuscore statistics for the basic case of monitoring for signals in white noise, which is the assumption underlying the traditional Shewhart, EWMA, and Cusum charts. We will develop them without the reference value in (14.4), but the reference value will help to improve the average run-length performance of the chart when used in practice. We can write the white-noise null model using (14.1) where the ϕ and θ parameters are set equal to zero, i. e.,

$$Y_t = T + a_{t0}.$$

Writing a_{t0} on the left makes it clear that each residual is the difference between the output and the target:

$$a_{t0} = Y_t - T \,. \tag{14.7}$$

If the model is correct and there is no signal, the result will be a white-noise sequence that can be monitored for the appearance of a signal. When the signal does show up, the discrepancy model is thus

$$Y_t = T + a_t + \gamma f(t)$$

which can be equivalently written with the white noise quantity a_t on the left as

$$a_t = Y_t - T - \gamma f(t) \,.$$

The form of the signal will determine the form of the detector and hence the form of the Cuscore.

The Shewhart chart is developed under the assumption of white noise and that the signal for which the chart detects efficiently is a spike signal:

$$f(t) = \begin{cases} 0 & t \neq t_0 \\ 1 & t = t_0 \,. \end{cases} \tag{14.8}$$

For the spike signal in the discrepancy model, the appropriate detector d_t is

$$d_t = -\left.\frac{\partial a_t}{\partial \gamma}\right|_{\gamma=\gamma_0} = 1 \,. \tag{14.9}$$

By (14.4), (14.7), and (14.9) the Cuscore statistic is

$$\begin{aligned} Q_t &= \sum_{i=1}^{t} a_{i0} d_i \\ &= a_{t0} \,, \end{aligned}$$

where the last equality follows since the detector for the spike is only for one period (i.e, the current one) given that the signal series and detector series have the same length. Hence, the Cuscore tells us to plot the current residual, which is precisely the design of the Shewhart chart.

The EWMA chart is developed under the assumption of white noise and that the signal that the chart is designed to detect is an exponential signal with parameter γ:

$$f(t) = \begin{cases} 0 & t > t_0 \\ 1 + \gamma_{t-1} + \gamma_{t-2}^2 + \gamma_{t-3}^3 + \cdots & t \leq t_0 \,. \end{cases}$$

For the exponential signal in the discrepancy model, the appropriate detector d_t is

$$d_t = -\left.\frac{\partial a_t}{\partial \gamma}\right|_{\gamma=\gamma_0} = 1 + \gamma_{t-1} + \gamma_{t-2}^2 + \gamma_{t-3}^3 + \cdots \,. \tag{14.10}$$

By (14.4), (14.7), and (14.10) the appropriate Cuscore statistic is

$$\begin{aligned} Q_t &= \sum_{i=1}^{t} a_{i0} d_i \\ &= a_{t0} + \gamma a_{t0-1} + \gamma^2 a_{t0-2} + \gamma^3 a_{t0-3} + \cdots \,. \end{aligned}$$

Here the Cuscore tells us to sum the current and past residuals, applying an exponentially discounted weight to the past data, which is the design of the EWMA chart.

The Cusum chart is developed under the assumption of white noise and that signal to detect is a step change or mean shift given by

$$f(t) = \begin{cases} 0 & t < t_0 \\ 1 & t \geqslant t_0 \,. \end{cases} \tag{14.11}$$

In this case, the discrepancy model and the detector are the same as for the spike signal. However, since the signal remains in the process, the detector is applied over all periods to give the Cuscore statistic

$$Q_t = \sum_{i=1}^{t} a_{i0} \,.$$

Here the Cuscore tells us to plot the sum of all residuals, which is precisely the design of the Cusum chart.

A variation of the step change is one that lasts only temporarily, which is called a bump signal of length b

$$f(t) = \begin{cases} 1 & t_{0-b+1} \leqslant t \leqslant t_0 \\ 0 & \text{otherwise} \,. \end{cases}$$

When this signal appears in white noise, the detector is applied only as long as the bump, giving the Cuscore statistic

$$Q_t = \sum_{i=1}^{t} a_{i0-b-1} \,.$$

This is equivalent to the arithmetic moving-average (AMA) chart, which is frequently used in financial analysis (e.g., see TraderTalk.com or Investopedia.com).

The ramp signal that may start to appear at time t_{0-r} where r is the duration of the ramp with a final value m is modeled by

$$f(t) = \begin{cases} \frac{m}{r}t & t_{0-r} \leqslant t \leqslant t_0 \\ 0 & \text{otherwise} . \end{cases}$$

The discrepancy model is the same as with the Shewhart chart, but for this signal the detector is given by

$$d_t = -\left.\frac{\partial a_t}{\partial \gamma}\right|_{\gamma=\gamma_0} = t .$$

The Cuscore is hence

$$Q_t = \sum_{i=1}^{t} a_{i0} d_i = \sum_{i=1}^{t} a_{i0} t = \sum_{i=1}^{t} (Y_t - T)\, t$$

as the example in the introduction shows.

14.4 Cuscores to Monitor for Signals in Autocorrelated Data

In many real systems, the assumption of white-noise observations is not even approximately satisfied. Some examples include processes where consecutive measurements are made with short sampling intervals and where quality characteristics are assessed on every unit in order of production. Financial data, such as stock prices and economic indices are certainly not uncorrelated and independent observations. In the case of autocorrelated data the white-noise assumption is violated. Consequently the effectiveness of the Shewhart, Cusum, EWMA, and AMA charts is highly degraded because they give too many false alarms. This point has been made by many authors (e.g., see *Montgomery* [14.14] for a partial list).

Alwan and *Roberts* [14.15] proposed a solution to this problem by modeling the non-random patterns using ARIMA models. They proposed to construct two charts: 1) a common-cause chart to monitor the process, and 2) a special-cause chart on the residuals of the ARIMA model. Extensions of the these charts to handle autocorrelated data have been addressed by several authors. *Vasilopoulos* and *Stamboulis* [14.16] modified the control limits. *Montgomery* and *Mastrangelo* [14.17] and *Mastrangelo* and *Montgomery* [14.18] used the EWMA with a moving center line (MCEWMA). However, when signals occur in autocorrelated data, there is a pattern in the residuals that that the residuals-based control charts do not use. The Cuscore, on the other hand, does incorporate this information through the detector. As we have seen, the detector plays an important role in determining Cuscore statistics but this role is attenuated for autocorrelated data.

As in the previous section, we can use the reference value in practice, but will develop the main result without it. Assuming the null model in (14.1) is invertible, i. e., $|\theta| < 1$, it can be written in terms of the residuals as

$$a_{t0} = (Y_t - T)\frac{\phi(B)}{\theta(B)} . \tag{14.12}$$

The discrepancy model in (14.2) can be equivalently written with the white-noise quantity a_t on the left as

$$a_t = [Y_t - T - \gamma f(t)]\frac{\phi(B)}{\theta(B)} . \tag{14.13}$$

We see that to recover the white-noise sequence in an autocorrelated process, both the residuals and the signal must pass through the inverse filter $\phi(B)/\theta(B)$. Hence, the residuals have time-varying mean $\gamma f(t)\{[\phi(B)/\theta(B)]\}$ and variance σ_a^2. Using (14.13), the detector d_t is

$$d_t = -\left.\frac{\partial a_t}{\partial \gamma}\right|_{\gamma=\gamma_0} = f(t)\frac{\phi(B)}{\theta(B)} . \tag{14.14}$$

By (14.4), (14.13), and (14.14) the Cuscore statistic is

$$\begin{aligned} Q_t &= \sum_{i=1}^{t} a_{i0} d_i \\ &= \sum_{i=1}^{t} \left[(Y_i - T)\frac{\phi(B)}{\theta(B)}\right] f(t)\frac{\phi(B)}{\theta(B)} . \end{aligned}$$

Hu and *Roan* [14.19] mathematically and graphically showed the behavior of the detector for several combinations of signals and time-series models. Their study highlights that the behavior is different for different values of ϕ and θ determined by the stability conditions, the value of the first transient response, and the value of the steady-state response.

As an example, suppose we have the ARMA (1,1) noise model

$$(Y_t - T) - \phi_1(Y_{t-1} - T) = a_{t0} - \theta_1 a_{t0-1}$$

or

$$a_{t0} = (Y_t - T)\frac{1-\phi_1 B}{1-\theta_1 B} \,. \tag{14.15}$$

If the step signal in (14.11) occurs at time t_0, using (14.14) we can determine that a change pattern is produced:

$$d_t = f(t)\frac{\phi(B)}{\theta(B)} = \begin{cases} 0 & t < t_0 \\ 1 & t = t_0 \\ (\theta_1 - \phi_1)\theta_1^{t-(t_0+1)} & t \geqslant t_0 + 1 \,. \end{cases} \tag{14.16}$$

Then the Cuscore statistic is the sum of the product of (14.15) and (14.16).

However, we can see an important issue that arises in autocorrelated data, which is how the time-varying detector is paired with the current residuals. For example, if we assume that we know the time of the step signal or mean shift, there is a match between the residuals and the detector and we use t_0 in the calculation of d_t for the Cuscore. When we do not know the time of the mean shift, there is a mismatch between the residuals and the detector; in this case we make the estimate $\hat{t}_0$ and write the detector as $d_{\hat{t}}$. (When $\hat{t}_0 = t_0$ then $d_{\hat{t}} = d_t$.) The match or mismatch will affect the robustness of the Cuscore chart, as considered for limited cases in *Shu* et al. [14.20] and *Nembhard* and *Changpetch* [14.21]. There is an opportunity to increase the understanding of this behavior through additional studies.

Yet another issue is to determine over how many periods the detector should be used in the case of a finite signal such as a step or a bump. On this point, *Box* and *Luceño* [14.12] use equal lengths for both white-noise and autocorrelated-noise models. Although such an assumption seems intuitive for white-noise models, on open question is whether a longer detector would improve the efficiency of the Cuscore chart in the case of autocorrelated data.

14.5 Cuscores to Monitor for Signals in a Seasonal Process

In this section, we present the first example of a Cuscore application in an industry case. One of the major services of the Red Cross is to manage blood platelet inventory. Platelets are irregularly-shaped colorless bodies that are present in blood. If, for some unexpected reason, sudden blood loss occurs, the blood platelets go into action. Their sticky surface lets them, along with other substances, form clots to stop bleeding [14.22]. *Nembhard* and *Changpetch* [14.21] consider the problem of monitoring blood platelets, where the practical goal is to detect a step shift in the mean of a seasonal process as an indicator that demand has risen or fallen. This information is critical to Red Cross managers, as it indicates a need to request more donors or place orders for more blood with a regional blood bank. A distinction of this problem is that the step shift, although a special cause, is a characteristic of the system. That is, from time to time, shifts in the mean of the process occur due to natural disasters, weather emergencies, holiday travel, and so on. Given the structure of characteristic shifts in this application, directed monitoring is a natural choice.

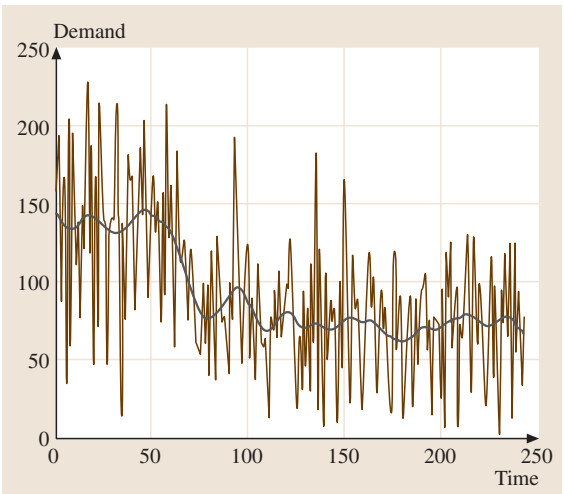

Fig. 14.3 The time-series plot and smooth curve for the quantity of blood platelets ordered from the Red Cross

Figure 14.3 shows the actual time-series data of the demand for platelets from the Red Cross from January 2002 to August 2002 and the smooth curve of the data. The smooth curve suggests that mean of the series has shifted down during the data-collection period. It is easy to visually identify the mean shift in this series. However, it is difficult to conclude that it is a mean shift as it is unfolding. This is the main issue: we want to detect the mean shift as soon as possible in real time. To detect a mean shift in seasonal autocorrelated data, we must use an appropriate time-series model of the original data. Following a three-step model-building

process of model identification, model fitting, and diagnostic checking (*Box*, *Jenkins*, and *Reinsel* [14.23]), we find that an appropriate null model of the data is the ARIMA $(1,0,0)\times(0,1,1)_7$ seasonal model given by

$$\begin{aligned} a_{t0} &= Y_t \frac{\phi(B)}{\theta(B)} = Y_t \frac{(1-B^7)(1+0.281B)}{(1-0.833B^7)} \\ &= Y_t + 0.281Y_{t-1} - Y_{t-7} - 0.281Y_{t-8} \\ &\quad + 0.833a_{t0-7} \,. \end{aligned} \tag{14.17}$$

The discrepancy model is

$$\begin{aligned} a_t &= [Y_t - \gamma f(t)]\frac{\phi(B)}{\theta(B)} \\ &= [Y_t - \gamma f(t)]\frac{(1-B^7)(1+0.281B)}{(1-0.833B^7)} \\ &= Y_t + 0.281Y_{t-1} - Y_{t-7} - 0.281Y_{t-8} - \gamma f(t) \\ &\quad - 0.281\gamma f(t-1) + \gamma f(t-7) + 0.281\gamma f(t-8) \\ &\quad + 0.833a_{t-7} \,. \end{aligned}$$

The detector for the model is

$$\begin{aligned} d_t &= -\left.\frac{\partial a_t}{\partial \gamma}\right|_{\gamma=\gamma_0} \\ &= f(t) + 0.281f(t-1) - f(t-7) \\ &\quad - 0.281f(t-8) + 0.833d_{t-7} \,. \end{aligned} \tag{14.18}$$

Using (14.16) and (14.17) in the one-sided Cuscore statistic of (14.5b) and using a reference value with $\eta = \sigma_a = 31.58$ yields the results shown in Fig. 14.4. The figure also shows that control limits are approximately 196 and −196, which are based on (14.6) with $\alpha = 1/500$. Here the Cuscore chart signals a negative mean shift at observation 67, just two time periods later than the actual occurrence.

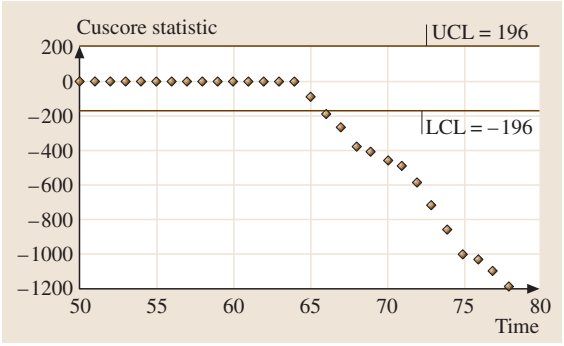

Fig. 14.4 A Cuscore chart for the Red Cross data

This example follows the best-case scenario, which is to predict the time of the occurrence of the mean shift at exactly the time that it really occurs, that is $\hat{t}_0 = t_0$. In such a case, there will be a match between the residuals and the detector, making the use of the Cuscore straightforward. In reality, we are unlikely to have prior information on when the mean shift will occur or, in terms of this application, when there will be a difference in the level of platelets ordered. Consequently, in the determination of the Cuscore statistic there will be a mismatch between the detector and the residuals. The mismatch case is considered fully for this application in *Nembhard* and *Changpetch* [14.21].

14.6 Cuscores in Process Monitoring and Control

As a second example of Cuscore in industry, we now consider a case from *Nembhard* and *Valverde-Ventura* [14.24] where cellular window blinds are produced using a pleating and gluing manufacturing process. Cellular shades form pockets of air that insulate windows from heat and cold. These shades start as 3000-yard rolls of horizontally striped fabric. On the machines, the fabric winds over, under and through several rollers, then a motorized arm whisks a thin layer of glue across it and a pleater curls it into a cell. When the process goes as planned, the crest of the pleat is in the center of the stripe and the finished product is white on the back and has a designer color on the front. When something goes wrong, defects can include a color that bleeds through to the other side, a problem known as "out of registration."

Using a high-speed camera, position data are acquired on the fabric every 20 pleats then a computer compares the edge of the colored band with the target position and measures the deviation (Fig. 14.5). If the two lines match then the deviation is zero and the blind is said to be "in-registration." If the lines do not match, a feedback controller is used to adjust the air cylinder pressure. Unfortunately, as can be seen from the displacement measurements in Fig. 14.5, the feedback controller performed very poorly.

To address this problem, we can use the Box–Jenkins transfer function plus noise and signal model in Fig. 14.6

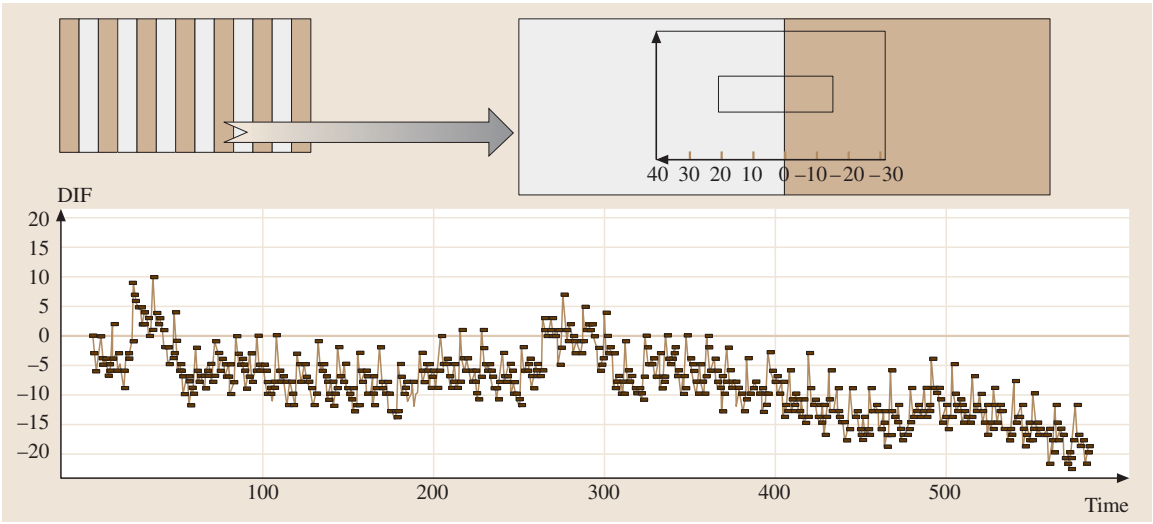

Fig. 14.5 Representation of the measurement of the displacement of the leading edge of the fabric with respect to a fixed point

for process representation. In this model, the output Y_t is the combination of the disturbance term that follows an ARIMA process, as we had in (14.1) and (14.2), plus an input (or explanatory) variable X_t, that is controllable but is affected by the process dynamics S_t. In this case, the combined model of the output in the presence of a signal is:

$$Y_t = \frac{L_2(B)}{L_1(B)} X_{t-k} + a_t \frac{\theta(B)}{\phi(B)} + \gamma \, , \, f(t)$$

where $L_1(B)$ and $L_2(B)$ are the process transfer function polynomials. The control equation tells us how to change X_t over time based on the observed error ε_t. In addition to the process transfer polynomials, the control equation contains the polynomials $L_3(B)$, which describes the noise plus signal Z_t in terms of white noise, and $L_4(B)$, which describes the error ε_t in terms of white noise.

Assuming that minimum variance [or minimum mean-square error (MMSE)] control is applied, we have the null model

$$a_{t0} = \frac{1}{L_4(B)} \varepsilon_t \, . \tag{14.19}$$

The discrepancy model is

$$a_t = \frac{1}{L_4(B)} \varepsilon_t - \gamma f(t) \frac{\phi(B)}{\theta(B)} \, . \tag{14.20}$$

(See *Nembhard* and *Valverde-Ventura* [14.24] for a complete derivation of the null and discrepancy models.)

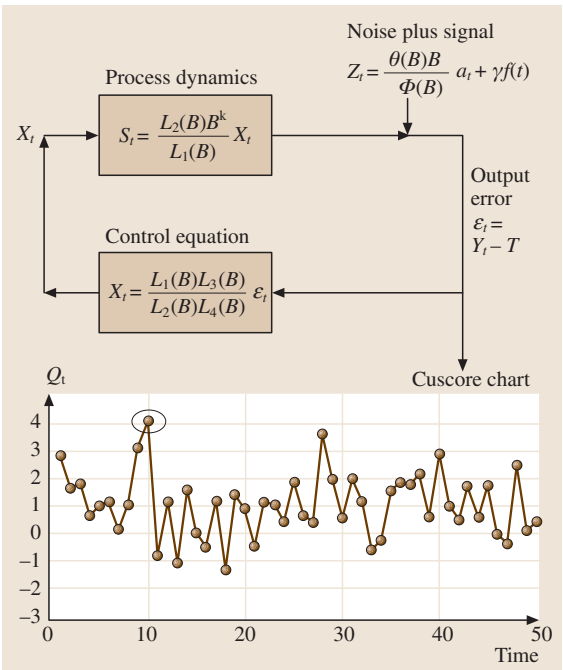

Fig. 14.6 A block diagram showing the input, output, and noise components and the relationship between feedback control and Cuscore monitoring of an anticipated signal

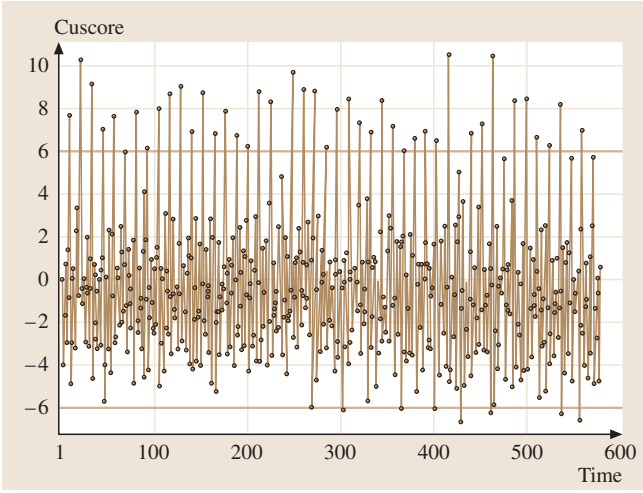

Fig. 14.7 Cuscore chart detects spike signals at every twelfth pleat

Notice that the noise disturbance and signal are assumed to occur after and independently of the process control.

Using (14.20), the detector is

$$d_i = -\left.\frac{\partial a_t}{\partial \gamma}\right|_{\gamma=0} = f(t)\frac{\phi(B)}{\theta(B)} \,. \tag{14.21}$$

Finally, using (14.4), the Cuscore statistic for detecting a signal $f(t)$ hidden in an ARIMA disturbance in an MMSE-controlled process (and omitting the reference value) is given by summing the product of equations (14.19) and (14.21):

$$Q_t = \sum \frac{1}{L_4(B)}\varepsilon_t \frac{\phi(B)}{\theta(B)} f(t) \,. \tag{14.22}$$

For the special case when $k = 1$ (i. e., a responsive system), and the disturbance is white noise, (14.22) simply reduces to the output error, ε_t, which is equivalent to using a Shewhart chart. However, in this pleating and gluing process $k = 2$ and the spike is hidden in an integrated moving-average (IMA) (1, 1) disturbance. The appropriate Cuscore for this case is

$$Q_t = \frac{1}{1+0.84B}\varepsilon_t \,. \tag{14.23}$$

We constructed the Cuscore chart in Fig. 14.7 using (14.23). In this application, during the null operation (i. e., when there is no signal) the Cuscore chart displays observations normally distributed with a mean of zero, and standard deviation $s\sigma_a$. At the moment the spike appears, the corresponding observation belongs to a normal distribution with mean of s^2 and standard deviation of $s\sigma_a$. This mean of s^2 gives the ability for us to observe the spike in the chart.

Note that the Cuscore chart identifies spike signals at pleat numbers 8, 20, 32, etc. In tracking down this problem, it appeared that the printing cylinder used by the supplier to print the fabric was the cause. In that process, the printing consists of passing the fabric over a screen roll with 12 channels. However, one of the twelve stripes had a different width, probably because the printing cylinder was not joined properly at the seam.

14.7 Discussion and Future Work

This chapter focuses on the development and application of Cuscore statistics. Since *Box* and *Ramírez* [14.10,11] presented a design for the Cuscore chart, other work has been done to use them in time series. For example, *Box* and *Luceño* [14.12] suggested monitoring for changes in the parameters of time-series models using Cuscores. *Box* et al. [14.25] and *Ramirez* [14.26] use Cuscores for monitoring industry systems. *Luceño* [14.27] and *Luceño* [14.28] considered average run-length properties for Cuscores with autocorrelated noise. *Shu* et al. [14.20] designed a Cuscore chart that is triggered by a Cusum statistic and uses a generalized likelihood ratio test (GLRT) to estimate the time of occurrence of the signal. These statistical aids help the Cuscore to perform better. *Runger* and *Testik* [14.29] compare the Cuscore and GLRT. *Graves* et al. [14.30] considered a Bayesian approach to incorporating the signal that is in some cases equivalent to the Cuscore. *Harrison* and *Lai* [14.31] develop a sequential probability ratio test (SPRT) that outperforms the Cuscore for the limited cases of data similar to the t-distribution and distributions with inverse polynomial tails.

Although the statistical foundation can be traced back to *Fisher*'s efficient score statistic [14.13], it still needs further development to realize its true potential as a quality engineering tool. Accordingly, *Nembhard* and *Valverde-Ventura* [14.24] developed a framework that may help to guide the development and use of Cuscore statistics in industry applica-

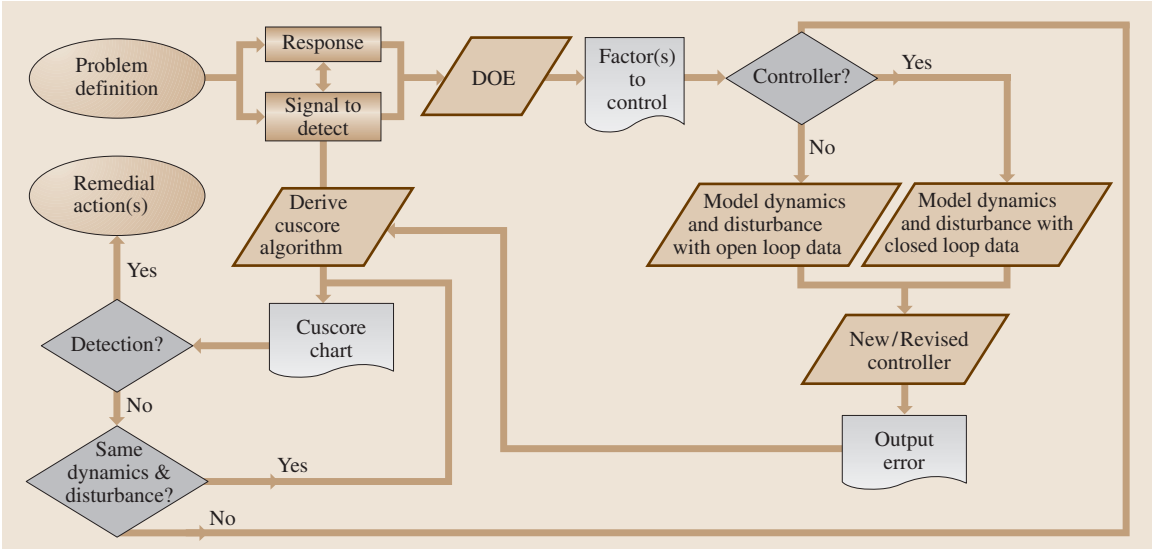

Fig. 14.8 Framework for using Cuscores with DOE and process control

tions, as shown in Fig. 14.8. This framework parallels the define, measure, analyze, improve, and control (DMAIC) approach used in Six Sigma (*Harry* and *Schroeder* [14.32]). The problem-definition step closely parallels the define step in DMAIC. Design of experiments (DOE) helps us to measure and analyze the process, the second two DMAIC steps. From DOE we develop an understanding of the factors to control, so we can then adjust and monitor in keeping with the last two DMAIC steps. The monitoring in this case is accomplished using a Cuscore chart.

The Cuscore is a natural fit with the DMAIC approach as it strives to incorporate what we learn about the problem into the solution. Some consideration needs to be given to the system to establish a clear understanding of the response, the expected signal to be detected, and the relationship between the two. More specifically, for the Cuscore to be applicable we should be able to describe how the signal might modify the response and, therefore, the output error.

This framework also recognizes that in many industrial systems, using only SPC to monitor a process will not be sufficient to achieve acceptable output. Real processes tend to drift away from target, use input material from different suppliers, and are run by operators who may use different techniques. For these and many other reasons, a system of active adjustment using engineering process control (EPC) is often necessary. *Box* and *Jenkins* [14.33] pioneered the integration of SPC and EPC to monitor and adjust industrial processes jointly by demonstrating the interrelationships between adaptive optimization, adaptive quality control, and prediction. *Box* and *Kramer* [14.34] revived the discussion on the complementary roles of SPC and EPC. Since then, many other authors have addressed the joint monitoring and adjustment of industrial processes. *Montgomery* and *Woodall* [14.35] give over 170 references in a discussion paper on statistically based process monitoring and control. Others since include *Shao* [14.36]; *Nembhard* [14.37]; *Nembhard* and *Mastrangelo* [14.38]; *Tsung*, *Shi*, and *Wu* [14.39]; *Tsung* and *Shi* [14.40]; *Ruhhal*, *Runger*, and *Dumitrescu* [14.41]; *Woodall* [14.42]; *Nembhard* [14.43]; *Nembhard*, *Mastrangelo*, and *Kao* [14.44]; and *Nembhard* and *Valverde–Ventura* [14.45]. The texts by *Box* and *Luceño* [14.12] and *del Castillo* [14.46] also address the topic.

In addition to those issues addressed in Sect. 14.5 for autocorrelated data, future work that will further advance the area of Cuscore statistics include their integration with suboptimal controllers, which are often used in practice. There is also a great need to expand the understanding of the robustness of Cuscores to detect signals (other than the one specifically designed for), to develop ways to detect multiple signals then identify or classify them once an out-of-control condition occurs, and to develop multivariate Cuscore detection capabilities.

15. Chain Sampling

A brief introduction to the concept of chain sampling is first presented. The chain sampling plan of type ChSP-1 is first reviewed, and a discussion on the design and application of ChSP-1 plans is then presented in the second section of this chapter. Various extensions of chain sampling plans such as the ChSP-4 plan are discussed in the third part. The representation of the ChSP-1 plan as a two-stage cumulative results criterion plan, and its design are discussed in the fourth part. The fifth section relates to the modification of the ChSP-1 plan. The sixth section of this chapter is on the relationship between chain sampling and deferred sentencing plans. A review of sampling inspection plans that are based on the ideas of chain or dependent sampling or deferred sentencing is also made in this section. The economics of chain sampling when compared to quick switching systems is discussed in the seventh section. The eighth section extends the attribute chain sampling to variables inspection. In the ninth section, chain sampling is then compared with the CUSUM approach. The tenth section gives several other interesting extensions of chain sampling, such as chain sampling for mixed attribute and variables inspection. The final section gives concluding remarks.

Acceptance sampling is the methodology that deals with procedures by which decisions to accept or not accept lots of items are based on the results of the inspection of samples. Special purpose acceptance sampling inspection plans (abbreviated to special purpose plans) are tailored for special applications as against general or universal use. Prof. Harold F. Dodge, who is regarded as the father of acceptance sampling, introduced the idea of chain sampling in his 1959 industrial quality control paper [15.1]. Chain sampling can be viewed as a plan based on a cumulative results criterion (CRC), where related batch information is chained or cumulated. The phrase chain sampling is also used in sample surveys to imply snowball sampling for collection of data. It should be noted that this phrase was originally coined in the acceptance sampling literature, and should be distinguished from its usage in other areas.

Chain sampling is extended to two or more stages of cumulation of inspection results with appropriate acceptance criteria for each stage. The theory of chain sampling is also closely related to the various other methods of sampling inspection such as dependent-deferred sentencing, tightened–normal–tightened (TNT) sampling, quick-switching inspection etc.

In this chapter, we provide an introduction to chain sampling and briefly discuss various generalizations of chain sampling plans. We also review a few sampling plans which are related to or based on the methodology of chain sampling. The selection or design of various chain sampling plans is also briefly presented.

15.1 ChSP-1 Chain Sampling Plan

A single-sampling attributes inspection plan calls for acceptance of a lot under consideration if the number of nonconforming units found in a random sample of size n is less than or equal to the acceptance number Ac. Whenever the operating characteristic (OC) curve of a single-sampling plan is required to pass through a prescribed point, the sample size n will be an increasing function of the acceptance number Ac. This fact can be verified from the table of np or unity values given in *Cameron* [15.2] for various values of the probability of acceptance $P_a(p)$ of the lot under consideration whose fraction of nonconforming units is p. The same result is true when the OC curve has to pass through two predetermined points, usually one at the top and the other at the bottom of the OC curve [15.3]. Thus, for situations where small sample sizes are preferred, only single-sampling plans with $Ac = 0$ are desirable [15.4]. However, as observed by *Dodge* [15.1] and several authors, the $Ac = 0$ plan has a pathological OC curve in that the curve starts to drop rapidly even for a very small increase in the fraction nonconforming. In other words, the OC curve of the $Ac = 0$ plan has no point of inflection. Whenever a sampling plan for costly or destructive testing is required, it is common to force the OC curve to pass through a point, say, (LQL, β) where LQL is the limiting quality level for ensuring consumer protection and β is the associated consumer's risk. All other sampling plans, such as double and multiple sampling plans, will require a larger sample size for a one-point protection such as (LQL, β). Unfortunately the $Ac = 0$ plan has the following two disadvantages:

1. The OC curve of the $Ac = 0$ plan has no point of inflection and hence it starts to drop rapidly even for the smallest increase in the fraction nonconforming p.
2. The producer dislikes an $Ac = 0$ plan since a single occasional nonconformity will call for the rejection of the lot.

The chain sampling plan ChPS-1 by *Dodge* [15.1] is an answer to the question of whether anything can be done to improve the pathological shape of the OC curve of a zero-acceptance-number plan. A production process, when in a state of statistical control, maintains a constant but unknown fraction nonconforming p. If a series of lots formed from such a stable process is submitted for inspection, which is known as a type B situation, then the samples drawn from the submitted lots are simply random samples drawn directly from the production process. So, it is logical to allow a single occasional nonconforming unit in the current sample whenever the evidence of good past quality, as demonstrated by the i preceding samples containing no nonconforming units, is available. Alternatively we can chain or cumulate the results of past lot inspections to take a decision on the current lot without increasing the sample size.

The operating procedure of the chain sampling plan of type ChSP-1 is formally stated below:

1. From each of the lots submitted, draw a random sample of size n and observe the number of nonconforming units d.
2. Accept the lot if d is zero. Reject the lot if $d > 1$. If $d = 1$, the lot is accepted provided all the samples of size n each drawn from the preceding i lots are free from nonconforming units; otherwise reject the lot.

Thus the chain sampling plan has two parameters: n, the sample size, and i, the number of preceding sample results chained for making a decision on the current lot. It is also required that the consumer has confidence in the producer, and the producer will deliberately not pass a poor-quality lot taking advantage of the small samples used and the utilization of preceding samples to take a decision on the current lot.

The ChSP-1 plan always accepts the lot if $d = 0$ and conditionally accepts it if $d = 1$. The probability that the preceding i samples of size n are free from nonconforming units is $P_{0,n}^i$. Hence, the OC function is $P_a(p) = P_{0,n} + P_{1,n} P_{0,n}^i$ where $P_{d,n}$ is the probability of getting d nonconforming units in a sample of size n. Figure 15.1 shows the improvement in the shape of the OC curve of the zero-acceptance-number single-sampling plan by the use of chain sampling. *Clark* [15.5] provided a discussion on the OC curves of chain sampling plans, a modification and some applications. *Liebesman* et al. [15.6] argue in favor of chain sampling as the attribute sampling standards have the deficiency for small or fractional acceptance number sampling plans. The authors also provided the necessary tables and examples for the chain sampling procedures. Most text books on statistical quality control also contain a section on chain sampling, and provide some applications.

Soundararajan [15.7] constructed tables for the selection of chain sampling plans for given acceptable quality level (AQL, denoted as p_1), producer's risk α, LQL (denoted as p_2) and β. The plans found from this source are approximate, and a more accurate procedure that also minimizes the sum of actual producer's and

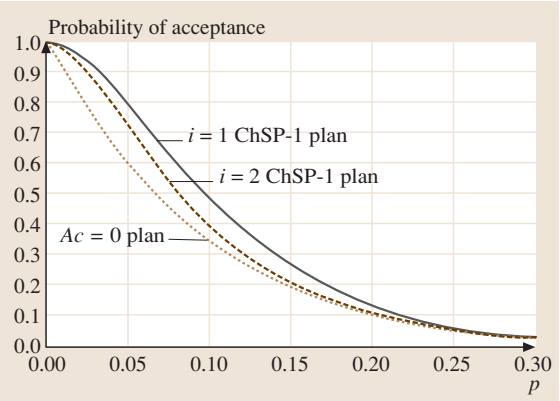

Fig. 15.1 Comparison of OC curves of $Ac = 0$ and ChSP-1 plans

consumer's risks is given by *Govindaraju* [15.8]. Table 15.1, adopted form *Govindaraju* [15.8] is based on the binomial distribution for OC curve of the ChSP-1 plan. This table can also be used to select ChSP-1 plans for given LQL and β only, which may be used in place of zero-acceptance-number plans.

Ohta [15.9] investigated the performance of ChSP-1 plans using the graphical evaluation and review technique (GERT) and derived measures such as OC and average sample number (ASN) for the ChSP-1 plan. *Raju* and *Jothikumar* [15.10] provided a ChSP-1 plan design procedure based on Kullback–Leibler information, and the necessary tables for the selection of the plan. *Govindaraju* [15.11] discussed the design ChSP-1 plan for minimum average total inspection (ATI). There are a number of other sources where the ChSP-1 plan design is discussed. This paper provides additional references on designing chain sampling plans, inter alia, while discussing various extensions and generalizations.

Table 15.1 ChSP-1 plans indexed by AQL and LQL ($\alpha = 0.05$, $\beta = 0.10$) for fraction nonconforming inspection [15.8]. Key $n : i$

LQL	AQL (%)

15.2 Extended Chain Sampling Plans

Frishman [15.12] extended the ChSP-1 plan and developed ChSP-4 and ChSP-4A plans which incorporate a rejection number greater than 1. Both ChSP-4 and ChSP-4A plans are operated like a traditional double-sampling attributes plan but uses $(k-1)$ past lot results instead of actually taking a second sample from the current lot. The following is a compact tabular representation of Frishman's ChSP-4A plan.

Stage	Sample size	Acceptance number	Rejection number
1	n	a	r
2	$(k\text{-}1)n$	a'	$a'+1$

The ChSP-4 plan restricts r to $a'+1$. The conditional double-sampling plans of *Baker* and *Brobst* [15.13], and the partial and full link-sampling plans of *Harishchandra* and *Srivenkataramana* [15.14] are actually particular cases of the ChSP-4A plan when $k = 2$ and $k = 3$ respectively. However the fact that the OC curves of these plans are the same as the ChSP-4A plan is not reported in both papers [15.15].

Extensive tables for the selection of ChSP-4 and ChSP-4A plans were constructed by *Raju* [15.16, 17] and *Raju* and *Murthy* [15.18–21]. *Raju* and *Jothikumar* [15.22] provided a complete summary of various selection procedures for ChSP-4 and ChSP-4A plans,

and also discussed two further types of optimal plans – the first involving minimum risks and the second based on Kullback–Leibler information. Unfortunately, the tables of Raju et al. for the ChSP-4 or ChSP-4A design require the user to specify the acceptance and rejection numbers. This serious design limitation is not an issue with the procedures and computer programs developed by *Vaerst* [15.23] who discussed the design of ChSP-4A plans involving minimum sample sizes for given AQL, α, LQL and β without assuming any specific acceptance numbers. Raju et al. considered a variety of design criteria while *Vaerst* [15.23] discussed only the (AQL, LQL) criterion. The ChSP-4 and ChSP-4A plans obtained from Raju's tables can be used in any type B situation of a series of lots from a stable production process, not necessarily when the product involves costly or destructive testing. This is because the acceptance numbers covered are above zero. The major disadvantage of *Frishman*'s [15.12] extended ChSP-4 and ChSP-4A plans is that the neighboring lot information is not always utilized. Even though ChSP-4 and ChSP-4A plans require smaller sample sizes than the traditional double-sampling plans, these plans may not be economical compared to other conditional sampling plans.

Bagchi [15.24] presented an extension of the ChSP-1 plan, which calls for additional sampling only when one nonconforming unit is found. The operating procedure of Bagchi's plan is given below:

1. At the outset, inspect n_1 units selected randomly from each lot. Accept the lot if all the n_1 units are conforming; otherwise, reject the lot.
2. If i successive lots are accepted, then inspect only $n_2\,(<n_1)$ items from each of the submitted lots. Accept the lot as long as no nonconforming units are found. If two or more nonconforming units are found, reject the lot. In the event of one nonconforming unit being found in n_2 inspected units, then inspect a further sample (n_1-n_2) units from the same lot. Accept the lot under consideration if no further nonconforming units are found in the additional (n_1-n_2) inspected units; otherwise reject the lot.

Representing Bagchi's plan as a Markov chain, *Subramani* and *Govindaraju* [15.25] derived the steady-state OC function and a few other performance measures.

15.3 Two-Stage Chain Sampling

Dodge and *Stephens* [15.26] viewed the chain sampling approach as a cumulative results criterion (CRC) applied in two stages and extended it to include larger acceptance numbers. Their approach calls for the first stage of cumulation of a maximum of k_1 consecutive lot results, during which acceptance is allowed if the maximum allowable nonconforming units is c_1 or less. After passing the first stage of cumulation (i.e. when k_1 consecutive lots are accepted), the second stage of cumulation of $k_2(>k_1)$ lot results begins. In the second stage of cumulation, an acceptance number of $c_2(>c_1)$ is applied. *Stephens* and *Dodge* [15.27] presented a further generalization of the family of two-stage chain sampling inspection plans by using different sample sizes in the two stages. We state below the complete operating procedure of a generalized two-stage chain sampling plan.

1. At the outset, draw a random sample of n_1 units from the first lot. In general, a sample of size $n_j (j=1,2)$ will be taken while operating in the j^{th} stage of cumulation.
2. Record d, the number of nonconforming units in each sample, as well as D, the cumulative number of nonconforming units from the first up to and including the current sample. As long as $D_i \le c_1 (1 \le i \le k_1)$, accept the i^{th} lot.
3. If k_1 consecutive lots are accepted, continue to cumulate the number of nonconforming units D in the k_1 samples plus additional samples up to but no more than k_2 samples. During this second stage of cumulation, accept the lots as long as $D_i \le c_2 (k_1 < i \le k_2)$.
4. After passing the second stage of k_2 lot acceptances, start cumulation as a moving total over k_2 consecutive samples (by adding the current lot result and dropping the k_2^{th} preceding lot result). Continue to accept lots as long as $D_i \le c_2 (i > k_2)$.
5. If, in any stage of sampling, $D_i > c_i$ then reject the lot and return to Step 1 (a fresh restart of the cumulation procedure).

Figure 15.2 shows how the cumulative results criterion is used in a two-stage chain sampling plan when $k_1 = 3$ and $k_2 = 5$.

An important subset of the generalized two-stage chain sampling plan is when $n_1 = n_2$ and this subset is designated as ChSP-(c_1, c_2); there are five parameters:

n, k_1, k_2, c_1, and c_2. The original chain sampling plan ChSP-1 of *Dodge* [15.1] is a further subset of the ChSP-(0, 1) plan with $k_1 = k_2 - 1$. That is, the OC curve of the generalized two-stage chain sampling plan is equivalent to the OC curve of the ChSP-1 plan when $k_1 = k_2 - 1$. *Dodge* and *Stephens* [15.26] derived the OC function of ChSP-(0, 1) plan as

$$P_a(p) = \frac{P_{0,n}\left(1 - P_{0,n}\right) + P_{0,n}^{k_1} P_{1,n}\left(1 - P_{0,n}^{k_2 - k_1}\right)}{1 - P_{0,n} + P_{0,n}^{k_1} P_{1,n}\left(1 - P_{0,n}^{k_2 - k_1}\right)}\,,$$

$$k_2 > k_1\,.$$

As achieved by the ChSP-1 plan, the ChSP-(0,1) plan also overcomes the disadvantages of the zero-acceptance-number plan. Its operating procedure can be succinctly stated as follows:

1. A random sample of size n is taken from each successive lot, and the number of nonconforming units in each sample is recorded, as well as the cumulative number of nonconforming units found so far.
2. Accept the lot associated with each new sample as long as no nonconforming units are found.
3. Once k_1 lots have been accepted, accept subsequent lots as long as the cumulative number of nonconforming units is no greater than one.
4. Once $k_2 > k_1$ lots have been accepted, cumulate the number of nonconforming units over at most k_2 lots, and continue to accept as long as this cumulative number of nonconforming units is one or none.
5. If, at any stage, the cumulative number of nonconforming units becomes greater than one, reject the current lot and return to Step 1.

Procedures and tables for the design of ChSP-(0,1) plan are available in *Soundararajan* and *Govindaraju* [15.28], and *Subramani* and *Govindaraju* [15.29]. *Govindaraju* and *Subramani* [15.30] showed that the choice of $k_1 = k_2 - 1$ is always forced on the parameters of the ChSP-(0,1) plan when a plan is selected for given AQL, α, LQL, and β. That is, a ChSP-1 plan will be sufficient, and one need not opt for a two-stage cumulation of nonconforming units.

In various technical reports from the Statistics Center at Rutgers University (see *Stephens* [15.31] for a list), *Stephens* and *Dodge* formulated the two-stage chain sampling plan as a Markov chain and evaluated its performance. The performance measures considered by them include the steady-state OC function, ASN and average run length (ARL) etc. For comparison of chain sampling plans with the traditional or noncumulative plans, two types of ARLs are used. The first type of ARL, say ARL_1, is the average number of samples to the first rejection after a sudden shift in the process level, say from p_0 to $p_s (> p_0)$. The usual ARL, say ARL_2, is the average number of samples to the first rejection given the stable process level p_0. The difference $(ARL_1 - ARL_2)$ measures the extra lag due to chain sampling. However, this extra lag may be compensated by gains in sampling efficiency, as explained by *Stephens* and *Dodge* [15.32].

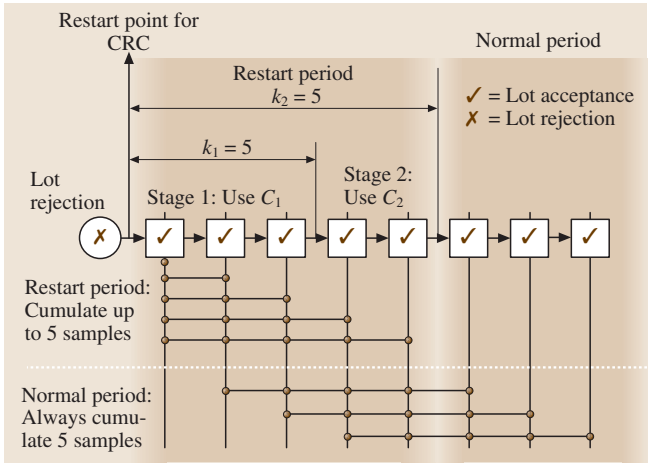

Fig. 15.2 Operation of a two-stage chain sampling plan with $k_1 = 3$ and $k_2 = 5$

Stephens and *Dodge* [15.33] summarized the mathematical approach they have taken to evaluate the performance of some selected two-stage chain sampling plans, while more detailed derivations were published in their technical reports. Based on the expressions for the OC function derived by Stephens and Dodge in their various technical reports (consult *Stephens* [15.31]), *Raju* and *Murthy* [15.34], and *Raju* and *Jothikumar* [15.35] discussed various design procedures for the ChSP-(0,2) and ChSP-(1,2) plans. *Raju* [15.36] extended the two-stage chain sampling to three stages, and evaluated the OC performances of a few selected chain sampling plans, fixing the acceptance numbers for the three stages. The three-stage cumulation procedure becomes very complex, and will play only a limited role for costly or destructive inspections. The three-stage plan will however be useful for general type B lot-by-lot inspections.

15.4 Modified ChSP-1 Plan

In *Dodge*'s [15.1] approach, chaining of past lot results does not always occur. It occurs only when a nonconforming unit is observed in the current sample. This means that the available historical evidence of quality is not fully utilized. *Govindaraju* and *Lai* [15.37] developed a modified chain sampling plan (MChSP-1) that always utilizes the recently available lot-quality history. The operating procedure of the MChSP-1 plan is given below.

1. From each of the submitted lots, draw a random sample of size n. Reject the lot if one or more nonconforming units are found in the sample.
2. Accept the lot if no nonconforming units are found in the sample, provided that the preceding i samples also contained no nonconforming units except in one sample, which may contain at most one nonconforming unit. Otherwise, reject the lot.

A flow chart showing the operation of the MChSP-1 plan is in Fig. 15.3.

The MChSP-1 plan allows a single nonconforming unit in any one of the preceding i samples but the lot under consideration is rejected if the current sample has a nonconforming unit. Thus, the plan gives a psychological protection to the consumer in that it allows acceptance only when all the current sample units are conforming. Allowing one nonconforming unit in any one of the preceding i samples is essential to offer protection to the producer, i.e. to achieve an OC curve with a point of inflection. In the MChSP-1 plan, rejection

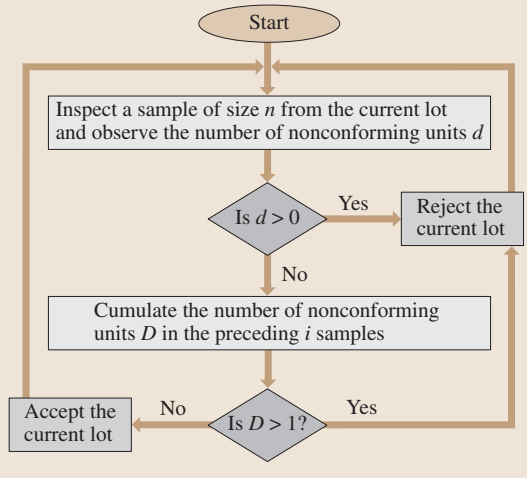

Fig. 15.3 Operation of the MChSP-1 plan

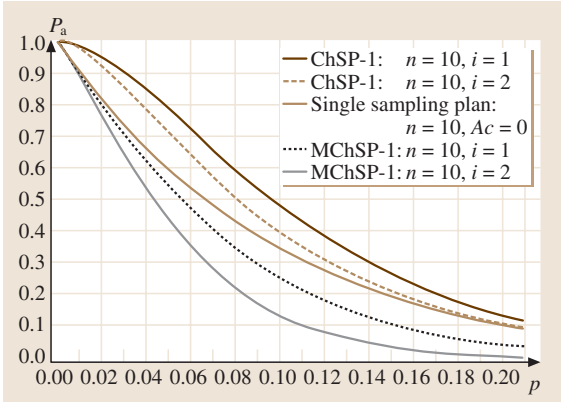

Fig. 15.4 Comparison of OC curves of ChSP-1 and MChSP-1 plans

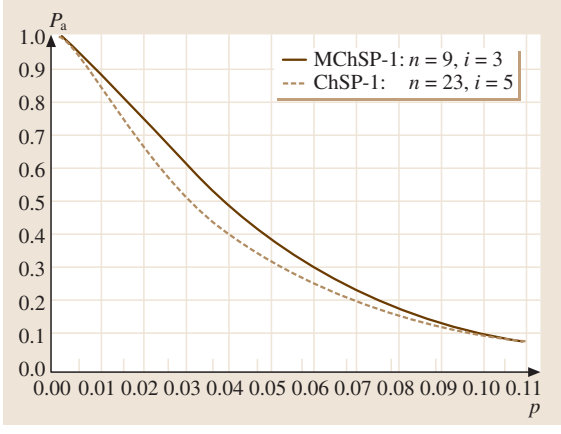

Fig. 15.5 OC curves of matched ChSP-1 and MChSP-1 plans

of lots would occur until the sequence of submissions advances to a stage where two or more nonconforming units were no longer included in the sequence of i samples. In other words, if two or more nonconforming units are found in a single sample, it will result in i subsequent lot rejections. In acceptance sampling, one has to look at the OC curve to have an idea of the protection to the producer as well as to the consumer and what happens in an individual sample or for a few lots is not very important. If two or more nonconforming units are found in a single sample, it does not mean that the subsequent lots need not be inspected since they will be automatically rejected under the proposed plan. It should be noted that results of subsequent lots will be utilized

continuously and the producer has to show an improvement in quality with one or none nonconforming units in the subsequent samples to permit future acceptances. This will act as a strong motivating factor for quality improvement.

The OC function $P_a(p)$ of the MChSP-1 plan was derived by *Govindaraju* and *Lai* [15.37] as $P_a(p) = P_{0,n}(P_{0,n}^i + iP_{0,n}^{i-1}P_{1,n})$. Figure 15.4 compares the OC curves of the ChSP-1 and MChSP-1 plans. From Fig. 15.4, we observe that the MChSP-1 plan decreases the probability of acceptance at poor quality levels but maintains the probability of acceptance at good quality levels when compared to the OC curve of the zero-acceptance-number single-sampling plan. The ChSP-1 plan, on the other hand, increases the probability of acceptance at good quality levels but maintains the probability of acceptance at poor quality levels. To compare the two sampling plans, we need to match them. That is, we need to design sampling plans whose OC curves pass approximately through two prescribed points such as (AQL, 1-α) and (LQL, β). Figure 15.5 gives such a comparison, and establishes that the MChSP-1 plan is efficient in requiring a very small sample size compared to the ChSP-1 plan. A two-stage chain sampling plan would generally require a sample size equal to or more than the sample size of a zero-acceptance single-sampling plan. The MChSP-1 plan will however require a sample size smaller than the zero-acceptance-number plan.

15.5 Chain Sampling and Deferred Sentencing

Like chain sampling plans, there are other plans that use the results of neighboring lots to take a conditional decision of acceptance or rejection. Plans that make use of past lot results are either called chain or dependent sampling plans. Similarly plans that make use of future lot results are known as deferred sentencing plans. These plans have a strategy of accepting the lots conditionally based on the neighboring lot-quality history and are hence referred to as conditional sampling plans. We will briefly review several such conditional sampling plans available in the literature.

In contrast to chain sampling plans, which make use of past lot results, deferred sentencing plans use future lot results. The idea of deferred sentencing was first published in a paper by *Anscombe* et al. [15.38]. The first and simplest type of deferred sentencing scheme [15.38] requires the produced units to be split into small size lots, and one item is selected from each lot for inspection. The lot-sentencing rule is that whenever Y nonconforming units are found out of X or fewer consecutive lots tested, all such clusters of consecutive lots starting from the lot that resulted in the first nonconforming unit to the lot that resulted in the Y^{th} nonconforming unit are rejected. Lots not rejected by this rule are accepted. This rule is further explained in the following sentences. A run of good lots of length X will be accepted at once. If a nonconforming unit occurs, then the lot sentencing or disposition will be deferred until either a further $(X-1)$ lots have been tested or $(Y-1)$ further nonconforming items are found, whichever occurs sooner. At the outset, if the $(X-1)$ succeeding lots result in fewer than $(Y-1)$ nonconforming units, the lot that resulted in the first nonconforming unit and any succeeding lots clear of nonconforming units will be accepted. As soon as Y nonconforming units occur in no more than X lots, all lots not so far sentenced will be rejected. Thus the lot disposition will sometimes be made at once, and sometimes with a delay not exceeding $(X-1)$ lots. Some of the lots to be rejected according to the sentencing rule may already have been rejected through the operation of the rule on a previous cluster of Y nonconforming units that partially overlaps with the cluster being considered. The actual number of new lots rejected under the deferred sentencing rule can be any number from 1 to X. *Anscombe* et al. [15.38] also considered modifications of the above deferred sentencing rule, including inspection of a sample of size more than one from each lot. *Anscombe* et al. [15.38] originally presented their scheme as an alternative to *Dodge*'s [15.39] continuous sampling plan of type CSP-1, which is primarily intended for the partial screening inspection of produced units directly (when lot formation is difficult).

The deferred sentencing idea was formally tailored into an acceptance sampling plan by *Hill* et al. [15.40]. The operating procedure of *Hill* et al. [15.40] scheme is described below:

1. From each lot, select a sample of size n. These lots are accepted as long as no nonconforming units are found in the samples. If one or more nonconforming unit is found, the disposition of the current lot will be deferred until $(X-1)$ succeeding lots are inspected.
2. If the cumulative number of nonconforming units for X consecutive lots is Y or more, then a second sample of size n is taken from each of the lots (beginning with the first lot and ending with the last batch that

showed a nonconforming unit in the sequence of X nonconforming units). If there are less than Y nonconforming units in the X, accept all lots from the first up to, but not including, the next batch that showed a nonconforming unit. The decision on this batch will be deferred until $(X-1)$ succeeding lots are inspected.

Hill et al. [15.40] also evaluated the OC function of some selected schemes and found them to be very economical compared to the traditional sampling plans, including the sequential attribute sampling plan.

Wortham and *Mogg* [15.41] developed a dependent stage sampling (DSSP) plan (DSSP(r, b)), which is operated under steady state as follows:

1. For each lot, draw a sample of size n and observe the number of nonconforming units d.
2. If $d \le r$, accept the lot; if $d > r+b$, reject the lot. If $r+1 \le d \le r+b$, accept the lot if the $(r+b+1-d)^{\text{th}}$ previous lot was accepted; otherwise reject the current lot.

Govindaraju [15.42] observed that the OC function of DSSP(r, b) is the same as the OC function of the repetitive group sampling (RGS) plan of *Sherman* [15.43]. This means that the existing design procedures for the RGS plan can also be used for the design of DSSP(r, b) plan. The deferred state sampling plan of *Wortham* and *Baker* [15.44] has a similar operating procedure except in step 2 in which, when $r+1 \le d \le r+b$, the current lot is accepted if the forthcoming $(r+b+1-d)^{\text{th}}$ lot is accepted. The steady-state OC function of the dependent (deferred) stage sampling plan DSSP(r, b) is given by

$$P_{\text{a}}(p) = \frac{P_{\text{a},r}(p)}{1 - P_{\text{a},r+b}(p) + P_{\text{a},r}(p)}$$

where $P_{\text{a},r}(p)$ is the OC function of the single-sampling plan with acceptance number r and sample size n. Similarly $P_{\text{a},r+b}(p)$ is the OC function of the single-sampling plan with acceptance number $r+b$ and sample size n. A procedure for the determination of the DSSP(r, b) plan for given AQL, α, LQL, and β was also developed by *Vaerst* [15.23].

Wortham and *Baker* [15.45] extended the dependent (deferred) state sampling into a multiple dependent (deferred) state (MDS) plan MDS(r, b, m). The operating procedure of the MDS(r, b, m) plan is given below:

1. For each lot, draw a sample of size n and observe the number of nonconforming units d.
2. If $d \le r$, accept the lot; if $d > r+b$, reject the lot. If $r+1 \le d \le r+b$, accept the lot if the consecutive m preceding lots were all accepted (the consecutive m succeeding lots must be accepted for the deferred MDS(r, b, m) plan).

The steady-state OC function of the MDS(r, b, m) plan is given by the recursive equation

$$P_{\text{a}}(p) = P_{\text{a},r}(p) + \left[P_{\text{a},r+b}(p) + P_{\text{a},r}(p)\right]\left[P_{\text{a}}(p)\right]^m$$

Vaerst [15.46], *Soundararajan* and *Vijayaraghavan* [15.47], *Kuralmani* and *Govindaraju* [15.48], and *Govindaraju* and *Subramani* [15.49] provided detailed tables and procedures for the design of MDS(r, b, m) plans for various requirements.

Vaerst [15.23, 46] modified the MDS(r, b, m) plan to make it on a par with the ChSP-1 plan. The operating procedure of the modified MDS(r, b, m) plan, called MDS-1(r, b, m), is given below:

1. For each lot, draw a sample of size n and observe the number of nonconforming units d.
2. If $d \le r$, accept the lot; if $d > r+b$, reject the lot. If $r+1 \le d \le r+b$, accept the lot if r or fewer nonconforming units are found in each of the consecutive m preceding (succeeding) lots.

When $r=0$, $b=1$, and $m=i$, MDS-1(r, b, m) becomes the ChSP-1 plan. The OC function of the MDS-1(r, b, m) plan is given by the recursive equation

$$P_{\text{a}}(p) = P_{\text{a},r}(p) + \left[P_{\text{a},r+b}(p) + P_{\text{a},r}(p)\right]\left[P_{\text{a},r}(p)\right]^m$$

Vaerst [15.46], *Soundararajan* and *Vijayaraghavan* [15.50], and *Govindaraju* and *Subramani* [15.51] provided detailed tables and procedures for the design of MDS-1(r, b, m) plans for various requirements.

The major and obvious shortcoming of the chain sampling plans is that, since they use sample information from past lots to dispose of the current lot, there is a tendency to reject the current lot of given good quality when the process quality is improving, or to accept the current lot of given bad quality when the process quality is deteriorating. Similar criticisms (in reverse) can be leveled against the deferred sentencing plans. As mentioned earlier, *Stephens* and *Dodge* [15.32] recognizedg this disadvantage of chain sampling and defined the ARL performance measures ARL_1 and ARL_2. Recall that ARL_2 is the average number of lots that will be accepted as a function of the true fraction nonconforming. ARL_1 is the average number of lots accepted after an upward shift in the true fraction nonconforming from the existing level. *Stephens* and *Dodge* [15.52]

evaluated the performance of the two-stage chain sampling plans, comparing the ARLs with matching single- and double-sampling plans having approximately the same OC curve. It was noted that the slightly poorer ARL property due to chaining of lot results is well compensated by the gain in sampling economy. For deferred sentencing schemes, *Hill* et al. [15.40] investigated trends as well as sudden changes in quality. It was found that the deferred sentencing schemes will discriminate better between fairly constant quality at one level and fairly constant quality at another level than will a lot-by-lot plan scheme with the same sample size. However when quality varies considerably from lot to lot, the deferred sentencing scheme was found to operate less satisfactorily, and in certain circumstances the discrimination between good and bad batches may even be worse than for traditional unconditional plans with the same sample size. Furthermore, the deferred sentencing scheme may pose problems of flow, supp1y storage space, and uneven work loads (which is not a problem with chain sampling).

Cox [15.53] provided a more theoretical treatment and considered one-step forward and two-step backward schemes. He represented the lot-sentencing rules as a stochastic process, and applied Bayes's theorem for the sentencing rule. He did recognize the complexity of modeling a multistage procedure. When the submitted lot fraction nonconforming varies, say when a trend exists, both chain and deferred sentencing rules have disadvantages. But this disadvantage can be overcome by combining chain and deferred sentencing rules into a single scheme. This idea was first suggested by *Baker* [15.54] in his dependent deferred state (DDS) plan. *Osanaiye* [15.55] provided a complete methodology of combining chain and deferred sentencing rules, and developed the chain-deferred (ChDP) plan. The ChDP plan has two stages for lot disposition and its operating procedure is given below:

1. From lot number k, inspect n units and count the number of nonconforming units d_k. If $d_k \le c_1$, accept lot number k. If $d_k > c_2$, reject lot numbered k. If $c_1 < d_k \le c_2$, then combine the number of nonconforming units from the immediately succeeding and preceding samples, namely d_{k-1} and d_{k+1}. (Stage 1)
2. If $d_k \le c$, accept the k^{th} lot provided $d_k + d_{k-1} \le c_3$ (chain approach). If $d_k > c$, accept the k^{th} lot provided that $d_k + d_{k+1} \le c_3$ (deferred sentencing).

One possible choice of c is the average of c_1 and $c_3 + 1$. *Osanaiye* [15.55] also provided a comparison of ChDP with the traditional unconditional double-sampling plans as the OC curves of the two types of plans are the same (but the ChDP plan utilizes the neighboring lot results). *Shankar* and *Srivastava* [15.56] and *Shankar* and *Joseph* [15.57] provided a GERT analysis of ChDP plans, following the approach of *Ohta* [15.9]. *Shankar* and *Srivastava* [15.58] discussed the selection of ChDP plans using tables. *Osanaiye* [15.59] provided a multiple-sampling-plan extension of the ChDP plan (called the MChDP plan). MChDP plan uses several neighboring lot results to achieve sampling economy.

Osanaiye [15.60] provided a useful practical discussion on the choice of conditional sampling plans considering autoregressive processes, inert processes (constant process quality shift) and linear trends in quality. Based on a simulation study, it was recommended that the chain-deferred schemes are the cheapest if either the cost of 100% inspection or sampling inspection is high. He recommended the use of the traditional single or double sampling plans only if the opportunity cost of rejected items is very high. *Osanaiye* and *Alebiosu* [15.61] considered the effect of inspection errors on dependent and deferred double-sampling plans vis-a-vis ChDP plans. They observed that the chain-deferred plan in general has a greater tendency to reject nonconforming items than any other plans, irrespective of the magnitude of the inspection error.

Many of the conditional sampling plans, which follow either the approach of chaining or deferring or both, have the same OC curve as a double-sampling (or multiple-sampling) plan. Exploiting this equivalence, *Kuralmani* and *Govindaraju* [15.62] provided a general selection procedure for conditional sampling plans for given AQL and LQL. The plans considered include the conditional double-sampling plan of the ChSP-4A plans of *Frishman* [15.12], the conditional double-sampling plan of *Baker* and *Brobst* [15.13], the link-sampling plan of *Harishchandra* and *Srivenkataramana* [15.14], and the ChDP plan of *Osanaiye* [15.55]. A perusal of the operating ratio LQL/AQL of the tables by *Kuralmani* and *Govindaraju* [15.62] reveals that these conditional sampling plans apply in all type B situations, as a wide range of discrimination between good and bad qualities is provided. However the sample sizes, even though smaller than the traditional unconditional plans, will not be as small as the zero-acceptance-number single-sampling plans. This limits the application of the conditional sampling plans to this special-purpose situation, where the ChSP1 or MChSP-1 plans are most suitable.

Govindaraju [15.63] developed a conditional single-sampling (CSS) plan, which has desirable properties for general applications as well as for costly or destructive

testing. The operating procedure of the CSS plan is as follows.

1. From lot numbered k, select a sample of size n and observe the number of nonconforming units d_k.
2. Cumulate the number of nonconforming units observed for the current lot and the related lots. The related lots will be either past lots, future lots or a combination, depending on whether one is using dependent sampling or deferred sentencing. The lot under consideration is accepted if the total number of nonconforming units in the current lot and the m related lots is less than or equal to the acceptance number, Ac. If d_k is the number of nonconforming units recorded for the k^{th} lot, the rule for the disposition of the k^{th} lot can be stated as:
   a) For dependent or chain single sampling, accept the lot if $d_{k-m} + \cdots + d_{k-1} + d_k \le Ac$; otherwise, reject the lot.
   b) For deferred single sampling, accept the lot if $d_k + d_{k-1} + \cdots + d_{k+m} \le Ac$; otherwise, reject the lot
   c) For dependent-deferred single sampling, where m is desired to be even, accept the lot if $d_{k-\frac{m}{2}} + \cdots + d_k + \cdots + d_{k+\frac{m}{2}} \le Ac$; otherwise, reject the lot.

Thus the CSS plan has three parameters: the sample size n, the acceptance number Ac, and the number of related lot results used, m. As in the case of any dependent sampling procedure, dependent single sampling takes full effect only from the $(m+1)^{\text{st}}$ lot. To maintain equivalent OC protection for the first m lots, an additional sample of mn units can be taken from each lot and the lot be accepted if the total number of nonconforming units is less than or equal to Ac, or additional samples of size $(m+1-i)\,n$ can be taken for the i^{th} lot ($i = 1, 2, \ldots, m$) and the same decision rule be applied. In either case, the results of the additional samples should not be used for lot disposition from lot $(m+1)$. *Govindaraju* [15.63] has shown that the CSS plans require much smaller sample sizes than all other conditional sampling plans. In case of trends in quality, the CSS plan can also be operated as a chain-deferred plan and this will ensure that the changes in lot qualities are somewhat averaged out.

15.6 Comparison of Chain Sampling with Switching Sampling Systems

Dodge [15.64] originally proposed quick-switching sampling (QSS) systems. *Romboski* [15.65] investigated the QSSs and introduced several modifications of the original quick-switching system, which basically consists of two intensities of inspection, say, normal (N) and tightened (T) plans. If a lot is rejected under normal inspection, a switch to tightened inspection will be made; otherwise normal inspection will continue. If a lot is accepted under the tightened inspection, then the normal inspection will be restored; otherwise tightened inspection will be continued. For a review of quick-switching systems, see *Taylor* [15.66] or *Soundararajan* and *Arumainayagam* [15.67].

Taylor [15.66] introduced a new switch number to the original QSS-1 system of *Romboski* [15.65] and compared it with the chain sampling plans. When the sample sizes of normal and tightened plans are equal, the quick-switching systems and the two-stage chain sampling plans were found to give nearly identical performance. Taylor's comparison is only valid for a general situation where acceptance numbers greater than zero are used. For costly or destructive testing, acceptance numbers are kept at zero to achieve minimum sample sizes. In such situations, the chain sampling plans ChSP-1 and ChSP-(0, 1) will fare poorly against other comparable schemes when the incoming quality is at AQL. This fact is explained in the following paragraph using an example.

For costly or destructive testing, a quick-switching system employing zero acceptance number was studied by *Govindaraju* [15.68], and *Soundararajan* and *Arumainayagam* [15.69]. Under this scheme, the normal inspection plan has a sample size of n_{N} units, while the tightened inspection plan has a higher sample size n_{T} $(> n_{\text{N}})$. The acceptance number is kept at zero for both normal and tightened inspection. The switching rule is that a rejection under the normal plan $(n_{\text{N}}, 0)$ will invoke the tightened plan $(n_{\text{T}}, 0)$. An acceptance under the $(n_{\text{T}}, 0)$ plan will revert back to normal inspection. This QSS system, designated as type QSS-$1(n_{\text{N}}, n_{\text{T}}; 0)$, can be used in place of the ChSP-1 and ChSP(0,1) plans. Let AQL $= 1\%$, $\alpha = 5\%$, LQL $= 15\%$, and $\beta = 10\%$. The ChSP-1 plan for the prescribed AQL and LQL conditions is found to be $n = 15$ and $i = 2$ (Table 15.1). The matching QSS-1 system for the prescribed AQL and LQL conditions can be found to be

QSS-1($n_N = 5, n_T = 19$) from the tables given in *Govindaraju* [15.68] or *Kuralmani* and *Govindaraju* [15.70]. At good quality levels, the normal inspection plan will require sampling only five units. Only at poor quality levels, 19 units will be sampled under the QSS system. So, it is obvious that *Dodge*'s [15.1] chain sampling approach is not truly economical at good quality levels but fares well at poor quality levels. However, if the modified chain sampling plan MChSP-1 by *Govindaraju* and *Lai* [15.37] is used, then the sample size needed will only be three units (and i, the number of related lot results to be used, is fixed at seven or eight).

A more general two-plan system having zero acceptance number for the tightened and normal plans was studied by *Calvin* [15.71], *Soundararajan* and *Vijayaraghavan* [15.72], and *Subramani* and *Govindaraju* [15.73]. Calvin's TNT scheme uses zero acceptance numbers for normal and tightened inspection and employs the switching rules of MIL-STD-105 D [15.74], which is also roughly employed in ISO 2859-1:1989 [15.75]. The operating procedure of the TNT scheme, designated TNT (n_N, n_T; $Ac = 0$), is given below:

1. Start with the tightened inspection plan ($n_T, 0$). Switch to normal inspection (Step 2) when t lots in a row are accepted; otherwise continue with the tightened inspection plan.
2. Apply the normal inspection plan ($n_N, 0$). Switch to the tightened plan if a lot rejection is followed by another lot rejection within the next s lots.

Using the tables of *Soundararajan* and *Vijayaraghavan* [15.76], the zero-acceptance-number TNT(n_N, n_T; 0) plan for given AQL = 1%, α = 5%, LQL = 15%, and $\beta = 10\%$ is found to be TNT($n_N = 5, n_T = 16$; $Ac = 0$). We again find that the MChSP-1 plan calls for a smaller sample size when compared to Calvin's zero-acceptance-number TNT plan.

The skip-lot sampling plans of *Dodge* [15.77] and *Perry* [15.78] are based on skipping of sampling inspection of lots on the evidence of good quality history. For a detailed discussion of skip-lot sampling, *Stephens* [15.31] may be consulted. In the skip-lot sampling plan of type SkSP-2 by *Perry* [15.78], once m successive lots are accepted under the reference plan, the chosen reference sampling plan is applied only for a fraction f of the time. *Govindaraju* [15.79] studied the employment of the zero-acceptance-number plan as a reference plan (among several other reference sampling plans) in the skip-lot context. For given AQL = 1%, $\alpha = 5\%$, LQL = 15%, and $\beta = 10\%$, the SkSP-2 plan with a zero-acceptance-number reference plan is found to be $n = 15$ $m = 6$, and $f \simeq 1/5$. Hence the matching ChSP-1 plan $n = 15$ and $i = 2$ is not economical at good quality levels when compared to the SkSP-2 plan $n = 15$, $m = 6$, and $f \simeq 1/5$. This is because the SkSP-2 plan requires the zero-acceptance-number reference plan with a sample size of 15 to be applied only to one in every five lots submitted for inspection once six consecutive lots are accepted under the reference single-sampling plan ($n = 10$, $Ac = 0$). However, the modified MChSP-1 plan is more economical at poor quality levels when compared to the SkSP-2 plan. Both plans require about the same sampling effort at good quality levels.

15.7 Chain Sampling for Variables Inspection

Govindaraju and *Balamurali* [15.80] extended the idea of chain sampling to sampling inspection by variables. This approach is particularly useful when testing is costly or destructive provided the quality variable is measurable on a continuous scale. It is well known that variables plans do call for very low sample sizes when compared to the attribute plans. However not all variables plans possess a satisfactory OC curve, as shown by *Govindaraju* and *Kuralmani* [15.81]. Often, a variables plan is unsatisfactory if the acceptability constant is too large, particularly when the sample size is small. Only in such cases is it necessary to follow the chain sampling approach to improve upon the OC curve of the variables plan. Table 15.2 is useful for deciding whether a given variables sampling plan has a satisfactory OC curve or not. If the acceptability constant k_σ of a known sigma variables plan exceeds $k_{\sigma l}$ then the plan is deemed to have an unsatisfactory OC curve, like an $Ac = 0$ attributes plan.

The operating procedure of the chain sampling plan for variables inspection is as follows:

1. Take a random sample of size n_σ, say $(x_1, x_2, ..., x_{n_\sigma})$ and compute

$$v = \left(\frac{U - \bar{X}}{\sigma}\right), \text{ where } \bar{X} = \frac{1}{n_\sigma}\sum_{i=1}^{n_\sigma} x_i .$$

Table 15.2 Limits for deciding unsatisfactory variables plans

n_σ	$k_{\sigma l}$	n_σ	$k_{\sigma l}$	n_σ	$k_{\sigma l}$	n_σ	$k_{\sigma l}$
1	0	16	2.3642	31	3.3970	46	4.1830
2	0.4458	17	2.4465	32	3.4549	47	4.2302
3	0.7280	18	2.5262	33	3.5119	48	4.2769
4	0.9457	19	2.6034	34	3.5680	49	4.3231
5	1.1278	20	2.6785	35	3.6232	50	4.3688
6	1.2869	21	2.7515	36	3.6776	51	4.4140
7	1.4297	22	2.8227	37	3.7312	52	4.4588
8	1.5603	23	2.8921	38	3.7841	53	4.5032
9	1.6812	24	2.9599	39	3.8362	54	4.5471
10	1.7943	25	3.0262	40	3.8876	55	4.5905
11	1.9009	26	3.0910	41	3.9384	56	4.6336
12	2.0020	27	3.1546	42	3.9885	57	4.6763
13	2.0983	28	3.2169	43	4.0380	58	4.7186
14	2.1904	29	3.2780	44	4.0869	59	4.7605
15	2.2789	30	3.3380	45	4.1352	60	4.8021

2. Accept the lot if $v \geq k_\sigma$ and reject if $v < k'_\sigma$. If $k'_\sigma \leq v < k_\sigma$, accept the lot provided the preceding i lots were accepted on the condition that $v \geq k_\sigma$.

Thus the variables chain sampling plan has four parameters: the sample size n_σ, the acceptability constants k_σ and k'_σ $(< k_\sigma)$, and i, the number of preceding lots used for conditionally accepting the lot. The OC function of this plan is given by $P_a(p) = P_V + (P'_V - P_V)P_V^i$, where $P_V = \Pr(v \geq k_\sigma)$ is the probability of accepting the lot under the variables plan (n_σ, k_σ) and $P'_V = \Pr(v \geq k'_\sigma)$ is the probability of accepting the lot under the variables plan (n_σ, k'_σ). Even though the above operating procedure of the variables chain sampling plan is of general nature, it would be appropriate to fix $k'_\sigma = k_{\sigma l}$. For example, suppose that a variables plan with $n_\sigma = 5$ and $k_\sigma = 2.46$ is currently under use. From Table 15.2, the limit for the undesirable acceptability constant $k_{\sigma l}$ for $n_\sigma = 5$ is obtained as 1.1278. As the actual acceptability constant $k_\sigma (= 2.26)$ is greater than $k_{\sigma l} (= 1.1278)$, the variables plan can be declared to possess an unsatisfactory OC curve. Hence it is desirable to chain the results of neighboring lots to improve upon the shape of the OC curve of the variables plan $n_\sigma = 5$ and $k_\sigma = 2.46$. That is, the variables plan currently under use with $n_\sigma = 5$ and $k_\sigma = 2.46$ will be operated as a chain sampling plan fixing $i = 4$. A more detailed procedure on designing chain sampling for variables inspection, including the case when sigma is unknown, is available in *Govindaraju* and *Balamurali* [15.80]. The chain sampling for variables will be particularly useful when inspection costs are prohibitively high, and the quality characteristic is measurable on a continuous scale.

15.8 Chain Sampling and CUSUM

In this section, we will discuss some of the interesting relationships between the cumulative sum (CUSUM) approach of *Page* [15.82, 83] and the chain sampling approach of *Dodge* [15.1]. The CUSUM approach is largely popular in the area of statistical process control (SPC) but *Page* [15.82] intended it for use in acceptance sampling as well. *Page* [15.82] compares his CUSUM-based inspection scheme with the deferred sentencing schemes of *Anscombe* et al. [15.38], and the continuous sampling plan CSP-1 of *Dodge* [15.39] to evaluate their relative performance. In fact Dodge's CSP-1 plan forms the theoretical basis for his ChSP-1 chain sampling plan. A more formal acceptance sampling scheme based on the one-sided CUSUM for lot-by-lot inspection was proposed by *Beattie* [15.84]. Beattie's plan calls for drawing a random sample of size n from each lot and observing the number of nonconforming units d. For each lot, a CUSUM value is calculated for a given

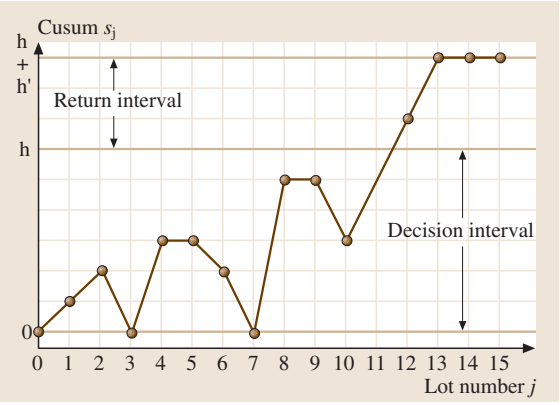

Fig. 15.6 Beattie's CUSUM acceptance sampling plan

slack parameter k. If the computed CUSUM is within the decision interval $(0, h)$, then the lot is accepted. If the CUSUM is within the return interval $(h, h+h')$, then the lot is rejected. If the CUSUM falls below zero, it is reset to zero. Similarly if the CUSUM exceeds $h+h'$, it is reset to $h+h'$. In other words, for the j-th lot, the plotted CUSUM can be succinctly defined as $S_j = \text{Min}\{h+h',\ \text{Max}\{(d_j - k) + S_{j-1}, 0\}\}$ with $S_0 = 0$. Beattie's plan is easily implemented using the typical number of nonconforming units CUSUM chart for lot-by-lot inspection Fig. 15.6. *Prairie* and *Zimmer* [15.85] provided detailed tables and nomographs for the selection of Beattie's CUSUM acceptance sampling plan. An application is also reported in [15.86].

Beattie [15.87] introduced a two-stage semi-continuous plan where the CUSUM approach is followed, and the product is accepted as long as the CUSUM, S_j, is within the decision interval $(0, h)$. For product falling in the return interval $(h, h+h')$, an acceptance sampling plan such as the single- or double-sampling plan is used to dispose of the lots. *Beattie* [15.87] compared the two-stage semi-continuous plan with the ChSP-4A plan of *Frishman* [15.12] and the deferred sentencing scheme of *Hill* et al. [15.40]. Beattie remarked that chain sampling plans (ChSP-4A type) call for a steady rate of sampling and are simple to administer. The two-stage semi-continuous sampling plan achieved some gain in the average sample number at good quality levels, but it is more difficult to administer. The two-stage semi-continuous plan also requires a larger sample size than the ChSP-4A plans when the true quality is poorer than acceptable levels.

We will now explore an interesting equivalence between the ChSP-1 plan, and a CUSUM scheme intended for high-yield or low-fraction-nonconforming production processes for which the traditional p or np control charts are not useful. *Lucas* [15.88] gave a signal rule for lack of statistical control if there are two or more counts within an interval of t samples. In the case of a process with a low fraction nonconforming, this means that, if two or more nonconforming units are observed in any t consecutive samples or less, a signal for an upward shift in the process fraction level is obtained. It should be noted that, if two or more nonconforming units are found even in the same sample, a signal for lack of statistical control will be obtained. *Govindaraju* and *Lai* [15.89] discuss the design of *Lucas*'s [15.88] scheme, and provided a method of obtaining the parameters n (the subgroup or sample size) and t (the maximum number of consecutive samples considered for a signal).

Lucas [15.88] has shown that his signal rule is equivalent to a CUSUM scheme having a reference value k of $1/t$ and decision interval $h = 1$ for detecting an increase in the process count level. It was also shown that a fast initial response (FIR) feature can be added to the CUSUM scheme (see *Lucas* and *Crosier* [15.90]) with an additional sub-rule that signals lack of statistical control if the first count occurs before the t-th sample. This FIR CUSUM scheme has a head start of $S_0 = 1 - k$ with $k = 1/t$ and $h = 1$. Consider the ChSP-1 plan of *Dodge* [15.1], which rejects a lot if two or more counts (of nonconformity or nonconforming units) occur but allows acceptance of the lot if no counts occur or a single count is preceded by t (the symbol i was used before) lots having samples with no counts. If the decision to reject a lot is translated as the decision of declaring the process to be not in statistical control, then it is seen that Lucas's scheme and the ChSP-1 plan are the same. This equivalence will be even clearer if one considers the operation of the two-stage chain sampling plan ChSP(0,1) of *Dodge* and *Stephens* [15.26] given in Sect. 15.3. When $k_2 = k_1 + 1$, the ChSP(0,1) plan is equivalent to the ChSP-1 plan with $t = k_1$. So it can also be noted that the sub-rule of not allowing any count for the first t samples suggested for the FIR CUSUM scheme of *Lucas* [15.88] is an inherent feature of the two-stage chain sampling scheme. This means that the ChSP-1 plan is equivalent to the FIR CUSUM scheme with the head start of $(1-k)$ with $k = 1/t$ and $h = 1$.

15.9 Other Interesting Extensions

Mixed sampling plans are two-phase sampling plans in which both variable quality characteristics and attribute quality measures are used in deciding the acceptance or rejection of the lot. *Baker* and *Thomas* [15.91] reported the application of chain sampling for acceptance testing for armor packages. Their procedure uses chain sampling for testing structural integrity (attributes inspection) while a variables sampling plan is used for testing penetration-depth quality characteristic. The authors also suggested the simultaneous use of control charts along with their proposed acceptance sampling procedures. *Suresh* and *Devaarul* [15.92] proposed a more formal mixed acceptance sampling plan where a chain sampling plan is used for the attribute phase. *Suresh* and *Devaarul* [15.92] also obtained the OC function for their mixed plan, and discussed various selection procedures. To control multidimensional characteristics, *Suresh* and *Devaarul* [15.93] developed multidimensional mixed sampling plans (MDMSP). These plans handles several quality characteristics during the variable phase of the plan, while the attribute sampling phase can be based on chain sampling or other attribute plans.

In some situations it is desirable to adopt three attribute classes, where items are classified into three categories: good, marginal and bad [15.94]. *Shankar* et al. [15.95] developed three-class chain sampling plans and derived various performance measures through the GERT approach and also discussed their design.

Suresh and *Deepa* [15.96] provided a discussion on formulating a chain sampling plan given a prior gamma or beta distribution for product quality. Tables for the selection of the plans and examples are also provided by *Suresh* and *Deepa* [15.96]. This approach will further improve the sampling efficiency of chain sampling plans.

15.10 Concluding Remarks

This chapter largely reviews the methodology of chain sampling for lot-by-lot inspection of quality. Various extensions of the original chain sampling plan ChSP-1 of *Dodge* [15.1] and modifications are briefly reviewed. The chain sampling approach is primarily useful for costly or destructive testing, where small sample sizes are preferred. As chain sampling plans achieve greater sampling economy, these are combined with the approach of deferred sentencing so that the combined plan can be used for any general situation. This chapter does not cover design of chain sampling plans in any great detail. One may consult textbooks such as *Schilling* [15.97] or *Stephens* [15.31,98] for detailed tables. A large number of papers primarily dealing with the design of chain sampling plans are available only in journals, and some of them are listed as references. It is often remarked that designing sampling plans is more of an art than a science. There are statistical, engineering and other administrative aspects to be taken into account for successful implementation of any sampling inspection plan, including chain sampling plans. For example, for administrative and other reasons, the sample size may be fixed. Given this limitation, which sampling plan should be used requires careful consideration. Several candidate sampling plans, including chain sampling plans, must first be sought, and then the selection of a particular type of plan must be made based on performance measures such as the OC curve etc. The effectiveness of the chosen plan or sampling scheme must be monitored over time, and changes made if necessary.

16. Some Statistical Models for the Monitoring of High-Quality Processes

One important application of statistical models in industry is statistical process control. Many control charts have been developed and used in industry. They are easy to use, but have been developed based on statistical principles. However, for today's high-quality processes, traditional control-charting techniques are not applicable in many situations. Research has been going on in the last two decades and new methods have been proposed. This chapter summarizes some of these techniques.

High-quality processes are those with very low defect-occurrence rates. Control charts based on the cumulative count of conforming items are recommended for such processes. The use of such charts has opened up new frontiers in the research and applications of statistical control charts in general. In this chapter, several extended or modified statistical models are described. They are useful when the simple and basic geometric distribution is not appropriate or is insufficient.

In particular, we present some extended Poisson distribution models that can be used for count data with large numbers of zero counts. We also extend the chart to the case of general time-between-event monitoring; such an extension can be useful in service or reliability monitoring.

Traditionally, the exponential distribution is used for the modeling of time-between-events, although other distributions such as the Weibull or gamma distribution can also be used in this context.

Control charting is one of the most widely used statistical techniques in industry for process control and monitoring. It dates back to the 1920s when Walter Shewhart introduced the basic charting techniques in the United States [16.1]. Since then, it has been widely adopted worldwide, mainly in manufacturing and also in service industries. The simplicity of the application procedure allows a non-specialist user to observe the data and plot the control chart for simple decision making. At the same time, it provides sophisticated statistical interpretation in terms of false-alarm probability and average run length, among other important statistical properties associated with decision making based on sample information. The implementation of control charts had helped many companies to focus on important quality issues and problems such as those raised by out-of-control points on a control chart.

However, for high-quality or near-zero-defect processes, traditional Shewhart charts may not be suitable for process monitoring and decision making. This is especially the case for Shewhart attribute charts [16.2]. Many problems such as high false-alarm probability, inability to detect process improvement, unnecessary plotting of many zeros etc., have been identified by various researchers [16.3–6]. To resolve these problems, new models and monitoring techniques have been developed recently.

Traditional charts are all based on the principle of normal distribution and the upper control limit (UCL) and lower control limit (LCL) are routinely computed as the mean plus and minus three times the standard deviation. That is, if the plotted quantity Y has mean μ and standard deviation σ, the control limits are given by

$$\text{UCL} = \mu + 3\sigma \quad \textit{and} \quad \text{LCL} = \mu - 3\sigma \,. \tag{16.1}$$

Generally, when the distribution of Y is skewed, the probability of false alarm, i. e. the probability that a point indicating out-of-control when the process has actually not changed, is different from the nominal value of 0.0027 associated with a truly normal distribution. Note that for attribute charts, the plotted quantities usually follow a binomial or Poisson distribution, and this is far from the normal distribution unless the sample size is very large.

The purpose of this chapter is to review the important models and techniques that can be used to monitor high-quality processes. The procedure based on a general principle of the cumulative count of conforming items is first described; this is then extended to other distributions. The emphasis is on recent developments and also on practical methods that can be used by practitioners.

This chapter is organized as follows. First, the use of probability limits is described. Next, control charts based on monitoring of the cumulative count of conforming items and simple extensions are discussed. Control charts based on the zero-inflated Poisson distribution and generalize Poisson distribution are then presented. These charts are widely discussed in the literature and they are suitable for count or attribute data. For process monitoring, time-between-events monitoring is of growing importance, and we also provide a summary of methods that can be used to monitor process change based on time-between-events data. Typical models are the exponential, Weibull and gamma distribution.

16.1 Use of Exact Probability Limits

For high-quality processes it is important to use probability limits instead of traditional three-sigma limits. This is true when the quality characteristic that is being plotted follows a skewed distribution. For any plotted quality characteristic Y, the probability limits LCL_Y and UCL_Y can be derived as

$$P(X < \text{LCL}_Y) = P(X > \text{UCL}_Y) = \alpha/2 \,, \tag{16.2}$$

where α is the false-alarm probability, i. e., when the process is in control, the probability that the control chart raises an alarm. Assuming that the distribution $F(x)$ is known or has been estimated accurately from the data, the control limits can be computed.

Probability limits are very important for attribute charts as the quality characteristics are usually not normally distributed. If this is the case, the false-alarm probability could be much higher than the nominal value ($\alpha = 0.0027$ for traditional three-sigma limits). *Xie* and *Goh* [16.7] studied the exact probability limits calculated from the binomial distribution and the Poisson distribution applied for the *np* chart and the *c* chart.

For control-chart monitoring the number of nonconforming items in samples of size n, assuming that the process fraction nonconforming is p, the probability that there are exactly k nonconforming items in the sample is

$$P(X = k) = \binom{n}{k} p^k (1-p)^{n-k} \,, \quad k = 0, 1, \ldots n \tag{16.3}$$

and the probability limits can be computed as

$$P(X \leqslant \text{LCL}) = \sum_{i=0}^{\text{LCL}} \binom{n}{i} p^i (1-p)^{n-i} = \frac{\alpha}{2} \tag{16.4}$$

and

$$P(X \leqslant \text{UCL}) = \sum_{i=0}^{\text{UCL}} \binom{n}{i} p^i (1-p)^{n-i} = 1 - \frac{\alpha}{2} \,. \tag{16.5}$$

As discussed, probability limits can be computed for any distributions, and should be used when the distribution is skewed. This will form the basis of the following discussion in this chapter. In some cases, although the solution is analytically intractable, they can be obtained with computer programs. It is advisable that probability limits be used unless the normality test indicates that deviation from normal distribution is not significant.

16.2 Control Charts Based on Cumulative Count of Conforming Items

High-quality processes are usually characterized by low defective rates. In a near-zero-defect manufacturing environment, items are commonly produced and inspected one-by-one, sometimes automatically. We can record and use the cumulative count of conforming items produced before a nonconforming item is detected. This technique has been intensively studied in recent years.

16.2.1 CCC Chart Based on Geometric Distribution

The idea of tracking cumulative count of conforming (CCC) items to detect the onset of assignable causes in an automated (high-quality) manufacturing environment was first introduced in [16.3]. *Goh* [16.4] further developed this idea into what is known as the CCC charting technique. Some related discussions and further studies can be found in [16.8–14], among others. *Xie* et al. [16.15] provided extensive coverage of this charting technique and further analysis of this procedure.

For a process with a defective rate of p, the cumulative count of conforming items before the appearance of a nonconforming item, Y, follows a geometric distribution. This is given by

$$P(Y = n) = (1 - p)^{n-1} p, \quad n = 1, 2, \ldots . \tag{16.6}$$

The cumulative probability function of count Y is given by

$$P(Y \leqslant n) = \sum_{i=1}^{n} (1 - p)^{i-1} p = 1 - (1 - p)^n . \tag{16.7}$$

Assuming that the acceptable false-alarm probability is α, the probability limits for the CCC chart are obtained as

$$\mathrm{UCL} = \ln(\alpha/2)/\ln(1 - p) \tag{16.8}$$

and

$$\mathrm{LCL} = \ln(1 - \alpha/2)/\ln(1 - p) \tag{16.9}$$

Usually the center line (CL) is computed as

$$\mathrm{CL} = \ln(1/2)/\ln(1 - p) . \tag{16.10}$$

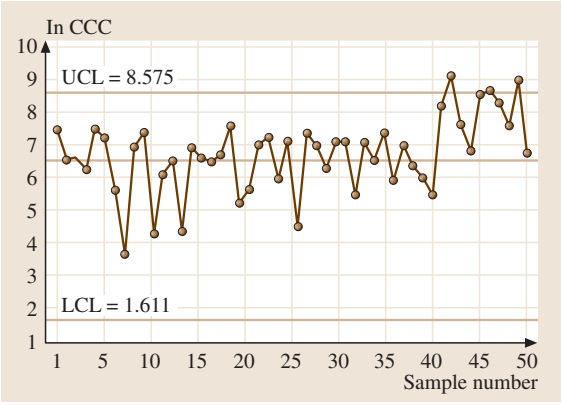

Fig. 16.1 A typical cumulative count of conforming (CCC) items chart

A typical CCC chart is shown in Fig. 16.1 The first 40 data points are simulated with $p = 0.001$ and the last one was simulated with $p = 0.0002$. The value of α is set to be 0.01 for the calculation of control limits. Note that we have also used a log scale for CCC.

Note that the decision rule is different from that of the traditional p or np chart. If a point is plotted above the UCL, the process is considered to have improved. When a point falls below the LCL, the process is judged to have deteriorated. An important advantage is that the CCC chart can detect not only the increase in the defective rate (process deterioration), but also the decrease in the defective rate (process improvement).

16.2.2 CCC-r Chart Based on Negative Binomial Distribution

A simple idea to generalize a CCC chart is to consider plotting of the cumulative count of items inspected until observing two nonconforming items. This was studied in [16.16] resulting in the CCC-2 control chart. This chart increases the sensitivity of the original CCC chart for the detection of small process shifts in p. The CCC-2 chart has smaller type II error, which is related to chart sensitivity, and steeper OC (Operating Characteristic) curves than the CCC chart with the same type I, error which is the false alarm probability.

A CCC-r chart [16.17,18] plots the cumulative count of items inspected until r nonconforming items are observed. This will further improve the sensitivity and detect small changes faster. However, it requires more

counts to be cumulated in order to generate an alarm signal. The CCC-r charting technique was also studied by *Lu* et al. [16.17].

Let Y be the cumulative count of items inspected until r nonconforming items have been observed. Let the probability of an item to be nonconforming be p. Then Y follows a negative binomial distribution given by

$$P(Y=n)=\binom{n-1}{r-1}p^r(1-p)^{n-r}\,,\quad n=r,r+1,\ldots\,. \tag{16.11}$$

The cumulative distribution function of count Y would be

$$\begin{aligned}F(n,r,p)&=\sum_{i=r}^{n}P(Y=i)\\&=\sum_{i=r}^{n}\binom{i-1}{r-1}p^r(1-p)^{i-r}\,.\end{aligned} \tag{16.12}$$

If the acceptable false-alarm probability is α, then the upper control limit and the lower control limit, UCL_r and LCL_r, respectively, of the CCC$-r$ chart can be obtained as the solution of the following equations:

$$\begin{aligned}F(\mathrm{UCL}_r,r,p)&=\sum_{i=r}^{\mathrm{UCL}_r}\binom{i-1}{r-1}p^r(1-p)^{i-r}\\&=1-\alpha/2\end{aligned} \tag{16.13}$$

and

$$F(\mathrm{LCL}_r,r,p)=\sum_{i=r}^{\mathrm{LCL}_r}\binom{i-1}{r-1}p^r(1-p)^{i-r}=\alpha/2\,. \tag{16.14}$$

Note that this chart is suitable for one-by-one inspection process and so no subjective sample size is needed. On the other hand, the selection of r is a subjective issue if the cost involved is not a consideration. As the value of r increases the sensitivity of the chart may increase, but the user probably needs to wait too long to plot a point. *Ohta* et al. [16.18] addressed this issue from an economic design perspective and proposed a simplified design method to select a suitable value of r based on the economic design method for control charts that monitor discrete quality characteristics.

16.3 Generalization of the *c*-Chart

The c-chart is based on monitoring of the number of defects in a sample. Traditionally, the number of defect in a sample follows the Poisson distribution. The control limits are computed as

$$\mathrm{UCL}=c+3\sqrt{c}\quad\text{and}\quad\mathrm{LCL}=c-3\sqrt{c}\,, \tag{16.15}$$

where c is the average number of defects in the sample and the LCL is set to be zero when the value computed with (16.15) is negative.

However, for high-quality processes, it has been shown that these limits may not be appropriate. Some extensions of this chart are described in this section.

16.3.1 Charts Based on the Zero-Inflated Poisson Distribution

In a near-zero-defect manufacturing environment, many samples will have no defects. However, for those containing defects, we have observed that there could be many defects in a sample and hence the data has an over-dispersion pattern relative to the Poisson distribution. To overcome this problem, a generalization of Poisson distribution was used in [16.6, 19].

This distribution is commonly called the zero-inflated Poisson distribution. Let Y be the number of defects in a sample; the probability mass function is given by

$$\begin{cases}P(Y=0)=(1-p)+p\,\mathrm{e}^{-\lambda}\\P(Y=d)=p\frac{\lambda^d\mathrm{e}^{-\lambda}}{d!}\quad d=1,2,\ldots\,.\end{cases} \tag{16.16}$$

This has an interesting interpretation. The process is basically zero-defect although it is affected by causes that lead to one or more defects. If the occurrence of these causes is p, and the severity is λ, then the number of defects in the sample will follow a zero-inflated Poisson distribution.

When the zero-inflated Poisson distribution provides a good fit to the data, two types of control charts can be applied. One is the exact probability limits control chart, and the other is the CCC chart. When implementing the exact probability limits chart, *Xie* and *Goh* [16.6] suggested that only the upper control limit n_u should be considered, since the process is in a near-zero-defect manufacturing environment and the probability of zero is usually very large. The upper control limit can be

determined by:

$$\sum_{d=n_u}^{\infty} p\frac{\lambda^d e^{-\lambda}}{d!} \le \alpha\,, \tag{16.17}$$

where α is the probability of the type I error. It should be noticed that n_u could easily be solved because it takes only discrete values.

Control charts based on the zero-inflated Poisson distribution commonly have better performance in the near-zero-defect manufacturing environment. However, the control procedure is more complicated than the traditional methods since more effort is required to test the suitability of this model with more parameters.

For the zero-inflation Poisson distribution we have that [16.20]

$$E(Y) = p\lambda \tag{16.18}$$

and

$$\mathrm{Var}(Y) = p\lambda + p\lambda(\mu - p\lambda)\,. \tag{16.19}$$

It should be pointed out that the zero-inflation Poisson model is very easy to use, as the mean and variance are of close form. For example, the moment estimates can be obtained straightforward. On the other hand, the maximum-likelihood estimates can also be obtained.

The maximum-likelihood estimates can be obtained by solving

$$\begin{cases} p = \dfrac{1 - n_0/n}{1 - \exp(-\lambda)} \\ \lambda = \bar{y}/p \end{cases}, \tag{16.20}$$

where $\bar{y} = \sum_{i=1}^{n} y_i/n$, [16.20].

When the count data can be fitted by a zero-inflation Poisson model, statistical process control procedures can be modified. Usually, the lower control limit for zero-inflation Poisson model will not exist, because the probability of zero is larger than the predetermined type I error level. This is common for the attribute control chart. In the following section, the upper control limit will be studied.

The upper control limit n_u for a control chart based on the number of nonconformities can be obtained as the smallest integer solution of the following equation:

$$P(n_u \text{ or more nonconformities in a sample}) \leqslant \alpha_L\,, \tag{16.21}$$

where α_L is the predetermined false-alarm probability for the upper control limit n_u.

Here our focus is on data modeling with appropriate distribution. It can be noted that the model contains two parameters. To be able to monitor the change in each parameter, a single chart may no be appropriate. *Xie* and *Goh* [16.6] developed a procedure for the monitoring of individual parameter. First, a CCC chart is used for data with zero count. Second, a *c*-chart is used for those with one or more non-zero count.

Note that a useful model should have practical interpretations. In this case, p is the occurrence probability of problem in the process, and λ measures the severity of the problem when it occurs. Hence it is a useful model and important to be able to monitor each of these parameters, so that any change from normal behavior can be identified.

Example 1

An example is used here for illustration [16.2]. The data set used in Table 16.1 is the read–write errors discovered in a computer hard disk in a manufacturing process.

For the data set in Table 16.1, it can be seen that it contains many samples with no nonconformities. From the data set, the maximum-likelihood estimates are $\hat{p} = 0.1346$ and $\hat{\mu} = 8.6413$. The overall zero-inflation

Table 16.1 A set of defect count data

0	0	0	0	0	0	0	0	0	0	0	0	1	0	0	0	0	6	0	9
11	0	1	2	0	0	0	0	0	0	0	0	3	3	0	0	5	0	15	6
0	0	0	4	2	0	0	0	1	1	0	1	0	0	0	0	0	0	0	0
0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
75	0	0	0	0	75	0	0	0	0	0	0	0	0	0	0	0	0	0	0
0	0	0	2	0	0	0	0	0	0	0	0	0	0	0	0	0	1	0	0
0	0	0	0	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0
0	1	0	0	1	0	0	0	0	0	0	0	0	0	0	0	0	0	9	0
0	2	0	0	0	0	0	0	0	0	0	0	1	0	0	0	0	0	0	0
0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	2	0
0	0	1	0	0	0	0	0												

Poisson model for the data set is

$$f(y) = \begin{cases} 1 - 0.1346 + 0.1346\exp(-8.6413)\,, \\ \quad \text{if } y = 0\,, \\ 0.1346\frac{8.6413^y \exp(-8.6413)}{y!}\,, \\ \quad \text{if } y > 0\,. \end{cases} \tag{16.22}$$

For the data set in Table 16.1, it can be calculated that the upper control limit is 14 at an acceptable false-alarm rate of 0.01. This means that there should not be any alarm for values less than or equal to 14 when the underlying distribution model is a zero-inflated Poisson distribution.

16.3.2 Chart Based on the Generalized Poisson Distribution

The generalized Poisson distribution is another useful model that extends the traditional Poisson distribution, which only has one parameter. A two-parameter model is usually much more flexible and able to model different types of data sets. Since in the situation of over-dispersion or under-dispersion the Poisson distribution is no longer preferable as it must have equal mean and variance, the generalized Poisson distribution [16.21] can be used.

This distribution has two parameters (θ, λ) and the probability mass function is defined as

$$P_X(\theta, \lambda) = \frac{\theta(\theta + x\lambda)^{x-1}\,\mathrm{e}^{-\theta - x\lambda}}{x!}, \quad x = 0, 1, 2\ldots\,, \tag{16.23}$$

where $\lambda, \theta > 0$.

For the generalized Poisson distribution we have that [16.21]

$$E(X) = \theta(1-\lambda)^{-1} \tag{16.24}$$

and

$$\mathrm{Var}(X) = \theta(1-\lambda)^{-3}\,. \tag{16.25}$$

It should be pointed out that the generalized Poisson distribution model is very easy to use as both the mean and variance are of closed form. For example, the moment estimates can easily be calculated. On the other hand, the maximum-likelihood estimates can also be obtained straightforwardly. Consider a set of observations $\{X_1, X_2, \ldots, X_n\}$ with sample size n, the maximum-likelihood estimation $(\hat{\theta}, \hat{\lambda})$ can be obtained by solving

$$\begin{cases} \sum_{i=1}^{n} \frac{x_i(x_i - 1)}{\bar{x} + (x_i - \bar{x})\hat{\lambda}} - n\bar{x} = 0\,, \\ \hat{\theta} = \bar{x}(1 - \hat{\lambda})\,. \end{cases} \tag{16.26}$$

Here a similar approach as for the zero-inflated Poisson model can be used. One could also developed two charts for practical monitoring. One chart can be used to monitor the severity and another to monitor the dispersion or variability in terms of the occurrence of defects.

Example 2

The data in Table 16.1 can also be modeled with a generalized Poisson distribution. Based on the data, the maximum-likelihood estimates can be computed as $\hat{\theta} = 0.144297$ and $\hat{\lambda} = 0.875977$. The overall generalized Poisson distribution model for the data set is

$$f(x) = \frac{0.144297(0.144297 + 0.875977x)^{x-1}}{x!} \times \frac{\mathrm{e}^{-0.144297 - 0.875977x}}{x!}, \quad x = 0, 1, 2\ldots\,. \tag{16.27}$$

With this model, it can be calculated that the upper control limit is 26 at a false-alarm rate of 0.01. This means that there should not be any alarm for the values less than or equal to 26 when the underlying distribution model is the generalized Poisson distribution. It should be mentioned here that, for this data set, both models can fit the data well, and the traditional Poisson distribution is rejected by statistical tests.

16.4 Control Charts for the Monitoring of Time-Between-Events

Chan et al. [16.22] proposed a charting method called the cumulative quantity control chart (CQC chart). Suppose that defects in a process are observed according to a Poisson process with mean rate of occurrence equal to λ (>0). Then the number of units Q required to observe exactly one defect is an exponential random variable. The control chart for Q can be constructed to monitor possible shifts of λ in the process, which is the CQC chart.

The CQC chart has several advantages. It can be used for low-defective-rate processes as well as moderate-defective-rate processes. When the process defect rate

is low or moderate, the CQC chart does not have the shortcoming of showing up frequent false alarms. Furthermore, the CQC chart does not require rational grouping of samples. The data required is the time between defects or defective items. This type of data is commonly available in equipment and process monitoring for production and maintenance.

When process failures can be described by a Poisson process, the time between failures will be exponential and the same procedure can be used in reliability monitoring. Here we briefly describe the procedure for this type of monitoring. Since time is our preliminary concern, the control chart will be termed a t-chart in this paper. This is in line with the traditional c-chart or u-chart, to which our t-chart may be a more suitable alternative. In fact, the notation also makes it easier for the extension to be discussed later.

16.4.1 CQC Chart Based on the Exponential Distribution

The distribution function of the exponential distribution with parameter λ is given by

$$F(t;\lambda) = 1 - \mathrm{e}^{-\lambda t}, \quad t \geqslant 0\,. \tag{16.28}$$

The control limits for t-chart are defined in such a manner that the process is considered to be out of control when the time to observe exactly one failure is less than the lower control limit (LCL), T_{L}, or greater than the upper control limit (UCL), T_{U}. When the behavior of the process is normal, there is a chance for this to happen and it is commonly known as a false alarm. The traditional false-alarm probability is set to be 0.27%, although any other false-alarm probability can be used. The actual acceptable false-alarm probability should in fact depend on the actual product or process. Assuming an acceptable probability for false alarms of α, the control limits can be obtained from the exponential distribution as:

$$T_{\mathrm{L}} = \lambda^{-1} \ln \frac{1}{1-\alpha/2} \tag{16.29}$$

and

$$T_{\mathrm{U}} = \lambda^{-1} \ln \frac{2}{\alpha}\,. \tag{16.30}$$

The median of the distribution is the center line (CL), T_{C}, and it can be computed as

$$T_{\mathrm{C}} = \lambda^{-1} \ln 2 = 0.693\lambda^{-1}\,. \tag{16.31}$$

These control limits can then be utilized to monitor the failure times of components. After each failure the time can be plotted on the chart. If the plotted point falls between the calculated control limits, this indicates that the process is in the state of statistical control and no action is warranted. If the point falls above the upper control limit, this indicates that the process average, or the failure occurrence rate, may have decreased, resulting in an increase in the time between failures. This is an important indication of possible process improvement. If this happens the management should look for possible causes for this improvement and if the causes are discovered then action should be taken to maintain them. If the plotted point falls below the lower control limit, this indicates that the process average, or the failure occurrence rate, may have increased, resulting in a decrease in the failure time. This means that the process may have deteriorated and thus actions should be taken to identify and remove them.

In either case the people involved can know when the reliability of the system has changed and by a proper follow-up they can maintain and improve the reliability. Another advantage of using the control chart is that it informs the maintenance crew when to leave the process alone, thus saving time and resources.

16.4.2 Chart Based on the Weibull Distribution

It is well known that the lifetime distribution of many components follows a Weibull distribution [16.23]. Hence when monitoring reliability or equipment failure, this distribution has been shown to be very useful. The Weibull distribution function is given as

$$F(t) = 1 - \exp\left[-\left(\frac{t}{\theta}\right)^{\beta}\right], \quad t \geq 0\,, \tag{16.32}$$

where $\theta > 0$ and $\beta > 0$ are the so called scale parameter and shape parameter, respectively.

The Weibull distribution is a generalization of exponential distribution, which is recovered for $\beta = 1$. Although the exponential distribution has been widely used for times-between-event, Weibull distribution is more suitable as it is more flexible and is able to deal with different types of aging phenomenon in reliability. Hence in reliability monitoring of equipment failures, the Weibull distribution is a good alternative.

A process can be monitored with a control chart and the time-between-events can be used. For the Weibull distribution, the control limits can be calculated as:

$$\mathrm{UCL} = \theta_0 \left[\ln\left(\frac{2}{\alpha}\right)\right]^{1/\beta_0} \tag{16.33}$$

and

$$\mathrm{LCL} = \theta_0 \left[\ln\left(\frac{2}{2-\alpha}\right)\right]^{1/\beta_0} , \qquad (16.34)$$

where α is the acceptable false-alarm probability, and β_0 and θ_0 are the in-control shape and scale parameter, respectively. Generally, the false-alarm probability is fixed at $\alpha = 0.0027$, which is equivalent to the three-sigma limits for an X-bar chart under the normal-distribution assumption.

The center line can be defined as

$$\mathrm{CL} = \theta_0 \, [\ln 2]^{1/\beta_0} . \qquad (16.35)$$

Xie et al. [16.24] carried out some detailed analysis of this procedure. Since this model has two parameters, a single chart may not be able to identify changes in a parameter. However, since in a reliability context, it is unlikely that the shape parameter will change and it is the scale parameter that could be affected by ageing or wear, a control chart as shown in Fig. 16.2 can be useful in reliability monitoring.

16.4.3 General *t*-Chart

In general, to model time-between-events, any distribution for positive random variables could be used. Which distribution is used should depend on the actual data, with the exponential, Weibull and Gamma being the most common distributions. However, these distributions are usually very skewed. The best approach is to use probability limits. It is also possible to use a transformation so that the data is transformed to near-normality, so that traditional chart for individual data can be used; such charting procedure is commonly available in statistical process control (SPC) software.

In general, if the variable Y follows the distribution $F(t)$, the probability limits can be computed as usual, that is:

$$F(\mathrm{LCL}_Y) = 1 - F(\mathrm{UCL}_Y) = \alpha/2 , \qquad (16.36)$$

where α is the fixed false-alarm rate. This is an approach that summarizes the specific cases described earlier. However, it is important to be able to identify the distribution to be used.

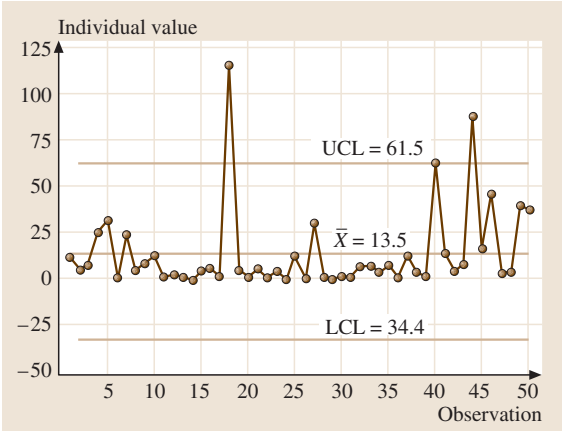

Fig. 16.2 A set of Weibull data and the plot

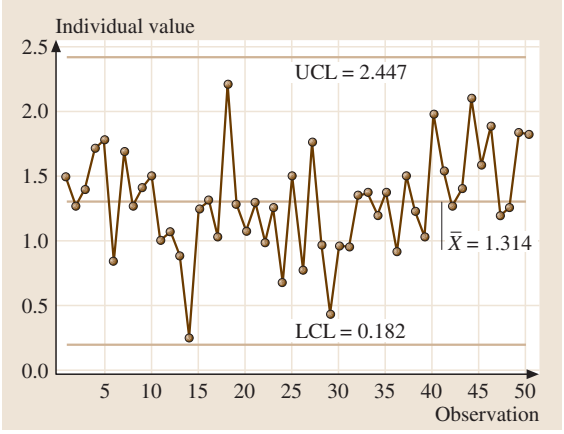

Fig. 16.3 The same data set as in Fig. 16.2 with the plot of the Box–Cox transformation

Furthermore, to make better use of the traditional monitoring approach, we could use a simple normality transformation. The most common ones are the Box–Cox transformation and the log or power transformations. They can be easily realized in software such as MINITAB. Figure 16.2 shows a chart for a Weibull-distributed process characteristic and Fig. 16.3 shows the individual chart with a Box–Cox transformation.

16.5 Discussion

In this chapter, some effective control-charting techniques are described. the statistical monitoring technique should be tailored to the specific distribution of the data that are collected from the process. Perfunctory use of

the traditional chart will not help much in today's manufacturing environment towards near-zero-defect process. For high-quality processes, it is more appropriate to monitor items inspected between two nonconforming items or the time between two events.

The focus in this article is to highlight some common statistical distributions for process monitoring. Several statistical models such as the geometric, negative binomial, zero-inflated Poisson, and generalized Poisson can be used for count-data monitoring in this context. The exponential, Weibull and Gamma distributions can be used to monitor time-between-events data, which is common in reliability or equipment failure monitoring. Other general distributions of time-between-events can also be used when appropriate. The approach is still simple: by computing the probability limits for a fixed false-alarm probability, any distribution can be used in a similar way. The simple procedure is summarized below:

Step 1. Study the process and identify the statistical distribution for the process characteristic;

Step 2. Collect data and estimate the parameters (and validate the model, if needed);

Step 3. Compute the probability limits or use an appropriate normality transformation with an individual chart;

Step 4. Identify any assignable cause and take appropriate action.

The distributions presented in this paper open the door to further implementation of statistical process control techniques in a near-zero-defect era. Several research issues remain. For example, the problem with correlated data and the estimation problem has to be studied. In a high-quality environment, failure or defect data is rare, and the estimation problem becomes serious. In the case of continuous production and measurement, data correlation also becomes an important issue. It is possible to extend the approach to consider the exponentially weighted moving-average (EWMA) or cumulative-sum (CUSUM) charts that are widely advocated by statisticians. A further area of importance is multivariate quality characteristics. However, a good balance between statistical performance and ease of implementation and understanding by practitioners is essential.

17. Monitoring Process Variability Using EWMA

During the last decade, the use of the exponentially weighted moving average (EWMA) statistic as a process-monitoring tool has become more and more popular in the statistical process-control field. If the properties and design strategies of the EWMA control chart for the mean have been thoroughly investigated, the use of the EWMA as a tool for monitoring process variability has received little attention in the literature. The goal of this chapter is to present some recent innovative EWMA-type control charts for the monitoring of process variability (i. e. the sample variance, sample standard-deviation and the range). In the first section of this chapter, the definition of an EWMA sequence and its main properties will be presented together with the commonly used procedures for the numerical computation of the average run length (ARL). The second section will be dedicated to the use of the EWMA as a monitoring tool for the process position, i. e. sample mean and sample median. In the third section, the use of the EWMA for monitoring the sample variance, sample standard deviation and the range will be presented, assuming a fixed sampling interval (FSI) strategy. Finally, in the fourth section of this chapter, the variable sampling interval adaptive version of the EWMA-S^2 and EWMA-R control charts will be presented.

During the last decade, the use of the exponentially weighted moving average (EWMA) statistic as a process monitoring tool has become increasingly popular in the field of statistical process control (SPC). If the properties and design strategies of the EWMA control chart for the mean (introduced by *Roberts* [17.1]) have been thoroughly investigated by *Robinson* and *Ho* [17.2], *Crowder* [17.3] [17.4], *Lucas* and *Saccucci* [17.5] and *Steiner* [17.6], the use of the EWMA as a tool for monitoring the process variability has received little attention in the literature. Some exceptions are the papers by *Wortham* and *Ringer* [17.7], *Sweet* [17.8], *Ng* and *Case* [17.9], *Crowder* and *Hamilton* [17.10], *Hamilton* and *Crowder* [17.11] and *MacGregor* and *Harris* [17.12], *Gan* [17.13], *Amin* et al. [17.14], *Lu* and *Reynolds* [17.15], *Acosta-Mejia* et al. [17.16] and *Castagliola* [17.17]. The goal of this chapter is to present some recent innovative EWMA-type control charts for the monitoring of process variability (i. e. the sample variance, sample standard deviation and the range). From an industrial perspective, the potential of EWMA charts is important. Since their pioneer applications, these charts have proved highly sensitivity in the detection of small shifts in the monitored process parameter, due to the structure of the plotted EWMA statistic, which takes into account the past history of the process at each

sampling time: this allowed them to be considered as valuable alternatives to the standard Shewhart charts, especially when the sample data needed to determine the EWMA statistic can be collected individually and evaluated automatically. As a consequence, the EWMAs have been implemented successfully on continuous processes such as those in chemical or food industries, where data involving operating variables such as temperatures, pressures, viscosity, etc. can be gathered and represented on the chart directly by the control system for the process. In the recent years, thanks to the development of simple quality-control software tools, that can be easily managed by workers and implemented on a common PC or notebook, use of EWMAs has systematically been extended to processes for manufacturing discrete parts; in this case, EWMAs that consider sample statistics like mean, median or sample variance are particularly well suited. Therefore, EWMA charts for monitoring process mean or dispersion have been successfully implemented in the semiconductor industry at the level of wafer fabrication; these processes are characterized by an extremely high level of precision in critical dimensions of parts and therefore there is the need of a statistical tool that is able to identify very small drifts in the process parameter to avoid the rejection of the product at the testing stage or, in the worst case, during the operating conditions, i.e., when the electronic device has been installed on highly expensive boards. Other applications of EWMAs to manufacturing processes involve the assembly operations in automotive industry, the technological processes involving the production of mechanical parts like CNC operations on machining centers, where process variability should be maintained as small as possible, and many others. Finally, it is important to note how EWMAs are also spreading in service control activities; an interesting example is represented by recent applications of EWMA charts to monitor healthcare outcomes such as the occurrence of infections or mortality rate after surgeries. Finally, EWMA charts can be adopted for any manufacturing process or service with a low effort and should always be preferred to Shewhart charts when there is the need to detect small shifts in the process parameters, as will be proven later in this chapter.

Therefore, in the second section of this chapter the definition of an EWMA sequence and its main properties will be presented together with the commonly used procedures for the numerical computation of the average run length (ARL). An important part of this section will focus on the numerical computation of the average run length (ARL). The third section will be dedicated to the use of the EWMA as a monitoring tool for the process position, i. e. sample mean (EWMA-$\bar{X}$) and sample median (EWMA-$\tilde{X}$). In the fourth section, the use of the EWMA for monitoring the sample variance (EWMA-S^2), sample standard deviation (EWMA-S) and the range (EWMA-R) will be presented, assuming a fixed sampling interval (FSI) strategy. In the fifth section the variable sampling interval adaptive version of the EWMA-S^2 and EWMA-R control charts will be presented.

The following notations are used – *ARL*: average run length; *ATS*: average time to signal, h_S, h_L: short and long sampling interval; K: width of the control limits; λ: EWMA smoothing parameter; *LCL*, *UCL*: lower and upper control limits; *LWL*, *UWL*: lower and upper warning limits; μ_0, σ_0: in-control mean and standard deviation; μ_1, σ_1: out-of-control mean and standard deviation; R, S, S^2: range, sample standard deviation and sample variance; τ: shift in the process position or dispersion; W: width of the warning limits; $\bar{X}$, $\tilde{X}$: sample mean and sample median.

17.1 Definition and Properties of EWMA Sequences

17.1.1 Definition

Let $T_1, \ldots, T_k, \ldots$ be a sequence of independently and identically distributed (i.i.d.) random variables and let $\lambda \in [0, 1]$ be a constant. From the sequence $T_1, \ldots, T_k, \ldots$ we define a new sequence $Y_1, \ldots, Y_k, \ldots$ using the following recurrence formula

$$Y_k = (1-\lambda)Y_{k-1} + \lambda T_k \,.$$

By decomposing Y_{k-1} in terms of Y_{k-2}, and Y_{k-2} in terms of Y_{k-3} and so on, it is straightforward to demonstrate that

$$Y_k = (1-\lambda)^k Y_0 + \lambda \sum_{j=0}^{k-1} (1-\lambda)^j T_{k-j} \,. \tag{17.1}$$

This formula clearly shows that Y_k is a linear combination of the initial random variable Y_0 weighted by a coefficient $(1-\lambda)^k$ and the random variables $T_1, \ldots, T_k$ weighted by the coefficients $\lambda(1-\lambda)^{k-1}, \lambda(1-\lambda)^{k-2}, \ldots, \lambda$. For this reason, the sequence $Y_1, \ldots, Y_k, \ldots$ is called an exponentially

weighted moving average (EWMA) sequence. If the random variables $T_1, \ldots, T_k, \ldots$ are, by definition, independent, the random variables $Y_1, \ldots, Y_k, \ldots$ are, by definition, not independent. We can notice that

- when $\lambda \to 0$ the sequence $Y_1, \ldots, Y_k, \ldots$ tends to be a smoothed version of the initial sequence $T_1, \ldots, T_k, \ldots$. When $\lambda = 0$ we have $Y_k = Y_{k-1} = \cdots = Y_0$.
- when $\lambda \to 1$ the sequence $Y_1, \ldots, Y_k, \ldots$ tends to be a copy of the initial sequence $T_1, \ldots, T_k, \ldots$ When $\lambda = 1$ we have $Y_k = T_k$ for $k \geq 1$.

17.1.2 Expectation and Variance of EWMA Sequences

Let $\mu_T = E(T_k)$ and $\sigma_T^2 = V(T_k)$ be the expectation and the variance of the random variables $T_1, \ldots, T_k, \ldots$ Using (17.1), we find that the expected value of the random variable Y_k is:

$$E(Y_k) = (1-\lambda)^k E(Y_0) + \lambda\mu_T \sum_{j=0}^{k-1} (1-\lambda)^j$$

or, equivalently, that

$$E(Y_k) = (1-\lambda)^k E(Y_0) + \mu_T[1-(1-\lambda)^k] .$$

Assuming $E(Y_0) = \mu_T$, for $k \geq 1$ it results that

$$E(Y_k) = \mu_T .$$

Because the random variables $T_1, T_2, \ldots$ are supposed to be independent, the variance $V(Y_k)$ of the random variable Y_k is

$$V(Y_k) = (1-\lambda)^{2k} V(Y_0) + \lambda^2\sigma_T^2 \sum_{j=0}^{k-1} (1-\lambda)^{2j} .$$

Replacing $\sum_{j=0}^{k-1}(1-\lambda)^{2j}$ by $[1-(1-\lambda)^{2k}]/[\lambda(2-\lambda)]$ gives

$$V(Y_k) = (1-\lambda)^{2k} V(Y_0) + \lambda^2\sigma_T^2 \left(\frac{1-(1-\lambda)^{2k}}{\lambda(2-\lambda)}\right) .$$

Finally, after some simplifications, we have

$$V(Y_k) = (1-\lambda)^{2k} V(Y_0) + \left(\frac{\lambda}{2-\lambda}\right)[1-(1-\lambda)^{2k}]\sigma_T^2 .$$

Two common assumptions can be made to determine the variance $V(Y_0)$ of the initial random variable Y_0:

- If we assume $V(Y_0) = 0$ (i. e., $Y_0 = \mu_T$ is a constant) then we have, for $k \geq 1$,

$$V(Y_k) = \left(\frac{\lambda}{2-\lambda}\right)[1-(1-\lambda)^{2k}]\sigma_T^2 .$$

- If we assume $V(Y_0) = \sigma_T^2$ then we have, for $k \geq 1$,

$$V(Y_k) = \left(\frac{\lambda + 2(1-\lambda)^{2k+1}}{2-\lambda}\right)\sigma_T^2 .$$

For either choice $V(Y_0) = 0$ or $V(Y_0) = \sigma_T^2$, the asymptotic variance $V_\infty(Y_k)$ of the random variable Y_k is

$$V_\infty(Y_k) = \lim_{k\to+\infty} V(Y_k) = \left(\frac{\lambda}{2-\lambda}\right)\sigma_T^2 .$$

17.1.3 The ARL for an EWMA Sequence

Let LCL and UCL be two constants satisfying $LCL < \mu_T < UCL$. Let $f_T(t)$ and $F_T(t)$ be the probability density function (p.d.f.) and the cumulative distribution function (c.d.f.) of the random variables $T_1, \ldots, T_k, \ldots$ Because the random variables $T_1, \ldots, T_k, \ldots$ are assumed to be independent, the average run length ARL_T for the sequence $T_1, \ldots, T_k, \ldots$ is given by

$$ARL_T = \frac{1}{F_T(LCL) + 1 - F_T(UCL)} . \qquad (17.2)$$

Let $ARL_Y(y)$ be the average run length of the EWMA sequence $Y_1, \ldots, Y_k, \ldots$ assuming $Y_0 = y$ and let $ARL_Y = ARL_Y(\mu_T)$. The fact that the random variables $Y_1, \ldots, Y_k, \ldots$ are not independent prevents the use of (17.2) for computing $ARL_Y(y)$. There are two main approaches for computing ARL_Y.

The first approach is based on the fact that $ARL_Y(y)$ must satisfy the following equation

$$ARL_Y(y) = 1 + \int_{LCL}^{UCL} \frac{1}{\lambda} \times f_T\left(\frac{z-(1-\lambda)y}{\lambda}\right) ARL_Y(z)\,\mathrm{d}z .$$

This equation is a Fredholm equation of the second kind, i. e.

$$f(y) = g(y) + \int_{z_1}^{z_n} h(y,z) f(z)\,\mathrm{d}z ,$$

where $h(y,z)$ and $g(y)$ are two known functions and where $f(z)$ is an unknown function that satisfies the equation above. In our case, we have $g(y)=1$, $h(y,z)=f_T[z-(1-\lambda)y]/\lambda/\lambda$ and $f(y)=ARL_Y(y)$. The numerical evaluation of a Fredholm equation (see *Press* et al. [17.18]) of the second kind consists of approximating the integral operand by a weighted sum

$$f(y) \simeq g(y) + \sum_{i=1}^{n} w_i h(y, z_i) f(z_i)\,, \tag{17.3}$$

where $z_1, z_2, \ldots, z_n$ and $w_1, w_2, \ldots, w_n$ are, respectively, the abscissas and weights of a quadrature method on $[z_1, z_n]$ such as, for instance, the n-point Gauss–Legendre quadrature. If we apply (17.3) for $y = z_1, z_2, \ldots, z_n$, we have

$$\begin{aligned}
f_1 &\simeq g_1 + w_1 h_{1,1} f_1 + w_2 h_{1,2} f_2 + \cdots + w_n h_{1,n} f_n\,,\\
f_2 &\simeq g_2 + w_1 h_{2,1} f_1 + w_2 h_{2,2} f_2 + \cdots + w_n h_{2,n} f_n\,,\\
&\vdots\ \vdots\ \vdots\\
f_n &\simeq g_n + w_1 h_{n,1} f_1 + w_2 h_{n,2} f_2 + \cdots + w_n h_{n,n} f_n\,,
\end{aligned}$$

where $f_i = f(z_i)$, $g_i = g(z_i)$ and $h_{i,j} = h(z_i, z_j)$. This set of equations can be rewritten in a matrix form

$$\begin{pmatrix} f_1 \\ f_2 \\ \vdots \\ f_n \end{pmatrix} \simeq \begin{pmatrix} g_1 \\ g_2 \\ \vdots \\ g_n \end{pmatrix} + \begin{pmatrix} w_1 h_{1,1} & w_2 h_{1,2} & \cdots & w_n h_{1,n} \\ w_1 h_{2,1} & w_2 h_{2,2} & \cdots & w_n h_{2,n} \\ \vdots & \vdots & \ddots & \vdots \\ w_1 h_{n,1} & w_2 h_{n,2} & \cdots & w_n h_{n,n} \end{pmatrix} \begin{pmatrix} f_1 \\ f_2 \\ \vdots \\ f_n \end{pmatrix}$$

or in a more compact way as

$$\boldsymbol{f} \simeq \boldsymbol{g} + \mathbf{H}\boldsymbol{f}\,.$$

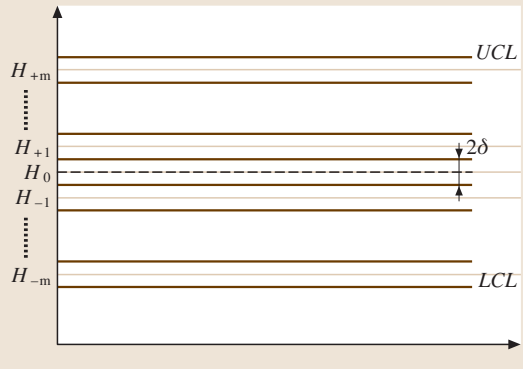

Fig. 17.1 Interval between *LCL* and *UCL* divided into $p = 2m+1$ subintervals of width 2δ

Solving the equation above for $\boldsymbol{f}$, we obtain $(\mathbf{I}-\mathbf{H})\boldsymbol{f} \simeq \boldsymbol{g}$, and finally

$$\boldsymbol{f} \simeq (\mathbf{I}-\mathbf{H})^{-1}\boldsymbol{g}\,.$$

The second approach is based on the flexible and relatively easy to use Markov-chain approach, originally proposed by *Brook* and *Evans* [17.19]. This procedure involves dividing the interval between *LCL* and *UCL* (Fig. 17.1) into $p = 2m+1$ subintervals of width 2δ, where $\delta = (UCL - LCL)/(2p)$. When the number of subintervals p is sufficiently large, the finite approach provides an effective method that allows ARL_Y to be accurately evaluated. The statistic $Y_k = (1-\lambda)Y_{k-1} + \lambda T_k$ is said to be in *transient state* j at time k if $H_j - \delta < Y_k < H_j + \delta$ for $j = -m, \ldots, -1, 0, +1, \ldots, m$, where H_j represents the midpoint of the j-th subinterval. The statistic Y_k is in the *absorbing state* if $Y_k \notin [LCL, UCL]$. An approximation for ARL_Y is given by

$$ARL_Y \simeq \boldsymbol{d}^{\mathrm{T}}\mathbf{Q}\boldsymbol{g}\,,$$

where $\boldsymbol{d}$ is the $(p,1)$ initial probability vector, $\mathbf{Q} = (\mathbf{I} - \mathbf{P})^{-1}$ is the fundamental (p,p) matrix, $\mathbf{P}$ is the (p,p) transition-probabilities matrix and $\boldsymbol{g} = \boldsymbol{1}$ is a $(p,1)$ vector of 1s. The initial probability vector $\boldsymbol{d}$ contains the probabilities that the statistic Y_k starts in a given state. This vector is such that, for $j = -m, \ldots, -1, 0, +1, \ldots, m$,

$$d_j = \begin{cases} 1 & \text{if } H_j - \delta < Y_0 < H_j + \delta \\ 0 & \text{otherwise}\,. \end{cases}$$

This vector contains a single entry equal to 1, whereas its $2m$ remaining elements are all equal to 0. The transition-probability matrix $\mathbf{P}$ contains the one-step transition probabilities. The generic element $p_{i,j}$ of $\mathbf{P}$ represents the probability that the statistic Y_k goes from state i to state j in one step. In order to approximate this probability, it is assumed that the statistic Y_k is equal to H_j whenever it is in state j, i. e.

$$p_{i,j} \simeq P\left(\frac{H_j - \delta - (1-\lambda)H_i}{\lambda} < T_k < \frac{H_j + \delta - (1-\lambda)H_i}{\lambda}\right).$$

This probability can be rewritten

$$p_{i,j} \simeq F_T\left(\frac{H_j + \delta - (1-\lambda)H_i}{\lambda}\right) - F_T\left(\frac{H_j - \delta - (1-\lambda)H_i}{\lambda}\right).$$

17.2 EWMA Control Charts for Process Position

17.2.1 EWMA-$\bar{X}$ Control Chart

Let $X_{k,1}, \ldots, X_{k,n}$ be a sample of n independent normal (μ_0, σ_0) random variables, where μ_0 is the nominal process mean, σ_0 is the nominal process standard deviation and k is the subgroup number. Let $\bar{X}_k$ be the sample mean of subgroup k, i. e.,

$$\bar{X}_k = \frac{1}{n}\sum_{j=1}^{n} X_{k,j} \,.$$

Traditional Shewhart control charts $(\bar{X}, R)$ or $(\bar{X}, S)$ directly monitor the sample mean $\bar{X}_k$, in contrast to EWMA-$\bar{X}$ control charts, which monitor the statistic $Y_k = (1-\lambda)Y_{k-1} + \lambda\bar{X}_k$, i. e., $T_k = \bar{X}_k$. This implies that $\mu_T = \mu_0$ and $\sigma_T = \sigma_0/\sqrt{n}$ and, consequently, the (fixed) control limits of the EWMA-$\bar{X}$ control chart (introduced by *Roberts* [17.1]) are

$$LCL = \mu_0 - K\sqrt{\frac{\lambda}{2-\lambda}}\frac{\sigma_0}{\sqrt{n}} \,,$$

$$UCL = \mu_0 + K\sqrt{\frac{\lambda}{2-\lambda}}\frac{\sigma_0}{\sqrt{n}} \,,$$

where K is a positive constant.

Example 17.1: Figure 17.2 reports a simulation of 200 data obtained from a manufacturing process: the 150 first data plotted in Fig. 17.2 consist of $m = 30$ subgroups of $n = 5$ observations randomly generated from a normal $(\mu_0 = 20, \sigma_0 = 0.1)$ distribution; the remaining 50 data are collected within 10 subgroups of $n = 5$ observations randomly generated from a normal (20.05, 0.1) distribution: that is, the process position was shifted up by half the nominal standard deviation. The process mean and standard deviation were estimated by considering the subgroups $1, \ldots, 30$, corresponding to the in-control condition: $\hat{\mu}_0 = 19.99$, $\hat{\sigma}_0 = 0.099$. Assuming $K = 3$, the control limits of the EWMA chart are, respectively, equal to:

- if $\lambda = 0.1$, $LCL = 19.959$ and $UCL = 20.020$,
- if $\lambda = 0.3$, $LCL = 19.934$ and $UCL = 20.046$.

In Fig. 17.3, we plot the EWMA-$\bar{X}$ control charts for the cases $\lambda = 0.1$ and $\lambda = 0.3$. We can see that these control charts detect an out-of-control signal at the 34-th subgroup (in the case $\lambda = 0.1$) and at the 33-rd subgroup (in the case $\lambda = 0.3$), point-

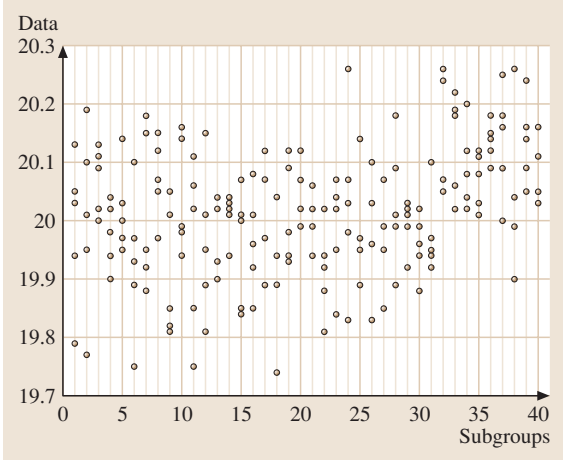

Fig. 17.2 Data with a half-standard-deviation shift in the process mean/median

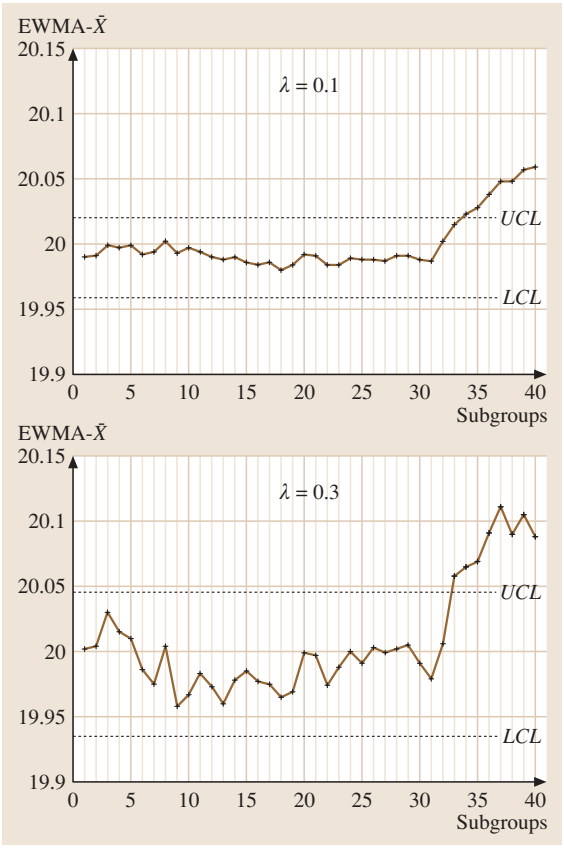

Fig. 17.3 EWMA-$\bar{X}$ control charts corresponding to the data in Fig. 17.2 for $\lambda = 0.1$ and $\lambda = 0.3$

ing out that an increasing of the process position occurred.

17.2.2 EWMA-$\tilde{X}$ Control Chart

Let $X_{k,(1)}, \ldots, X_{k,(n)}$ be the ordered sample corresponding to $X_{k,1}, \ldots, X_{k,n}$ and let $\tilde{X}_k$ be the sample median of subgroup k, i. e.

$$\tilde{X}_k = \begin{cases} X_{k,[(n+1)/2]} & \text{if } n \text{ is odd} \\ \dfrac{X_{k,(n/2)} + X_{k,(n/2+1)}}{2} & \text{if } n \text{ is even}. \end{cases}$$

The EWMA-$\tilde{X}$ control chart is a natural extension of the EWMA-$\bar{X}$ control chart investigated by *Castagliola* [17.20] where the monitored statistic is $Y_k = (1-\lambda)Y_{k-1} + \lambda\tilde{X}_k$, i. e., $T_k = \tilde{X}_k$. The (fixed) control limits of the EWMA-$\tilde{X}$ control chart are

$$LCL = \mu_0 - K\sqrt{\frac{\lambda}{2-\lambda}}\sigma(\tilde{X}),$$

$$UCL = \mu_0 + K\sqrt{\frac{\lambda}{2-\lambda}}\sigma(\tilde{X}),$$

where $\sigma(\tilde{X})$ is the standard deviation of the sample median $\tilde{X}$. It is straightforward to show that $\sigma(\tilde{X}) = \sigma_0 \times \sigma(\tilde{Z})$ where $\sigma(\tilde{Z})$ is the standard deviation of the normal $(0, 1)$ sample median. The values of $\sigma(\tilde{Z})$ are tabulated in Table 17.1 for $n \in \{3, 5, \ldots, 25\}$, but they can also be computed, when n is odd, (see *Castagliola* [17.21]), using the following approximation

$$\sigma(\tilde{Z}) \simeq \sqrt{\frac{\pi}{2(n+2)} + \frac{\pi^2}{4(n+2)^2} + \frac{\pi^2(\frac{13}{24}\pi - 1)}{2(n+2)^3}}.$$

Table 17.1 Standard-deviation $\sigma(\tilde{Z})$ of the normal $(0, 1)$ sample median, for $n \in \{3, 5, \ldots, 25\}$

n	$\sigma(\tilde{Z})$
3	0.6698
5	0.5356
7	0.4587
9	0.4076
11	0.3704
13	0.3418
15	0.3189
17	0.3001
19	0.2842
21	0.2707
23	0.2589
25	0.2485

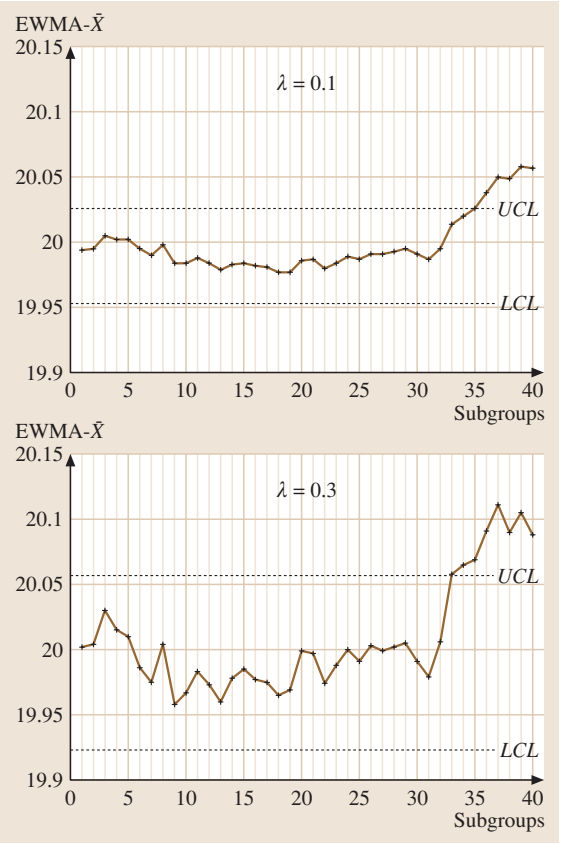

Fig. 17.4 EWMA-$\tilde{X}$ control charts corresponding to the data in Fig. 17.2 for $\lambda = 0.1$ and $\lambda = 0.3$

Example 17.2: using the same data (Fig. 17.2) as in the previous example, we computed the control limits of the EWMA-$\tilde{X}$ control chart ($K = 3$ assumed)

- if $\lambda = 0.1$, $LCL = 19.953$ and $UCL = 20.026$,
- if $\lambda = 0.3$, $LCL = 19.923$ and $UCL = 20.057$.

In Fig. 17.4 we plot the EWMA-$\tilde{X}$ control charts for the cases $\lambda = 0.1$ and $\lambda = 0.3$. Similarly to the EWMA-$\bar{X}$ control charts, we can see that these control charts detect an out-of-control signal at the 36-th subgroup (in the case $\lambda = 0.1$) and at the 33-rd subgroup (in the case $\lambda = 0.3$), pointing out again that an increasing of the process position occurred.

17.2.3 ARL Optimization for the EWMA-$\bar{X}$ and EWMA-$\tilde{X}$ Control Charts

Let $\tau = |\mu_1 - \mu_0|/\sigma_0$ be the usual variable reflecting the shift in the process position, where μ_1 is the new out-

Table 17.2 Optimal couples (λ^*, K^*) and optimal ARL^* of the EWMA-$\bar{X}$ (*half top*) and EWMA-$\tilde{X}$ (*half bottom*) control charts, for $\tau \in \{0.1, 0.2, \ldots, 2\}$, $n \in \{1, 3, 5, 7, 9\}$ and $ARL_0 = 370.4$

of-control process position. The *ARL* of the EWMA-$\bar{X}$ and EWMA-$\tilde{X}$ control charts can be computed using one of the methods presented in Sect. 17.2.3. The p.d.f and c.d.f. $f_T(t)$ and $F_T(t)$, required for the computation of ARL_Y, are

- for the EWMA-$\bar{X}$ control chart

$$f_T(t) = \sqrt{n}\phi[(t-\tau)\sqrt{n}]$$
$$F_T(t) = \Phi[(t-\tau)\sqrt{n}]$$

  where $\phi(x)$ and $\Phi(x)$ are the p.d.f. and the c.d.f. of the normal (0, 1) distribution.
- for the EWMA-$\tilde{X}$ control chart

$$f_T(t) = \phi(t-\tau) f_\beta\left[\Phi(t-\tau)|\frac{n+1}{2}, \frac{n+1}{2}\right],$$
$$F_T(t) = F_\beta\left[\Phi(t-\tau)|\frac{n+1}{2}, \frac{n+1}{2}\right],$$

  where $f_\beta(x|a,b)$ and $F_\beta(x|a,b)$ are the p.d.f. and the c.d.f. of the (a,b) beta distribution.

The quality practitioner should be interested in determining the optimal couples (λ^*, K^*) that allow one to achieve:

- $ARL_Y = ARL_0$, where ARL_0 is the in-control *ARL*, corresponding to the process functioning at nominal position $\mu = \mu_0$, that is to $\tau = 0$;
- A minimum value for the out-of-control *ARL*, $ARL_Y = ARL_Y^*$, valid when $\tau > 0$.

Each couple (λ^*, K^*) is then optimally designed for detecting a particular shift τ. We chose to take $ARL_0 = 370.4$ for the in-control *ARL* (corresponding to the classical 3σ Shewhart control limits). In order to compute the couples (λ^*, K^*), we adopted the following approach

1. For every $\lambda \in \{0.01, 0.02, \ldots, 1\}$ and for $\tau = 0$, we computed (using a basic Newton-type algorithm) the corresponding value K such that $ARL_Y = ARL_0$. At the end of this step, we have a set of pairs $\{(0.01, K_{0.01}), (0.02, K_{0.02}), \ldots, (1, K_1)\}$ candidating for the second step.
2. For every shift $\tau \in \{0.1, 0.2, \ldots, 2\}$, and for every pair $\{(0.01, K_{0.01}), (0.02, K_{0.02}), \ldots, (1, K_1)\}$ we computed ARL_Y and chose the pair (λ^*, K^*) that gave the minimum $ARL_Y = ARL_Y^*$.

The optimal couples (λ^*, K^*) and the corresponding minimal ARL^* are shown in Table 17.2, for both the EWMA-$\bar{X}$ and EWMA-$\tilde{X}$ control charts. In Table 17.2, we also added, for comparison purpose, the *ARL* of the Shewhart $\bar{X}$ and $\tilde{X}$ control charts. For example, the optimal couple (λ^*, K^*) ensuring the smallest *ARL* for a shift $\tau = 0.5$ and $n = 7$ are $(0.21, 2.869)$ for the EWMA-$\bar{X}$ control chart and $(0.16, 3.420)$ for the EWMA-$\tilde{X}$ control chart. In that case, the minimal *ARL* is $ARL^* = 6.3$ for the EWMA-$\bar{X}$ control chart ($ARL = 21.4$ for the $\bar{X}$ control chart) and $ARL^* = 8.4$ for the EWMA-$\tilde{X}$ control chart ($ARL = 37.1$ for the $\tilde{X}$ control chart). Table 17.2 clearly demonstrates that, in terms of *ARL*, the EWMA-$\bar{X}$ control chart is more efficient than the EWMA-$\tilde{X}$ control chart and both the EWMA-$\bar{X}$ and EWMA-$\tilde{X}$ control charts are more efficient, for small and medium shift, than the traditional $\bar{X}$ and $\tilde{X}$ control charts.

17.3 EWMA Control Charts for Process Dispersion

17.3.1 EWMA-S^2 Control Chart

Let S_k^2 be the sample variance of subgroup k, i. e.,

$$S_k^2 = \frac{1}{n-1}\sum_{j=1}^{n}(X_{k,j} - \bar{X}_k)^2,$$

where $\bar{X}_k$ is the sample mean of subgroup k. In order to monitor the process variance, *Crowder* and *Hamilton* [17.10], following a recommendation by *Box* [17.22], suggested the application of the classical EWMA approach to the logarithm of the successive sample variances, i. e. $T_k = \ln S_k^2$. The main motivation for this approach is that $T_k = \ln S_k^2$, which has a log-gamma distribution (*Johnson* et al. [17.23]), tends to be more normally distributed than the sample variance S_k^2. A more recent idea developed by *Castagliola* [17.24] was to apply a three-parameter $(a_{S^2}, b_{S^2}, c_{S^2})$ logarithmic transformation to S_k^2, i. e. $T_k = a_{S^2} + b_{S^2}\ln(S_k^2 + c_{S^2})$, with $c_{S^2} > 0$ (in order to avoid problems with the logarithmic transformation). The main expectation of this approach is that, if the parameters a_{S^2}, b_{S^2} and c_{S^2} are judiciously selected, then this transformation may result in better normality of T_k than the approach of *Crowder* and *Hamilton* [17.10]. Trying to make T_k more normally distributed is related to making the distribu-

tion of T_k more symmetric. If the value of the expectation $E(T_k)$ and the standard deviation $\sigma(T_k)$ of T_k corresponding to the parameters a_{S^2}, b_{S^2} and c_{S^2} are known, then the (fixed) control limits of the EWMA-S^2 control chart are

$$LCL = E(T_k) - K\sqrt{\frac{\lambda}{2-\lambda}}\sigma(T_k)\,, \tag{17.4}$$

$$UCL = E(T_k) + K\sqrt{\frac{\lambda}{2-\lambda}}\sigma(T_k)\,. \tag{17.5}$$

The control limits given above correspond to a two-sided EWMA control chart, but one-sided EWMA control limits can also be considered. The approach suggested by *Castagliola* [17.24] needs to define a_{S^2}, b_{S^2}, c_{S^2}, $E(T_k)$, $\sigma(T_k)$ and Y_0. Let S^2 be the sample variance of n independent normal $(\mu_0, 1)$ random variables. The p.d.f. and the c.d.f of S^2 are defined for $s \geq 0$ and are equal to

$$f_{S^2}(s) = f_\gamma\left(s|\frac{n-1}{2}, \frac{2}{n-1}\right)\,,$$

$$F_{S^2}(s) = F_\gamma\left(s|\frac{n-1}{2}, \frac{2}{n-1}\right)\,,$$

where $f_\gamma(x|u, v)$ and $F_\gamma(x|u, v)$ are the p.d.f. and c.d.f. of the gamma (u, v) distribution

$$f_\gamma(x|u, v) = \begin{cases} 0 & (x \leq 0) \\ \dfrac{x^{u-1}\exp(-x/v)}{v^u\,\Gamma(u)} & (x > 0)\,. \end{cases}$$

Consequently, the expectation $E(S^2)$, the variance $V(S^2)$, and the skewness coefficient $\gamma_3(S^2)$ of S^2 are equal to

$$E(S^2) = 1\,,$$

$$V(S^2) = \frac{2}{n-1}\,,$$

$$\gamma_3(S^2) = \sqrt{\frac{8}{n-1}}\,.$$

In the approach developed by *Castagliola* [17.24], three parameters $A_{S^2}(n)$, $B_{S^2}(n)$, and $C_{S^2}(n)$, depending only on n, must be computed such that $T = A_{S^2}(n) + B_{S^2}(n)\ln[S^2 + C_{S^2}(n)]$ is approximately a normal $(0, 1)$ random variable. Remembering that S^2 has a gamma distribution, i. e. a unimodal skewed distribution, Castagliola suggested to find the three parameters log-normal distribution (another skewed distribution), defined for $x \geq -C_{S^2}(n)$,

$$f_L(x) = \frac{B_{S^2}(n)}{x}\phi\left[A_{S^2}(n) + B_{S^2}(n)\ln[x + C_{S^2}(n)]\right]\,,$$

which is the closest to the distribution of S^2, according to a criterion based on the first three moments $E(S^2)$, $V(S^2)$, and $\gamma_3(S^2)$ of S^2. If S^2 would have a log-normal distribution, then $T = A_{S^2}(n) + B_{S^2}(n)\ln[S^2 + C_{S^2}(n)]$ would have exactly a normal $(0, 1)$ distribution. By looking for a log-normal distribution which fits approximately the (gamma) distribution of S^2, we expect that T will have an approximate normal $(0, 1)$ distribution. What Castagliola suggested is to find parameters $A_{S^2}(n)$, $B_{S^2}(n)$, and $C_{S^2}(n)$ such that the log-normal distribution $f_L(x)$ fits the first three moments $E(S^2)$, $V(S^2)$, and $\gamma_3(S^2)$ of S^2. This can be achieved (*Stuart* and *Ord* [17.25]) by firstly computing

$$w = \left[\sqrt{\gamma_3^2(S^2)/4 + 1} + \gamma_3(S^2)/2\right]^{1/3} - \left[\sqrt{\gamma_3^2(S^2)/4 + 1} - \gamma_3(S^2)/2\right]^{1/3}$$

and then

$$B_{S^2}(n) = \frac{1}{\sqrt{\ln(w^2+1)}}\,,$$

$$A_{S^2}(n) = \frac{B_{S^2}(n)}{2}\ln\left(\frac{w^2(w^2+1)}{V(S^2)}\right)\,,$$

$$C_{S^2}(n) = \frac{\sqrt{V(S^2)}}{w} - E(S^2)\,.$$

The value of the constants $A_{S^2}(n)$, $B_{S^2}(n)$ and $C_{S^2}(n)$ can be found in Table 17.3 for $n \in \{3, \ldots, 15\}$. For the random variable $S_k^2 = \sigma_0^2 S^2$ [corresponding to the sample variance of n independent normal (μ_0, σ_0) random variables], it is straightforward to see that

$$\begin{aligned} T &= A_{S^2}(n) + B_{S^2}(n)\ln\left[S^2 + C_{S^2}(n)\right] \\ &= A_{S^2}(n) + B_{S^2}(n)\ln\left[S_k^2/\sigma_0^2 + C_{S^2}(n)\right] \\ &= A_{S^2}(n) - 2B_{S^2}(n)\ln(\sigma_0) + B_{S^2}(n)\ln\left[S_k^2 + C_{S^2}(n)\sigma_0^2\right]\,. \end{aligned}$$

Consequently, if the parameters a_{S^2}, b_{S^2} and c_{S^2} are defined such that

$$b_{S^2} = B_{S^2}(n)\,,$$

$$c_{S^2} = C_{S^2}(n)\sigma_0^2\,,$$

$$a_{S^2} = A_{S^2}(n) - 2B_{S^2}(n)\ln(\sigma_0)\,,$$

then $T = a_{S^2} + b_{S^2}\ln(S_k^2 + c_{S^2}) = T_k$. This ensures that $T_k = a_{S^2} + b_{S^2}\ln(S_k^2 + c_{S^2})$ will also be approximately a normal $(0, 1)$ random variable. Because $T_k = T$, the distribution $f_T(t)$ of T_k depends only on n. This distribution is defined for $t \geq A_{S^2}(n) + B_{S^2}(n)\ln[C_{S^2}(n)]$ and

Table 17.3 Constants $A_{S^2}(n)$, $B_{S^2}(n)$, $C_{S^2}(n)$, Y_0, $E(T_k)$, $\sigma(T_k)$, $\gamma_3(T_k)$ and $\gamma_4(T_k)$ for the EWMA-S^2 control chart, for $n \in \{3, \ldots, 15\}$

is equal to

$$f_T(t) = \frac{1}{B_{S^2}(n)} \exp\left(\frac{t - A_{S^2}(n)}{B_{S^2}(n)}\right) \times f_{S^2}\left[\exp\left(\frac{t - A_{S^2}(n)}{B_{S^2}(n)}\right) - C_{S^2}(n) | n\right].$$

The fact that the distribution $f_T(t)$ of T_k depends only on n is important since it allows the calculation of the values of $E(T_k)$ and $\sigma(T_k)$ independently of the value of σ_0. The computation of $E(T_k)$ and $\sigma(T_k)$ has been achieved by numerical quadrature for $n \in \{3, \ldots, 15\}$, and the results are also shown in Table 17.3. Due to the fact that $E(T_k)$ approximates 0, whatever the sample size n, setting $E(T_k) = 0$ does not introduce significant errors into the statistical model. Finally, it seems logical to define the first value $Y_0 = E[a_{S^2} + b_{S^2} \ln(S^2 + c_{S^2})]$.

Using the first-order expansion of the expectation, we deduce $Y_0 \simeq a_{S^2} + b_{S^2} \ln(\sigma_0^2 + c_{S^2})$. Then by replacing a_{S^2}, b_{S^2} and c_{S^2} with $A_{S^2}(n) - 2B_{S^2}(n)\ln(\sigma_0)$, $B_{S^2}(n)$ and $C_{S^2}(n)\sigma_0^2$, we have

$$Y_0 \simeq A_{S^2}(n) - 2B_{S^2}(n)\ln(\sigma_0) + B_{S^2}(n)\ln[\sigma_0^2 + C_{S^2}(n)\sigma_0^2] .$$

After simplifications, we obtain:

$$Y_0 \simeq A_{S^2}(n) + B_{S^2}(n)\ln[1 + C_{S^2}(n)] .$$

As can be noticed, this value depends only on n and not on σ_0. The values for Y_0 are given in Table 17.3. One can note that these values are also close to 0 and can be replaced by 0 in practice with little practical effect.

Example 17.3: The goal of this example is to show how the EWMA-S^2 control chart behaves in the case of an increase and a decrease in the nominal process variability. The first 100 data points plotted in Fig. 17.5 (top and bottom) consist of 20 identical subgroups of $n = 5$ observations randomly generated from a normal (20, 0.1) distribution (corresponding to an in-control process), while the last 50 data points of Fig. 17.5 (top) consist of 10 subgroups of $n = 5$ observations randomly generated from a normal (20, 0.2) distribution (the nominal process standard deviation σ_0 has increased by a factor of 2), and the last 50 data points of Fig. 17.5 (bottom) consist of 10 subgroups of $n = 5$ observations randomly generated from a normal (20, 0.05) distribution (the nominal process standard deviation σ_0 has decreased by a factor of 2). The corresponding 30 sample variances are plotted in Fig. 17.6, for the two cases (increasing and

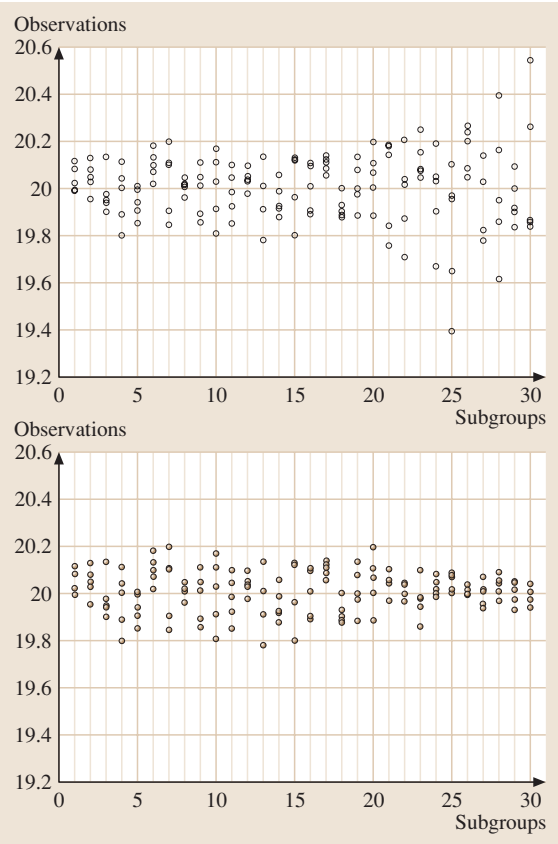

Fig. 17.5 Data with an increasing variance (*top*), and with a decreasing variance (*bottom*)

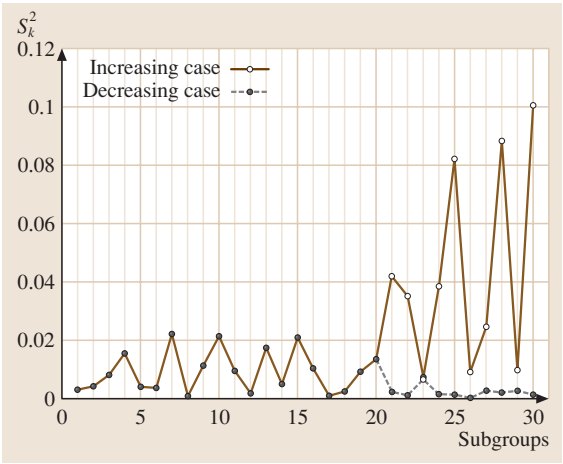

Fig. 17.6 Sample variances S_k^2 corresponding to the data of Fig. 17.5

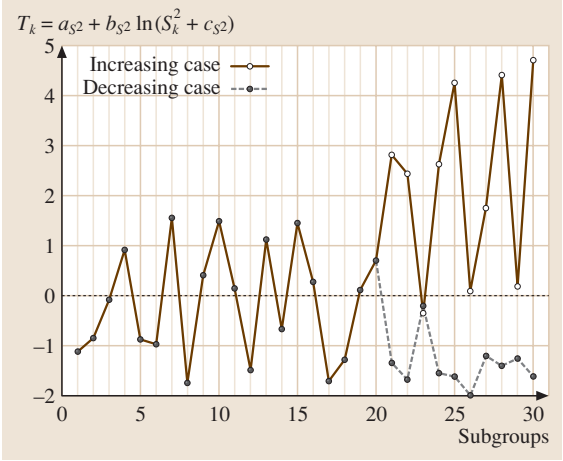

Fig. 17.7 Transformed sample variances $T_k = a_{S^2} + b_{S^2} \ln(S_k^2 + c_{S^2})$ corresponding to the data of Fig. 17.5

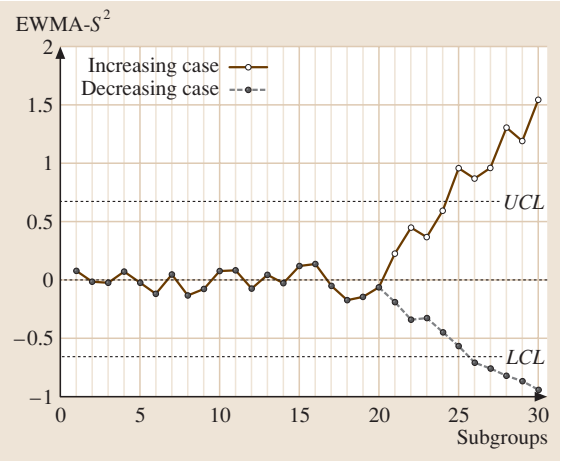

Fig. 17.8 EWMA-S^2 control chart ($\lambda = 0.1$, $K = 3$) corresponding to the data of Fig. 17.5

decreasing). At this step, the asymmetry between increasing and decreasing sample variances is particularly noticeable. If $n = 5$ and $\sigma_0 = 0.1$, then $b_{S^2} = 2.3647$, $c_{S^2} = 0.5979 \times 0.1^2 = 0.005\,979$ and $a_{S^2} = -0.8969 - 2 \times 2.3647 \times \ln(0.1) = 9.9929$. The 30 transformed sample variances are plotted in Fig. 17.7 and the EWMA-S^2 sequence along with the EWMA-S^2 control limits $LCL = 0.0075 - 3\sqrt{0.1/1.9} \times 0.967 = -0.658$ and $UCL = 0.0075 + 3\sqrt{0.1/1.9} \times 0.967 = 0.673$ ($\lambda = 0.1$ and $K = 3$) are plotted in Fig. 17.8. The EWMA-S^2 control chart clearly detects an out-of-control signal at the 25-th subgroup (in the increasing case) and at the 26-th subgroup (in the decreasing case), pointing out that an increase/decrease of the process variability occurred.

The distribution $f_T(t)$ of $T_k = a_{S^2} + b_{S^2} \ln(S_k^2 + c_{S^2})$ (plain line) for $n \in \{3, 5, 7, 9\}$, and the normal (0, 1) distribution (dotted line) are plotted in Fig. 17.9. The distribution of T_k is defined for $t \geq A_{S^2}(n) + B_{S^2}(n) \ln[C_{S^2}(n)]$, while the normal (0, 1) distribution is defined on $]-\infty, +\infty[$. This difference is particularly important for $n = 3$. It is clear that when n increases, the distribution of T_k becomes closer to the normal (0, 1) distribution, and the lower bound $A_{S^2}(n) + B_{S^2}(n) \ln[C_{S^2}(n)] \to -\infty$. By numerical quadrature, the skewness coefficient $\gamma_3(T_k) = \mu_3(T_k)/V^{3/2}(T_k)$ and the kurtosis coefficient $\gamma_4(T_k) = \mu_4(T_k)/V^2(T_k) - 3$ of T_k have been computed for $n = 3, \ldots, 15$. The results are shown in Table 17.3. As expected, when n increases, T_k becomes more normally distributed, i. e., $\gamma_3(T_k) \to 0$ and $\gamma_4(T_k) \to 0$.

Let σ_1 be the new out-of-control process standard deviation and let $\tau = \sigma_1/\sigma_0$ be the variable reflecting the shift in the process variability. Let $S_k'^2 = \sigma_1^2 S^2$ be the sample variance of n independent normal (μ_0, σ_1) random variables (i. e. the sample variance after a shift τ), and let $T_k' = a_{S^2} + b_{S^2} \ln(S_k'^2 + c_{S^2})$. If a_{S^2}, b_{S^2}, c_{S^2} and $S_k'^2$ are respectively replaced by $A_{S^2}(n) - 2B_{S^2}(n) \ln(\sigma_0)$, $B_{S^2}(n)$, $\sigma_0 C_{S^2}(n)$ and $\sigma_1^2 S^2$, then

$$\begin{aligned} T_k' &= A_{S^2}(n) - 2B_{S^2}(n) \ln(\sigma_0) \\ &\quad + B_{S^2}(n) \ln\left[\sigma_1^2 S^2 + \sigma_0^2 C_{S^2}(n)\right] \\ &= A_{S^2}(n) - 2B_{S^2}(n) \ln(\sigma_0) \\ &\quad + B_{S^2}(n) \ln\left\{\sigma_0^2 [\tau^2 S^2 + C_{S^2}(n)]\right\} \\ &= A_{S^2}(n) + B_{S^2}(n) \ln[\tau^2 S^2 + C_{S^2}(n)]\,. \end{aligned}$$

This result clearly shows that the distribution $f_{T'}(t)$ of T_k' is equal to the distribution of the transformed random variable $\tau^2 S^2$. Consequently the p.d.f and the c.d.f of T_k' are

$$\begin{aligned} f_{T'}(t) &= \frac{1}{\tau^2 B_{S^2}(n)} \exp\left(\frac{t - A_{S^2}(n)}{B_{S^2}(n)}\right) \\ &\quad \times f_{S^2}\left\{\frac{1}{\tau^2}\left[\exp\left(\frac{t - A_{S^2}(n)}{B_{S^2}(n)}\right) - C_{S^2}(n)\right] | n\right\}, \\ F_{T'}(t) &= F_{S^2}\left\{\frac{1}{\tau^2}\left[\exp\left(\frac{t - A_{S^2}(n)}{B_{S^2}(n)}\right) - C_{S^2}(n)\right] | n\right\}. \end{aligned}$$

The ARL of the EWMA-S^2 control chart can be computed using one of the methods presented in Sect. 17.1.3. Like for the EWMA-$\bar{X}$ and EWMA-$\tilde{X}$ control charts, it is sometimes interesting for the quality practitioner to know the optimal couples (λ^*, K^*) that give the same in-control $ARL_Y = ARL_0$ (i. e. the ARL when the process is functioning at the nominal variability $\sigma = \sigma_0$ or equivalently $\tau = 1$) and then find, for a specified value of the shift τ, the unique couple (λ^*, K^*) which yields the smallest possible out-of-control $ARL_Y = ARL^*$. In order to compute the couples (λ^*, K^*) for the EWMA-S^2 control chart, the same approach as in the EWMA-$\bar{X}$ and EWMA-$\tilde{X}$ control charts was adopted:

1. For every $\lambda \in \{0.05, 0.06, \ldots, 1\}$ and for $\tau = 1$, we computed the corresponding value K such that $ARL_Y = ARL_0$. At the end of this step, we have a set of pairs $\{(0.05, K_{0.05}), (0.06, K_{0.06}), \ldots, (1, K_1)\}$ candidating for the second step.
2. For every shift $\tau \in \{0.6, 0.7, 0.8, 0.9, 0.95, 1.05, 1.1, 1.2, \ldots, 2\}$, and for every pair $\{(0.05, K_{0.05}), (0.06, K_{0.06}), \ldots, (1, K_1)\}$ we computed ARL_Y and chose the pair (λ^*, K^*) which gave the minimum $ARL_Y = ARL_Y^*$.

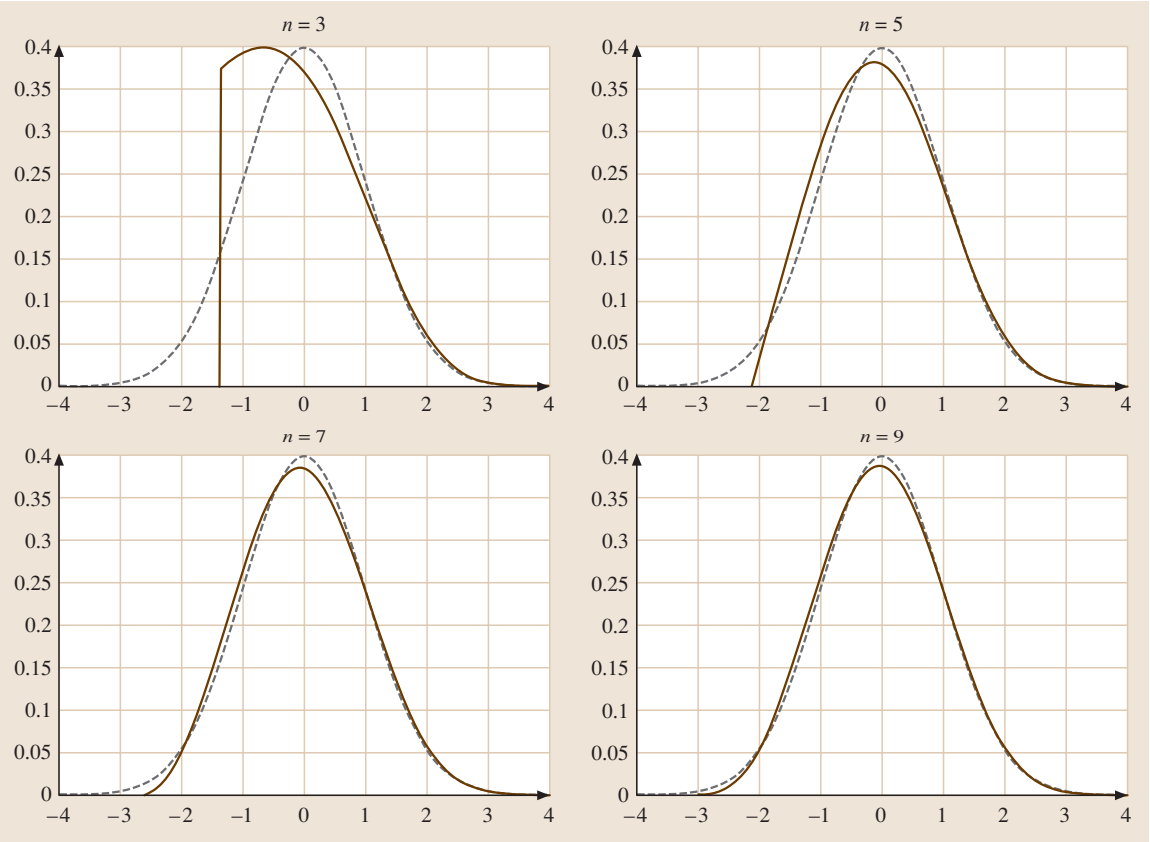

Fig. 17.9 Distribution $f_T(t)$ of $T_k = a_{S^2} + b_{S^2} \ln(S_k^2 + c_{S^2})$ (*plain line*) compared with the normal $(0, 1)$ distribution (*dotted line*), for $n \in \{3, 5, 7, 9\}$

The optimal couples (λ^*, K^*) for the EWMA-S^2 control chart and the corresponding minimal ARL^* are shown in Table 17.4. In Table 17.4, we also added, for comparison purpose, the ARL of the classic S^2 control chart. For example, the optimal couple (λ^*, K^*) ensuring the smallest ARL for a shift $\tau = 1.2$ and $n = 7$ is $(0.05, 2.505)$ and the corresponding minimal ARL is $ARL^* = 12.4$, while for the classic S^2 control chart, we have $ARL = 50.0$. This is just an example of the superiority of the EWMA-S^2 control chart (with optimized parameters) over the classical S^2 control chart when the shift τ is small.

17.3.2 EWMA-S Control Chart

The EWMA-S control chart proposed by *Castagliola* [17.26] is a natural extension of the EWMA-S^2 control chart where a three-parameter (a_S, b_S, c_S) logarithmic transformation is applied to the sample standard deviation S_k, [i. e. $T_k = a_S + b_S \ln(S_k + c_S)$], instead of the sample variance S_k^2. The control limits of the EWMA-S control chart are given by (17.4) and (17.5) but with different values for $E(T_k)$ and $\sigma(T_k)$. The p.d.f. and the c.d.f. of S are defined for $s \geq 0$ and are equal to

$$f_S(s) = 2s f_\gamma\left(s^2 | \frac{n-1}{2}, \frac{2}{n-1}\right),$$
$$F_S(s) = F_\gamma\left(s^2 | \frac{n-1}{2}, \frac{2}{n-1}\right),$$

and the mean $E(S)$, the variance $V(S)$, and the skewness coefficient $\gamma_3(S)$ of S are equal to

$$E(S) = K_S(n, 1),$$
$$V(S) = 1 - K_S^2(n, 1),$$

Table 17.5 Constants $A_S(n)$, $B_S(n)$, $C_S(n)$, Y_0, $E(T_k)$, $\sigma(T_k)$, $\gamma_3(T_k)$ and $\gamma_4(T_k)$ for the EWMA-S control chart, for $n \in \{3, \ldots, 15\}$

$$\gamma_3(S) = \frac{K_S(n,3) - 3K_S(n,1) + 2K_S^3(n,1)}{[1 - K_S^2(n,1)]^{3/2}} ,$$

where

$$K_S(n,r) = \frac{\Gamma[(n-1+r)/2]}{\Gamma[(n-1)/2]} \left(\frac{2}{n-1}\right)^{r/2} .$$

Using similar demonstrations as for the EWMA-S^2 control chart, it can be proven that the constants a_S, b_S and c_S required for the transformation $T_k = a_S + b_S \ln(S_k + c_S)$ can be deduced from the constants $A_S(n)$, $B_S(n)$ and $C_S(n)$ using the following relations

$$b_S = B_S(n) ,$$
$$c_S = C_S(n)\sigma_0 ,$$
$$a_S = A_S(n) - B_S(n)\ln(\sigma_0) .$$

It can also be proven that the initial value Y_0 is equal to

$$Y_0 = A_S(n) + B_S(n)\ln[K_S(n,1) + C_S(n)] .$$

All the constants $A_S(n)$, $B_S(n)$, $C_S(n)$, Y_0, $E(T_k)$ and $\sigma(T_k)$, useful for the EWMA-S control chart, are shown in Table 17.5 for $n \in \{3, \ldots, 15\}$.

Example 17.4: The goal of this example is to show how the EWMA-S control chart behaves in the case of an increase and a decrease in the nominal process variability. We reuse the data in Fig. 17.5 (top and bottom). The corresponding 30 sample standard deviations are plotted in Fig. 17.10, for the two cases (increasing and decreasing). If $n = 5$ and $\sigma_0 = 0.1$, then $b_S = 7.4727$, $c_S = 1.5984 \times 0.1 = 0.159\,84$ and $a_S = -6.8941 - 7.4727 \times \ln(0.1) = 10.3124$. The 30 transformed sample standard deviations are plotted in Fig. 17.11 and the EWMA-S sequence along with the EWMA-S control limits $LCL = 0.000\,14 - 3\sqrt{0.1/1.9} \times 0.9981 = -0.687$ and $UCL = 0.000\,14 + 3\sqrt{0.1/1.9} \times 0.9981 = 0.687$ ($\lambda = 0.1$ and $K = 3$) are plotted in Fig. 17.12. The EWMA-S control chart clearly detects an out-of-control signal at the 25-th subgroup (in the increasing case) and at the 26-th subgroup (in the decreasing case), pointing out that an increase/decrease of the standard deviation occurred.

The distribution $f_T(t)$ of $T_k = a_S + b_S \ln(S_k + c_S)$ (plain line) for $n \in \{3, 5, 7, 9\}$, and the normal (0, 1) distribution (dotted line) are plotted in Fig. 17.13. It is clear that, when n increases, the distribution of T_k becomes closer to the normal (0, 1) distribution, and the lower bound $A_S(n) + B_S(n) \ln[C_S(n)] \to -\infty$. By numerical quadrature, the skewness coefficient $\gamma_3(T_k)$ and the kurtosis coefficient $\gamma_4(T_k)$ of T_k have been computed for $n \in \{3, \ldots, 15\}$; see Table 17.5. As expected, when n increases, T_k becomes more normally distributed, i. e., $\gamma_3(T_k) \to 0$ and $\gamma_4(T_k) \to 0$.

The p.d.f and the c.d.f of the transformed sample standard deviation $T'_k = a_S + b_S \ln(S'_k + c_S)$ after a shift τ are equal to

$$f_{T'}(t) = \frac{1}{\tau B_S(n)} \exp\left(\frac{t - A_S(n)}{B_S(n)}\right) \times f_S\left\{\frac{1}{\tau}\left[\exp\left(\frac{t - A_S(n)}{B_S(n)}\right) - C_S(n)\right] | n\right\},$$

$$F_{T'}(t) = F_S\left\{\frac{1}{\tau}\left[\exp\left(\frac{t - A_S(n)}{B_S(n)}\right) - C_S(n)\right] | n\right\}.$$

The ARL of the EWMA-S control chart can be computed using one of the methods presented in Sect. 17.2.3. The method used for computing the optimal couples (λ^*, K^*) and the corresponding minimal ARL^* for the EWMA-S control chart is exactly the same as the one used for the EWMA-S^2 control chart. The results are shown in Table 17.6. In Table 17.6, we also added, for comparison purpose, the ARL of the classical S control chart. For example, the optimal couple (λ^*, K^*) ensuring the smallest ARL for a shift $\tau = 1.2$ and $n = 7$ is (0.05, 2.490) and the corresponding minimal ARL is $ARL^* = 16.7$, while for the classic S control chart, we have $ARL = 50.0$. Like the EWMA-S^2 control chart, the EWMA-S control chart (with optimized parameters) is more efficient, in terms of ARL, than the S^2 or S control chart. The results of both EWMA-S^2 and EWMA-S control chart are very similar. The main difference is that for the decreasing case ($\tau < 1$) the optimal ARL^*s of the EWMA-S control chart are smaller than those of the EWMA-S^2 control chart, while for the increasing case ($\tau > 1$) the opposite results.

17.3.3 EWMA-*R* Control Chart

Let R_k be the range of the subgroup k, i. e.,

$$R_k = \max(X_{k,1}, \ldots, X_{k,n}) - \min(X_{k,1}, \ldots, X_{k,n}).$$

The EWMA-R control chart proposed by *Castagliola* [17.27] is a natural extension of the EWMA-S^2 control chart where a three-parameter (a_R, b_R, c_R) logarithmic transformation is applied to the range R_k, [i. e. $T_k = a_R + b_R \ln(R_k + c_R)$], instead of the sample vari-

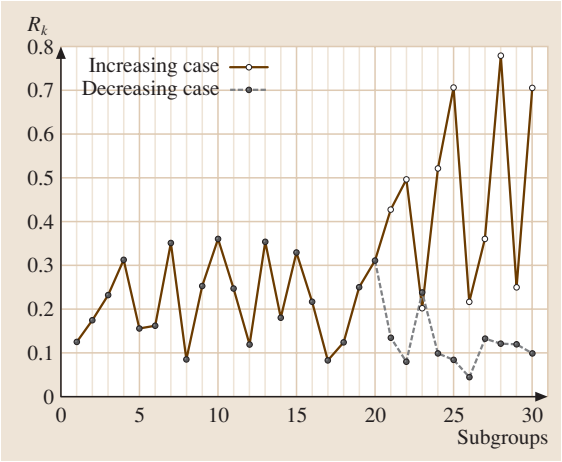

Fig. 17.14 Sample ranges R_k corresponding to the data of Fig. 17.5

ance S_k^2. The control limits of the EWMA-R control chart are given by (17.4) and (17.5) but with different values for $E(T_k)$ and $\sigma(T_k)$. Let R be the range of n independent normal $(\mu_0, 1)$ random variables. The p.d.f. $f_R(r)$ of R is defined for $r \geq 0$ and is given by the well-known relation

$$f_R(r) = n(n-1) \int_{-\infty}^{+\infty} \phi(u)\phi(r+u)[\Phi(r+u) - \Phi(u)]^{n-2} \, \mathrm{d}u \, .$$

In order to compute the constants $A_R(n)$, $B_R(n)$ and $C_R(n)$, the expectation $E(R)$, the variance $V(R)$ and the skewness coefficient $\gamma_3(R)$ of R have been computed by numerical quadrature and are tabulated in Table 17.7. Using similar demonstrations as for the EWMA-S control chart, it can be proven that the constants a_R, b_R and c_R required for the transformation $T_k = a_R + b_R \ln(R_k + c_R)$ can be deduced from the constants $A_R(n)$, $B_R(n)$ and $C_R(n)$ using the following relations

$$b_R = B_R(n) \, ,$$
$$c_R = C_R(n)\sigma_0 \, ,$$

$$a_R = A_R(n) - B_R(n)\ln(\sigma_0)\,.$$

It can also be proven that the initial value Y_0 is equal to

$$Y_0 = A_R(n) + B_R(n)\ln[K_R(n) + C_R(n)]\,,$$

where $K_R(n)$ is equal to

$$K_R(n) = 2\int_0^{+\infty} 1 - \left[\Phi(x)\right]^n - \left[1-\Phi(x)\right]^n \mathrm{d}x\,.$$

All the constants $A_R(n)$, $B_R(n)$, $C_R(n)$, Y_0, $E(T_k)$ and $\sigma(T_k)$, useful for the EWMA-R control chart, are shown in Table 17.8 for $n \in \{3, \ldots, 15\}$.

Example 17.5: The goal of this example is to show how the EWMA-R control chart behaves in the case of an increase and a decrease in the nominal variability. We reuse the data in Fig. 17.5 (top and bottom). The corresponding 30 sample ranges are plotted in Fig. 17.14, for the two cases (increasing and decreasing). If $n = 5$ and $\sigma_0 = 0.1$, then $b_R = 6.5336$, $c_R = 3.2866 \times 0.1 = 0.328\,66$ and $a_R = -11.1940 - 6.5336 \times \ln(0.1) = 3.8502$. The 30 transformed ranges are plotted in Fig. 17.15 and the EWMA-R sequence along with the EWMA-R control limits $LCL = 0.000\,19 - 3\sqrt{0.1/1.9} \times 0.9977 = -0.686$ and $UCL = 0.000\,19 + 3\sqrt{0.1/1.9} \times 0.9977 = 0.687$ ($\lambda = 0.1$ and $K = 3$) are plotted in Fig. 17.16. The EWMA-R control chart clearly detects an out-of-control signal at the 25-th subgroup (in the increasing case) and at the 26-th subgroup (in the decreasing case), pointing out that an increase/decrease of the dispersion occurred.

The distribution $f_T(t)$ of $T_k = a_R + b_R \ln(R_k + c_R)$ (plain line) for $n \in \{3, 5, 7, 9\}$, and the normal (0, 1) distribution (dotted line) are plotted in Fig. 17.17. It is clear that, when n increases, the distribution of T_k becomes closer to the normal (0, 1) distribution, and the lower bound $A_R(n) + B_R(n)\ln[C_R(n)] \to -\infty$. By numerical quadrature, the skewness coefficient $\gamma_3(T_k)$ and the kurtosis coefficient $\gamma_4(T_k)$ of T_k have been computed for $n \in \{3, \ldots, 15\}$; see Table 17.8. As expected, when n increases, T_k becomes more normally distributed, i. e., $\gamma_3(T_k) \to 0$ and $\gamma_4(T_k) \to 0$.

The p.d.f and the c.d.f of the transformed range $T'_k = a_R + b_R \ln(R'_k + c_R)$ after a shift τ are equal to

$$f_{T'}(t) = \frac{1}{\tau B_R(n)} \exp\left(\frac{t - A_R(n)}{B_R(n)}\right) \times f_R\left\{\frac{1}{\tau}\left[\exp\left(\frac{t - A_R(n)}{B_R(n)}\right) - C_R(n)\right] | n\right\}\,,$$

$$F_{T'}(t) = F_R\left\{\frac{1}{\tau}\left[\exp\left(\frac{t - A_R(n)}{B_R(n)}\right) - C_R(n)\right] | n\right\}\,.$$

The *ARL* of the EWMA-*R* control chart can be computed using one of the methods presented in Sect. 17.2.3. The method used for computing the optimal couples (λ^*, K^*) and the corresponding minimal ARL^* for the EWMA-*R* control chart is exactly the same as the one used for the EWMA-*S* control chart. The results are shown in Table 17.9. In Table 17.9, we also added, for comparison purpose, the *ARL* of the classic *R* control chart. For example, the optimal couple (λ^*, K^*) ensuring the smallest *ARL* for a shift $\tau = 1.2$ and $n = 7$ is (0.05, 2.491) and the corresponding minimal *ARL* is $ARL^* = 17.6$, while for the classic *R* control chart, we have $ARL = 60.9$. The EWMA-*R* control chart (with optimized parameters) is more efficient, in terms of *ARL*, than the *R* control chart, but is slightly less efficient than both the EWMA-S^2 and EWMA-*S* control charts.

17.4 Variable Sampling Interval EWMA Control Charts for Process Dispersion

17.4.1 Introduction

Variable sampling intervals (VSI) control charts are a class of adaptive control charts whose sampling intervals are selected depending on what is observed from the process. VSI control charts have been demonstrated to detect process changes faster than fixed sampling interval (FSI) control charts.

For the VSI charts investigated here, the policy of sampling interval selection is dual: if a point falls into a warning zone near to one of the control limits, the sampling interval to the successive sample should be shorter; otherwise, if the last plotted point is plotted near to the central line, the successive sampling interval can be enlarged, because there is not doubt about a possible out-of-control condition. Most work on developing VSI control charts has been done for the problem of monitoring the mean of the process (see *Reynolds* et al. [17.28], *Reynolds* et al. [17.29], *Runger* and *Pignatiello* [17.30], *Saccucci* et al. [17.31] and *Reynolds* [17.32]). However, fewer works have been done on control charts for the process variance. *Chengular* et al. [17.33] considered a VSI Shewhart chart for monitoring process mean and variance, and very recently, *Reynolds* and *Stoumbos* [17.34] investigated a combination of different control charts for both process mean and variance, using individual observations and variable sampling intervals.

17.4.2 VSI Strategy

Unlike FSI control schemes, the sampling interval between T_k and T_{k+1} depends on the current value of Y_k. A longer sampling interval h_L is used when the control statistic falls within the region $R_L = [LWL, UWL]$, defined as

$$LWL = E(T_k) - W\sqrt{\frac{\lambda}{2-\lambda}}\sigma(T_k)\,,$$

$$UWL = E(T_k) + W\sqrt{\frac{\lambda}{2-\lambda}}\sigma(T_k)\,,$$

where *W* is the width of the *warning limits*, which are always inside the control interval, i.e., $W < K$. Similarly, a short sampling interval h_S is used when the control statistic falls within the region $R_S = [LCL, LWL] \cup [UWL, UCL]$. The process is considered out of control and action should be taken whenever Y_k falls outside the range of the control limits $[LCL, UCL]$. This dual-waiting-time control chart is known to be optimal and easy to implement in practice. *Reynolds* et al. [17.28] have empirically shown that it is optimal to use only two sampling intervals with VSI Shewhart and VSI cumulative sum (CUSUM) control scheme for detecting a specified shift in the process target values. They also gave a general proof for any control scheme that can be represented as a Markov chain. *Saccucci* et al. [17.31] gave a simplified proof based on the theory of Markov chain. In general, these optimality proofs show that the short sampling interval h_S should be made as short as possible, while the long sampling interval h_L should be made as long as possible (i. e. the longest amount of time that is reasonable for the process to run without sampling). As pointed out by *Lucas* and *Saccucci* [17.5], there are practical limitations on how short h_S should be. The value of h_S represents the shortest feasible time interval between subgroups from the process. Any shorter time between subgroups would be impossible due to the amount of time that is required to form the rational subgroups, carry out the inspection, analyze the results from any testing procedures, transport parts and materials, and other delays that would be otherwise inconvenient. So, in this paper we will consider the impact on the expected time until detection, using small but nonzero values of h_S.

Table 17.10 Optimal out-of-control ATS^* of the VSI EWMA-S^2 for $\tau \in \{0.6, 0.7, 0.8, 0.9, 0.95, 1.05, 1.1, 1.2, \ldots, 2\}$, $n \in \{3, 5\}$, $h_S \in \{0.1, 0.5\}$, $W = \{0.1, 0.3, 0.6, 0.9\}$, $ATS_0 = 370.4$

17.4.3 Average Time to Signal for a VSI Control Chart

If the *ARL* is a useful tool for comparing the performance of various control charts, this indicator cannot be used in the case of VSI-type control charts since the interval between two consecutive samples is not constant. As a consequence, it is common to use the *average time to signal* (*ATS*): when the process is in-control and remains in this state, it is desirable to have

Table 17.12 Optimal h_L^* values of the VSI EWMA-S^2 for $n \in \{3, 5, 7, 9\}$, $\tau \in \{0.6, 0.7, 0.8, 0.9, 0.95, 1.05, 1.1, 1.2, \ldots, 2\}$, $h_S \in \{0.1, 0.5\}$, $W = \{0.1, 0.3, 0.6, 0.9\}$, $ATS_0 = 370.4$

a large *ATS* since it represents the expected value of the elapsed time between two consecutive false alarms. Otherwise, if the characteristic of the process has shifted, it is desirable to have an *ATS* that is as small as possible. Since it represents the expected value of the elapsed time between the occurence of a special cause,

i. e. the transition of the process to an out-of-control state, and the signal from the control chart. For an FSI model, the *ATS* is a multiple of the *ARL* since the time h_F between samples is fixed. Thus, in this case we have

$$ATS^{FSI} = h_F \times ARL^{FSI} .$$

For a VSI model, the *ATS* depends on both the number of samples to signal (the *ARL*) and the sampling frequency, which is variable,

$$ATS^{VSI} = E(h) \times ARL^{VSI} ,$$

where $E(h)$ represents the expected value of the sampling interval. For given λ and K, the value of $E(h)$ depends on W, h_S and h_L. For fixed values of h_S and $E(h)$, with $h_S < E(h)$, there is (see *Reynolds* [17.35]) a one-to-one correspondence between W and h_L such that, if the first one decreases, the second one has to increase, and conversely. If we have to compare the out-of-control *ATS* performance of two FSI-type control charts, we only need to define them with the same in-control $ARL_Y = ARL_0$. For VSI-type control charts, this is a little more complex because, if one control chart samples the process more frequently than another, it will necessarily detect a shift in the process sooner than the other one. Consequently, if we have to compare the out-of-control *ATS* performance of two VSI-type control charts, we need to define them with the same in-control $ARL_Y = ARL_0$ *and* the same in-control average sampling interval $E_0(h)$. Because, for *FSI*-type control charts, we have $h_S = h_L = h_F = 1$ time units, the in-control average sampling interval is chosen to be $E_0(h) = 1$. This ensures that we have the same $ATS_Y = ATS_0$ for both FSI- and VSI-type control charts.

17.4.4 Performance of the VSI EWMA-S^2 Control Chart

The performance of the VSI EWMA-S^2 control chart has been investigated by *Castagliola* et al. [17.36]. The *ATS* of the VSI EWMA-S^2 control chart can be computed using the second approach presented in Sect. 17.2.3, where the element g_j of the $(p, 1)$ vector $\boldsymbol{g}$ is defined by

$$g_j = \begin{cases} h_L & \text{if } LWL < H_j < UWL \\ h_S & \text{otherwise} \end{cases} .$$

The optimization scheme of the VSI EWMA-S^2 control chart consists of finding the optimal combination (λ^*, K^*, h_L^*) that give the same in-control $ATS_Y = ATS_0$ (i. e. the *ATS* when the process is functioning at the nominal variability $\sigma = \sigma_0$ or equivalently $\tau = 1$) and then, for predefined values of τ, W and h_S, find the unique combination (λ^*, K^*, h_L^*) which yields the smallest possible out-of-control $ATS_Y = ATS^*$, subject to the constraint $E_0(h) = 1$. The minimal *ATS* values achieved using the optimal VSI model are summarized in Table 17.10 and Table 17.11 for shift $\tau \in \{0.6, 0.7, 0.8, 0.9, 0.95, 1.05, 1.1, 1.2, \ldots, 2\}$ and $n \in \{3, 5, 7, 9\}$. The values used for h_S are 0.5 and 0.1 time units. For comparison purposes, Tables 17.10 and 17.11 also show the minimal *ATS* of the FSI EWMA-S^2 (column $h_L = 1$). As expected, the results clearly indicate that the VSI model outperforms the FSI scheme for all considered shifts of variability since the VSI model gives a signal earlier than the FSI model. For example, for $n = 5$, $h_S = 0.5$ and $W = 0.6$ we have $ATS^* = 65.3$ when $\tau = 0.9$, while for the FSI model we have $ATS^* = 81.0$. When $\tau = 1.2$, we have $ATS^* = 8.8$ for the VSI EWMA-S^2 control chart, while for the FSI model we have $ATS^* = 15.3$. We can also notice that the performance in term of *ATS* is improved when a smaller short sampling interval h_S is considered and, for a selected value of h_S, the *ATS* is improved as the value of W decreases. Table 17.12 shows the optimal long sampling interval h_L^* for several combinations of n, W, h_S and τ. For a defined value of h_S, when W decreases it is no surprise to remark that the length of the long sampling interval h_L^* increases. Finally, Tables 17.13 and 17.14 summarize the optimal couples (λ^*, K^*).

Example 17.6: The goal of this example is to illustrate the use of the VSI EWMA-S^2 control chart using a simulated process. The sample size is assumed to be $n = 5$. We assume that during the first 20 units of time the data are generated according to a normal $(20, 0.1)$ distribution (corresponding to an in-control process) while, after the first 20 units of time, the data are generated according to a normal $(20, 0.13)$ distribution (the nominal process standard deviation σ_0 has increased by a factor of 1.3). If $n = 5$ and $\sigma_0 = 0.1$, then we deduce from Table 17.3: $b_{S^2} = 2.3647$, $c_{S^2} = 0.5979 \times 0.1^2 = 0.005\,979$ and $a_{S^2} = -0.8969 - 2 \times 2.3647 \times \ln(0.1) = 9.9929$. The FSI EWMA chart has been designed by considering $\lambda = 0.05$, $K = 2.515$ and $h_F = 1$; the VSI EWMA was implemented by considering the same couple (λ, K) and $h_S = 0.5$, $h_L = 1.27$, $W = 0.9$. This choice ensures that both the FSI and VSI EWMA-S^2 control charts are designed to have the

same in control $ARL_0 = 370.4$ and are designed to optimally detect a $\tau = 1.5$ shift for the process variability. The control and warning limits are $LCL = 0.0075 - 2.515\sqrt{0.05/1.95} \times 0.967 = -0.382$, $UCL = 0.0075 + 2.515\sqrt{0.05/1.95} \times 0.967 = 0.397$, $LWL = 0.0075 - 0.9\sqrt{0.05/1.95} \times 0.967 = -0.132$ and $UWL = 0.0075 + 0.9\sqrt{0.05/1.95} \times 0.967 = 0.147$. In Table 17.15 we summarize the results of this simulation, i. e. the subgroup number, the sampling interval (h_S or h_L) used for each sample, the total elapsed time from the start of the process simulation and the statistics S_k^2, T_k and Y_k. In Fig. 17.18 (top), we plot the VSI EWMA-S^2 control chart (i. e. the Y_ks) corresponding to our data. As we can see, the VSI EWMA-S^2 control chart clearly detects an out-of-control signal after 25.2 units of time (35-th subgroup), pointing out that an increase of the variance occurred. In Fig. 17.18 (bottom), we plotted the FSI EWMA-S^2 control chart using the same data but

assuming a fixed sampling rate $h_F = 1$. The difference between the FSI and the VSI EWMA-S^2 control chart appears clearly and, in this example, the difference in terms of detection time is 9.8 units of time.

Table 17.18 Optimal h_L^* values of the VSI EWMA-R for $n \in \{3, 5, 7, 9\}$, $\tau \in \{0.6, 0.7, 0.8, 0.9, 0.95, 1.05, 1.1, 1.2, \ldots, 2\}$, $h_S \in \{0.1, 0.5\}$, $W = \{0.1, 0.3, 0.6, 0.9\}$, $ATS_0 = 370.4$

17.4.5 Performance of the VSI EWMA-*R* Control Chart

Concerning the EWMA-R control chart, similar investigations were performed for determining the minimal *ATS* values achieved using the optimal VSI model. These minimal *ATS* values are summarized in Tables 17.16 and 17.17 for shifts $\tau \in \{0.6, 0.7, 0.8, 0.9, 0.95, 1.05, 1.1, 1.2, \ldots, 2\}$ and $n \in \{3, 5, 7, 9\}$. The values used for h_S are 0.5 and 0.1 time units. For comparison purposes, Tables 17.16 and 17.17 also show the minimal *ATS* of the FSI

Table 17.19 Optimal couples (λ^*, K^*) of the VSI EWMA-R for $n \in \{3, 5\}$, $\tau \in \{0.6, 0.7, 0.8, 0.9, 0.95, 1.05, 1.1, 1.2, \ldots, 2\}$, $h_S \in \{0.1, 0.5\}$, $W = \{0.1, 0.3, 0.6, 0.9\}$, $ATS_0 = 370.4$

EWMA-R (column $h_L = 1$). Like the VSI EWMA-S^2 control chart, the results clearly indicate that the VSI EWMA-R control chart outperforms the FSI scheme for all considered shifts of variability since the VSI model gives a signal earlier than the FSI model. For example, for $n = 5$, $h_S = 0.5$ and $W = 0.6$ we have $ATS^* = 63.4$ when $\tau = 0.9$, while for the FSI model we have $ATS^* = 75.0$. When $\tau = 1.2$, we have $ATS^* = 16.6$ for the VSI EWMA-R control chart, while for the FSI model we have $ATS^* = 22.5$. Table 17.18 shows the optimal long sampling interval h_L^* for several combinations of n, W, h_S and τ. Finally, Tables 17.19 and 17.20 summarize the optimal couples (λ^*, K^*).

17.5 Conclusions

This chapter presented several EWMA control charts, both with static or adaptive design parameters, as effective means to monitor the process variability, involving both process position and dispersion. The EWMA control charts are a tool of statistical process control widely adopted in the manufacturing environments, due to their sensitivity in the detection of process drifts caused by special causes influencing variability. EWMA charts outperform the statistical performance of traditional Shewhart control charts thanks to the definition of the statistic to be monitored, which contains information about the past process history: this translates into a faster response on the chart to the presence of an out-of-control condition. Reducing the number of samples to be taken between the occurrence of a special cause and its detection on the control chart is very important because this allows the probability of nonconforming units to be controlled. The average run length (*ARL*), defined as the expected number of samples to be taken before a signal from the chart, was assumed as a quantitative parameter to measure the speed of the chart in revealing the occurrence of a special cause. Through this parameter, different control chart schemes can be directly compared assuming as a common constraint the same probability to signal for a false alarm. To evaluate the *ARL* of static EWMAs, two procedures were presented in this chapter: an approach based on the numerical integration of a Fredholm equation and another based on an approximate discrete Markov-chain model. The *ARL* evaluation of the adaptive EWMAs was performed through the Markov chain, which, in this case, allows for an easy mathematical formulation to be modeled. Traditionally, static and adaptive EWMA charts have been implemented in order to monitor the process position with respect to a particular target value: EWMAs for the process mean and median monitoring have been developed in the literature and compared each other or with Shewhart schemes for the sample mean or median. Here, an extensive set of results are presented for the out-of-control *ARL* of these charts: the analysis of the data shows how the static EWMA-$\bar{X}$ always outperforms the static EWMA-$\tilde{X}$ and the corresponding Shewhart scheme for a wide range of assumed drifts, whatever the sample size. Therefore, the adoption of the EWMA-$\bar{X}$ is suggested to the practitioner whenever small process drifts must be detected. However, in statistical quality control the monitoring of

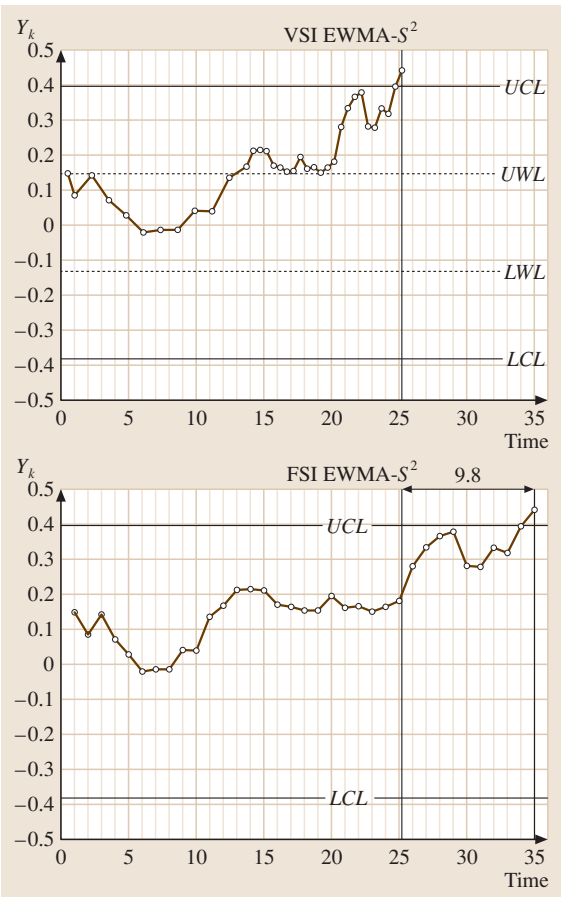

Fig. 17.18 FSI and VSI EWMA-S^2 control chart corresponding to the data in Table 17.15

the process dispersion is equally important as the position, which can be conducted by applying EWMAs to statistics based on the sample dispersion. A survey of EWMAs for monitoring the sample standard deviation S, sample variance S^2 and sample range R was reported in this chapter. The investigated charts work on logarithmic transformations of the measures of dispersion to cope with a variable approximately normally distributed: the formulas adopted to achieve this transformed variable are widely reported throughout the text. The reason for this approach lies in the possibility of managing charts characterized by symmetrical limits, which is common practice in industrial applications to simplify the operator's tasks in the management of the chart. The selected logarithmic transformations work well for all the considered statistics and allow for a direct comparison of the statistical properties of the three charts investigated. The *ARL* computation, optimization and comparison for the three static EWMAs allowed us to demonstrate that the EWMA-S^2 always outperforms both the EWMA-S and EWMA-R when the occurrence of a special cause results in an increase in the dispersion of the data; i.e., when a process is monitored and a deterioration in process repeatability is expected, the EWMA-S^2 is suitable to detect it. Otherwise, if a reduction in process dispersion is expected, for example after a machine maintenance intervention or technological improvement, then the EWMA-R or EWMA-S should be used: in particular, for small sample sizes, ($n \leq 5$), implementing the EWMA monitoring the sample range R is statistically more correct than the EWMA-S, due to the scarce number of measures adopted to evaluate the dispersion statistic. When $n > 5$, the EWMA-S should be used. A further step in the analysis involved the investigation of the adaptive version of the EWMA-S^2 and EWMA-R charts. These adaptive charts have a sampling frequency which is a function of the position of the last plotted point on the chart. The underlying idea is that, when a point is plotted near to the control limits, a possible special cause could be occurring, even if the chart still has not signaled an out-of-control condition; if this is the case, then the next sample should be taken after a shorter time interval. For this reason the variable sampling interval versions of EWMA-S^2 and EWMA-R have been designed and investigated; the EWMA control interval was divided into three zones: a point falling within the central zone, containing the central line of the chart, calls for a longer sampling interval, whereas a point plotted within one of the two external zones included between the central zone and the control limits calls for a shorter time interval. Due to the variability of the time between two samples, the statistical efficiency of these charts was not measured through the *ARL* but through the average time to signal *ATS*. *ATS*s were computed for several sample sizes and expected shifts in process dispersion through the approximate Markov-chain model. For each of the two investigated charts several tables were reported, including the optimal *ATS*s, a comparison with the corresponding static schemes and the values of the optimal parameters. The results show that the variable sampling interval charts always statistically outperform the static charts; furthermore, the differences between S^2 and R found for the static schemes also occur for the adaptive versions: therefore, when increases in process dispersion are expected, the VSI EWMA-S^2 should be used, otherwise the VSI EWMA-R represents the best choice. Finally, it must be argued that EWMA schemes represent a more powerful tool than the traditional Shewhart control charts when process variability is to be monitored, enhancing their statistical properties through the possibility of varying the sampling frequency is effective, whichever the entity of the drift. As a consequence future research should be devoted to the development of adaptive schemes involving the possibility of changing sample size or both sample frequency and sample size.

18. Multivariate Statistical Process Control Schemes for Controlling a Mean

The quality of products produced and services provided can only be improved by examining the process to identify causes of variation. Modern production processes can involve tens to hundreds of variables, and multivariate procedures play an essential role when evaluating their stability and the amount of variation produced by common causes. Our treatment emphasizes the detection of a change in level of a multivariate process.

After a brief introduction, in Sect. 18.1 we review several of the important univariate procedures for detecting a change in level among a sequence of independent random variables. These include Shewhart's X–bar chart, Page's cumulative sum, Crosier's cumulative sum, and exponentially weighted moving-average schemes.

Multivariate schemes are examined in Sect. 18.2. In particular, we consider the multivariate T^2 chart and the related bivariate ellipse format chart, the cumulative sum of T chart, Crosier's multivariate scheme, and multivariate exponentially weighted moving-average schemes.

An application to a sheet metal assembly process is discussed in Sect. 18.3 and the various multivariate procedures are illustrated.

Comparisons are made between the various multivariate quality monitoring schemes in Sect. 18.4. A small simulation study compares average run lengths of the different procedures under some selected persistent shifts.

When the number of variables is large, it is often useful to base the monitoring procedures on principal components. Section 18.5 discussesthis approach. An example is also given using the sheet metal assembly data.

Finally, in Sect. 18.6, we warn against using the standard monitoring procedures without first checking for independence among the observations. Some calculations, involving first-order autoregressive dependence, demonstrate that dependence causes a substantial deviation from the nominal average run length.

Today, with automated data collection a common practice, data on many characteristics need to be continually monitored. In this chapter, we briefly review the major univariate methods and then discuss the multivariate quality monitoring methods for detecting a change in the level of a process. We concentrate on the sequential schemes where the average run length curve is of primary importance for describing the performance. All univariate monitoring schemes attempt to determine if a sequence of observations $X_1, X_2, \cdots$ is stable. That is, to confirm that the mean and variance remain constant. Throughout our discussion we assume that the X_i are in-

dependent. However, in the last section, we do consider the effect of dependence on average run length.

We begin with a review of univariate procedures in Sect. 18.1 and then go on to multivariate extensions in Sect. 18.2. In Sect. 18.3, an example is used to illustrate the behavior of different multivariate procedures. The performance of the multivariate schemes is also compared via simulation in Sect. 18.4. Control charts based on principle components are introduced in Sect. 18.5. In Sect. 18.6, we discuss the difficulties caused by time dependence in the sequence of observations.

18.1 Univariate Quality Monitoring Schemes

To set notation, let $X_1, X_2, \cdots$ be the sequence of independent random variables produced by a process being monitored. Let a denote the target mean value. In the fixed-sample-size setting, the hypothesis to be tested is $H_0 : \mu = a$ versus $H_1 : \mu \neq a$. However, in the sequential setting, we develop statistics based on the deviation from the target value. The statistics will all involve s, an estimate of the standard deviation of a single observation.

Typically, the sequential schemes involve a constant k, called a reference value, and a positive constant h, that defines the decision rule. The two constants (k, h) are selected to give good average run length (ARL) properties. Sometimes, separate reference values k^+ and k^- are used to detect an increase and a decrease in the mean, respectively.

Figure 18.1 shows 50 observations collected on an automotive sheet metal assembly process. These measurements, made by sensors, are deviations from the nominal values (millimeters) at the back right-hand side of the car body. Measurements made at various locations of the car body are presented along with more details in Sect. 18.4.

Figures 18.2–18.5 present different univariate statistics for detecting a change within that data.

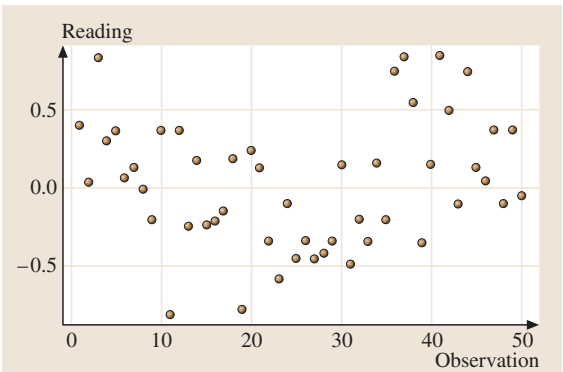

Fig. 18.1 Automotive assembly data

18.1.1 Shewhart *X*-Bar Chart

Historically, the first quality control chart was defined by *Shewhart* [18.1]. This procedure has been widely used since the 1940s. The Shewhart X-bar chart is generally based on the mean of a small sample. That is, the plotted point is usually the mean $\overline{x}_n$ of a few $(m \geq 1)$ observations. When samples are available, rather than just individual observations, charts are also maintained to monitor the process standard deviation.

A widely used Shewhart's X-bar chart [18.1] signals a shift in mean when

$$\overline{X}_n \geq a + 3\frac{s}{\sqrt{m}} \quad \text{or} \quad \overline{X}_n \leq a - 3\frac{s}{\sqrt{m}} ,$$

where s is an estimate of the standard deviation of an individual observation obtained from data collected during stable operation.

Figure 18.2 illustrates Shewhart's X-bar chart applied to automotive assembly data with $m = 1$.

Figure 18.1 suggests that there is a small increase in the mean towards the end of the sequence. However, it is not detected by the Shewhart's X-bar chart.

The Shewhart X-bar chart is very simple and effective for detecting an isolated large shift. However,

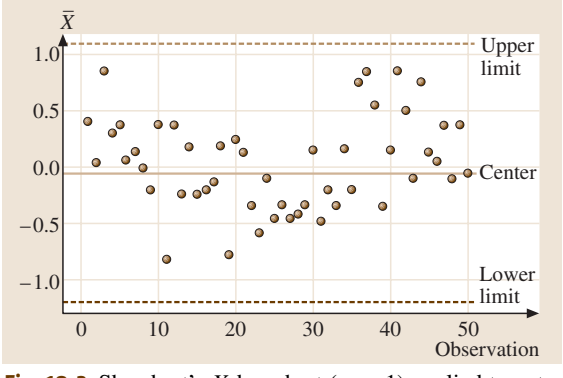

Fig. 18.2 Shewhart's X-bar chart $(m = 1)$ applied to automotive assembly data

because any decision using the Shewhart chart is based only on the most recent observation and has no memory, it is not effective in detecting small or moderate shifts, even if the shifts are persistent.

To help remedy the insensitivity to small shifts, practitioners often apply additional rules for signaling a change. These conditions to signal include:

i) nine points in a row on the same side of the centerline

ii) six points in a row that are decreasing or six that are increasing.

18.1.2 Page's Two-Sided CUSUM Scheme

The univariate two-sided cumulative sum (CUSUM) scheme proposed by *Page* [18.2] uses two cumulative sums: one to detect an increase in mean and another to detect a decrease. It is based on single observations X_n rather than means.

For $n > 1$, Page iteratively defines the two statistics

$$S_{H(n)} = \max(0, S_{H(n-1)} + X_n - k^+) , \tag{18.1}$$

$$S_{L(n)} = \min(0, S_{L(n-1)} + X_n - k^-) \tag{18.2}$$

with specified starting values $S_{H(0)} \geq 0$, $S_{L(0)} \leq 0$. Separate reference values k^+ and k^- are used in Page's CUSUM scheme to detect an increase in the mean and a decrease in the mean, respectively. Specifically, k^+ is selected to be larger than the target a so each term in the sum has a slightly negative expected value, and k^- is selected to be smaller than a. When the sequence of random variables X_1, $X_2, \cdots$ are normally distributed, typically we can set $k^+ = a + ks$ and $k^- = a - ks$, where k is one half of the specified shift in mean (expressed in standard deviations) that should be quickly detected by the scheme.

If the process remains in control at the target value, the CUSUM statistics defined in (18.1) and (18.2) should vary randomly but stay close to zero. When there is an increase in the process mean, a positive drift will develop in the CUSUM statistics S_H. Conversely, if there is a decrease in the mean, then a negative drift will develop in S_L. Therefore, an increasing trend in S_H or a decreasing trend in S_L is taken to indicate a shift in the process mean.

Page's CUSUM scheme signals a shift in mean when

$S_{H(n)} \geq hs$ (signals an increase), or

$S_{L(n)} \leq -hs$ (signals a decrease) .

The positive constant h is chosen to obtain a desired value of in-control ARL.

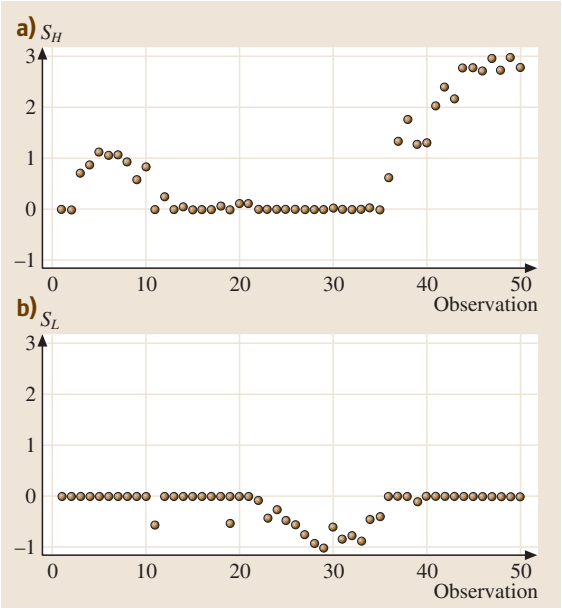

Fig. 18.3 Page's CUSUM statistics S_H (a) and S_L (b) using automotive assembly data

Figure 18.3 illustrates Page's CUSUM statistics applied to the automotive assembly data. The increasing trend in the plot of S_H indicates an increase in the mean towards the end of the sequence. Generally, Page's CUSUM scheme is more effective in detecting small but persistent shifts than the Shewhart X-bar chart.

18.1.3 Crosier's Two-Sided CUSUM Scheme

Crosier [18.3] proposed a two-sided CUSUM scheme which first updates the previous CUSUM by a new observation. Depending on the updated value of this sum, the new value of the CUSUM is either set equal to zero or the sum is shrunk towards zero. This modification reduces the chance of giving a false alarm. It seems from *Crosier* [18.3] that this procedure was arrived at empirically by trying a great many different schemes.

In particular, Crosier's two-sided CUSUM starts with $S_0 = 0$. For each step, first calculate the tentative sum $C_n = |S_{n-1} + (X_n - a)|$. Then Crosier's CUSUM statistic S_n is iteratively defined as

$$S_n = \begin{cases} 0 & \text{if } C_n \leq ks \\ (S_{n-1} + X_n - a)(1 - ks/C_n) & \text{otherwise.} \end{cases} \tag{18.3}$$

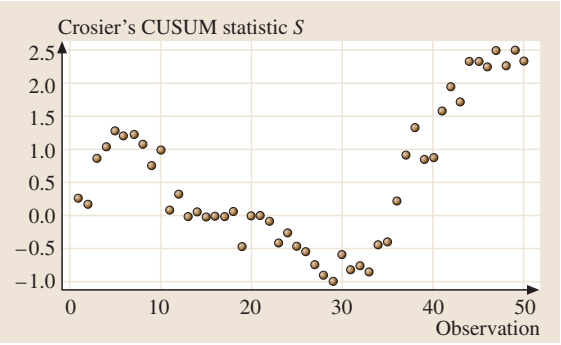

Fig. 18.4 Crosier's CUSUM statistic using automotive assembly data

Here, the constant k can also be set equal to one half of a specified mean-shift (expressed in standard deviations) that should be detected quickly.

Crosier's scheme signals that the mean has shifted when

$$S_n \geq hs \quad \text{(increase)}$$

or

$$S_n \leq -hs \ \text{(decrease)} .$$

Figure 18.4 illustrates Crosier's two-sided CUSUM statistic applied to automotive assembly data.

The plot indicates a possible small decrease in the mean near the middle of the sequence and an increase towards the end.

18.1.4 EWMA Scheme

The univariate exponentially weighted moving-average (EWMA) scheme [18.4] is based on the weighted average of the current CUSUM and the new observation. The EWMA scheme smooths the sequence of observations by taking an average where the most recent observation receives the highest weight. Starting at $Z_0 = 0$, the updated EWMA sum is defined as

$$Z_n = r(X_n - a) + (1-r)Z_{n-1} \qquad (18.4)$$

for $n = 1, 2, \cdots$, where $0 \leq r \leq 1$ is a specified constant. Expressed in terms of all the observations, we have

$$\begin{aligned} Z_n &= r\sum_{i=0}^{n-1}(1-r)^i(X_{n-i} - a) \\ &= r(X_n - a) + r(1-r)(X_{n-1} - a) \\ &\quad + r(1-r)^2(X_{n-2} - a) + \cdots , \end{aligned}$$

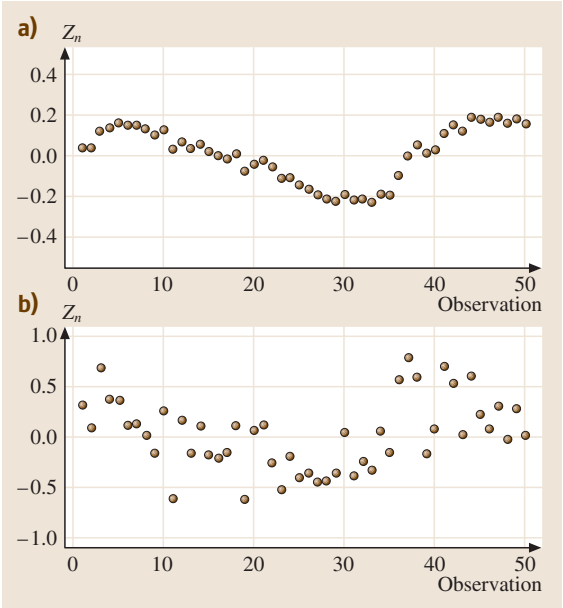

Fig. 18.5 EWMA with $r = 0.1$ (a) and $r = 0.8$ (b), using automotive assembly data

where the weights $r(1-r)^i$ fall off exponentially, giving rise to the name of the EWMA scheme.

The EWMA scheme signals a change in mean when

$$Z_n \geq hs \ \text{(increase)} \ \text{ or } \ Z_n \leq -hs \ \text{(decrease)} .$$

Figure 18.5 shows the EWMA statistics with different choices of r applied to automotive assembly data. In the plot we can see that the EWMA statistic with the smaller value of parameter r is more sensitive to small shifts in this process mean. To be specific, the plot of the EWMA statistics with $r = 0.1$ has a decreasing trend in the middle and then an increasing towards the end of the sequence, which suggests a decrease and then an increase in the mean. However, in the plot of EWMA statistics with $r = 0.8$, such patterns can hardly be recognized.

As shown in Fig. 18.5, the choice of the value for r is critical to the performance of an EWMA scheme. Usually a small value for r is used for detecting a small shift. *Lucas* and *Saccucci* [18.4] extensively discuss the design of EWMA control schemes. For normal observations, they provide a table of *optimal* parameters r and h, which give the minimum ARL at the specified shift in process for specified in-control ARL. Lucas and Saccucci also compare the ARLs of the EWMA and Page's CUSUM schemes. They show that, with carefully chosen parameters r and h, the ARLs for EWMA are usually

smaller than the ARLs of Page's CUSUM scheme when the shift is smaller than the specified value for the shift that the scheme is designed to detect. However, the ARLs for the EWMA are larger than those of Page's CUSUM procedure when the shift in process mean is larger than the specified value, unless r is very large.

18.1.5 Summary Comments

Our review above included most of the popular univariate quality monitoring schemes. See [18.5] for further discussion of univariate schemes for process control. The well-known Shewhart X-bar chart is very effective for detecting large shifts but may be slow to detect small or moderate shifts. This fact gave rise to the setting of warning limits and rules concerning the number of consecutive observations that are increasing or decreasing in value. Page's CUSUM scheme uses a positive (negative) drift when defining the CUSUM statistics for detecting an increase (decrease) in mean. Crosier's CUSUM scheme shrinks the CUSUM statistic instead of adding a drift. Both of these CUSUM procedures make good choices for detecting small but persisting shifts in the process mean. They provide similar ARL performance according to our simulation study in Sect. 18.5 and in *Li* [18.6]. The EWMA scheme proposed by *Lucas* and *Saccucci* [18.4] is also an effective method for detecting small and persisting shifts. Unlike the other two univariate CUSUM schemes, the EWMA does not require the user to specify the shift in mean that should be detected. The EWMA scheme could have better ARL performance than these other CUSUM schemes when the shift is smaller than the specified value. However, the choice of the weight parameter r in (18.4) is somewhat crucial.

18.2 Multivariate Quality Monitoring Schemes

Often, more than one quality characteristics is measured on each unit. We then model the observations as a sequence of independent $p \times 1$ random vectors $\boldsymbol{X}_1$, $\cdots$, $\boldsymbol{X}_n$, $\cdots$ where each has the target mean value $\boldsymbol{a}$ and the same covariance matrix $\boldsymbol{\Sigma}$. If $\boldsymbol{\Sigma}$ is unknown, it must be estimated from a long sequence of observations taken when the process is stable. Any out-of-control observations, detected by a T^2 chart, are deleted. The sample covariance matrix is calculated from the reduced data set. Usually only one data cleaning stage is conducted. As in most of the literature, we will describe the multivariate monitoring schemes in terms of known covariance matrix $\boldsymbol{\Sigma}$. Most of the multivariate schemes discussed below involve a constant k and a positive control limit h.

The literature on multivariate process control includes [18.7–11]. Further discussion is given in [18.12], [18.13, Chapt. 10], and [18.14, Sects. 5.6 and 8.6].

To illustrate what might be the typical behavior of the various multivariate statistics, we generated a sequence of 100 bivariate normal observations with $\boldsymbol{\Sigma} = \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix}$. Our process mean shifted from (0,0) to (0,1) after the 40th observation. This is a moderate shift of one standard deviation in one of the two components.

In this section, we apply each monitoring scheme to that single bivariate sequence of observations. In Sect. 18.5, we look at various other choices and perform simulation studies to determine the ARL under a range of alternatives.

18.2.1 Multivariate T^2 Chart

The traditional T^2 chart reduces each multivariate observation to a scalar by defining

$$T_n^2 = (\boldsymbol{X}_n - \boldsymbol{a})' \boldsymbol{\Sigma}^{-1} (\boldsymbol{X}_n - \boldsymbol{a}) \,. \tag{18.5}$$

The multivariate T^2 scheme signals a shift in mean when T_n^2 first exceeds a specified level h. That is, a change in mean is signaled when

$$T_n^2 \geq h \,.$$

The usual upper control limit is the upper χ^2 percentile $\chi_p^2(\alpha)$ with $\alpha = 0.01$. If the estimated covariance matrix $\boldsymbol{S}$ is based on a relatively small number of observations K, then the appropriate upper control limit is

$$\mathrm{UCL} = \frac{p(K-1)}{K-p} F_{p,K-p}(\alpha) \,.$$

As in the case with its univariate counterpart, the Shewhart X-bar chart, the multivariate T^2 procedure is not very sensitive to small or moderate shifts from the target $\boldsymbol{a}$ because it is only based on the most recent observation and has no *memory* of previous observations.

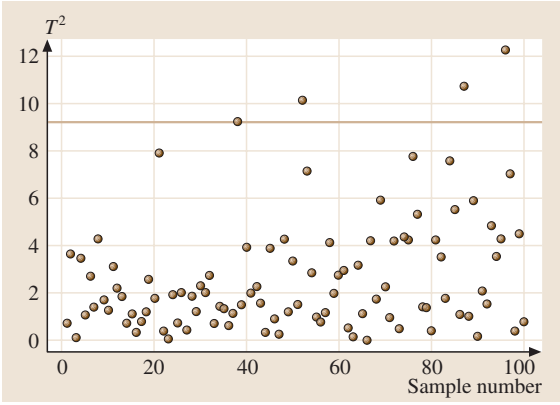

Fig. 18.6 T^2 chart with a 99% control limit using our generated bivariate data

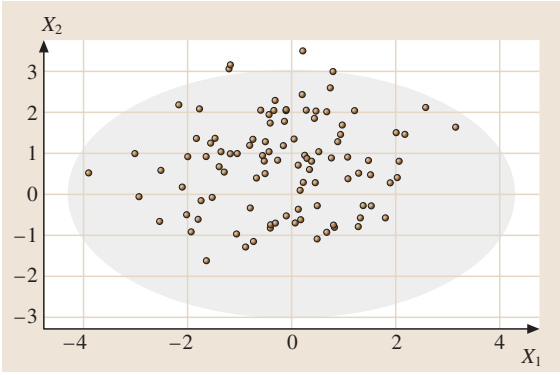

Fig. 18.7 The T^2 99% control ellipse using our generated bivariate data

Figure 18.6 illustrates the traditional multivariate T^2 scheme applied to our generated bivariate normal observations. As shown in the graph, there is a false alarm at $n = 38$ and the first correct detection of a shift is at $n = 52$. The shift from (0,0) to (1,0) at $n = 40$ is not detected particularly quickly and persistently by the T^2 chart with $\boldsymbol{a} = (0, 0)$.

When there are only two important variables, it is more informative to plot the individual 2×1 vectors $\boldsymbol{X}_n$ with the control ellipse in an ellipse format chart for T^2 statistics. The 99% control ellipse is

$$T_n^2 = (\boldsymbol{X}_n - \boldsymbol{a})' \boldsymbol{\Sigma}^{-1} (\boldsymbol{X}_n - \boldsymbol{a}) \le \chi_2^2(0.01) \, .$$

The generated bivariate normal data and the 99% control ellipse are shown in Fig. 18.7. There is one false detection outside the control ellipse at $n = 38$ and a few correct detections of the shift in mean at $n = 52$, 87 and 96.

T^2 Control Charts Based on Means

Often, rather than using a single observation, a control chart is based on points that correspond to the mean of a small sample of size m. We still assume that the population is $p-$variate normal with mean vector $\boldsymbol{0}$ and covariance matrix $\boldsymbol{\Sigma}$. However, because of the central limit effect that sample means are more normal than individual observations, the normality of the population is not as crucial. It is now assumed that each random vector of observations from the process is independently distributed as $N_p(\boldsymbol{0}, \boldsymbol{\Sigma})$. We proceed differently, when the sampling procedure specifies that $m > 1$ units be selected, at the same time, from the process. From the first sample, we determine its sample mean $\overline{\boldsymbol{X}}_1$ and covariance matrix $\mathbf{S}_1$. When the population is normal, these two random quantities are independent.

Starting with K samples, where the the $j-$th sample has mean vector $\overline{\boldsymbol{X}}_j$ and covariance matrix $\mathbf{S}_j$, the estimator of the population mean vector $\boldsymbol{\mu}$ is the overall sample mean

$$\overline{\overline{\boldsymbol{X}}} = \frac{1}{K} \sum_{j=1}^{K} \overline{\boldsymbol{X}}_j \, .$$

The sample covariances from the n samples can be combined to give a single estimate (called $\boldsymbol{S}_{\text{pooled}}$) of $\boldsymbol{\Sigma}$ as

$$\mathbf{S} = \frac{1}{K} (\mathbf{S}_1 + \mathbf{S}_2 + \cdots + \mathbf{S}_K) \, ,$$

where $(mK - K)\mathbf{S}$ is independent of each $\overline{\boldsymbol{X}}_j$ and therefore of their mean $\overline{\overline{\boldsymbol{X}}}$. That is, we can now estimate $\boldsymbol{\Sigma}$ internally from the data collected in any given period. These estimators are combined into a single estimator with a large number of degrees of freedom.

T^2 Chart When Means Are Plotted. When the chart is based on the sample mean $\overline{\boldsymbol{X}}_n$ of m observations rather than a single observation, the values of

$$T_n^2 = m(\overline{\boldsymbol{X}}_n - \boldsymbol{a})' \boldsymbol{\Sigma}^{-1} (\overline{\boldsymbol{X}}_n - \boldsymbol{a})$$

are plotted for $n = 1, 2, \cdots$, where the

$$\text{UCL} = \chi_p^2(0.01)$$

or some other upper percentile of the chi-square distribution with p degrees of freedom.

Ellipse Format Chart. The control ellipse, expressed in terms of the sample mean $\overline{\boldsymbol{X}}_n$ of m observations, is

$$(\overline{\boldsymbol{x}} - \boldsymbol{a})' \boldsymbol{\Sigma}^{-1} (\overline{\boldsymbol{x}} - \boldsymbol{a}) \le \chi_p^2(0.01)/m \, ,$$

where $\chi^2_p(0.01)/m$, on the right-hand side, can be replaced by some other upper percentile. For $p = 2$, a graph of the ellipse is usually presented for visual inspection of the data.

18.2.2 CUSUM of T_n (COT) Scheme

The cumulative sum of T, COT or CUSUM of T_n scheme, is the most direct extension of the multivariate T^2 chart to a CUSUM procedure. It forms a CUSUM of the scalar statistics T_n, where T_n^2 is defined in (18.5).

Let $S_0 \geq 0$ and $k > 0$ be specified constants. Iteratively define

$$S_n = \max(0, S_{n-1} + T_n - k), \quad \text{for} \quad n = 1, 2, \cdots, \tag{18.6}$$

where k is a specified positive constant.

The COT scheme signals when it surpasses a specified level h. That is, the COT scheme signals a change in mean when

$$S_n \geq h \, .$$

Figure 18.8 illustrates the performance of the CUSUM of T. As we can see, the COT scheme does show an increasing trend which indicates a shift in the sequence mean, while the multivariate T^2 chart does not persistently indicate a change because the shift is not large enough.

18.2.3 Crosier's Multivariate CUSUM Scheme

Crosier [18.11] also generalized his univariate CUSUM scheme to the multivariate setting. Crosier's multivariate statistic starts at $\boldsymbol{S}_0 = \boldsymbol{0}$. With a specified constant k, iteratively define

$$\boldsymbol{S}_n = \begin{cases} \boldsymbol{0} & \text{if } C_n \leq k \\ (\boldsymbol{S}_{n-1} + \boldsymbol{X}_n - \boldsymbol{a})(1 - k/C_n) & \text{otherwise,} \end{cases} \tag{18.7}$$

where

$$C_n = [(\boldsymbol{S}_{n-1} + \boldsymbol{X}_n - \boldsymbol{a})' \boldsymbol{\Sigma}^{-1} (\boldsymbol{S}_{n-1} + \boldsymbol{X}_n - \boldsymbol{a})]^{1/2} \, .$$

For a specified constant h, Crosier's multivariate scheme signals a shift in mean from $\boldsymbol{a}$ when

$$Y_n = (\boldsymbol{S}_n' \boldsymbol{\Sigma}^{-1} \boldsymbol{S}_n)^{1/2} \geq h \, .$$

Figure 18.9 illustrates the performance of Crosier's multivariate CUSUM scheme with the generated bivariate normal data. In the plot, a increasing trend was shown shortly after the shift in process occurs at the 41st observation. Therefore, the shift is detected faster than it is detected by the COT scheme.

18.2.4 Multivariate EWMA Scheme [MEWMA(r)]

In multivariate settings, *Lowry* and *Woodall* [18.15] proposed a natural extension of the univariate EWMA scheme. Starting with $\boldsymbol{Z}_0 = \boldsymbol{0}$, the multivariate EWMA statistic $\boldsymbol{Z}_n$ is defined, iteratively, by

$$\boldsymbol{Z}_n = \mathbf{R}(\boldsymbol{X}_n - \boldsymbol{a}) + (\mathbf{I} - \mathbf{R})\boldsymbol{Z}_{n-1} \quad \text{for} \quad n = 1, 2, \cdots, \tag{18.8}$$

where the weight matrix $\mathbf{R} = diag(r_1, \cdots, r_p), 0 \leq r_j \leq 1, \, j = 1, \cdots, p$. That is, Lowry and Woodall specialize

to cases where $\mathbf{R}$ is a diagonal matrix. This reduces to the situation where a univariate EWMA is applied to each individual component. When there is no a priori reason to weight the p quality characteristics differently, they further suggest the use of a common value $r_1 = \cdots = r_p = r$, where $0 \le r \le 1$ is a constant.

The MEWMA scheme signals if the scalar $\boldsymbol{Z}_n' \boldsymbol{\Sigma}^{-1} \boldsymbol{Z}_n$ is large. More particularly, for a specified constant h, the MEWMA scheme signals a shift in mean from $\boldsymbol{a}$ when

$$(\boldsymbol{Z}_n' \boldsymbol{\Sigma}^{-1} \boldsymbol{Z}_n)^{1/2} \ge h \, .$$

Analogous to the univariate case, the choice of weight matrix $\mathbf{R}$ has a considerable influence on the resulting ARL behavior. Usually a small value of r is selected to detect small shifts in each component of mean.

Figure 18.10 illustrates the performance of the MEWMA scheme evaluated for our generated bivariate normal data under two different choices of the constant r. Again, we see that the MEWMA scheme with a small value of r is more effective in detecting a small but persisting shift like the one in our generated data.

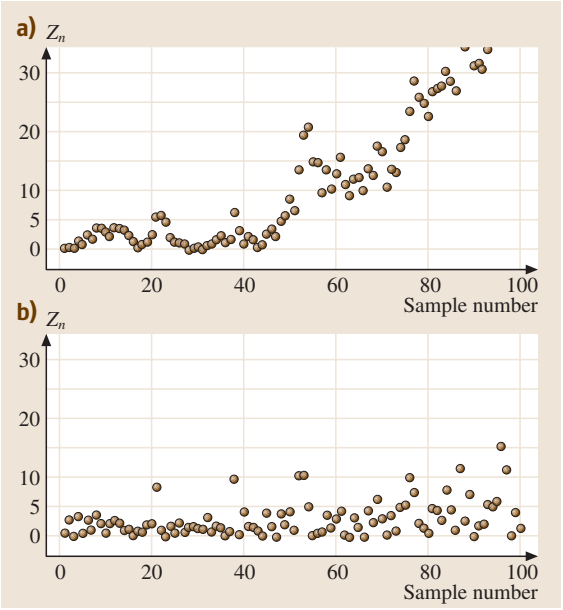

Fig. 18.10 MEWMA with $r = 0.1$ (a) and $r = 0.8$ (b), using our generated bivariate normal data

18.3 An Application of the Multivariate Procedures

The data that we use to illustrate the various control charts is courtesy of Darek Ceglarek. He collected these measurements on the sheet metal assembly process as part of a study conducted with a major automobile manufacturer. *Ceglarek* and *Shi* [18.16] give more detail on the body assembly process. There are six variables of which four were measured when the car body was complete and two were measured on the underbody at an earlier stage of assembly.

All measurements were taken by sensors that recorded the deviation from the nominal value in millimeters:

x_1 = deviation at mid right-hand side, body complete,
x_2 = deviation at mid left-hand side, body complete,
x_3 = deviation at back right-hand side, body complete,
x_4 = deviation at back left-hand side, body complete,
x_5 = deviation at mid right-hand side of underbody,
x_6 = deviation at mid left-hand side of underbody.

The covariance matrix and the mean estimated from the first 30 observations are

$$\mathbf{S} = \begin{pmatrix} 0.0626 & 0.0616 & 0.0474 & 0.0083 & 0.0197 & 0.0031 \\ 0.0616 & 0.0924 & 0.0268 & -0.0008 & 0.0228 & 0.0155 \\ 0.0474 & 0.0268 & 0.1446 & 0.0078 & 0.0211 & -0.0049 \\ 0.0083 & -0.0008 & 0.0078 & 0.1086 & 0.0221 & 0.0066 \\ 0.0197 & 0.0228 & 0.0211 & 0.0221 & 0.3428 & 0.0146 \\ 0.0031 & 0.0155 & -0.0049 & 0.0066 & 0.0146 & 0.0366 \end{pmatrix}$$

$$\bar{\boldsymbol{x}} = (\,-0.5063 \quad -0.2070 \quad -0.0620 \quad -0.0317 \quad 0.6980 \quad -0.0650\,)'.$$

Figure 18.11 gives the Shewhart X-bar charts for each of the six variables. Except for two cases with the last variable measured at the left side of the underbody, all of the observations are within their 99% control limits.

Figures 18.12 and 18.13 show the multivariate T^2 chart and the CUSUM of T chart applied to the automotive assembly data. In the multivariate T^2 chart we can see that a few values between the 30th and 40th observations are out of the control limits. The CUSUM of T chart indicates a small and persistent shift at the end of the sequence, which is not detected by the multivariate T^2 chart.

The Crosier's CUSUM statistic illustrated in Fig. 18.14 also indicates a small and persistent shift, which is consistent with the CUSUM of T chart.

The multivariate EWMA schemes are illustrated in Fig. 18.15. There is a considerable difference in the appearance depending on the choice of the common weight r. In the plot of multivariate EWMA

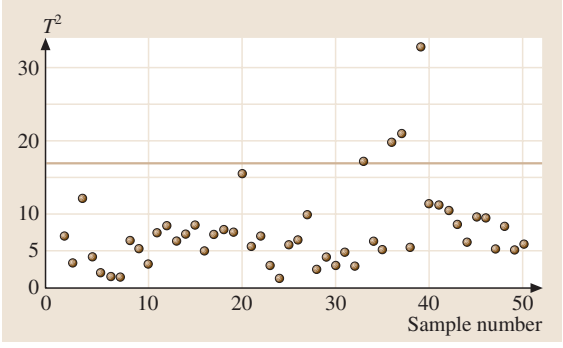

Fig. 18.12 Multivariate T^2 chart for automotive assembly data

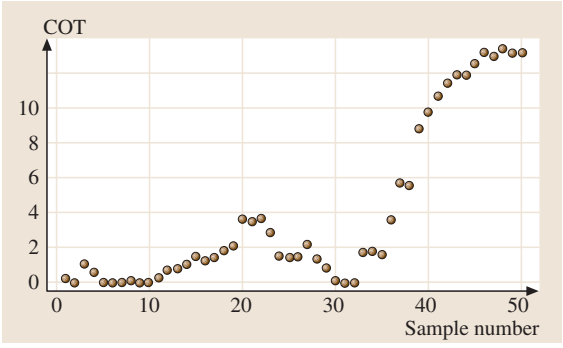

Fig. 18.13 CUSUM of T chart for automotive assembly data

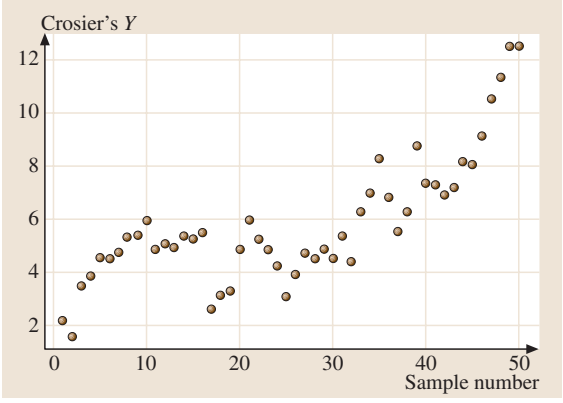

Fig. 18.14 Crosier's CUSUM statistic applied to automotive assembly data

statistics with $r = 0.1$, an increasing trend indicates an increase in the mean, which is consistent with the CUSUM of T chart and Crosier's CUSUM scheme. However, with $r = 0.8$, we can not see the increasing pattern in the plot for the multivariate EWMA statistics.

18.4 Comparison of Multivariate Quality Monitoring Methods

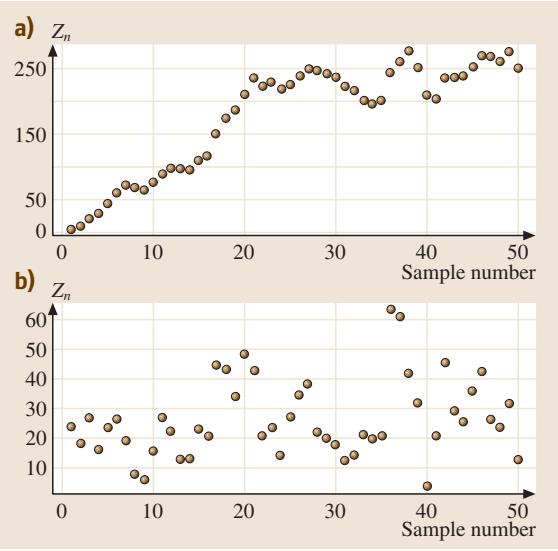

Fig. 18.15a,b Multivariate EWMA statistics with $r = 0.1$ (**a**) and $r = 0.8$ (**b**), using automotive assembly data

Several authors, including *Pignatiello* [18.17] and *Lowry* [18.18], have compared various multivariate monitoring procedures. To confirm their general conclusions, we use simulation to study the average run length (ARL) properties of the multivariate sequential schemes discussed above. Specifically, the ARL is defined as the average number of observations before the scheme gives a signal. If the shift did not occur at the beginning of the series of observations, it is common practice to use the steady-state ARL, which is the average additional run length after the shift occurs. An effective scheme should have a large ARL when the process is *in control* and a small ARL when the process is *out of control*. Usually, to compare different schemes, we can set the in-control ARLs to be nearly equal and compare the ARLs when there is a shift.

In our simulation, we generate bivariate normal observations with either $\boldsymbol{\Sigma} = \boldsymbol{I}$ (uncorrelated) or $\boldsymbol{\Sigma} = \begin{pmatrix} 1.0 & -0.6 \\ -0.6 & 1.0 \end{pmatrix}$. For each choice of $\boldsymbol{\Sigma}$ and

shift in mean, series of observations were generated and the multivariate statistics were calculated until a shift is signaled. This procedure was repeated 5000 times and we calculate the ARL and the estimated standard error of ARL for each scheme. Table 18.1 and 18.2 show the results of our simulation, where the estimated standard errors are given in smaller type.

From our simulation and existing literature, we conclude that, due to the fact that the value of the T^2 statistic only depends on the most current observation, it is not sensitive to small and moderate shifts in the mean of a process even if the shift is persistent. By taking the CUSUM of T, The COT procedure has ARL performance that is significantly improved over that of the T^2 chart. The ARL of Crosier's scheme is considerably better than that of the COT scheme. The performance of multivariate EWMA schemes depend heavily on the value of the weight parameters. If the weight is appropriately selected, the multivariate EWMA will have very good ARL performance which is comparable with Crosier's scheme.

18.5 Control Charts Based on Principal Components

The first two sample principal components concentrate the sample variability. Starting with a sample $\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_K$, of size K, collected when the process is stable, the first sample principal component is the linear combination with values, $y_j = \boldsymbol{a}'(\boldsymbol{x}_j - \overline{\boldsymbol{x}})$ that has maximum sample variance among all choices with $\boldsymbol{a}'\boldsymbol{a} = 1$. The second sample principal component is the linear combination, having values $\boldsymbol{b}'(\boldsymbol{x}_j - \overline{\boldsymbol{x}})$, that has maximum variance among all linear combinations with $\boldsymbol{b}'\boldsymbol{b} = 1$ and that have zero correlation with the first principal component. The third sample principal component is the linear combination with maximum sample variance, subject to being uncorrelated with each of the first two principal components and having coefficient vector of length one. See *Johnson* and *Wichern* [18.14] for a thorough description of principal components.

The coefficients that provide the maximum variance are the eigenvectors $\boldsymbol{e}$ of the sample covariance matrix $\mathbf{S}$. That is, they are the solutions of

$$\mathbf{S}\,\boldsymbol{e} = \lambda\,\boldsymbol{e}$$

with the $\boldsymbol{e}$ normalized so that $\boldsymbol{e}'\boldsymbol{e} = 1$. There are p solutions $(\lambda_i, \boldsymbol{e}_i)$ where $\lambda_1 \geq \lambda_2 \cdots \geq \lambda_p$. The first sample principal component

$$\hat{y}_{1j} = \boldsymbol{e}_1'(\boldsymbol{x}_j - \overline{\boldsymbol{x}})$$

has the maximum possible variance λ_1. More generally, the k-th principal component

$$\hat{y}_{kj} = \boldsymbol{e}_k'(\boldsymbol{x}_j - \overline{\boldsymbol{x}}), \quad k = 1, 2, \cdots, p$$

has sample variance λ_k.

If the process is stable over time, then the values of the first two principal components should be stable. Conversely, if the principal components remain stable over time, the common effects which influence the process are likely to remain constant.

Through an example, we introduce a two-part monitoring procedure based on principal components.

18.5.1 An Application Using Principal Components

Today, with electronic and other automated methods of data collection, major chemical and drug companies regularly measure over 100 different process variables such as temperature, pressure, concentrations and weights at various positions along the production process. Even with 11 variables to monitor, there are 55 possible pairs of variables for which ellipse format charts could be created. Consequently, we need to consider an alternative approach that both produces visual displays of important quantities and still has the sensitivity to detect special causes. Here we introduce a two-part multivariate quality control procedure that is widely applied when a large number of variables are being monitored [18.19].

The first part is an ellipse format chart to monitor the first two principal components. The second part is a T^2 chart based on the remaining principal components.

If the p variables have quite different variances, it is usual to standardize the variables before finding the principal components. This is equivalent to extracting the eigenvectors from the correlation matrix $\mathbf{R}$. Here we skip that step because the variables are comparable.

The values of the first and second sample principal components for the $n-$th observation are

$$\hat{y}_{1n} = \boldsymbol{e}_1'(\boldsymbol{x}_n - \overline{\boldsymbol{x}}) ,$$
$$\hat{y}_{2n} = \boldsymbol{e}_2'(\boldsymbol{x}_n - \overline{\boldsymbol{x}}) .$$

The first part of the multivariate quality control procedure is to construct a ellipse format chart for the pairs of values $(\hat{y}_{1n}, \hat{y}_{2n})$, $n = 1, 2, \ldots$.

Recall that the variance of the first principal component $\hat{y}_1$ is λ_1, that of the second principal component $\hat{y}_2$ is λ_2, and the two are uncorrelated. Consequently, the control format ellipse reduces to the collection of possible values $(\hat{y}_1, \hat{y}_2)$ such that

$$\frac{\hat{y}_1^2}{\lambda_1} + \frac{\hat{y}_2^2}{\lambda_2} \le \chi_2^2(\alpha) .$$

Chart 1: The elliptical control region for the first two principal components

Refer to the automotive assembly data on $p = 6$ variables. We base our estimate $\mathbf{S}$ of $\boldsymbol{\Sigma}$ on the first 30 stable observations. A computer calculation gives the eigenvalues and eigenvectors in Table 18.3.

The 99% ellipse format chart for the first two principal components

$$\frac{\hat{y}_1^2}{\lambda_1} + \frac{\hat{y}_2^2}{\lambda_2} \le \chi_2^2(0.01)$$

is shown in Fig. 18.16 along with the pairs of values of the principal components for the first 30 observations as well as the additional cases. There are no points out of control.

Special causes may still produce shocks to the system not apparent in the values of the first two principal components and a second chart is required.

Chart 2: A T^2 chart for the remaining principal components

For the 30 stable observations, the approximation to $\boldsymbol{x}_j - \overline{\boldsymbol{x}}$ by the first two principal components has the form $\hat{y}_{1j}\boldsymbol{e}_1 + \hat{y}_{1j}\boldsymbol{e}_2$ [18.14]. This leaves an unexplained component of the j-th deviation $\boldsymbol{x}_j - \overline{\boldsymbol{x}}$. Namely,

$$\boldsymbol{x}_j - \overline{\boldsymbol{x}} - \hat{y}_{1j}\boldsymbol{e}_1 - \hat{y}_{2j}\boldsymbol{e}_2 .$$

For each j, this unexplained component is perpendicular to both of the eigenvectors $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$. Consequently,

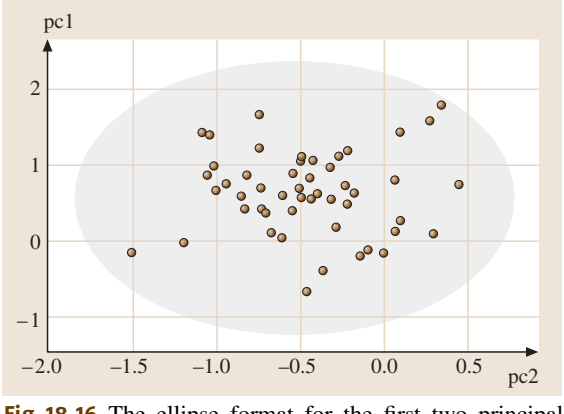

Fig. 18.16 The ellipse format for the first two principal components – automotive data

Table 18.3 Eigenvectors and eigenvalues from the 30 stable observations

	e_1	e_2	e_3	e_4	e_5	e_6
x_1	0.1193	0.4691	0.0752	0.2906	0.2672	0.7773
x_2	0.1295	0.4576	0.2508	0.6237	0.0366	−0.5661
x_3	0.1432	0.7170	−0.1161	−0.6323	−0.1746	−0.1471
x_4	0.0964	0.0529	−0.9555	0.2568	0.0619	−0.0715
x_5	0.9677	−0.2312	0.0700	−0.0641	0.0322	−0.0030
x_6	0.0517	0.0135	−0.0078	0.2380	−0.9444	0.2204
λ_i	0.3544	0.1864	0.1076	0.0972	0.0333	0.0088

it is perpendicular to its approximation $\hat{y}_{1j}\boldsymbol{e}_1 + \hat{y}_{1j}\boldsymbol{e}_2$, which implies that the approximation and unexplained component have zero sample covariance.

Seen another way, let $\mathbf{E} = (\boldsymbol{e}_1, \boldsymbol{e}_2, \cdots, \boldsymbol{e}_p)$ be the orthogonal matrix whose columns are the eigenvectors of $\mathbf{S}$. The orthogonal transformation of the unexplained part is

$$\mathbf{E}'(\boldsymbol{x}_j - \overline{\boldsymbol{x}} - \hat{y}_{1j}\boldsymbol{e}_1 - \hat{y}_{2j}\boldsymbol{e}_2) = \begin{pmatrix} 0 \\ 0 \\ \hat{y}_{3j} \\ \cdot \\ \cdot \\ \cdot \\ \hat{y}_{pj} \end{pmatrix} .$$

The first two components are always zero so we base the T^2 chart on the values of the last $p-2$ principal components. Because the

$$\text{sample variance } (\hat{y}_{ij}) = \lambda_i \text{ for } i = 1, 2, 3, \cdots, p$$

and the principal components have zero sample covariances, the T^2 based on the original quantities $\boldsymbol{x}_j - \overline{\boldsymbol{x}} - \hat{y}_{1j}\boldsymbol{e}_1 - \hat{y}_{2j}\boldsymbol{e}_2$ is equivalent to the one based on the values

$$T_j^2 = \frac{\hat{y}_{3j}^2}{\lambda_3} + \frac{\hat{y}_{4j}^2}{\lambda_4} + \cdots + \frac{\hat{y}_{pj}^2}{\lambda_p} .$$

Because the coefficients of the linear combinations, $\boldsymbol{e}_i$, are also estimates, the principal components do not have a normal distribution even when the underlying population is normal. Consequently, it is customary to use the large-sample approximation to the upper control limit, UCL $= \chi^2_{p-2}(\alpha)$.

This T^2 statistic can be based on high-dimensional data. When $p = 20$ variables are measured, it concerns the 18-dimensional space perpendicular to the first two eigenvectors. Still, it is reported as highly effective in picking up special causes.

Refer the automobile assembly data. The quality ellipse for the first two principal components was shown in Fig. 18.16. To illustrate the second step of the two step monitoring procedure, we create the chart for the other variables. Since $p = 6$, this 99% chart is based on $6-2 = 4$ dimensions and the upper control limit is $\chi^2_4(0.01) = 13.28$. We plot the time sequence of values

$$T_n^2 = \frac{\hat{y}_{3n}^2}{\lambda_3} + \frac{\hat{y}_{4n}^2}{\lambda_4} + \frac{\hat{y}_{5n}^2}{\lambda_5} + \frac{\hat{y}_{6n}^2}{\lambda_6} .$$

The T^2 chart is shown as Fig. 18.17.

Something has likely happened at the 33rd, 36th, 37th and the 39th observations. For the 39th observation, the values of the last principal components are -0.2712, -0.2105, 0.8663, -0.2745, respectively. The value of $\hat{y}_{5,39} = 0.8663$ is particularly large, with reference to the coefficient vector $\boldsymbol{e}_5$ in Table 18.3, we see that the fifth principal component is essentially X_6. From the data and the univariate Shewhart X-bar charts in Fig. 18.11, we see that the mean of the last variable has increased.

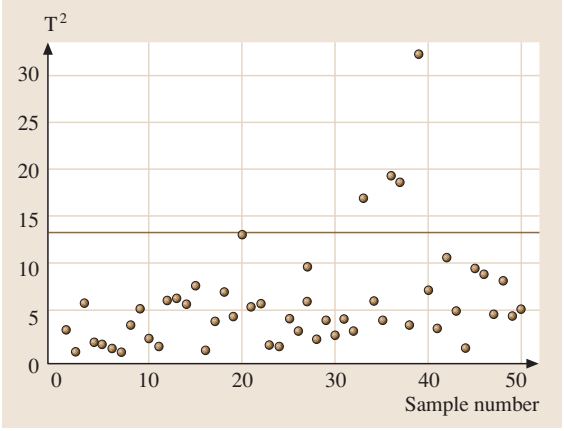

Fig. 18.17 T^2 chart based on the last four principal components – automotive data

In some applications in the pharmaceutical industry hundreds of variables are monitored. Then, the space orthogonal to the first few principal components has dimension greater than 100 and some the eigenvalues are very small. An alternative approach [18.19], which avoids the difficulty of dividing by very small numbers, has been successful applied. For each of the K stable observations, take the sum of squares of its unexplained component

$$d^2_{\perp j} = (\boldsymbol{x}_j - \overline{\boldsymbol{x}} - \hat{y}_{1j}\boldsymbol{e}_1 - \hat{y}_{2j}\boldsymbol{e}_2)' \times (\boldsymbol{x}_j - \overline{\boldsymbol{x}} - \hat{y}_{1j}\boldsymbol{e}_1 - \hat{y}_{2j}\boldsymbol{e}_2) \,.$$

Note that, by inserting $\mathbf{E}\mathbf{E}' = \mathbf{I}$, we also have

$$d^2_{\perp j} = \left(\boldsymbol{x}_j - \overline{\boldsymbol{x}} - \hat{y}_{1j}\boldsymbol{e}_1 - \hat{y}_{2j}\boldsymbol{e}_2\right)' \mathbf{E}\mathbf{E}' \times \left(\boldsymbol{x}_j - \overline{\boldsymbol{x}} - \hat{y}_{1j}\boldsymbol{e}_1 - \hat{y}_{2j}\boldsymbol{e}_2\right) = \sum_{k=3}^{p} \hat{y}^2_{kj}$$

which is just the sum of squares of the neglected principal components.

Using either form, the $d^2_{\perp n}$ are plotted versus n to create a control chart. The lower control limit is zero and the upper limit is set by approximating the distribution of $d^2_{\perp n}$ as a constant c times a chi-square random variable with ν degrees of freedom. The constant c and degrees of freedom ν are chosen to match the sample mean and variance of the $d^2_{\perp j}$, $j = 1, \cdots, K$. In particular, setting

$$\overline{d^2_{\perp}} = \frac{1}{K}\sum_{j=1}^{K} d^2_{\perp j} = c\,\nu \,,$$

$$s_{dd} = \frac{1}{K}\sum_{j=1}^{K}\left(d^2_{\perp j} - \overline{d^2_{\perp}}\right)^2 = 2c^2\nu \,,$$

we determine that

$$c = \frac{s_{dd}}{2\overline{d^2_{\perp}}} \quad \text{and} \quad \nu = 2\frac{(\overline{d^2_{\perp}})^2}{s_{dd}} \,.$$

The upper control limit is then $c\chi^2_\nu(\alpha)$, where $\alpha = 0.05$ or 0.01.

We remark that this two-step procedure can be made more sensitive by using, for instance, Crosier's scheme.

18.6 Difficulties of Time Dependence in the Sequence of Observations

We must include a warning that pertains to the application of any of the quality monitoring procedures we have discussed. They are all based on the assumption that the observations are independent. Most often, especially with automated collection procedures, observations may be taken close together in time or space. This can produce a series of observations that are not independent but correlated in time.

We emphasize that the methods described in this chapter are based on the assumption that the multivariate observations $\boldsymbol{X}_1, \boldsymbol{X}_2, \cdots, \boldsymbol{X}_n$ are independent of one another. The presence of even a moderate amount of time dependence among the observations can cause serious difficulties for monitoring procedures.

One common and simple univariate model that usually captures much of the time dependence is a first-order autoregressive process (AR(1))

$$X_n - \mu = \phi\,(\,X_{n-1} - \mu\,) + \varepsilon_n \,,$$

where $-1 < \phi < 1$. The ε_n are independent, mean-zero, shocks all having the same variance σ^2_ε. The AR(1) model relates the observation at time n, to the observation at time $n-1$, through the coefficient ϕ. The name autoregressive model comes from the fact that the model looks like a regression model with X_n as the dependent variable and the previous value X_{n-1} as the independent variable.

Under normality of errors, if $\phi = 0$, the autoregressive model implies that the observations are independent. It is not at all unusual in practice to find values of ϕ as high as 0.3 or 0.4.

The AR(1) model, implies that all of the X_n have the same variance $\sigma^2_X = \sigma^2_\varepsilon / (1-\phi^2)$. As shown in *Johnson* and *Langeland* [18.20], if the sample variance s^2 is calculated from a long series of adjacent observations, s^2 will closely approximate σ^2_X. That is, the correct variance is being estimated.

We first consider the effects of dependence in the context of the X-bar chart. When the individual observations X_n are plotted, with limits set at $\pm 3\sigma_X$, we still have

$$P(\,|\,X_n - \mu\,|\,> 3\sigma_X\,) = 0.0027 \,.$$

The observations are correlated but we expect the same number of false alarms.

In this sense, the X-bar chart is robust with respect to dependence. If the points being plotted, $\overline{X}_n$, correspond

Table 18.4 Probability of false alarms when the process is in control. Normal populations and X-bar chart

	$\phi = -0.4$	$\phi = -0.2$	$\phi = -0.1$	$\phi = 0$	$\phi = 0.1$	$\phi = 0.2$	$\phi = 0.4$
$k = 0.5,\ \ h = 4.24$	9549.0	884.0	390.5	206.1	121.8	82.6	43.9
$k = 0.75,\ \ h = 2.96$	2901.2	706.3	356.2	204.1	128.5	88.5	48.1

Table 18.6 The h value to get in-control ARL ≈ 200, $k = 0.5$. Page's CUSUM

	$\phi = -0.6$	$\phi = -0.3$	$\phi = -0.1$	$\phi = 0$	$\phi = 0.1$	$\phi = 0.3$	$\phi = 0.6$
h	2.34	2.94	3.77	4.24	4.76	6.38	10.6
in-control ARL	214.6	205.5	213.2	206.1	202.7	205.8	210.3

to the sample mean of m adjacent observations, then

$$\sigma^2_{\overline{X}} = \mathrm{Var}(\overline{X}_n) = \frac{\sigma^2_X}{m}\left(1 + \sum_{j=1}^{m-1}\frac{m-j}{m}\phi^j\right).$$

In this case, the probability of a false alarm when the limits are set at $3\sigma_X/\sqrt{m}$, is

$$P\left(\lvert\overline{X}_n - \mu\rvert > 3\frac{\sigma_X}{\sqrt{m}}\right) = P\left(\left|\frac{\overline{X}_n - \mu}{\sigma_{\overline{X}}}\right| > 3\frac{\sigma_X/\sqrt{m}}{\sigma_{\overline{X}}}\right).$$

There are some dramatic changes from the nominal value of the probability of a false alarm when the process is in control. Some values are given in Table 18.4.

The consequences of dependence are much more severe on the CUSUM statistic. *Johnson* and *Bagshaw* [18.21] present some limiting results for the distribution of ARL when the centering values are selected so the contribution of the n-th observation has mean zero for every n. The presence of dependence greatly alters the ARL. Essentially, this occurs because the CUSUM is a smooth function of the stochastic process defined at $n = 0, 1, \cdots$ by

$$n^{-1/2}S_n = n^{-1/2}\sum_{i=1}^{n}(X_i - \mu).$$

For large fixed n, $n^{-1/2}S_n$ is normal with variance approaching $\sigma^2_X(1+\phi)/(1-\phi)$. This is quite different from σ^2_X, which is the value if we ignore the dependence in the model.

Table 18.5 gives the estimated ARL using Page's CUSUM procedure, for in-control normal populations, for a few values of ϕ. The h values in the CUSUM scheme are chosen carefully so that the in-control ARL at $\phi = 0$ is around 200. The ARL values are based on 5000 trials and apply to the situation where the dependence is not noticed when $\phi \neq 0$, but that variance is estimated by the usual formula using a long series of consecutive observations.

We see dramatic reductions in ARL even for small positive values of ϕ. To be able to get the desired in-control ARL when there is time dependence in the sequence of observations, the h values in the control schemes have to be changed. Table 18.6 presents the h values obtained from simulation to get in-control ARL near 200, for different values of ϕ, using Page's CUSUM scheme when the dependence is not noticed.

In the context of multivariate procedures, dependence can often be represented as a multivariate first-order autoregressive model. Let the $p \times 1$ random vector $\boldsymbol{X}_t$ follow the multivariate AR(1) model

$$\boldsymbol{X}_n - \boldsymbol{\mu} = \boldsymbol{\Phi}(\boldsymbol{X}_{n-1} - \boldsymbol{\mu}) + \varepsilon_n \qquad (18.9)$$

where the ε_n are independent and identically distributed with $E(\varepsilon_n) = \boldsymbol{0}$ and $\mathrm{Cov}(\varepsilon_n) = \boldsymbol{\Sigma}_\varepsilon$ and all of the eigenvalues of $\boldsymbol{\Phi}$ are between -1 and 1. Under this model

$$\mathrm{Cov}(\boldsymbol{X}_n, \boldsymbol{X}_{n-j}) = \boldsymbol{\Phi}^j\boldsymbol{\Sigma}_X,$$

$$\text{where } \boldsymbol{\Sigma}_X = \sum_{j=0}^{\infty}\boldsymbol{\Phi}^j\boldsymbol{\Sigma}_\varepsilon\boldsymbol{\Phi}'^j.$$

Table 18.7 The estimate in-control ARL using Crosier's multivariate scheme

	$\phi = -0.3$	$\phi = -0.2$	$\phi = -0.1$	$\phi = 0$	$\phi = 0.1$	$\phi = 0.2$	$\phi = 0.3$
$k = 0.5,\ h = 5.55$	4881.3	1295.2	454.8	203.6	105.5	65.6	43.2

The multivariate AR(1) model relates the observation at time n to the observation at time $n-1$ through the coefficient matrix Φ. Further, the autoregressive model says the observations are independent, under multivariate normality, if all the entries in the coefficient matrix Φ are 0.

As shown in *Johnson* and *Langeland* [18.20],

$$\overline{\boldsymbol{X}} \to^{P} \boldsymbol{\mu}\ ,$$

$$\boldsymbol{S} = \frac{1}{n-1}\sum_{t=1}^{n}(\boldsymbol{X}_t - \overline{\boldsymbol{X}})(\boldsymbol{X}_t - \overline{\boldsymbol{X}})' \to^{P} \boldsymbol{\Sigma}_X\ ,$$

where the arrow indicates convergence in probability.

Similar to the X-bar chart, the T^2 chart is robust with respect to dependence when individual observations are plotted. The probability of a false alarm at any time n is still

$$P\left[(\boldsymbol{X}_n - \boldsymbol{\mu})'\boldsymbol{\Sigma}_X^{-1}(\boldsymbol{X}_n - \boldsymbol{\mu}) \geq \chi_p^2(0.01)\right] = 0.01$$

since, under normality, $\boldsymbol{X}_n - \boldsymbol{\mu}$ has a $p-$variate normal distribution with mean $\boldsymbol{0}$ and covariance matrix $\boldsymbol{\Sigma}_X$. If the observations are independent, and the process is in control, the probability is 0.01 that a single observation will falsely signal that a change has occurred. The ARL is then $1/0.01 = 100$.

When the plotted points correspond to the sample mean of m adjacent observations, the situation is more complicated. To simplify our calculations, we consider the case where has $\boldsymbol{\Phi} = \phi\mathbf{I}$, where $|\phi| < 1$. Consider the multivariate T^2 chart where the process is considered to be in control if

$$m(\overline{\boldsymbol{X}}_n - \boldsymbol{\mu})'\Sigma_X^{-1}(\overline{\boldsymbol{X}}_n - \boldsymbol{\mu}) \leq \chi_p^2(0.01)\ .$$

If the observations are independent, and the process is in control, the probability is 0.01 that a single observation will falsely signal that a change has occurred. The ARL is $1/0.01 = 100$. Using $\chi_p^2(0.005)$ as limit gives an ARL of $1/0.005 = 200$ when the process is in control. However, if the observations are related by our simplified multivariate AR(1) model, the average of m adjacent observations has covariance matrix

$$\mathrm{Cov}(\overline{\boldsymbol{X}}_n) = \frac{1}{m}\boldsymbol{\Sigma}_X\left(1 + \sum_{j=1}^{m-1}\frac{m-j}{m}\phi^j\right)\ .$$

not $\boldsymbol{\Sigma}_X/m$, and this will cause some change from the nominal probability.

The multivariate CUSUM statistics are all based on the stochastic process, defined at $n = 1, 2, \cdots$ by

$$n^{-1/2}\boldsymbol{S}_n = n^{-1/2}\sum_{j=1}^{n}(\boldsymbol{X}_j - \boldsymbol{\mu})$$

whose covariance at time n

$$\mathrm{Cov}\left(n^{-1/2}\sum_{t=1}^{n}\boldsymbol{X}_t\right) \to (\boldsymbol{I} - \Phi)^{-1}\boldsymbol{\Sigma}_X + \boldsymbol{\Sigma}_X(\boldsymbol{I} - \Phi')^{-1} - \boldsymbol{\Sigma}_X\ .$$

This can be considerably different from the covariance $\boldsymbol{\Sigma}_X$ used when dependence is ignored.

Table 18.7 provides the estimated ARL for in-control normal populations with covariance matrix $\boldsymbol{\Sigma} = \begin{pmatrix} 1.0 & 0.5 \\ 0.5 & 1.0 \end{pmatrix}$, using Crosier's CUSUM scheme. The ARL values are based on 5000 trials where the covariance matrix is estimated by $\boldsymbol{S}$ using a long series of consecutive observations.

For more details on large-sample approximations, including a limit for Crosiers statistic, see *Li* [18.6].

Based on the calculations above and consideration of other cases, we must emphasize that the independence assumption is crucial to all of the procedures we discussed that are based on cumulative sums. The results based on this assumption can be seriously misleading if the observations are, in fact, even moderately dependent.

The best approach, when dependence is identified as being present, is to fit a time-series model. Then, as suggested in *Bagshaw* and *Johnson* [18.22], the residuals can be monitored for a shift. In the univariate case a CUSUM statistic can be applied. See also *Hawkins* and *Olwell* [18.23], Section 9.3.

Reliability Part C

Part C Reliability Models and Survival Analysis

Part C focuses on reliability models, statistical accelerated testing and survival analysis. The first five chapters in this part emphasize general system modeling while the last four chapters emphasize software systems. The first chapter in this part, Chapt. 19, discusses variations of the statistical survival model and the step-stress accelerated-failure-time model and their important applications to both biomedical and engineering studies, followed by Chapt. 20, which focuses on failure-rate modeling with respect to heterogeneous populations and presents the concepts and properties of mixture failure rates, proportional hazards, additive hazards and accelerated life tests in heterogeneous populations. Chapter 21 provides an overview of various proportional hazard regression (PHR) models, including the stratified Cox model, the Cox model with time-dependent covariates and various hypothesis-testing methods for validating PHR models. Several extended models such as nonproportional random effects are also discussed. Chapter 22 outlines various statistical models for describing lifetime distributions, such as the log-normal and Weibull, with the inclusion of multiple accelerating variables in accelerated-life tests, and discusses some of the potential difficulties of accelerated testing in practice. Chapter 23 details the statistical methods for designing various types of accelerated reliability tests, including constant-stress tests, step-stress tests, and step-stress accelerated degradation tests under harsher environments with multiple-step stress levels.

The next four chapters focus on statistical models in software systems, starting with Chapt. 24, which focuses on aspects of technology evolution for high-assurance systems, including dynamic verification and validation, reliability and security issues, safety assurance, automated dependency analysis, model checking on system specifications and model checking based on test-case generation. Chapter 25 discusses in detail and reviews software reliability growth modeling and optimization problems including software testing effort, growth models, parameter estimation, optimal release policies, and resource allocation, while Chapt. 26 focuses on a software development design-review process based on a quality engineering approach to analyze the relationships among the quality of the design-review activities, including software reliability and human factors in the development process. Chapter 27 discusses a generalized prediction model based on a nonhomogeneous Poisson process framework for evaluating the reliability and its corresponding confidence intervals for software systems in a random field environment.

19. Statistical Survival Analysis with Applications

This chapter discusses several important and interesting applications of statistical survival analysis which are relevant to both medical studies and reliability studies. Although it seems to be true that the proportional hazards models have been more extensively used in the application of biomedical research, the accelerated failure time models are much more popular in engineering and reliability research. Through several applications, this chapter not only offers some unified approaches to statistical survival analysis in biomedical research and reliability/engineering studies, but also sets up necessary connections between the statistical survival models used by biostatisticians and those used by statisticians working in engineering and reliability studies. The first application is the determination of sample size in a typical clinical trial when the mean or a certain percentile of the survival distribution is to be compared. The approach to the problem is based on an accelerated failure time model and therefore can have direct application in designing reliability studies to compare the reliability of two or more groups of differentially manufactured items. The other application we discuss in this chapter is the statistical analysis of reliability data collected from several variations of step-stress accelerated life test. The approach to the problem is based on the accelerated failure time model, but we will point out that these methodologies can be directly applied to medical and clinical studies when different doses of a therapeutic compound are administered in a sequential order to experimental subjects.

Failure time data or survival data are frequently encountered in biomedical studies, engineering, and reliability research. Applications of lifetime distribution methodologies range from investigations into the reliability of manufactured items to research involving human diseases. In medical studies, clinical endpoints for assessment of efficacy and safety of a promising therapy usually include occurrence of some predefined events such as deaths, the onset of a specific disease, the response to a new chemotherapy in treatment of some advanced cancer, the eradication of an infection caused by a certain microorganism, or serious adverse events. In engineering and reliability studies, manufactured items such as mechanical or electronic components are often subjected to life tests to obtain information on their endurance. This involves putting items into operation, often in a laboratory setting, and observing them until they fail. For example, *Nelson* [19.1] described a life test experiment in which specimens of a type of electronic insulating fluid were subjected to a constant voltage stress. The length of time until each specimen broke down was observed and investigated in its association with the voltage level. In all of the studies mentioned above, the primary variable of interest is usually the *survival time* to the occurrence of a specific predetermined event. One of the important features in survival data encountered

in both medical research and engineering studies is the existence of censored observations when only a lower (or upper) bound of the failure time on some experimental units are available. Censoring occurs frequently because of time limits and other restrictions during the process of data collection. In a life test experiment of manufactured items, for example, it may not be feasible to continue experimentation until all items under study have failed. If the study is terminated before all have failed, then for items that have not failed at the time of termination only a lower bound on lifetime is available.

The statistical analysis of survival data has been well developed in the literature. The estimation of the survival distribution can be done by the Kaplan–Meier product-limit estimator [19.2], which can also be viewed as a kind of nonparametric maximum likelihood estimator [19.3]. For studies in which the aim is to compare the survival distribution of two groups of subjects, the logrank test has been the most common method, although other rank tests such as the generalized Wilcoxon test are also used [19.2]. The logrank test can also be extended to allow an adjustment to be made for other covariates [19.4]. The major developments in the analysis of survival data have focused on several families of survival distributions. Two very important models of survival distribution are the model of proportional hazards and the accelerated failure time model. The proportional hazard model is a regression method introduced by *Cox* [19.5], which can be used to investigate the effects of several covariates on survival distribution at the same time. Cox's method is a semi-parametric approach – no particular type of distribution is assumed for the survival data, but a strong assumption is made on the effects of differences, which is referred to as the assumption of proportional hazards. Regression diagnostic procedures are also available to assess the assumption of proportional hazards [19.6,7], and some tests of the assumption of proportional hazards are also introduced through the incorporation of time-dependent covariates [19.8]. Extensions to Cox's proportional hazards model are the analysis of residuals, time-dependent coefficient, multiple/correlated observations, time-dependent strata, and estimation of underlying hazard function [19.8–10]. The accelerated failure time model, on the other hand, assumes that the covariates act by expanding or contracting time by a factor which is the exponential of a linear function of the covariates. In the logarithmic scale of the survival time, the accelerated failure time model is essentially a scale-location family of distributions.

It is quite interesting to observe that the proportional hazards models have been more extensively used in the application of biomedical research, while the accelerated failure time models are much more popular in engineering and reliability research. Part of the reason that Cox's proportional hazards models are popular in biomedical studies is the very fact that the assumption of proportional hazards summarizes the risk factor for a specific disease into a single quantity, the hazard ratio, which makes the interpretation easy to understand for clinicians. As an example, medical literature has demonstrated that a key protein, apolipoprotein E4 (ApoE4), contributes to the development of Alzheimer's disease [19.11]. Clinicians are interested in knowing how much the risk of Alzheimer's disease is increased for ApoE4-positive subjects compared to ApoE4-negative subjects. The point and confidence interval estimate to the hazard ratio associated with ApoE4 will adequately address the question if the assumption of proportional hazards can be adequately verified. On the other hand, the accelerated failure time models often make very good sense when the multiplicative time scale is assumed based on the level of covariate. As an example, assume that the lifetime of photocopiers has a hazard function that is a function of the total number of copies made, but the data on their failures were recorded in calendar time. Covariates that were related to the number of copies per day might be very successful in an accelerated failure time model. If the underlying hazard function had a particular form, say a sharp upturn after 25 000 cycles, a proportional hazard model would not fit as well. Similar examples can also be found for biological data related to cumulative toxicity or other damage.

Whether or not a statistical model is appropriate in a specific application depends on the distributional property of the observed variable and the specific research questions to be addressed. This chapter focuses on several applications of survival analysis in both medical/biological research and engineering/reliability research. We discuss several interesting applications which are relevant to both medical studies and reliability studies. The first application is the determination of sample size in a typical clinical trial when the mean or a certain percentile of the survival distribution is to be compared. The approach to the problem is based on an accelerated failure time model and therefore can have direct application in designing reliability studies to compare the reliability of two or more groups of differentially manufactured items. The other application we discuss in this chapter is the statistical

analysis of reliability data collected from several variations of step-stress accelerated life test. The approach to the problem is based on the accelerated failure time model, but we will point out that these methodologies can be directly applied to medical and clinical studies when different doses of a therapeutic compound are administered in a sequential order to experimental subjects.

19.1 Sample Size Determination to Compare Mean or Percentile of Two Lifetime Distributions

The determination of sample size is an important subject in planning long-term medical trials. In a randomized longitudinal clinical trial involving a treatment group and a control group, if the survival time to a particular event (e.g., death, relapse of symptoms) is the primary concern for the study, there are two important types of comparisons between the treatment group and the control group. One is the comparison of two survival curves and the other is the comparison of two common survival characteristics such as two means and two percentiles. Although the comparison of two survival curves is the major interest in many studies, the comparison of two means or two percentiles is important in many other applications. For example, in the announcement of the aging intervention testing program (RFA-AG-02-005), the National Institute on Aging (NIA) of USA states that one of the major research objectives of this program is to identify interventions that increase mean life expectancy by 10% in phase I studies, which may be terminated at 50% survivorship. This type of aging intervention study based on animal models has recently received much attention in the community of aging research. For example, caloric restriction has been identified as an intervention that extends the life span of both mammalian animal models and a variety of invertebrate animal models [19.12]. Mutations in the *dw* and *df* genes have been shown to attenuate the rate of aging in mice [19.13, 14]. *Warner* et al. [19.15] provided more details of biological interventions to promote healthy aging. The sample size computation for this type of study requires a statistical test that compares the mean lifetime between the control group and the treatment group based on type II censored observations.

Sample size determination methods are always based on certain parametric or semiparametric statistical models. This section concerns two important families of distributions used in the analysis of lifetime data: one is the family of proportional hazards and the other is the location-scale family of the log-transformed lifetime. The traditional approach to the sample size problem in planning long-term medical trials is based on the logrank test for the comparison of two lifetime distributions between the control group and the treatment group. Although the logrank test can be derived from both the proportional hazards family and the location-scale family of log-transformed lifetime, it is the proportional hazards family that most sample size computation methods with logrank test in the literature have been based on. In fact, the statistics literature on sample size calculation for failure time data is almost entirely devoted to tests based on exponential survival distributions [19.16–18] or binomial distributions [19.19, 20]. This is largely due to the fact that with the more general conditions hazard functions and ratios are no longer constant over time, so that the usual tests based on exponential models with constant hazard ratios no longer apply. *Schoenfeld* [19.21] and *Freedman* [19.22] presented methods for sample size calculation based on the asymptotic expectation and variance of the logrank statistic and the assumption of proportional hazards. *Lakatos* [19.23] proposed a Markov model to estimate the sample sizes for the comparison of lifetime distributions based on the logrank test. *Wu* et al. [19.24] provided a sample size computation method that allows time-dependent event (dropout) rate. *Lakatos* and *Lan* [19.25] compared several sample size calculation methods associated with the logrank test.

When the primary concern in a medical or reliability study is to compare the means or certain percentiles of two lifetime distributions, such as in the aging intervention testing program, the sample size determination based on proportional hazards assumption runs into the problem of expressing the difference or ratio of two means or two percentiles of lifetime distributions into the ratio of two hazard functions. Although this is no problem with exponential distributions or Weibull distributions with the same shape parameter, it might not always be possible for other families of proportional hazards. On the other hand, the location-scale family of log-transformed lifetime seems to be a very natural family of lifetime distributions to use for this type of sample size problem. This is based on the fact that,

when the scale parameters are assumed to be the same across different groups, the comparison of the means in lifetimes is equivalent to the comparison of location parameters. Although nonparametric tests such as the logrank test are appealing when the underlying lifetime distributions are unknown, they tend to be less efficient when the pilot information suggests a certain family of lifetime distributions and such information is ignored based on nonparametric tests. In fact, the logrank test bears 100% asymptotic relative efficiency when there is no censoring or when there is random but equal censoring in two groups within the family of Weibull distributions [19.26]. When data are from lognormal distributions differing only with respect to location, however, the asymptotic relative efficiency of the logrank test decreases to 82% [19.3].

Another common feature of most sample size determination methods in the literature is that they all deal with type I censored samples in which a prespecified time is used to terminate the experiment. This section studies the sample size determination to compare the means or certain percentiles of two lifetime distributions when both samples are subject to type II censoring. Our approach is based on a location-scale family of log-transformed lifetime distributions and the asymptotic normality of maximum likelihood estimates (MLEs). We also apply our methods to both the family of lognormal distributions and the family of Weibull distributions and compare our method with other well-known methods such as those based on *Rubinstein* et al. [19.18] and *Freedman* [19.22].

Although we will discuss the sample size determination in the context of designing a medical and biological study in this section, the basic ideas and results can be readily applied to the design of various engineering studies to compare the reliability of different groups of manufactured items. In fact, the application of our proposed methods to designing engineering studies will be even more intuitive to engineers as our approach is based on a location-scale family of log-transformed lifetime distributions, which is essentially equivalent to the accelerated failure time model popularly used in engineering and reliability studies.

19.1.1 The Model and Sample Size

Let T_c be the survival time for the control group, and T_t be the survival time for the treatment group. Assume that $Y_i = \ln T_i$ follows a probability distribution that belongs to a location-scale family with probability density function $\frac{1}{\sigma_i} g\left(\frac{y-\mu_i}{\sigma_i}\right)$, $-\infty < y < \infty$, $i = c, t$, where $g(s) > 0$ is a differentiable positive function whose derivative $g'(s) = \frac{dg(s)}{ds}$ makes all integrations used in this chapter exist. Let $G(s) = \int_{-\infty}^{s} g(t)\,dt$ be the cumulative distribution of $g(s)$. We also assume that both σ_c and σ_t are given and that $\sigma_c = \sigma_t = \sigma > 0$. The mean of $T_i = \exp(Y_i)$ is

$$ET_i = \int_{-\infty}^{\infty} e^y \frac{1}{\sigma} g\left(\frac{y-\mu_i}{\sigma}\right) dy = e^{\mu_i} \int_{-\infty}^{\infty} e^{\sigma s} g(s)\,ds\,, \tag{19.1}$$

for $i = c, t$. Hence,

$$\frac{ET_t}{ET_c} = e^{\mu_t - \mu_c}\,. \tag{19.2}$$

Let $0 < \delta < 1$. For $i = c, t$, a straightforward integration gives the $100\delta\%$ percentile of T_i as

$$\tau_i(\delta) = e^{\mu_i + \sigma G^{-1}(\delta)}\,, \tag{19.3}$$

where G^{-1} is the inverse function of G. It follows that

$$\frac{\tau_t(\delta)}{\tau_c(\delta)} = e^{\mu_t - \mu_c}\,. \tag{19.4}$$

Therefore, the problem of testing the ratio of two means or two percentiles between the control group and the treatment group can always be reduced to the problem of testing the difference between μ_t and μ_c.

Suppose that two independent samples of size n_c and n_t are drawn from the distributions of T_c and T_t, respectively. For $i = c, t$, we assume that only the smallest $100\,q_i\%$ of the samples are observed for some given $0 < q_i < 1$. If we let $r_i = [q_i n_i]$, then only the order statistics up to r_i-th are observed for group $i = c, t$. Let γ be the ratio of two sample sizes: $\gamma = \frac{n_t}{n_c}$. We want to decide the sample sizes for testing the null hypothesis $H_0 : \mu_c = \mu_t$ against the alternative $H_1 : \mu_c \neq \mu_t$ at an asymptotic significance level α $(0 < \alpha < 1)$. If this test is to achieve $100(1-\beta)\%$ power to detect a difference of $d = \mu_t - \mu_c$, the required sample size n_c for the control group is the unique solution to the following equation:

$$\beta = \Phi\left(z_{\alpha/2} - \frac{d}{\sqrt{\frac{1}{n_c}\left(\frac{1}{K_c^2} + \frac{1}{\gamma K_t^2}\right)}}\right) - \Phi\left(-z_{\alpha/2} - \frac{d}{\sqrt{\frac{1}{n_c}\left(\frac{1}{K_c^2} + \frac{1}{\gamma K_t^2}\right)}}\right)\,, \tag{19.5}$$

where $z_{\alpha/2}$ is the upper $\alpha/2$ percentage point of the standard normal distribution, Φ is the cumulative distribution function of the standard normal distribution, K_i, $i = \mathrm{c}, \mathrm{t}$, is given by

$$K_i^2 = \frac{1}{\sigma^2} \int_{-\infty}^{(\lambda_i-\mu_i)/\sigma} \frac{[g'(s)]^2}{g(s)}\,\mathrm{d}s + \frac{1}{p_i\sigma^2}\left[g\left(\frac{\lambda_i-\mu_i}{\sigma}\right)\right]^2 , \tag{19.6}$$

and λ_i is such that

$$q_i = G\left(\frac{\lambda_i-\mu_i}{\sigma}\right) , \tag{19.7}$$

and $p_i = 1 - q_i$. The required sample size for the treatment group is then $n_\mathrm{t} = \gamma n_\mathrm{c}$. The proof of (19.5) is based on the asymptotic normality of the MLEs of μ_i and can be found in [19.27].

If we want to test the null hypothesis $H_0 : \mu_\mathrm{c} = \mu_\mathrm{t}$ against the one-sided alternative $H_1 : \mu_\mathrm{t} > \mu_\mathrm{c}$ at an asymptotic significance level α $(0 < \alpha < 1)$ and assume that this test is to achieve $100(1-\beta)\%$ power to detect a difference of $d = \mu_\mathrm{t} - \mu_\mathrm{c} > 0$, the required sample size for the control group n_c is given by

$$n_\mathrm{c} = \left(\frac{z_\alpha + z_\beta}{d}\right)^2 \left(\frac{1}{K_\mathrm{c}^2} + \frac{1}{\gamma K_\mathrm{t}^2}\right) , \tag{19.8}$$

and the required sample size for the treatment group is then $n_\mathrm{t} = \gamma n_\mathrm{c}$. The proof of (19.8) can also be found in [19.27].

19.1.2 Examples

Since the family of lognormal distributions and the family of Weibull distributions are two important location-scale families of log-transformed lifetime distributions, we apply our method to these two families.

Example 1: Lognormal Distribution

We first study the family of lognormal distribution in which

$$g(s) = \frac{1}{\sqrt{2\pi}}\,\mathrm{e}^{-s^2/2} . \tag{19.9}$$

For $i = \mathrm{c}, \mathrm{t}$, using integration by parts, we find

$$K_i^2 = -\frac{(\lambda_i-\mu_i)}{\sigma^3} g\left(\frac{\lambda_i-\mu_i}{\sigma}\right) + \frac{q_i}{\sigma^2} + \frac{1}{p_i\sigma^2}\left[g\left(\frac{\lambda_i-\mu_i}{\sigma}\right)\right]^2 , \tag{19.10}$$

where λ_i is such that

$$q_i = \Phi\left(\frac{\lambda_i-\mu_i}{\sigma}\right) . \tag{19.11}$$

If $q_\mathrm{c} = q_\mathrm{t} = 50\%$, then

$$K_i^2 = \frac{1}{2\sigma^2} + \frac{1}{\pi\sigma^2} . \tag{19.12}$$

Example 2: Weibull Distribution

In the family of Weibull distributions,

$$g(s) = \exp(s - \mathrm{e}^s) . \tag{19.13}$$

For $i = \mathrm{c}, \mathrm{t}$, by repeatedly using the technique of integration by parts, we have

$$K_i^2 = \frac{1-p_i}{\sigma^2} . \tag{19.14}$$

If $q_\mathrm{c} = q_\mathrm{t} = 50\%$, then

$$K_i^2 = \frac{1}{2\sigma^2} . \tag{19.15}$$

19.1.3 Effect of Guarantee Time on Sample Size Determination

A very simple feature of lifetime distributions is the existence of a threshold time, or *guarantee time*, during which no subjects will die. For example, the type of mice to be used in the aging intervention testing program of the National Institute on Aging exhibit a guarantee survival time of about 500 days in the survival distribution, as estimated from the survival curves reported by *Turturro* et al. [19.28]. When the comparison of two mean lifetimes is in terms of the difference and when the two distributions share the same guarantee time, this time contributes nothing to the comparison. When the comparison of two mean lifetimes is in terms of the ratio, however, the guarantee time plays an important role in the comparison, especially in the determination of sample sizes at the design stage of the clinical trials.

When the primary concern in a medical study is to compare the means or certain percentiles of two lifetime distributions with type II censored observations such as the aging intervention testing program from the National Institute on Aging, the sample size determination may be based on the method of *Rubinstein* et al. [19.18], the method of *Freedman* [19.22], and the method described by (19.5) and (19.8). The methods of *Rubinstein* et al. [19.18] can be used since the hazard ratio is simply

the reciprocal of the ratio of two means under the exponential distributions. The method of *Freedman* [19.22] refers to the logrank test of the hazard ratio and requires the assumptions of proportional hazards between two groups. It could be used to compare the means or certain percentiles of two lifetime distributions as long as the comparison of means or certain percentiles can be related to the hazard ratio between two distributions such as in the family of Weibull distributions. The method described by (19.5) and (19.8) directly applies to the comparison of means or certain percentiles of two lifetime distributions and requires the assumption of location-scale family of log-transformed lifetime distributions.

If two lifetime distributions under study exhibit survival thresholds, or *guarantee times* as in the survival distribution of mice used in the aging intervention testing program from the National Institute on Aging, these thresholds have an important role in the ratio of means from two distributions. Mathematically, let T_c be the survival time for the control group, and T_t be the survival time for the treatment group. Let ET_c and ET_t be the corresponding means of the two distributions. We are interested in testing the null hypothesis $H_0 : ET_t/ET_c = 1$ against the alternative $H_1 : ET_t/ET_c \neq 1$ at an asymptotic significance level α $(0 < \alpha < 1)$. For $i = c, t$, suppose that T_i follows a distribution with a threshold, or a *guarantee time* $\psi_i > 0$. We assume that both the control group and the treatment group share the same threshold parameter $\psi_1 = \psi_2 = \psi$ and that ψ is known. Let $T_i' = T_i - \psi$, then $ET_i' = ET_i - \psi, i = t, c$. The alternative hypothesis on which the sample size computation is based is

$$\rho = \frac{ET_t}{ET_c} = \frac{ET_t' + \psi}{ET_c' + \psi} . \tag{19.16}$$

Therefore

$$\frac{ET_t'}{ET_c'} = \frac{\rho ET_c - \psi}{ET_c - \psi} . \tag{19.17}$$

Since $ET_t/ET_c = 1$ if and only if $ET_t'/ET_c' = 1$. The original null and alternative hypotheses translate into the corresponding hypotheses in terms of distributions T_t' and T_c' : $H_0' : ET_t'/ET_c' = 1$ and $H_1' : ET_t'/ET_c' \neq 1$.

Since the distributions of T_t' and T_c' begin with time 0 and have no guarantee times, the sample size methods reviewed above can be directly applied to test the reduced hypotheses H_0' against H_1'. The alternative hypothesis on which the sample size computation should be based, however, now becomes $ET_t'/ET_c' = (\rho ET_c - \psi)/(ET_c - \psi)$. We call ET_t'/ET_c' the adjusted effect size. Note that for any $\rho \neq 1$, $ET_t'/ET_c' = \rho$ if and only if $\psi = 0$. Hence, when the ratio of the mean between two lifetime distributions is to be tested, it is crucial that the sample size determination based on the logrank test and the proportional hazards assumption or the location-scale family of log-transformed lifetime distributions takes into account the possible guarantee time in the lifetime distributions. Table 19.1 presents the sample size computation based on the method of *Rubinstein* et al. [19.18] for a selected set of the guarantee time ψ and the percentage p_t of censorship for the treatment group. Table 19.2 presents the sample size computation based on the method of *Freedman* [19.22] for the same selected set of ψ and p_t. The computation in Table 19.2 assumes Weibull distributions with the same shape parameter of 1.5 for both the treatment group and the control group so that the ratio of two means can be expressed as a function of the ratio of hazard functions between the two groups. Table 19.3 presents the sample size computation based on the method described by (19.8) for the same selected set of ψ and p_t under the assumption of lognormal distributions with a scale parameter of 0.8 in the log-transformed lifetime distribution. Table 19.4 presents the sample size computation based on the method described by (19.8) for the same selected set of ψ and p_t under the assumption of Weibull distributions with a scale parameter of 0.8 in the log-transformed lifetime distribution. All these computations in four tables are based on a one-sided test for

the ratio of two means at a significance level of 5%, a mean lifetime of 150 units for the control group, and a statistical power of 80%. The 80% power is assumed at $\rho = 1.2$ in the original alternative hypotheses with the equal sample size between the treatment group and the control group. In addition, both groups are assumed the simultaneous entry to the study and the simultaneous stopping time, which is the time of achieving censorship p_t for the treatment group. The censorship for the control group is then decided by ρ and p_t under the appropriate distributional assumptions and is less than p_t by the assumption that $\rho > 1$. The sample size when there is no *guarantee time* or the *guarantee time* is ignored is given when $\psi = 0$.

Although Tables 19.1–19.4 are based on different sample size determination methods, they demonstrate two common important observations. First, if a guarantee time exists in the two lifetime distributions to be compared, the ignorance of the guarantee time leads to the overestimation of the sample size. Second, if the significance level of the test, the statistical power of the test, and the degree of censoring are fixed, the required sample size decreases as the guarantee time increases. All these can be explained by (19.17), which expresses the ratio of two means ET_t'/ET_c' after the guarantee time ψ is subtracted (i. e., the adjusted effect size) as a function of the guarantee time ψ, the original ratio ρ of mean lifetime when the guarantee time is included, and the mean lifetime ET_c for the control group. Let $\rho > 1$ and ET_c be fixed. We denote the adjusted effect size [the right-hand side of (19.17)] by $h(\psi)$. This function has two important features. First, $h(\psi) = \rho$ if and only if $\psi = 0$. Second, the derivative of $h(\psi)$ with respect to ψ is always positive, which implies that it is an increasing function of ψ. Since the sample size methods are applied to the lifetime distributions when the guarantee time is subtracted, the effect size used in these sample size computations is based on $h(\psi)$ instead of ρ. The fact that $h(\psi) = \rho$ if and only if $\psi = 0$ implies that the ig-

norance of the guarantee time (i. e., by assuming $\psi = 0$) will always lead to an inadequate sample size when in fact $\psi > 0$. Since a common feature of the sample size methods is that the sample size decreases when the effect size $h(\psi)$ increases, this explains why the sample size decreases as the guarantee time ψ increases from Tables 19.1 to 19.4.

19.1.4 Application to NIA Aging Intervention Testing Program

We now demonstrate the sample size determination by applying it to the aging intervention testing program (RFA-AG-02-005) of the National Institute on Aging (NIA). One of the major research objectives of this program is to identify interventions that increase mean life expectancy by 10% in phase 1 studies which may be terminated at 50% survivorship. The experimental units in this study are the 4WCNIA mice obtained from the National Institute of Health (NIH) aging rodent colony. Pilot data such as the survival curves reported by *Turturro* et al. [19.28] on similar mice have suggested a guarantee survival time of about 500 days in the survival distribution. In addition, *Pugh* et al. [19.29] reported a mean life expectancy of 876 days and a standard deviation of 18 days for similar mice.

Assume that we ignore the guarantee time in the sample size computation and use $\rho = 1.1$ as the ratio of mean lifetime between the intervention group and the control group. The method of *Rubinstein* et al. [19.18] gives a sample size of 2637 per group. The method of *Freedman* [19.22] gives a sample size of 323 per group based on two Weibull distributions with the same shape parameter which is estimated as 2.793 by the survival curves reported by *Turturro* et al. [19.28]. Our proposed method gives a sample size of 387 per group based on two lognormal distributions with the same scale parameter σ (in the log-transformed lifetime). This computation uses $\sigma = 0.482$ as estimated by the survival curves reported in [19.28]. When applied under the family of Weibull distributions, the projected sample size per group based on our method is 338.

When the 500-days guarantee survival time is taken into account in the sample size computation, these methods are applied to the survival distributions after the 500-days guarantee survival time is subtracted. The pilot information of $ET_c = 876$ and $\rho = 1.1$ along with (19.17) implies that $ET_t'/ET_c' = 1.233$. The sample size methods are then applied to the distributions of T_t' and T_c' when testing H_0' against H_1' at a 5% significance level and an 80% statistical power. We assume that both groups use the same number of mice, that the treatment group is terminated at the 50% censorship, and that the control group is allowed to continue until the treatment group terminates. The method of *Rubinstein* et al. [19.18] gives a sample size of 528 per group. The method of *Freedman* [19.22] under the assumption of Weibull distributions gives a sample size of 64 per group. Assuming the lognormal distribution for the lifetimes with the same scale parameter σ in the log-transformed lifetime distributions between the control and treatment groups, our proposed method gives the sample size required per group as 81. Assuming a Weibull distribution for the lifetimes with the same scale parameter σ in the log-transformed lifetime distributions between the control and treatment groups, our proposed method gives the sample size required per group as 68.

Similar to observations from Tables 19.1–19.4, the real-life example again demonstrates the importance of taking into account the guarantee time in sample size computation when it exists. A considerable waste of resources would occur if the guarantee time is ignored in the sample size projection. Notice also that, while the methods of *Freedman* [19.22] and ours give fairly consistent results about the sample size per group, the method of *Rubinstein* et al. [19.18], however, results in a very different sample size compared to the others. The reason behind this difference is the assumption of an exponential distribution for the method in [19.18]. The mathematically attractive but practically unrealistic property of the exponential distribution is its constant hazard function over time, which then implies the memoryless feature for the survival distribution [19.3]. Although the exponential distribution is a distribution extensively discussed in the fields of biometrics, reliability and industrial life testing literature [19.30, 31], it has long been pointed out by many authors such as *Zelen* and *Dannemiller* [19.32] that the estimations and inferences associated with an exponential distribution are not robust and that exponential distribution is a very unrealistic distribution in many applications, especially in studies associated with the aging process.

19.2 Analysis of Survival Data from Special Cases of Step-Stress Life Tests

We now discuss some applications of survival analysis in engineering and reliability studies. Accelerated life tests (ALT) consist of a variety of test methods for shortening the life of products or hastening the degradation of their performance. The aim of such testing is to obtain data quickly which, properly modeled and analyzed, yield desired information on product life or performance under normal use. ALT can be carried out using constant stress, step-stress, or linearly increasing stress. The step-stress scheme applies stress to test units in the way that the stress setting of test units will be changed at specified times. Generally, a test unit starts at a specified low stress. If the unit does not fail at a specified time, the stress on it is raised and held for a specified time. The stress is repeatedly increased and held, until the test unit fails or a censoring time is reached. A simple step-stress ALT (SSALT) uses only two stress levels. The problem of modeling data from ALT and making inferences from such data has been studied by many authors. *Chernoff* [19.33] considered optimal life tests for estimation of model parameters based on data from ALT. *Meeker* and *Nelson* [19.34] obtained optimum ALT plans for Weibull and extreme-value distributions with censored data. *Nelson* and *Kielpinski* [19.35] further studied optimum ALT plans for normal and lognormal life distributions based on censored data. *Nelson* [19.36] considered data from SSALT and obtained maximum likelihood estimates (MLE) for the parameters of a Weibull distribution under the inverse power law using the breakdown time data of an electrical insulation. *Miller* and *Nelson* [19.37] studied optimum test plans which minimized the asymptotic variance of the MLE of the mean life at a design stress for simple SSALT where all units were run to failure. *Bai* et al. [19.38] further studied the similar optimum simple SSALT plan for the case where a specified censoring time was involved. *Tyoskin* and *Krivolapov* [19.39] presented a nonparametric approach for making inferences for SSALT data. *Dorp* et al. [19.40] developed a Bayes model and studied the inferences of data from SSALT. *Xiong* [19.41] obtained inferences based on pivotal quantities for type II censored exponential data from a simple SSALT. *Alhadeed* and *Yang* [19.42] discussed the optimal simple step-stress plan for the Khamis–Higgins model. *Teng* and *Yeo* [19.43] used the method of least squares to estimate the life–stress relationship in SSALT. *Hobbs* [19.44] gave detailed discussion on highly accelerated life test (HALT) and highly accelerated stress screens (HASS). *Mann* et al. [19.45] and *Lawless* [19.3] provided the general theory and applications of lifetime data analysis. *Meeker* and *Escobar* [19.46] briefly surveyed optimum test plans for different types of ALT. *Nelson* [19.1, 47] provided an extensive and comprehensive source for theory and examples for ALT and SSALT.

During the step-stress life test, test units can be continuously or intermittently inspected for failure. The latter type of test is frequently used since it generally requires less testing effort and can be administratively more convenient. In some other cases, intermittent inspection is the only feasible way of checking the status of test units (see, for example, [19.48]). The data obtained from intermittent inspections are called grouped data and consist of only the number of failures in the inspection intervals. The first problem we consider in this section is the statistical inference of model parameters and optimum test plans based on only grouped and type I censored data obtained from a step-stress life test. We will also study another important and interesting variation associated with grouped and censored data from a simple SSALT, when both the stress change time and the censoring time are random variables, such as the order statistics at the current stress levels, and when only these order statistics (stress-change time and type II censoring time) are observed during the test.

Throughout the section, we denote the design stress by x_0, the i-th test stress by x_i, $i = 1, 2, \cdots, m$, $x_1 < x_2 < \cdots < x_m$, where m is the total number of test stress levels. We assume that the i-th stress change time is constant τ_i, $i = 1, 2, \cdots, m-1$, and the fixed censoring time is $\tau_m > \tau_{m-1}$. Let $\tau_{m+1} = \infty$, $\tau_0 = 0$, $\Delta\tau_i = \tau_i - \tau_{i-1}$. We also make following assumptions:

(A1). At any constant stress x_i, $i = 0, 1, 2, \cdots, m$, the cumulative distribution function (CDF)of a test unit lifetime is

$$F_i(t) = F(t/\theta_i) \quad \text{for} \quad t > 0\,, \tag{19.18}$$

where the stress–response relationship (SRR) θ_i is a function of stress x_i and F is a strictly increasing distribution function.

(A2). The stresses are applied in the order $x_1 < x_2 < \cdots < x_m$.

(A3). The lifetimes of test units under SSALT are statistically independent.

For the step-stress life test, there is a probability distribution $G(t)$ of time T to failure on test. Data from this distribution are observed during the test. The cumulative exposure model of time T assumes that the remaining

life of a test unit depends only on the current cumulative fraction failed and the current stress, regardless of how the fraction is accumulated. Moreover, if held at the current stress, survivors will fail according to the cumulative distribution for that stress but starting at the previously accumulated fraction failed. Also, the change in stress has no effect on life, only the level of the stress does. As pointed out by *Miller* and *Nelson* [19.37] and *Yin* and *Sheng* [19.49], this model has many applications in industrial life testing.

Mathematically, the cumulative distribution $G(t)$ of time T to failure from a step-stress test described above is

$$G(t) = \begin{cases} F_i(t - \tau_{i-1} + s_{i-1}) \,, \\ \quad \text{for} \quad \tau_{i-1} \le t < \tau_i \,, \\ \qquad\qquad i = 1, 2, \cdots, m-1, \\ F_m(t - \tau_{m-1} + s_{m-1}) \,, \\ \quad \text{for} \quad \tau_{m-1} \le t < \infty \,, \end{cases} \tag{19.19}$$

where s_{i-1} is the equivalent start time at step i satisfying

$$F_i(s_{i-1}) = F_{i-1}(\tau_{i-1} - \tau_{i-2} + s_{i-2}) \,. \tag{19.20}$$

We further assume:

(A4). The stress-response relationship (SRR) $\theta_i = \theta(x_i)$ is a log–linear function of stress x_i. That is,

$$\log \theta(x_i) = \alpha + \beta x_i \,, \tag{19.21}$$

where α and β are unknown model parameters which typically depend on the nature of the product and the test method. Although the specification of $\theta(x)$ looks rather restrictive, it covers some of the most important models used in industry, such as the power-law model, the Eyring model and the Arrhenius model [19.47]. With the above specifications, it is straightforward to find that $s_{i-1} = (\tau_{i-1} - \tau_{i-2} + s_{i-2})\theta_i/\theta_{i-1} = \theta_i \sum_{j=1}^{i-1} \Delta\tau_j/\theta_j$, $i = 2, 3, 4, \cdots, m$. Thus, the distribution function of the step-stress failure time T is

$$G(t) = \begin{cases} F\left(\dfrac{t - \tau_{i-1}}{\theta_i} + \sum_{j=1}^{i-1} \dfrac{\Delta\tau_j}{\theta_j}\right) \,, \\ \quad \text{for } \tau_{i-1} \le t < \tau_i, \, i = 1, 2, ..., m-1 \,. \\ F\left(\dfrac{t - \tau_{m-1}}{\theta_m} + \sum_{j=1}^{m-1} \dfrac{\Delta\tau_j}{\theta_j}\right) \,, \\ \quad \text{for } \tau_{m-1} \le t < \infty \end{cases} \tag{19.22}$$

Although we will discuss the statistical analysis of data collected from SSALT in the context of engineering studies, we point out that the statistical models and methods discussed in this section can be readily used in medical and biological research. Many clinical trials on therapeutical compounds of a disease contain a novel treatment group and a control group. At the completion of well-designed clinical studies, especially when the novel treatment has been found efficacious for the protection against the disease development based on the available data, many clinical trials are extended for another specified time period so that subjects from the original control group can receive the treatment. When a survival endpoint such as the time from the study baseline to the onset of a specific disease is measured on subjects from the original control group throughout the entire trial period, the resulting survival data are very analogous to these collected from the standard SSALT in engineering studies. In fact, the drug dose used in such clinical trials can be thought of as the stress level in which 0 is the stress at the initial phase of the original control group and a positive dose is the stress at the extension phase of the trial.

19.2.1 Analysis of Grouped and Censored Data from Step-Stress Life Tests

MLE

We first consider the case when all test units are subject to the same censoring time and the same stress-change patterns with the same set of stresses and the same stress-change times. We assume that data obtained from such step-stress tests are grouped and type I censored. More specifically, we assume that the intermittent inspection times during the step-stress test coincide with the stress-change times and the censoring time. Suppose that n test units begin at low stress x_1. If the unit does not fail at a specified time τ_1, the stress on it is raised to a higher stress x_2. The stress is repeatedly increased and held in this fashion, until the test unit fails or the fixed censoring time τ_m ($> \tau_{m-1}$) is reached. Assume that n_i units fail during the inspection time interval $[\tau_{i-1}, \tau_i)$, $i = 1, 2, \cdots, m, m+1$, ($\tau_{m+1} = \infty$). To simplify the notations, we denote, for $i = 1, 2, \cdots, m+1$,

$$\begin{aligned} u_i(\alpha, \beta) &= \sum_{j=1}^{i} \Delta\tau_j \, \exp(-\alpha - \beta x_j) \\ v_i(\alpha, \beta) &= \sum_{j=1}^{i} x_j \Delta\tau_j \, \exp(-\alpha - \beta x_j) \,. \end{aligned} \tag{19.23}$$

Let $p_i = \Pr(\tau_{i-1} \le T < \tau_i)$ for $1 \le i \le m+1$. The cumulative exposure model (19.22) implies that, for

$1 \le i \le m+1$,

$$p_i = F[u_i(\alpha,\beta)] - F[u_{i-1}(\alpha,\beta)] \,. \tag{19.24}$$

The likelihood function based on data vector $(n_1, n_2, \cdots, n_{m+1})$ is (up to a constant):

$$L(\alpha,\beta) \propto \prod_{i=1}^{m+1} \{F[u_i(\alpha,\beta)] - F[u_{i-1}(\alpha,\beta)]\}^{n_i} \,, \tag{19.25}$$

where θ_i is specified by the SRR (19.21) and $F(\infty) = 1$. Thus, the log likelihood function is a function of the unknown parameters α and β :

$$\log L(\alpha,\beta) \propto \sum_{i=1}^{m+1} n_i \log \{F[u_i(\alpha,\beta)] - F[u_{i-1}(\alpha,\beta)]\} \,. \tag{19.26}$$

To find the maximum likelihood estimators (MLE) for α and β, we maximize $\log L(\alpha,\beta)$ over α and β. The maximization of $\log L(\alpha,\beta)$ requires the solution to the system:

$$\begin{cases} \dfrac{\partial L(\alpha,\beta)}{\partial \alpha} = -\sum_{i=1}^{m+1} n_i \times \dfrac{u_i(\alpha,\beta) f[u_i(\alpha,\beta)]}{F[u_i(\alpha,\beta)] - F[u_{i-1}(\alpha,\beta)]} - \dfrac{u_{i-1}(\alpha,\beta) f[u_{i-1}(\alpha,\beta)]}{F[u_i(\alpha,\beta)] - F[u_{i-1}(\alpha,\beta)]} = 0 \,, \\ \dfrac{\partial L(\alpha,\beta)}{\partial \beta} = -\sum_{i=1}^{m+1} n_i \times \dfrac{v_i(\alpha,\beta) f[u_i(\alpha,\beta)]}{F[u_i(\alpha,\beta)] - F(u_{i-1}(\alpha,\beta))} - \dfrac{v_{i-1}(\alpha,\beta) f[u_{i-1}(\alpha,\beta)]}{F[u_i(\alpha,\beta)] - F(u_{i-1}(\alpha,\beta))} = 0 \,, \end{cases} \tag{19.27}$$

where $f(t) = \mathrm{d}F(t)/\mathrm{d}t$ is the probability density function of $F(t)$. Generally, the solution of (19.27) requires a numerical method such as Newton–Raphson. *Seo* and *Yum* [19.50] proposed several approximate ML estimators and compared with the MLE by a Monte Carlo simulation when the lifetime distribution is assumed exponential. The expected second partial derivatives of the log likelihood function at $(\alpha,\beta)'$ are

$$\begin{aligned} \sigma_{11} &= -E\frac{\partial^2 L(\alpha,\beta)}{\partial \alpha^2} \\ &= -n\sum_{i=1}^{m+1} \frac{\partial^2 p_i}{\partial \alpha^2} + \sum_{i=1}^{m+1} \frac{1}{p_i}\left(\frac{\partial p_i}{\partial \alpha}\right)^2 \,, \\ \sigma_{12} &= -E\frac{\partial^2 L(\alpha,\beta)}{\partial \alpha \partial \beta} \\ &= -n\sum_{i=1}^{m+1} \frac{\partial^2 p_i}{\partial \alpha \partial \beta} + \sum_{i=1}^{m+1} \frac{1}{p_i}\frac{\partial p_i}{\partial \alpha}\frac{\partial p_i}{\partial \beta} \,, \\ \sigma_{22} &= -E\frac{\partial^2 L(\alpha,\beta)}{\partial \beta^2} \\ &= -n\sum_{i=1}^{m+1} \frac{\partial^2 p_i}{\partial \beta^2} + \sum_{i=1}^{m+1} \frac{1}{p_i}\left(\frac{\partial p_i}{\partial \beta}\right)^2 \,. \end{aligned} \tag{19.28}$$

Let D be the $(m+1)$ by $(m+1)$ diagonal matrix with $1/p_i$, $i = 1, 2, \cdots, m+1$, as its diagonal elements. Let $J = (j_{st})$, $1 \le s \le m+1$, $1 \le t \le 2$, be the $(m+1)\times 2$ Jacobian matrix of $(p_1, p_2, \cdots, p_{m+1})'$ with respect to $(\alpha,\beta)'$, i. e.,

$$\begin{aligned} j_{s1} = \frac{\partial p_i}{\partial \alpha} &= -u_i(\alpha,\beta) f[u_i(\alpha,\beta)] \\ &\quad + u_{i-1}(\alpha,\beta) f[u_{i-1}(\alpha,\beta)] \,, \\ j_{s2} = \frac{\partial p_i}{\partial \beta} &= -v_i(\alpha,\beta) f[u_i(\alpha,\beta)] \\ &\quad + v_{i-1}(\alpha,\beta) f[u_{i-1}(\alpha,\beta)] \,, \end{aligned} \tag{19.29}$$

for $s = 1, 2, \cdots, m+1$. Because

$$E\left(\sum_{i=1}^{m+1} \frac{\partial p_i}{\partial \alpha}\right) = E\left(\sum_{i=1}^{m+1} \frac{\partial p_i}{\partial \beta}\right) = 0 \,,$$

the expected Fisher information matrix $\boldsymbol{\Sigma} = (\sigma_{ij})$, $i, j = 1, 2$, is given by $\boldsymbol{\Sigma} = n \cdot J' D J$. Let $(\widehat{\alpha}, \widehat{\beta})'$ be the MLE of $(\alpha,\beta)'$ obtained from solving (19.27). $n^{-1}\boldsymbol{\Sigma}$ can be consistently estimated by $n^{-1}\widehat{\boldsymbol{\Sigma}}$, where $\widehat{\boldsymbol{\Sigma}} = (\widehat{\sigma_{ij}})$, $i, j = 1, 2$, is obtained by replacing $(\alpha,\beta)'$ in $\boldsymbol{\Sigma}$ by its MLE $(\widehat{\alpha}, \widehat{\beta})'$.

Based on the asymptotic normality of $(\widehat{\alpha}, \widehat{\beta})'$ with estimated covariance matrix $\widehat{\Sigma}^{-1}$, we can set up the asymptotic confidence interval (CI) for α, β, the SRR of lifetime at design stress $\theta_0 = \theta(x_0) = \exp(\alpha + \beta x_0)$, and the reliability function at design stress $R_0(t) = 1 - F(t/\theta_0)$. Let $\widehat{\Sigma}^{-1} = (\widehat{m_{ij}})$, $i, j = 1, 2$, be the estimated asymptotic covariance matrix of $(\widehat{\alpha}, \widehat{\beta})'$. It is straightforward to show that an asymptotic $100(1-\gamma)\%$ CI for α is $\widehat{\alpha} \pm z_{\gamma/2}\widehat{m}_{11}$, and an asymptotic $100(1-$

$\gamma)\%$ CI for β is $\widehat{\beta} \pm z_{\gamma/2}\widehat{m}_{22}$, where $z_{\gamma/2}$ is the $\gamma/2$ point of the standard normal distribution. The asymptotic variance for $\log\widehat{\theta(x_0)} = \widehat{\alpha} + \widehat{\beta}x_0$ is given by

$$\widehat{\sigma} = (1, x_0)\widehat{\boldsymbol{\Sigma}}^{-1}(1, x_0)' \,. \tag{19.30}$$

An asymptotic $100(1-\gamma)\%$ CI for θ_0 is

$$\exp\left(\widehat{\alpha} + \widehat{\beta}x_0 \pm z_{\gamma/2}\widehat{\sigma}\right) \,.$$

Finally, because $F(t)$ is a strictly increasing function of t, an asymptotic $100(1-\gamma)\%$ CI for $R_0(t) = 1 - F(t/\theta_0)$ at a given time t is $1 - F\left[t/\exp\left(\widehat{\alpha} + \widehat{\beta}x_0 \pm z_{\gamma/2}\widehat{\sigma}\right)\right]$.

When the step-stress test is a simple SSALT, i. e., when $m = 2$, there exist closed form MLE for α and β. The MLE of α and β solves

$$\begin{cases} F\left(\dfrac{\tau_1}{\theta_1}\right) & = \dfrac{n_1}{n} \\ F\left(\dfrac{\tau_2 - \tau_1}{\theta_2} + \frac{\tau_1}{\theta_1}\right) - F\left(\dfrac{\tau_1}{\theta_1}\right) & = \dfrac{n_2}{n} \,. \end{cases} \tag{19.31}$$

The solutions are

$$\begin{aligned} \widehat{\alpha} &= \frac{x_2}{x_2 - x_1}\log\frac{\tau_1}{F^{-1}\left(\frac{n_1}{n}\right)} \\ &\quad - \frac{x_1}{x_2 - x_1}\log\frac{(\tau_2 - \tau_1)}{F^{-1}\left(\frac{n_1+n_2}{n}\right) - F^{-1}\left(\frac{n_1}{n}\right)} \,, \\ \widehat{\beta} &= \frac{1}{x_2 - x_1}\log\frac{(\tau_2 - \tau_1)F^{-1}\left(\frac{n_1}{n}\right)}{\tau_1\left[F^{-1}\left(\frac{n_1+n_2}{n}\right) - F^{-1}\left(\frac{n_1}{n}\right)\right]} \,, \end{aligned} \tag{19.32}$$

where F^{-1} is the inverse function of F.

In the more general situation when different test units are subject to different censoring times and different stress-change patterns with different sets of stresses and even different stress-change times, the likelihood function for each test unit can be given by (19.25) for each test unit with $\sum_{i=1}^{m+1} n_i = 1$. The likelihood function for a sample of size n test units is the product of all n individual likelihood functions by assumption (A3). The MLE of α and β can be obtained by maximizing this likelihood function using a numerical method such as Newton–Raphson. Although the lifetime distributions of n test units are independent, they are not identical. The asymptotic confidence interval estimates for various model parameters given above, however, are still valid when the Fisher information matrix $\boldsymbol{\Sigma}/n$ is replaced by the average information matrix to take into account of the difference in the lifetime distributions. The detailed theoretical justification can be found in Chapt. 9 of *Cox* and *Hinkley* [19.51].

A Statistical Test for the Cumulative Exposure Model when m>2

We only consider the case when all test units are subject to the same censoring time and the same stress-change patterns with the same set of stresses and the same stress-change times in this section. We again let $p_i = \Pr(\tau_{i-1} \le T < \tau_i)$ for $1 \le i \le m+1$. The cumulative exposure model (19.22) implies that

$$p_i = F[u_i(\alpha, \beta)] - F[u_{i-1}(\alpha, \beta)] \,. \tag{19.33}$$

A statistical test for the cumulative exposure model can be obtained by testing the null hypothesis $H_0: \; p_i = F[u_i(\alpha, \beta)] - F[u_{i-1}(\alpha, \beta)], \; 1 \le i \le m+1$, against the alternative H_a : there is no constraint on p_i, $1 \le i \le m+1$. When grouped and type I censored data are available from n test units, the likelihood function of p_i, $1 \le i \le m+1$, is

$$L \propto \prod_{i=1}^{m+1} {p_i}^{n_i} \,. \tag{19.34}$$

The MLE of p_i, $1 \le i \le m+1$, under H_0 are given by

$$\widehat{p_i^0} = F\left[u_i\left(\widehat{\alpha}, \widehat{\beta}\right)\right] - F\left[u_{i-1}\left(\widehat{\alpha}, \widehat{\beta}\right)\right] \,, \tag{19.35}$$

where $\widehat{\alpha}, \widehat{\beta}$ are the MLE of α and β. Under H_a, a straightforward maximization of the likelihood function gives the MLE of p_i, $1 \le i \le m+1$, as

$$\widehat{p_i^a} = \frac{n_i}{n} \,. \tag{19.36}$$

Therefore, an asymptotic likelihood ratio test of significance level γ $(0 < \gamma < 1)$ rejects H_0 if

$$\begin{aligned} &-2\sum_{i=1}^{m+1} n_i \left(\log\left\{F\left[u_i\left(\widehat{\alpha}, \widehat{\beta}\right)\right]\right. \right. \\ &\left. \left. - \; F\left[u_{i-1}\left(\widehat{\alpha}, \widehat{\beta}\right)\right]\right\} - \log\frac{n_i}{n}\right) \\ &> \chi^2_\gamma(m-2) \,, \end{aligned} \tag{19.37}$$

where $\chi^2_\gamma(m-2)$ is the upper $100\gamma\%$ percentile of the χ^2 distribution with $m-2$ degrees of freedom. Because

$$\begin{aligned} &-2\sum_{i=1}^{m+1} n_i \left(\log\left\{F\left[u_i\left(\widehat{\alpha}, \widehat{\beta}\right)\right]\right. \right. \\ &\left. \left. - \; F\left[u_{i-1}\left(\widehat{\alpha}, \widehat{\beta}\right)\right]\right\} - \log\frac{n_i}{n}\right) \end{aligned} \tag{19.38}$$

is stochastically equivalent to

$$\sum_{i=1}^{m+1} \frac{\left(n_i - n\left\{F\left[u_i\left(\widehat{\alpha},\widehat{\beta}\right)\right] - F\left[u_{i-1}\left(\widehat{\alpha},\widehat{\beta}\right)\right]\right\}\right)^2}{n\left\{F\left[u_i\left(\widehat{\alpha},\widehat{\beta}\right)\right] - F\left[u_{i-1}\left(\widehat{\alpha},\widehat{\beta}\right)\right]\right\}}, \tag{19.39}$$

another asymptotically equivalent test of significance level γ $(0 < \gamma < 1)$ is the well-known χ^2 goodness-of-fit test, which rejects H_0 if

$$\sum_{i=1}^{m+1} \frac{\left(n_i - n\left\{F\left[u_i\left(\widehat{\alpha},\widehat{\beta}\right)\right] - F\left[u_{i-1}\left(\widehat{\alpha},\widehat{\beta}\right)\right]\right\}\right)^2}{n\left\{F\left[u_i\left(\widehat{\alpha},\widehat{\beta}\right)\right] - F\left[u_{i-1}\left(\widehat{\alpha},\widehat{\beta}\right)\right]\right\}} > \chi^2_\gamma(m-2)\,. \tag{19.40}$$

The mathematical verification of these tests can be found in *Agresti* [19.52] and *Pearson* [19.53].

Optimum Test Plans

We next discuss the optimum test plan for choosing τ_1 in a particular case. Suppose that n test units are tested under a simple SSALT which uses the same censoring time τ_2 and the same stress-change patterns with the same set of stresses $(x_1 < x_2)$ and the same stress-change times τ_1. Assume that the censoring time τ_2 is given. Suppose that the lifetimes at constant stresses x_1 and x_2 are exponential with means θ_1 and θ_2, respectively, where $\theta_i = \exp(\alpha + \beta x_i)$, $i = 1, 2$. Thus, $F(t) = 1 - \exp(-t)$ for $t > 0$. The expected Fisher information matrix $\boldsymbol{\Sigma}$ is now simplified as

$$\boldsymbol{\Sigma} = n\begin{pmatrix} A\left(\frac{\tau_1}{\theta_1}\right)^2 + B\left(\frac{\Delta\tau_2}{\theta_2}\right)^2 & x_1 A\left(\frac{\tau_1}{\theta_1}\right)^2 + x_2 B\left(\frac{\Delta\tau_2}{\theta_2}\right)^2 \\ x_1 A\left(\frac{\tau_1}{\theta_1}\right)^2 + x_2 B\left(\frac{\Delta\tau_2}{\theta_2}\right)^2 & A\left(\frac{x_1\tau_1}{\theta_1}\right)^2 + B\left(\frac{x_2\Delta\tau_2}{\theta_2}\right)^2 \end{pmatrix}, \tag{19.41}$$

where

$$A = (1-p_1)p_1$$
$$B = (1-p_1)/[\exp(\Delta\tau_2/\theta_2) - 1]\,.$$

Because

$$\boldsymbol{\Sigma}^{-1} = \frac{(\theta_1\theta_2)^2}{n \cdot AB\tau_1^2\Delta\tau_2^2(x_2-x_1)^2} \times \begin{pmatrix} A\left(\frac{x_1\tau_1}{\theta_1}\right)^2 + B\left(\frac{x_2\Delta\tau_2}{\theta_2}\right)^2 & -x_1 A\left(\frac{\tau_1}{\theta_1}\right)^2 - x_2 B\left(\frac{\Delta\tau_2}{\theta_2}\right)^2 \\ -x_1 A\left(\frac{\tau_1}{\theta_1}\right)^2 - x_2 B\left(\frac{\Delta\tau_2}{\theta_2}\right)^2 & A\left(\frac{\tau_1}{\theta_1}\right)^2 + B\left(\frac{\Delta\tau_2}{\theta_2}\right)^2 \end{pmatrix}, \tag{19.42}$$

we find that the asymptotic variance of $\log\widehat{\theta}_0 = \widehat{\alpha} + \widehat{\beta}x_0$, denoted by $\mathrm{Asvar}\left(\log\widehat{\theta}_0\right)$, is given by

$$n \cdot \mathrm{Asvar}\left(\log\widehat{\theta}_0\right) = \xi^2 \frac{\theta_2^2\left[\exp(\Delta\tau_2/\theta_2) - 1\right]}{\exp(-\tau_1/\theta_1)\,(\Delta\tau_2)^2} + (1+\xi)^2 \times \frac{\theta_1^2\left[1 - \exp(-\tau_1/\theta_1)\right]}{\exp(-\tau_1/\theta_1)\tau_1^2}, \tag{19.43}$$

where $\xi = \frac{x_1 - x_0}{x_2 - x_1}$ is the amount of stress extrapolation. Our optimum criterion is to find the optimum stress change time τ_1 $(0 < \tau_1 < \tau_2)$ such that the $\mathrm{Asvar}(\log\widehat{\theta}_0)$ is minimized. Because

$$\lim_{\tau_1 \to 0^+} \mathrm{Asvar}\left(\log\widehat{\theta}_0\right) = \lim_{\tau_1 \to \tau_2^-} \mathrm{Asvar}\left(\log\widehat{\theta}_0\right) = +\infty\,, \tag{19.44}$$

the minimum of $\mathrm{Asvar}\left(\log\widehat{\theta}_0\right)$ is attained at some τ_1 between 0 and τ_2 based on the fact that $\mathrm{Asvar}\left(\log\widehat{\theta}_0\right)$ is a continuous function of τ_1 when τ_1 is between 0 and τ_2. The minimization of $\mathrm{Asvar}\left(\log\widehat{\theta}_0\right)$ over τ_1 solves the equation

$$\frac{\partial\left[n \cdot \mathrm{Asvar}\left(\log\widehat{\theta}_0\right)\right]}{\partial\tau_1} = 0\,, \tag{19.45}$$

where

$$\frac{\partial\left[n \cdot \mathrm{Asvar}\left(\log\widehat{\theta}_0\right)\right]}{\partial\tau_1} = \frac{\xi^2\theta_2^2}{(\Delta\tau_2)^3}\exp\left(\frac{\tau_1}{\theta_1}\right)\left\{\left[2 + \left(\frac{1}{\theta_1} - \frac{1}{\theta_2}\right)\Delta\tau_2\right]\exp\left(\frac{\Delta\tau_2}{\theta_2}\right) - \left(2 + \frac{\Delta\tau_2}{\theta_1}\right)\right\} + \frac{(1+\xi)^2\theta_1^2}{\tau_1^3}\left[2 + \left(\frac{\tau_1}{\theta_1} - 2\right)\exp\left(\frac{\tau_1}{\theta_1}\right)\right]. \tag{19.46}$$

The uniqueness of the solution to (19.45) is shown in [19.54]. In general, the solution to (19.45) is not in a closed form and therefore requires a numerical method such as the Newton–Raphson method.

An Example

We use a real data set reported in Table 17.2.1 of Chapt. 10 in *Nelson* [19.47] to demonstrate our estimation and testing procedure. The data set was obtained from a step-stress test of cryogenic cable insulation. Each specimen was first stressed for 10 min each at voltages of 5 kV, 10 kV, 15 kV, and 20 kV before it went into

step 5. Thereafter one group of specimens was stressed for 15 min at each step given in Table 19.5.

Three other groups were held for 60, 240, and 960 min at each step. Thus there were four step-stress patterns. The stress on a specimen (x) is the natural logarithm of the ratio between the voltage and the insulation thickness.

The original data were observed as exact failure times. To demonstrate our estimation process, we grouped the failure time data according to the intervals formed by consecutive stress-change times. There were five censored failure times in the data set. The grouped and censored data are summarized in Table 19.6.

Because of the different thickness for different specimens and different voltages at different steps in the testing, each specimen has its own stress pattern and censoring time. A likelihood function can be written for each specimen according to (19.25). The likelihood function for the whole sample is the product of all these individual likelihood functions in the sample. By using exact failure times instead of grouped count data, *Nelson* [19.47] fitted the Weibull model to the step-stress data and presented the MLE of model parameters on Table 17.2.2 of Chapt. 10 in *Nelson* [19.47]. The MLE estimate for the Weibull shape parameter is 0.755 97 with an asymptotic 95% confidence interval from 0.18 to 1.33. Because the confidence interval contains the value 1, there is no significant evidence against the hypothesis that the failure times of these specimens follow an exponential distribution when tested against the larger family of Weibull distributions based on the standard normal test at a significance level of 5%. We choose to base our analysis on exponential failure time in the step-stress test.

The analysis provided by Chapt. 10 in *Nelson* [19.47] assumed that the SRR is an inverse power-law model and used the stress as the ratio between the voltage and the insulation thickness. In our set up of log-linear SRR, the inverse power-law model translates into $\log\theta(x) = \alpha + \beta x$, where $\theta(x)$ is the mean of the exponential distribution at stress x, and stress x now becomes the natural logarithm of the ratio between the voltage and the insulation thickness. The design stress is at 400 V/mm, therefore, $x_0 = 5.99$. Table 19.7 presents the MLE and CI of various parameters.

To demonstrate how to find the optimum design under a simple step-stress life test, we assume that the voltage levels from step 5 (26 kV) and step 6

Table 19.5 Step-stress pattern after step 4

Step	5	6	7	8	9	10	11
kV	26.0	28.5	31.0	33.4	36.0	38.5	41.0

Table 19.6 Count data

Holding time (min)	Final step	Count (uncensored)	Censoring time	Count (censored)	Thickness (mm)
15	9	3		0	27

960	9	1		0	30

Table 19.7 Parameter estimates

Parameter	MLE	95% CI
α	97.5	[60.3, 134.7]
β	-12.9	$[-13.6, -12.2]$
$\theta(x_0) = \exp(\alpha + \beta x_0)$	6.1×10^{8}	$[2.05\times10^{-8}, 1.76\times10^{9}]$
$R_0(t) = \exp[-t/\theta(x_0)]$	$\exp(-10^{-8}t/6.1)$	$[\exp(-10^{-8}t/2.05), \exp(-10^{-9}t/1.76)]$

(28.5 kV) in the step-stress pattern are used to conduct a future simple step-stress life test. We also assume that the test uses the cable insulation with thickness equal to 30 mm (one of the four types used in the study). Therefore, the two stress levels for this simple step-stress test are $x_1 = \log(26\,000/30) = 6.765$ and $x_2 = \log(28\,500/30) = 6.856$. We still use a design stress of $x_0 = 5.99$. The amount of stress extrapolation is $\xi = 8.516$. We assume that the simple step-stress test has to stop after 1800 min (censoring time τ_2). Using the MLE of α and β obtained from the grouped and censored data in Table 19.7, we numerically solved (19.45) and found that the optimum stress-change time is after 1191.6 min (τ_1) of testing under stress x_1.

19.2.2 Analysis of a Very Simple Step-Stress Life Test with a Random Stress-Change Time

In this section we deal with a very special case of a simple SSALT that is subject to type II censoring. The traditional cumulative exposure model assumes that the stress-change time is a prespecified constant. The stress-change time in many applications, however, can be a random variable which follows a distribution. Here we consider a specific case of a simple step-stress life testing in which the stress-change time T_1 is an order statistic at the low-stress level. This type of simple SSALT occurs when experimenters want to change the stress level after a certain number of failures are observed at the low-stress level.

Throughout the section, we also denote the design stress by x_0, the i-th test stress by x_i, $i = 1, 2$, $x_1 < x_2$. We further assume that a sample of n test units begin at the low stress x_1 until the first n_1 units fail. The stress is then raised to the high stress x_2 and held until another n_2 units fail. Let $C = n(n-n_1)\binom{n-n_1-1}{n_2-1}\binom{n-1}{n_1-1}$ and $\binom{n}{k} = n!/[k!(n-k)!]$ for $0 \le k \le n$. For $0 \le i \le n_1 - 1$ and $0 \le j \le n_2 - 1$, let $\xi(n, n_1, i) = n - n_1 + i + 1$ and $\eta(n, n_1, n_2, j) = n - n_1 - n_2 + j + 1$. In addition to the assumption (A1) and (A2) made above, we further assume that only two order statistics are observed during the entire simple SSALT: one is the stress-change time, which is the n_1-th order statistic under the low stress x_1, the other is the final failure time of SSALT, which is the n_2-th order statistic under the high stress x_2. We will present the joint and marginal distributions of the two observed order statistics from the simple SSALT. We will also discuss the maximum likelihood estimates (MLE) and the method of moment estimates (MME) for the model parameters based on the joint distribution and present the exact confidence interval estimates for the model parameters based on various pivotal quantities.

Joint Distribution of Order Statistics under SSALT

Let T_1 be the stress-change time and T be the lifetime under such a simple SSALT. We further assume that the lifetime under the simple SSALT, given $T_1 = t_1$, follows the cumulative exposure model. Therefore, the conditional cumulative distribution function $G_{T|T_1}$ of T, given the stress-change time $T_1 = t_1$, is given by the classic cumulative exposure model [19.47]:

$$G_{T|T_1}(t) \begin{cases} F_1(t), & \text{for} \quad 0 \le t < t_1 \\ F_2(t - \tau_1 + s), & \text{for} \quad t_1 \le t < \infty \end{cases}, \tag{19.47}$$

where $s = t_1\theta_2/\theta_1$. The conditional probability distribution function (PDF) $g(t|t_1)$ of T, given $T_1 = t_1$, is then

$$g(t|t_1) = \begin{cases} \dfrac{1}{\theta_1} f\left(\dfrac{t_1}{\theta_1}\right), & \text{for} \quad 0 \le t < t_1 \\ \dfrac{1}{\theta_2} f\left(\dfrac{t_2 - t_1}{\theta_2} + \dfrac{t_1}{\theta_1}\right), & \text{for} \quad t_1 \le t < \infty \end{cases}. \tag{19.48}$$

The marginal probability density function (PDF) of T is given by $g(t|t_1)l(t_1)$, where $l(t_1)$ is the PDF of T_1 [19.55].

Suppose that T_2 ($T_1 < T_2$) is the final censoring observation under the simple SSALT. The observed data in such a test are the vector (T_1, T_2). Since T_1 is the n_1-th smallest observation from the distribution $F(\frac{t_1}{\theta_1})$. The probability density function of T_1 is [19.3]:

$$l(t_1) = \binom{n-1}{n_1-1} \frac{n}{\theta_1} f\left(\frac{t_1}{\theta_1}\right) F^{n_1-1}\left(\frac{t_1}{\theta_1}\right) \times \left[1 - F\left(\frac{t_1}{\theta_1}\right)\right]^{n-n_1}. \tag{19.49}$$

Given $T_1 = t_1$, the conditional cumulative exposure model implies that T_2 is the n_2-th order statistic from a sample of size $n - n_1$ with probability density function $(1/\theta_2) f[(t_2 - t_1)/\theta_2 + t_1/\theta_1]/[1 - F(t_1/\theta_1)]$, $t \ge t_1$. Thus, the conditional probability density function for T_2,

given $T_1 = t_1$, is [19.3]:

$$
\begin{aligned}
f_{T_2|T_1}(t_2) = & \binom{n-n_1-1}{n_2-1} \frac{(n-n_1)}{\theta_2} \\
& \times f\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) \\
& \times \left[F\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) - F\left(\frac{t_1}{\theta_1}\right)\right]^{n_2-1} \\
& \times R^{n-n_1-n_2}\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) \\
& \times R^{n_1-n}\left(\frac{t_1}{\theta_1}\right) , \qquad (19.50)
\end{aligned}
$$

where $R(t) = 1 - F(t)$. Therefore, the joint probability density for (T_1, T_2) is

$$
\begin{aligned}
f(t_1, t_2) &= f_{T_2|T_1}(t_2) l_1(t_1) \\
&= \frac{C}{\theta_1\theta_2} f\left(\frac{t_1}{\theta_1}\right) f\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) \\
&\quad \times F^{n_1-1}\left(\frac{t_1}{\theta_1}\right) \\
&\quad \times \left[F\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) - F\left(\frac{t_1}{\theta_1}\right)\right]^{n_2-1} \\
&\quad \times R^{n-n_1-n_2}\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) . \qquad (19.51)
\end{aligned}
$$

When the lifetime is exponential under constant stress, i. e., $f(t) = \exp(-t)$, $t > 0$,

$$
\begin{aligned}
f(t_1, t_2) = & \frac{C}{\theta_1\theta_2}\left\{\exp\left[-(n-n_1+1)\frac{t_1}{\theta_1}\right]\right\} \\
& \times \left[1-\exp\left(-\frac{t_1}{\theta_1}\right)\right]^{n_1-1} \\
& \times \left\{\exp\left[-(n-n_1-n_2+1)\frac{t_2-t_1}{\theta_2}\right]\right\} \\
& \times \left[1-\exp\left(-\frac{t_2-t_1}{\theta_2}\right)\right]^{n_2-1} . \qquad (19.52)
\end{aligned}
$$

MLE and MME

From now on we concentrate on the SRR, which assumes that $\theta(x)$ is a log-linear function of the stress x, i. e., $\ln[\theta(x)] = \alpha + \beta x$. The parameters α and β are characteristics of the products and test methods and we assume that $x > 0$ and $\beta < 0$. Notice that $\theta(x)$ is a multiple of the mean lifetime under the stress x based on the assumption (A1). In fact, if the lifetime distribution is exponential, then $\theta(x)$ is the mean lifetime under stress x. We discuss the point estimates for α, β, and $\theta_0 = \exp(\alpha + \beta x_0)$ in this section based on the method of maximum likelihood and the method of moment.

As a function of α and β, the joint density function $f(t_1, t_2)$ in (19.51) becomes the likelihood function $L(\alpha, \beta)$ based on the data vector (T_1, T_2). The maximum likelihood estimate for α and β can be obtained by solving the system of equations:

$$
\begin{cases}
\begin{aligned}
\frac{\partial \log L}{\partial \alpha} &= -2 - \frac{t_1 f'\left(\frac{t_1}{\theta_1}\right)}{\theta_1 f\left(\frac{t_1}{\theta_1}\right)} - \left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) \\
&\quad \times \frac{f'\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right)}{f\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right)} - \frac{(n_1-1)t_1 f\left(\frac{t_1}{\theta_1}\right)}{\theta_1 F\left(\frac{t_1}{\theta_1}\right)} \\
&\quad - (n_2-1) \\
&\quad \times \frac{\left[\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) f\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) - \frac{t_1}{\theta_1} f\left(\frac{t_1}{\theta_1}\right)\right]}{F\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) - F\left(\frac{t_1}{\theta_1}\right)} \\
&\quad + (n-n_1-n_2)\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) \\
&\quad \times \frac{f\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right)}{R\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right)} = 0
\end{aligned} \\
\begin{aligned}
\frac{\partial \log L}{\partial \beta} &= -\frac{x_1 t_1 f'\left(\frac{t_1}{\theta_1}\right)}{\theta_1 f\left(\frac{t_1}{\theta_1}\right)} - \left[\frac{x_2(t_2-t_1)}{\theta_2}+\frac{x_1 t_1}{\theta_1}\right] \\
&\quad \times \frac{f'\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right)}{f\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right)} - \frac{(n_1-1)x_1 t_1 f\left(\frac{t_1}{\theta_1}\right)}{\theta_1 F\left(\frac{t_1}{\theta_1}\right)} \\
&\quad - (x_1+x_2) \\
&\quad - (n_2-1) \\
&\quad \times \left[\frac{\left(\frac{x_2(t_2-t_1)}{\theta_2}+\frac{x_1 t_1}{\theta_1}\right) f\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right)}{F\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) - F\left(\frac{t_1}{\theta_1}\right)} - \frac{\frac{x_1 t_1}{\theta_1} f\left(\frac{t_1}{\theta_1}\right)}{F\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right) - F\left(\frac{t_1}{\theta_1}\right)}\right] \\
&\quad + (n-n_1-n_2)\left[\frac{x_2(t_2-t_1)}{\theta_2}+\frac{x_1 t_1}{\theta_1}\right] \\
&\quad \times \frac{f\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right)}{R\left(\frac{t_2-t_1}{\theta_2}+\frac{t_1}{\theta_1}\right)} = 0
\end{aligned}
\end{cases} , \qquad (19.53)
$$

where $f'(t) = \mathrm{d}f(t)/\mathrm{d}t$. In general, the solution of (19.53) requires a numerical method such as the Newton–Raphson method. The methods in *Seo* and *Yum* [19.50] can also be used. To find the MME of α and β, we notice that (by a change of variable)

$$
\begin{aligned}
ET_1 = & \int_0^\infty t_1 l(t_1)\,\mathrm{d}t_1 = n\binom{n-1}{n_1-1}\theta_1 \\
& \times \int_0^1 u^{n_1-1}(1-u)^{n-n_1} F^{-1}(u)\,\mathrm{d}u , \qquad (19.54)
\end{aligned}
$$

and

$$E(T_2|T_1=t_1)=\int_{t_1}^{\infty} t_2 f_{T_2|T_1}(t_2)\,\mathrm{d}t_2$$
$$=\binom{n-n_1-1}{n_2-1}\frac{(n-n_1)}{R^{n-n_1}\left(\frac{t_1}{\theta_1}\right)}$$
$$\times\int_{F(t_1/\theta_1)}^{1}\left[\theta_2 F^{-1}(v)+\left(1-\frac{\theta_2}{\theta_1}\right)t_1\right]$$
$$\times\left[v-F\left(\frac{t_1}{\theta_1}\right)\right]^{n_2-1}(1-v)^{n-n_1-n_2}\,\mathrm{d}v\,, \tag{19.55}$$

where F^{-1} is the inverse function of F. Thus, by letting $w=F(t_1/\theta_1)$,

$$E(T_2)=E_{T_1}\left[E(T_2|T_1)\right]$$
$$=C\int_0^1 w^{n_1-1}\,\mathrm{d}w$$
$$\times\int_w^1\left[\theta_2 F^{-1}(v)+(\theta_1-\theta_2)\,F^{-1}(w)\right]$$
$$\times[v-w]^{n_2-1}(1-v)^{n-n_1-n_2}\,\mathrm{d}v\,. \tag{19.56}$$

The MME of α and β can be found by solving the system of equations:

$$\begin{cases} T_1 &= n\binom{n-1}{n_1-1}\theta_1\int_0^1 u^{n_1-1}(1-u)^{n-n_1}F^{-1}(u)\,\mathrm{d}u \\ T_2 &= C\int_0^1 w^{n_1-1}\,\mathrm{d}w \\ &\quad\times\int_w^1\left[F^{-1}(v)+(\theta_1-\theta_2)\,F^{-1}(w)\right] \\ &\quad\times(v-w)^{n_2-1}(1-v)^{n-n_1-n_2}\,\mathrm{d}v\,. \end{cases} \tag{19.57}$$

When the lifetime is exponential under constant stress, i. e., $f(t)=\exp(-t)$, $t>0$, $ET_1=\theta_1\sum_{i=0}^{n_1-1}(n-i)^{-1}$ [19.3]. A direct binomial expansion in (19.52) along with the repeated use of integration by parts yields

$$E(T_2)=\theta_1\sum_{i=0}^{n_1-1}(n-i)^{-1}$$
$$+C\sum_{i=0}^{n_1-1}\sum_{j=0}^{n_2-1}(-1)^{i+j}\binom{n_1-1}{i}$$
$$\times\binom{n_2-1}{j}\frac{\theta_2}{\eta^2(n,n_1,n_2,j)\xi(n,n_1,i)}\,. \tag{19.58}$$

This also gives a closed form solution to the MME of α and β as

$$\widetilde{\beta}=\frac{1}{x_2-x_1}\left\{\ln\left[(T_2-T_1)\sum_{i=0}^{n_1-1}(n-i)^{-1}\right]\right.$$
$$-\ln\left[T_1 C\sum_{i=0}^{n_1-1}\sum_{j=0}^{n_2-1}(-1)^{i+j}\binom{n_1-1}{i}\binom{n_2-1}{j}\right.$$
$$\left.\left.\times\,\eta^{-2}(n,n_1,n_2,j)\zeta^{-1}(n,n_1,i)\right]\right\}$$
$$\widetilde{\alpha}=\ln\left(\frac{T_1}{\sum_{i=0}^{n_1-1}(n-i)^{-1}}\right)-\widetilde{\beta}x_1\,. \tag{19.59}$$

Confidence Interval Estimates of Model Parameters

Now we set up the exact confidence intervals for α, β, and $\theta_0=\exp(\alpha+\beta x_0)$ under the assumption that F is given. We first observe an important fact which will be used for the estimation of model parameters in this section. Let $S_1=\frac{T_1}{\theta_1}$, and $S_2=\frac{T_2-T_1}{\theta_2}$. The joint probability density function of (S_1, S_2) is

$$g(s_1,s_2)=Cf(s_1)f(s_2+s_1)F^{n_1-1}(s_1)$$
$$\times[F(s_2+s_1)-F(s_1)]^{n_2-1}$$
$$\times[1-F(s_2+s_1)]^{n-n_1-n_2}\,. \tag{19.60}$$

Therefore, (S_1, S_2) is a pivotal vector whose distribution does not depend on the unknown parameters θ_1 and θ_2.

We now set up a confidence interval for β. Let $S_3=\frac{S_2}{S_1}$. The marginal distribution of S_3 is given by

$$g_3(s_3)=\int_0^{\infty} g(s_1,s_1s_3)s_1\,\mathrm{d}s_1\,. \tag{19.61}$$

Since $S_3=\frac{T_2-T_1}{T_1}\exp\left[\beta(x_1-x_2)\right]$, a $100(1-\gamma)\%$ $(0<\gamma<1)$ confidence interval for β is $[\beta_1,\beta_2]$, where

$$\beta_1=\frac{1}{x_2-x_1}\ln\left(\frac{T_2-T_1}{T_1 S_{3,\gamma/2}}\right),$$
$$\beta_2=\frac{1}{x_2-x_1}\ln\left(\frac{T_2-T_1}{T_1 S_{3,1-\gamma/2}}\right), \tag{19.62}$$

and for $0<c<1$, $S_{3,c}$ is such that

$$\int_0^{S_{3,c}} g_3(s_3)\,\mathrm{d}s_3=1-c\,. \tag{19.63}$$

To set up a confidence interval for α, we let $S_4 = S_1^{x_2/x_1}$ and $S_5 = \frac{S_2}{S_4}$. The marginal distribution of S_5 is given by

$$g_5(s_5) = \frac{x_1}{x_2} \int_0^\infty g\left(s_4^{\frac{x_1}{x_2}}, s_4 s_5\right) s_4^{\frac{x_1}{x_2}} \, \mathrm{d}s_4 \,. \tag{19.64}$$

Since $S_5 = (T_2 - T_1)\, T_1^{-\frac{x_2}{x_1}} \exp\left(\frac{x_2 - x_1}{x_1}\alpha\right)$, a $100(1-\gamma)\%$ $(0 < \gamma < 1)$ confidence interval for α is $[\alpha_1, \alpha_2]$, where

$$\begin{aligned} \alpha_1 &= \frac{x_1}{x_1 - x_2}\left[\ln(T_2 - T_1) - \ln\left(T_1^{\frac{x_2}{x_1}} S_{5,1-\gamma/2}\right)\right], \\ \alpha_2 &= \frac{x_1}{x_1 - x_2}\left[\ln(T_2 - T_1) - \ln\left(T_1^{\frac{x_2}{x_1}} S_{5,\gamma/2}\right)\right], \end{aligned} \tag{19.65}$$

and, for $0 < c < 1$, $S_{5,c}$ is such that

$$\int_0^{S_{5,c}} g_5(s_5)\,\mathrm{d}s_5 = 1 - c \,. \tag{19.66}$$

The confidence interval for $\theta_0 = \exp(\alpha + \beta x_0)$ can also be obtained based on the distribution of a similar pivotal quantity to S_5. In fact, for $i = 1, 2$, we can always write $\theta_i = \exp(\alpha + \beta x_i) = \exp[(\alpha + \beta x_0) + \beta(x_i - x_0)]$. Therefore, by replacing the stress x_i by the transformed stress $x_i - x_0$ in the derivation of pivotal quantity S_5, we obtain another pivotal quantity:

$$\widetilde{S}_5 = (T_2 - T_1)\, T_1^{-\frac{x_2 - x_0}{x_1 - x_0}} \exp\left[\frac{x_2 - x_1}{x_1 - x_0}(\alpha + \beta x_0)\right] . \tag{19.67}$$

The distribution of $\widetilde{S}_5$ is given by the marginal density function

$$\widetilde{g}_5(s_5) = \frac{x_1 - x_0}{x_2 - x_0} \int_0^\infty g\left(s_4^{\frac{x_1 - x_0}{x_2 - x_0}}, s_4 s_5\right) s_4^{\frac{x_1 - x_0}{x_2 - x_0}} \, \mathrm{d}s_4 \,. \tag{19.68}$$

By using the distribution of pivotal quantity $\widetilde{S}_5$, we can set up a confidence interval for $\alpha + \beta x_0$ similar to the way that the confidence interval for α was set up based on the original stress x_i and the pivotal quantity S_5. Then a confidence interval for θ_0 can be obtained by the exponentiation of the confidence interval of $\alpha + \beta x_0$. More specifically, let $\xi = (x_1 - x_0)/(x_2 - x_1)$ be the amount of stress extrapolation [19.37]. A $100(1-\gamma)\%$ $(0 < \gamma < 1)$ confidence interval for $\theta_0 = \exp(\alpha + \beta x_0)$ is $[\theta_{01}, \theta_{02}]$, where

$$\begin{aligned} \theta_{01} &= \frac{T_1^{1+\xi}\, \widetilde{S}_{5,1-\gamma/2}^{\xi}}{(T_2 - T_1)^{\xi}} \,, \\ \theta_{02} &= \frac{T_1^{1+\xi}\, \widetilde{S}_{5,\gamma/2}^{\xi}}{(T_2 - T_1)^{\xi}} \,, \end{aligned} \tag{19.69}$$

Table 19.8 Percentiles of S_3 and S_5

Variable	Percentile	$n_2 = 6$	$n_2 = 8$	$n_2 = 10$
S_3	1	0.40	0.69	1.07
	2.5	0.52	0.86	1.31
	5	0.63	1.03	1.55
	10	0.80	1.27	1.88
	90	4.01	5.82	8.20
	95	5.12	7.38	10.36
	97.5	6.37	9.14	12.79
	99	8.28	11.83	16.52
S_5	1	0.84	1.32	1.91
	2.5	1.08	1.73	2.57
	5	1.42	2.25	3.32
	10	1.97	3.07	4.51
	90	27.14	40.05	56.98
	95	42.16	61.96	87.96
	97.5	62.95	92.25	130.75
	99	102.81	150.25	212.60

and, for $0 < c < 1$, $\widetilde{S}_{5,c}$ is such that

$$\int_0^{\widetilde{S}_{5,c}} \widetilde{g}_5(s_5)\,\mathrm{d}s_5 = 1 - c\,. \tag{19.70}$$

When the lifetime is exponential under constant stress, i. e., $f(t) = \exp(-t)$, $t > 0$, the marginal density functions for S_3 and S_5 are simplified. The marginal probability density function of S_3 is

$$g_3(s_3) = C \sum_{i=0}^{n_1-1} \sum_{j=0}^{n_2-1} (-1)^{i+j} \binom{n_1-1}{i} \binom{n_2-1}{j} \times \frac{1}{[\xi(n, n_1, i) + \eta(n, n_1, n_2, j)s_3]^2}\,. \tag{19.71}$$

A direct integration gives the marginal CDF of S_3 as

$$G_3(s_3) = C \sum_{i=0}^{n_1-1} \sum_{j=0}^{n_2-1} (-1)^{i+j} \binom{n_1-1}{i} \binom{n_2-1}{j} \times \frac{1}{\eta(n, n_1, n_2, j)} \left[\frac{1}{\xi(n, n_1, i)} - \frac{1}{[\xi(n, n_1, i) + \eta(n, n_1, n_2, j)s_3]} \right]. \tag{19.72}$$

The marginal density function of S_5 is

$$g_5(s_5) = C \frac{x_1}{x_2} \sum_{i=0}^{n_1-1} \sum_{j=0}^{n_2-1} (-1)^{i+j} \binom{n_1-1}{i} \binom{n_2-1}{j} \times \int_0^{\infty} \exp\left[-\xi(n, n_1, i) s_4^{\frac{x_1}{x_2}} - \eta(n, n_1, n_2, j) s_4 s_5 \right] s_4^{\frac{x_1}{x_2}}\,\mathrm{d}s_4\,. \tag{19.73}$$

A change in the order of integration and the use of integration by parts gives the marginal CDF of S_5 as

$$G_5(s_5) = C \frac{x_1}{x_2} \sum_{i=0}^{n_1-1} \sum_{j=0}^{n_2-1} (-1)^{i+j} \binom{n_1-1}{i} \binom{n_2-1}{j} \times \int_0^{\infty} \frac{1 - \exp[-\eta(n, n_1, n_2, j)s_4, s_5]}{\eta(n, n_1, n_2, j)s_4} \times \exp\left[-\zeta(n, n_1, i) s_4^{\frac{x_1}{x_2}} \right] s_4^{\frac{x_1}{x_2}}\,\mathrm{d}s_4 \tag{19.74}$$

The marginal density function and the marginal distribution function of $\widetilde{S}_5$ can be obtained by replacing the stress x_i by the transformed stress $x_i - x_0$, $i = 1, 2$, in the corresponding function of S_5. Except for trivial situations, numerical integration subroutines are typically required for the evaluation of the distribution functions associated with the pivotal quantities even when the exponential distributions are assumed. In addition, the approximation of these distributions can also be obtained through large simulations of the pivotal quantities.

Assume that a sample of 20 experimental units are placed under a simple step-stress life test. The test stress is changed from the lower stress x_1 to the higher stress x_2 after the fifth failure from the lower stress level x_1 is observed ($n_1 = 5$). The test is finished after another n_2 failures are observed at the higher stress x_2. Assume that the lifetime distribution under constant stress $x_i (i = 0, 1, 2)$ is exponential with mean parameter $\theta_i = \exp(\alpha + \beta x_i)$. For $x_0 = 0, x_2 = 2x_1 > 0$ and $n_2 = 6, 8, 10$, Table 19.8 presents the 1, 2.5, 5, 10, 90, 95, 97.5 and 99 percentiles for the distributions of S_3 and S_5. These percentiles are computed by numerical integration of the distribution function for S_3 and S_5. They can be used to set up appropriate confidence intervals for β, α, and θ_0.

20. Failure Rates in Heterogeneous Populations

Most of the papers on failure rate modeling deal with homogeneous populations. Mixtures of distributions present an effective tool for modeling heterogeneity. In this chapter we consider nonasymptotic and asymptotic properties of mixture failure rates in different settings.

After a short introduction, in the first section of this chapter we show (under rather general assumptions) that the mixture failure rate is 'bent-down' compared with the corresponding unconditional expectation of the baseline failure rate, which has been proved in the literature for some specific cases. This property is due to an effect where 'the weakest populations die out first', explicitly proved mathematically in this section. This should be taken into account when analyzing failure data for heterogeneous populations in practice. We also consider the problem of mixture failure rate ordering for the ordered mixing distributions. Two types of stochastic ordering are analyzed: ordering in the likelihood ratio sense and ordering the variances when the means are equal. Mixing distributions with equal expectations and different variances can lead to corresponding ordering for mixture failure rates in $[0,\infty)$ in some specific cases. For a general mixing distribution, however, this ordering is only guaranteed for sufficiently small t.

In the second section, the concept of proportional hazards (PH) in a homogeneous population is generalized to a heterogeneous case. For each subpopulation, the PH model is assumed to exist. It is shown that this proportionality is violated for observed (mixture) failure rates. The corresponding bounds for a mixture failure rate are obtained in this case. The change point in the environment is discussed. Shocks – changing the mixing distribution – are also considered. It is shown that shocks with the stochastic properties described also bend down the initial mixture failure rate.

Finally, the third section is devoted to new results on the asymptotic behavior of mixture failure rates. The suggested lifetime model generalizes all three conventional survival models (proportional hazards, additive hazards and accelerated life) and makes it possible to derive explicit asymptotic results. Some of the results obtained can be generalized to a wider class of lifetime distributions, but it appears that the class considered is 'optimal' in terms of the trade-off between the complexity of a model and the tractability (or applicability) of the results. It is shown that the mixture failure rate asymptotic behavior depends only on the behavior of a mixing distribution near to zero, and not on the whole mixing distribution.

Although most studies that model failure rates deal with homogeneous cases, homogeneous populations are rare in real life. Neglecting the existence of heterogeneity can lead to substantial errors during stochastic analy-

sis, reliability, survival and risk analysis, and in other disciplines.

Mixtures of distributions usually present an effective approach to modeling heterogeneity. There may be a physical origin for such mixing in practice. This may happen, for instance, if different (heterogeneous) types of devices that all perform the same function, and are not distinguishable during operation, are mixed together. This occurs in real life when we have 'identical' items that originate from different brands. A similar situation arises when data from different distributions are pooled to enlarge the sample size.

It is well-known that mixtures of decreasing failure rate (DFR) distributions are always also DFR [20.1]. On the other hand, mixtures of increasing failure rate distributions (IFR) can decrease, at least over some intervals of time, which means that the IFR class of distributions is not closed under the operation of mixing [20.2]. As IFR distributions are usually used to model lifetimes governed by aging processes, this means that the operation of mixing can change the pattern of aging dramatically; for example from positive aging (IFR) to negative aging (DFR). It should be noted, however, that the change in the aging pattern usually occurs at sufficiently large item age, and so asymptotic methods are clearly important in this type of analysis. These facts and other implications of heterogeneity should be taken into account in applications.

One specific natural approach to this modeling exploits a notion of a non-negative random unobserved parameter (the frailty) Z, introduced by *Vaupel* et al. [20.3] for a gamma-distributed Z. This, in fact, can be interpreted as a subjective approach and leads to a consideration of a random failure rate $\lambda(t, Z)$. Some interesting applications of the frailty concept in survival analysis were studied by *Aalen* [20.4]. Since the failure rate is a conditional characteristic, the 'ordinary' expectation $E[\lambda(t, Z)]$ with respect to Z does not define a mixture failure rate $\lambda_m(t)$, and a proper conditioning should be performed [20.5]. It is worth mentioning that a random failure rate is a specific case of a hazard rate process [*Kebir* [20.6] and *Yashin* and *Manton* [20.7]]. A convincing 'experiment' that shows a deceleration in the observed failure rate is performed by nature. It is well-known that human mortality follows the *Gompertz* [20.8] lifetime distribution with an exponentially increasing mortality rate. Assume that heterogeneity can be described by the proportional gamma frailty model:

$$\lambda(t, Z) = Z\alpha \exp(\beta t),$$

where α and β are positive constants. Due to its computational simplicity, the gamma frailty model is practically the only one that has been used in applications so far. It can be shown (see, e.g., *Finkelstein* and *Esaulova* [20.9]) that the mixture failure rate $\lambda_m(t)$ in this case is monotonic in $[0, \infty)$ and asymptotically tends to a constant as $t \to \infty$. However, $\lambda_m(t)$ monotonically increases for real values of the parameters of this model. This fact explains the recently observed deceleration in human mortality for the oldest humans (human mortality plateau, as in *Thatcher* [20.10]). A similar result has been experimentally obtained for a large cohort of medflies by *Carey* et al. [20.11]. On the other hand, in engineering applications a mixing operation can result in a failure rate that increases for $[0, t_m)$, $t_m > 0$ and decreases asymptotically to 0 for (t_m, ∞), which has been experimentally observed by *Finkelstein* [20.12] for example for a heterogeneous sample of miniature light bulbs (Example 20.1). This fact is easily explained theoretically using the gamma frailty model with a baseline failure rate that increases as a power function (Weibull law) [20.9, 13].

When considering heterogeneous populations in different environments, the problem of ordering mixture failure rates for stochastically ordered random mixing variables arises. This topic has not been addressed in the literature before. In Sect. 20.1 we show that the natural type of ordering for the mixing models under consideration is ordering by likelihood ratio [20.14, 15]. This correlates with the general considerations of *Block* et al. [20.16] with respect to burn-in of heterogeneous populations. Specifically, when two frailties are ordered in this way, the corresponding mixture failure rates are naturally ordered as functions of time in $[0, \infty)$. Some specific results for the case of frailties with equal means and different variances are also obtained.

In Sect. 20.2 we discuss a 'combination' of a frailty and a proportional hazards (PH) model. The case of a step-stress change-point in the proportional hazards framework is considered and the corresponding bounds for the mixture failure rate are also obtained. Another example deals with a special type of shock, which performs a burn-in for heterogeneous populations.

Section 20.3 is devoted to the important topic of the asymptotic behavior of mixture failure rates. In *Block* et al. [20.17], it was proved that, if the failure rate of each subpopulation converges to a constant and this convergence is uniform, then the mixture failure rate converges to the failure rate of the strongest subpopulation: in other words, the weakest subpopulations die out

first. (For convenience, from now on we shall use, where appropriate, the term "population" instead of "subpopulation") This result is a generalization of the case where populations have constant failure rates, as considered by *Clarotti* and *Spizzichino* [20.18], and it also represents a further development of the work by *Block* et al. in [20.16] (see also [20.19,20]). In *Block* and *Joe* [20.21] the following asymptotic result, which addresses the issue of ultimate monotonicity, was obtained. Let z_0 be a realization of a frailty Z, which corresponds to the strongest population. If $\lambda(t, z)/\lambda(t, z_0)$ uniformly decreases as $t \to \infty$, then $\lambda_m(t)/\lambda(t, z_0)$ also decreases. If, in addition, $\lim_{t\to\infty} \lambda(t, z_0)$ exists, then this quotient decreases to 1. Although the lifetime model obtained from these findings may be rather general, the analytical restrictions, such as uniform convergence, are rather stringent. Besides, the strongest population cannot always be identified.

We suggest a class of distributions that generalizes the proportional hazards, the additive hazards and the accelerated life models and we prove a simple asymptotic result for the mixture failure rate for this class of lifetime distributions. It turns out that the asymptotic behavior of mixture failure rates depends only on the behavior of the mixing distribution in the neighborhood of the left end point of its support, and not on the whole mixing distribution.

Notation

The following notation is used in this chapter

T	lifetime random variable,
$F(t)$	cumulative distribution function of T,
Z	unobserved random variable (frailty),
$F(t, z)$	cumulative distribution function indexed by parameter z,
$\Pi(z)$	distribution function of Z,
$\Pi(z\|t)$	conditional distribution function of Z,
$\pi(z)$	probability density function of Z,
$\pi_k(z)$	probability density function of kZ,
$\pi(z\|t)$	conditional probability density of Z,
$\lambda(t, z)$	failure rate indexed by parameter z,
$\Lambda(t, z)$	cumulative failure rate indexed by parameter z,
$\lambda_m(t)$	mixture failure rate,
$\lambda_P(t)$	unconditional expectation in the family of failure rates,
$\lambda_{mk}(t)$	mixture failure rate for the PH model,
$\tilde{\lambda}_{mk}(t)$	notation for $k\lambda_m(t)$,
$\lambda_{ms}(t)$	mixture failure rate after a shock,
$g(z)$	function decreasing in z
$\varepsilon(t)$	baseline stress,
$\varepsilon_s(t)$	more severe stress,
$A(s)$	function defining the general survival model,
$\phi(t)$	scale function in the general survival model,
$\Psi(t)$	additive part of the general survival model.

20.1 Mixture Failure Rates and Mixing Distributions

20.1.1 Definitions

Let $T \geq 0$ be a lifetime random variable with the cumulative distribution function (Cdf) $F(t)[\bar{F}(t) \equiv 1 - F(t)]$. Assume that $F(t)$ is indexed by a random variable Z in the following sense

$$P(T \leq t|Z = z) \equiv P(T \leq t|z) = F(t, z)$$

and that the probability density function (pdf) $f(t, z)$ exists. Then the corresponding failure rate $\lambda(t, z)$ is $f(t, z)/\bar{F}(t, z)$. Let Z be interpreted as a non-negative random variable with support $[a, b]$, $a \geq 0$, $b \leq \infty$ and pdf $\pi(z)$. Thus, a mixture Cdf is defined by

$$F_m(t) = \int_a^b F(t, z)\pi(z)\,dz\,.$$

As the failure rate is a conditional characteristic, the mixture failure rate $\lambda_m(t)$ should be defined in the following way (see, e.g., *Finkelstein* and *Esaulova* [20.9]):

$$\lambda_m(t) = \frac{\int_a^b f(t, z)\pi(z)\,dz}{\int_a^b \bar{F}(t, z)\pi(z)\,dz} = \int_a^b \lambda(t, z)\pi(z|t)\,dz\,, \tag{20.1}$$

where the conditional pdf (on the condition that $T > t$) is:

$$\pi(z|t) \equiv \pi(z|T > t) = \pi(z)\frac{\bar{F}(t, z)}{\int_a^b \bar{F}(t, z)\pi(z)\,dz}. \tag{20.2}$$

Therefore, this pdf defines a conditional random variable $Z|t$, $Z|0 \equiv Z$ with the same support. On the other hand,

consider the following *unconditional characteristic*

$$\lambda_{\mathrm{P}}(t) = \int_a^b \lambda(t, z)\pi(z)\,\mathrm{d}z\,, \tag{20.3}$$

which, in fact, defines an expected value (as a function of t) for a specific stochastic process $\lambda(t, Z)$. It follows from definitions (20.1) and (20.3) that $\lambda_{\mathrm{m}}(0) = \lambda_{\mathrm{P}}(0)$. The function $\lambda_{\mathrm{P}}(t)$ is a supplementary one, but as a trend function of a stochastic process, it captures the monotonic pattern of the family $\lambda(t, z)$. Therefore, under certain conditions, $\lambda_{\mathrm{P}}(t)$ has a similar shape to $\lambda(t, z)$: if, e.g., $\lambda(t, z)$, $z \in [a, b]$ increases with t, then $\lambda_{\mathrm{P}}(t)$ increases as well. For some specific cases (see later) $\lambda_{\mathrm{P}}(t)$ also characterizes the shape of the baseline failure rate. On the other hand, the mixture failure rate $\lambda_{\mathrm{m}}(t)$ can have a different pattern: it can ultimately decrease, for instance, or it can preserve the property that it increases with t, as in *Lynch* [20.2]. There is even the possibility of a few oscillations. However, despite all of the patterns that are possible, it will be proved that the mixture failure rate is majorized by $\lambda_{\mathrm{P}}(t)$:

$$\lambda_{\mathrm{m}}(t) < \lambda_{\mathrm{P}}(t),\ t > 0 \tag{20.4}$$

and under some additional assumptions, that

$$[\lambda_{\mathrm{P}}(t) - \lambda_{\mathrm{m}}(t)] \uparrow,\ t \geq 0. \tag{20.5}$$

Definition 20.1
[20.22]. Relation (20.4) defines a weak bending-down property for the mixture failure rate, whereas relation (20.5) is the definition of a strong bending-down property.

20.1.2 Multiplicative Model

Consider the following specific multiplicative model

$$\lambda(t, z) = z\,\lambda(t), \tag{20.6}$$

where $\lambda(t)$ is a baseline failure rate. This setting defines the widely used frailty (multiplicative) model. On the other hand, it can be also viewed as a proportional hazards (PH) model. Applying definition (20.1) gives:

$$\lambda_{\mathrm{m}}(t) = \int_a^b \lambda(t, z)\pi(z|t)\,\mathrm{d}\theta = \lambda(t)E[Z|t]. \tag{20.7}$$

The conditional expectation $E[Z|t](E[Z|0] \equiv E[Z])$ plays a crucial role in defining the shape of the mixture failure rate $\lambda_{\mathrm{m}}(t)$ in this model. The following result was proved in *Finkelstein* and *Esaulova* [20.9]:

$$E_t'[Z|t] = -\lambda(t)Var(Z|t) < 0,$$

which means that the conditional expectation of Z is a decreasing function of $t \in [0, \infty)$. On the other hand, (20.3) becomes

$$\lambda_{\mathrm{P}}(t) = \int_a^b \lambda(t, z)\pi(z)\,\mathrm{d}z = \lambda(t)E[Z|0]. \tag{20.8}$$

Therefore

$$\lambda_{\mathrm{P}}(t) - \lambda_{\mathrm{m}}(t) = \lambda(t)(E[Z|0] - E[Z|t]) > 0$$

and relation (20.4) holds, whereas under the additional sufficient condition that $\lambda(t)$ is increasing, the strong bending-down property (20.5) occurs.

20.1.3 Comparison with Unconditional Characteristics

The main additional assumption that will be needed for the following result is that the family of failure rates $\lambda(t, z)$, $z \in [a, b]$ should be ordered in z.

Theorem 20.1
Let the failure rate $\lambda(t, z)$ in the mixing model (20.1) be differentiable with respect to both arguments and be ordered as

$$\lambda(t, z_1) < \lambda(t, z_2),\ z_1 < z_2, \forall z_1, z_2 \in [a, b], t \geq 0. \tag{20.9}$$

Assume that the conditional and unconditional expectations in relations (20.1) and (20.3), respectively, are finite for $\forall t \in [0, \infty)$.

Then:

a) The mixture failure rate $\lambda_{\mathrm{m}}(t)$ bends down with time, weakly at least.

b) If, additionally, $\frac{\partial\lambda(t,z)}{\partial z}$ increases with t, then $\lambda_{\mathrm{m}}(t)$ strongly bends down with time.

Proof: It is clear that ordering (20.9) is equivalent to the condition that $\lambda(t, z)$ increases with z for each $t \geq 0$. In accordance with (20.1) and (20.3), and integrating by

parts [20.5]:

$$\begin{aligned}\Delta\lambda(t) &\equiv \int_a^b \lambda(t,z)[\pi(z)-\pi(z|t)]\,\mathrm{d}z \\ &= \lambda(t,z)[\Pi(z)-\Pi(z|t)]\big|_a^b \\ &\quad - \int_a^b \lambda'_z(t,z)[\Pi(z)-\Pi(z|t)]\,\mathrm{d}z \\ &= \int_a^b -\lambda'_z(t,z)[\Pi(z)-\Pi(z|t)]\,\mathrm{d}z > 0,\ t>0\,,\end{aligned} \tag{20.10}$$

where

$$\Pi(z) = P(Z \le z); \quad \Pi(z|t) = P(Z \le z | T > t)$$

and the term $\lambda(t,z)[\Pi(z)-\Pi(z|t)]\big|_a^b$ vanishes for $b=\infty$ as well. Inequality (20.10), and therefore the first part of the theorem, follows from $\lambda'_z(t,z)>0$ and the following inequality:

$$\Pi(z)-\Pi(z|t) < 0,\ \forall t>0, z\in(a,b). \tag{20.11}$$

Inequality (20.11) can be interpreted as: "the weakest populations die out first". This interpretation is widely used in various specific cases, especially in demographic literature [20.3]. To obtain (20.11), it is sufficient to prove that

$$\Pi(z|t) = \frac{\int_a^z \bar{F}(t,u)\pi(u)\,\mathrm{d}u}{\int_a^b \bar{F}(t,u)\pi(u)\,\mathrm{d}u}$$

increases with t, which can be easily done by considering the corresponding derivative [20.22].

The derivative $\Pi'_t(z|t) > 0$ if

$$\frac{\int_a^z \bar{F}'_t(t,u)\pi(u)\,\mathrm{d}u}{\int_a^z \bar{F}(t,u)\pi(u)\,\mathrm{d}u} > \frac{\int_a^b \bar{F}'_t(t,u)\pi(u)\,\mathrm{d}u}{\int_a^b \bar{F}(t,u)\pi(u)\,\mathrm{d}u}.$$

As $\bar{F}'_t(t,z) = -\lambda(t,z)\bar{F}(t,z)$, it is sufficient to show that

$$B(t,z) \equiv \frac{\int_a^z \lambda(t,u)\bar{F}(t,u)\pi(u)\,\mathrm{d}u}{\int_a^z \bar{F}(t,u)\pi(u)\,\mathrm{d}u}$$

increases with z. Inequality $B'_z(t,z)>0$ is equivalent to

$$\lambda(t,z)\int_a^z \bar{F}(t,u)\pi(u)\,\mathrm{d}u > \int_0^z \lambda(t,u)\bar{F}(t,u)\pi(u)\,\mathrm{d}u.$$

Thus, due to the additional assumption in Theorem 20.1b), the integrand at the end of (20.10) does increase and therefore $\Delta\lambda(t)$ does as well, which immediately leads to the strong bending-down property (20.5). ■

The following example shows the strong bending-down property of the mixture failure rate in practice.

Example 20.1: Technical devices have parameters that are also usually quite heterogeneous and should exhibit a similar deceleration in the failure rate or may even bend down practically to 0. In order to support this statement and to show that the effect of heterogeneity is significantly underestimated by most reliability practitioners, the following experiment was conducted at the Max Planck Institute for Demographic Research [20.12]. We recorded the failure times for a population of 750 miniature lamps and constructed an empirical failure rate function (in relative units) for a time interval of 250 h, which is shown in Fig. 20.1.

The results were very convincing: the failure rate initially increased (a tentative fit showed the Weibull law) and then it decreased to a very low level. This pattern for the observed failure rate is exactly the same as that predicted in *Finkelstein* and *Esaulova* [20.9] for the Weibull baseline Cdf.

We will now show now that the natural ordering for our mixing model is based on the likelihood ratio. Somewhat similar reasoning can be found in *Block*

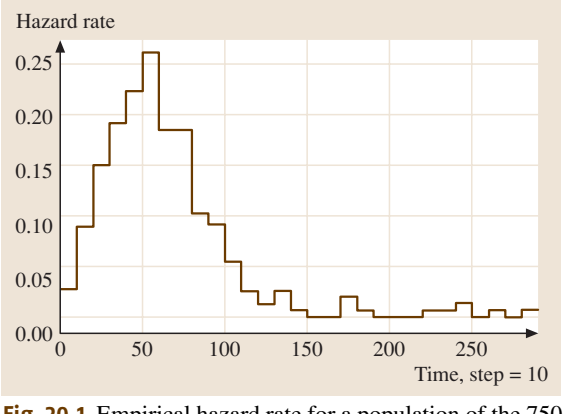

Fig. 20.1 Empirical hazard rate for a population of the 750 miniature lamps.

et al. [20.16] and *Shaked* and *Spizzichino* [20.23]. Let Z_1 and Z_2 be continuous non-negative random variables with the same support and with densities $\pi_1(z)$ and $\pi_2(z)$, respectively. Recall [20.14, 15] that Z_2 is smaller than Z_1 based on the likelihood ratio [20.24]:

$$Z_1 \geq_{\mathrm{LR}} Z_2 \,, \tag{20.12}$$

if $\pi_2(z)/\pi_1(z)$ is a decreasing function.

Definition 20.2

Let $Z(t)$, $t \in [0, \infty)$ be a family of random variables indexed by parameter t (time) with probability density functions $p(z, t)$. We say that $Z(t)$ decreases with t according to the likelihood ratio if

$$L(z, t_1, t_2) = \frac{p(z, t_2)}{p(z, t_1)}$$

decreases with z for all $t_2 > t_1$.

The following simple result states that our family of conditional mixing random variables $Z|t$, $t \in [0, \infty]$ decreases based on the likelihood ratio:

Theorem 20.2

Let the family of failure rates $\lambda(t, z)$ in the mixing model (20.1) be ordered as in the relation (20.9).

Then the family of random variables $Z|t \equiv Z|T > t$ decreases with $t \in [0, \infty)$ based on the likelihood ratio.

Proof: In accordance with (20.2):

$$L(z, t_1, t_2) = \frac{\pi(z|t_2)}{\pi(z|t_1)} = \frac{\bar{F}(t_2, z)\int_a^b \bar{F}(t_1, z)\pi(z)\,\mathrm{d}z}{\bar{F}(t_1, z)\int_a^b \bar{F}(t_2, z)\pi(z)\,\mathrm{d}z} \,. \tag{20.13}$$

Therefore, the monotonicity with z of $L(z, t_1, t_2)$ is defined by

$$\frac{\bar{F}(t_2, z)}{\bar{F}(t_1, z)} = \exp\left\{-\int_{t_1}^{t_2} \lambda(u, z)\,\mathrm{d}u\right\},$$

which, due to ordering given in (20.9), decreases with z for all $t_2 > t_1$. ■

20.1.4 Likelihood Ordering of Mixing Distributions

For the mixing model (20.1) and (20.2), consider two different mixing random variables Z_1 and Z_2 with probability density functions $\pi_1(z)$, $\pi_2(z)$ and cumulative distribution functions $\Pi_1(z)$, $\Pi_2(z)$, respectively. Assuming some type of stochastic ordering for Z_1 and Z_2, we intend to achieve simple ordering of the corresponding mixture failure rates. Using simple examples, it becomes apparent that the 'usual' stochastic ordering (stochastic dominance) is too weak to do this. It was shown in the previous section that likelihood ratio ordering is the natural one for the family of random variables $Z|t$ in our mixing model. Therefore, it seems reasonable to order Z_1 and Z_2 in this sense too.

Lemma 20.1

Let

$$\pi_2(z) = \frac{g(z)\pi_1(z)}{\int_a^b g(z)\pi_1(z)\,\mathrm{d}z} \,, \tag{20.14}$$

where $g(z)$ is a decreasing function.

Then Z_1 is stochastically larger than Z_2:

$$Z_1 \geq_{st} Z_2 \quad (\Pi_1(z) \leq \Pi_2(z),\ z \in [a, b]) \tag{20.15}$$

Proof:

$$\begin{aligned}
\Pi_2(z) &= \frac{\int_a^z g(u)\pi_1(u)\,\mathrm{d}u}{\int_a^b g(u)\pi_1(u)\,\mathrm{d}u} \\
&= \frac{\int_a^z g(u)\pi_1(u)\,\mathrm{d}u}{\int_a^z g(u)\pi_1(u)\,\mathrm{d}u + \int_z^b g(u)\pi_1(u)\,\mathrm{d}u} \\
&= \frac{g*(a, z)\int_a^z \pi_1(u)\,\mathrm{d}u}{g*(a, z)\int_a^z \pi_1(u)\,\mathrm{d}u + g*(z, b)\int_a^z \pi_1(u)\,\mathrm{d}u} \\
&\geq \int_a^z \pi_1(u)\,\mathrm{d}u = \Pi_1(z),
\end{aligned} \tag{20.16}$$

where $g*(a, z)$ and $g*(z, b)$ are the mean values of the function $g(z)$ in the corresponding integrals. As this function decreases, $g*(z, b) \leq g*(a, z)$. ■

Equation (20.14) with decreasing $g(z)$ means that $Z_1 \geq_{\mathrm{LR}} Z_2$, and it is well-known (see, e.g., [20.14]) that likelihood ratio ordering implies corresponding stochastic ordering. However, we need the previous reasoning to derive the following result.

Theorem 20.3

Let relation (20.14) (where $g(z)$ is a decreasing function) hold, which means that Z_1 is larger than Z_2 based on likelihood ratio ordering. Assume that the ordering from (20.9) holds.

Then for $\forall t \in [0, \infty)$:

$$\lambda_{\mathrm{m1}}(t) \equiv \frac{\int_a^b f(t,z)\pi_1(z)\,\mathrm{d}z}{\int_a^b \bar{F}(t,z)\pi_1(z)\,\mathrm{d}z} \geq \frac{\int_a^b f(t,z)\pi_2(z)\,\mathrm{d}z}{\int_a^b \bar{F}(t,z)\pi_2(z)\,\mathrm{d}z} \equiv \lambda_{\mathrm{m2}}(t). \tag{20.17}$$

Proof: Inequality (20.17) means that the mixture failure rate obtained for the stochastically larger (in the likelihood ratio ordering sense) mixing distribution is larger for $\forall t \in [0, \infty)$ than the one obtained for the stochastically smaller mixing distribution.

We shall first prove that

$$\Pi_1(z|t) = \frac{\int_a^z \bar{F}(t,u)\pi_1(u)\,\mathrm{d}u}{\int_a^b \bar{F}(t,u)\pi_1(u)\,\mathrm{d}u} \leq \frac{\int_a^z \bar{F}(t,u)\pi_2(u)\,\mathrm{d}u}{\int_a^b \bar{F}(t,u)\pi_2(u)\,\mathrm{d}u} \equiv \Pi_2(z|t). \tag{20.18}$$

Indeed:

$$\frac{\int_a^z \bar{F}(t,u)\pi_2(u)\,\mathrm{d}u}{\int_a^b \bar{F}(t,u)\pi_2(u)\,\mathrm{d}u} = \frac{\int_a^z \bar{F}(t,u)\frac{g(u)\pi_1(u)}{\int_a^b g(u)\pi_1(u)\,\mathrm{d}u}\,\mathrm{d}u}{\int_a^b \bar{F}(t,u)\frac{g(u)\pi_1(u)}{\int_a^b g(u)\pi_1(u)\,\mathrm{d}u}\,\mathrm{d}u} = \frac{\int_a^z g(u)\bar{F}(t,u)\pi_1(u)\,\mathrm{d}u}{\int_a^b g(u)\bar{F}(t,u)\pi_1(u)\,\mathrm{d}u} \geq \frac{\int_a^z \bar{F}(t,u)\pi_1(u)\,\mathrm{d}u}{\int_a^b \bar{F}(t,u)\pi_1(u)\,\mathrm{d}u},$$

where the last inequality follows using exactly the same argument, as in inequality (20.16) of Lemma 20.1. Similar to (20.10), and taking into account relation (20.18):

$$\begin{aligned}\lambda_{\mathrm{m1}}(t) - \lambda_{\mathrm{m2}}(t) &= \int_a^b \lambda(t,z)[\pi_1(z|t) - \pi_2(z|t)]\,\mathrm{d}z \\ &= \lambda(t,z)[\Pi_1(z|t) - \Pi_2(z|t)]\big|_a^b \\ &\quad - \int_a^b \lambda'_z(t,z)[\Pi_1(z|t) - \Pi_2(z|t)]\,\mathrm{d}z \\ &= \int_a^b -\lambda'_z(t,z)[\Pi_1(z|t) \\ &\quad - \Pi_2(z|t)]\,\mathrm{d}z \geq 0, \quad t > 0.\end{aligned} \tag{20.19}$$

The starting point of Theorem 20.3 was (20.14) with the crucial assumption of a decreasing $g(z)$ function. It should be noted, however, that this assumption can be rather formally and directly justified by considering the difference $\Delta\lambda(t) = \lambda_{\mathrm{m1}}(t) - \lambda_{\mathrm{m2}}(t)$ and using definitions (20.1) and (20.2). The corresponding numerator (the denominator is positive) is transformed into a double integral in the following way

$$\begin{aligned}&\int_a^b \lambda(t,z)\bar{F}(t,z)\pi_1(z)\,\mathrm{d}z \int_a^b \bar{F}(t,z)\pi_2(z)\,\mathrm{d}z \\ &\quad - \int_a^b \lambda(t,z)\bar{F}(t,z)\pi_2(z)\,\mathrm{d}z \int_a^b \bar{F}(t,z)\pi_1(z)\,\mathrm{d}z \\ &= \int_a^b \int_a^b \bar{F}(t,u)\bar{F}(t,s)[\lambda(t,u)\pi_1(u)\pi_2(s) \\ &\quad - \lambda(t,s)\pi_1(u)\pi_2(s)]\,\mathrm{d}u\,\mathrm{d}s \\ &= \int_{\substack{a\\u>s}}^b \int_a^b \bar{F}(t,u)\bar{F}(t,s)\{\pi_1(u)\pi_2(s)[\lambda(t,u) - \lambda(t,s)] \\ &\quad + \pi_1(s)\pi_2(u)[\lambda(t,s) - \lambda(t,u)]\}\,\mathrm{d}u\,\mathrm{d}s \\ &= \int_{\substack{a\\u>s}}^b \int_a^b \bar{F}(t,u)\bar{F}(t,s)[\lambda(t,u) - \lambda(t,s)][\pi_1(u)\pi_2(s) \\ &\quad - \pi_1(s)\pi_2(u)]\,\mathrm{d}u\,\mathrm{d}s.\end{aligned} \tag{20.20}$$

Therefore, the final double integral is positive if ordering (20.9) holds and $\pi_2(z)/\pi_1(z)$ is decreasing.

20.1.5 Ordering Variances of Mixing Distributions

Let $\Pi_1(z)$ and $\Pi_2(z)$ be two mixing distributions with equal means. It follows from equation (20.7) that, for the multiplicative model considered in this section, $\lambda_{m1}(0) = \lambda_{m2}(0)$. Intuitive considerations and reasoning based on the principle: "the weakest populations die out first" suggest that, unlike (20.17), the mixture failure rates will be ordered as $\lambda_{m1}(t) < \lambda_{m2}(t)$ for all $t > 0$ if, e.g., the variance of Z_1 is larger than the variance of Z_2. We will show that this is true for a specific case and that for a general multiplicative model this ordering only holds for a sufficiently small time t. Therefore, it is necessary to formulate a stronger condition to apply when ordering the 'variabilities' of Z_1 and Z_2.

Example 20.2: For a meaningful specific example, consider the frailty model (20.6), where Z has a gamma distribution

$$\pi(z) = \frac{\beta^\alpha}{\Gamma(\alpha)} z^{\alpha-1} \exp(-\beta z);\ \alpha > 0, \beta > 0.$$

Substituting this density into relation (20.1) gives

$$\lambda_m(t) = \frac{\lambda(t) \int_0^\infty \exp[-z\Lambda(t)] z \pi(z)\,dz}{\int_0^\infty \exp[-z\Lambda(t)]\pi(z)\,dz},$$

where $\Lambda(t) = \int_0^t \lambda(u)\,du$ is a cumulative baseline failure rate. Computing integrals results in

$$\lambda_m(t) = \frac{\alpha\lambda(t)}{\beta + \Lambda(t)}. \tag{20.21}$$

Equations (20.21) can now be written in terms of $E[Z]$ and $Var(Z)$:

$$\lambda_m(t) = \lambda(t)\frac{E^2[Z]}{E[Z] + Var(Z)\Lambda(t)}, \tag{20.22}$$

which, for the specific case $E[Z] = 1$, gives the result from *Vaupel* et al. [20.3], widely used in demography:

$$\lambda_m(t) = \frac{\lambda(t)}{1 + Var(Z)\Lambda(t)}.$$

Using equation (20.22), we can compare mixture failure rates of two populations with different Z_1 and Z_2 on the condition that $E[Z_2] = E[Z_1]$:

$$Var(Z_1) \geq Var(Z_2) \Rightarrow \lambda_{m1}(t) \leq \lambda_{m2}(t). \tag{20.23}$$

Intuitively it might be expected that this result would be valid for arbitrary mixing distributions in the multiplicative model. However, the mixture failure rate dynamics here can be much more complicated than this, even for this specific case, and this topic needs further attention in future research. A somewhat similar situation was observed in *Finkelstein* and *Esaulova* [20.9]: although the conditional variance $Var(Z|t)$ decreased with t for the multiplicative gamma frailty model, a counter example was constructed for the case of the uniform mixing distribution for [0, 1].

The following theorem shows that ordering variances is a sufficient and necessary condition for ordering mixture failure rates, but only for the initial time interval.

Theorem 20.4

Let Z_1 and Z_2 ($E[Z_2] = E[Z_1]$) be two mixing distributions in the multiplicative model (20.6), (20.7).

In this case, ordering the variances

$$Var(Z_1) > Var(Z_2) \tag{20.24}$$

is a sufficient and necessary condition for the ordering of mixture failure rates in the neighborhood of $t = 0$:

$$\lambda_{m1}(t) < \lambda_{m2}(t);\ t \in (0, \varepsilon), \tag{20.25}$$

where $\varepsilon > 0$ is sufficiently small.

Proof:

Sufficient condition:

From the results in Sect. 20.1.3:

$$\Delta\lambda(t) = \lambda_{m1}(t) - \lambda_{m2}(t) = \lambda(t)(E[Z_1|t] - E[Z_2|t]), \tag{20.26}$$

$$E_t'[Z_i|t] = -\lambda(t)Var(Z_i|t) < 0,\ i = 1, 2, t \geq 0, \tag{20.27}$$

where

$$E[Z_i|0] \equiv E[Z_i],\ Var(Z_i|t) \equiv Var(Z_i). \tag{20.28}$$

As the means of the mixing variables are equal, relation (20.26) for $t = 0$ reads $\Delta\lambda(0) = 0$, and therefore the time interval in (20.25) is opened. Thus, if the ordering in (20.24) holds, the ordering in (20.25) then follows immediately after, considering the derivative of

$$\frac{\lambda_{m1}(t)}{\lambda_{m2}(t)} = \frac{E[Z_1|t]}{E[Z_2|t]}$$

at $t = 0$ and taking into account relations (20.27) and notation (20.28).

Necessary condition:

Similar to (20.20), the numerator of the difference $\Delta\lambda(t)$ is

$$\lambda(t)\int_a^b\int_a^b\{\exp[-\Lambda(t)(u+s)]\}(u-s)\pi_1(u)\pi_2(s)\,\mathrm{d}u\,\mathrm{d}s,$$

where, as previously, $\Lambda(t)=\int_0^t\lambda(u)\,\mathrm{d}u$. After changing variables to $x=(u+s)/2$, $y=(u-s)/2$, the double integral is transformed to the iterated integral and denoted by $G(t)$:

$$G(t)\equiv\int_a^b\exp[-2\Lambda(t)x]\times\int_{-x}^{x}y\pi_1(x+y)\pi_2(x-y)\,\mathrm{d}y\,\mathrm{d}x. \qquad (20.29)$$

Denote the internal integral in (20.29) by $g(x)$. Then:

$$G(t)=\int_a^b\{\exp[-2\Lambda(t)x]\}g(x)\,\mathrm{d}x.$$

On the other hand, reverting back to the initial variables of integration and taking into account that $\Lambda(0)=0$, we get

$$\begin{aligned}G(0)&=\int_a^b g(x)\,\mathrm{d}x=\int_a^b\int_a^b(u-s)\pi_1(u)\pi_2(s)\,\mathrm{d}u\,\mathrm{d}s\\&=\int_a^b u\pi_1(u)\,\mathrm{d}u-\int_a^b u\pi_2(u)\,\mathrm{d}u\\&=E[Z_1]-E[Z_2]=0.\end{aligned}$$

Assume, firstly, that $\lambda(0)\neq 0$. As $G(0)=0$, the function $G(t)$ is negative in the neighborhood of 0 if $G'(0)<0$:

$$G'(t)=-2\lambda(t)\int_a^b\{\exp[-2\Lambda(t)x]\}xg(x)\,\mathrm{d}x,$$

$$G'(0)<0\Rightarrow\int_a^b xg(x)\,\mathrm{d}x>0.$$

If $\Delta\lambda(t)<0$, $t\in(0,\varepsilon)$ [condition (20.25)], then $G(t)<0$, $t\in(0,\varepsilon)$, and taking into account that

$$\begin{aligned}\int_a^b xg(x)\,\mathrm{d}x&=\int_a^b\int_a^b\frac{u+s}{2}(u-s)\pi_1(s)\pi_2(s)\,\mathrm{d}u\,\mathrm{d}s\\&=\frac{1}{2}\int_a^b\int_a^b(u^2-s^2)\pi_1(u)\pi_2(s)\,\mathrm{d}u\,\mathrm{d}s\\&=\frac{1}{2}[Var(Z_1)-Var(Z_2)],\end{aligned}$$

we arrive at the ordering given in (20.24).

Similar considerations are valid for $\lambda(0)=0$. The function $G(t)$ is negative in this case in the neighborhood of 0 if $G''(0)<0$. As

$$G''(0)=-2\lambda'(0)\int_a^b xg(x)\,\mathrm{d}x$$

and $\lambda'(0)>0$ [since $\lambda(t)>0$, $t>0$ and $\lambda(0)=0$], the same reasoning used for the case $\lambda(0)\neq 0$, also holds here. ■

A trivial but important consequence of this theorem is as follows:

Corollary

Let mixture failure rate ordering (20.25) hold for $t\in(0,\infty)$. Then inequality (20.24) holds.

20.2 Modeling the Impact of the Environment

20.2.1 Bounds in the Proportional Hazards Model

Consider the specific multiplicative frailty model (20.6) and (20.7). Formally combine this model with the proportional hazards (PH) model in a following way:

$$\lambda(t,z,k)=zk\lambda(t)\equiv z_k\lambda(t). \qquad (20.30)$$

Therefore, the baseline $F(t)$ is indexed by the random variable $Z_k=kZ$ with the pdf $\pi_k(z)=\pi(z/k)$, whereas the corresponding conditional pdf $\pi_k(z|t)$ is given by the right hand side of (20.2), where $\pi(z)$ is substituted by $\pi_k(z)$. Equivalently, (20.30) can be interpreted as a frailty model with a mixing random variable Z and a baseline failure rate $k\lambda(t)$. These two simple and equivalent interpretations will help us in what follows. Without losing

any generality, assume that $a = 0$ and $b = \infty$. Thus, similar to (20.6)–(20.9), the mixture failure rate in this case is

$$\lambda_{mk}(t) = k\lambda(t) \int_0^\infty z\pi_k(z|t)\,dz \equiv \lambda(t)E[Z_k|t]. \quad (20.31)$$

As $Z_k = kZ$, its density function is

$$\pi_k(z) = \frac{1}{k}\pi\left(\frac{z}{k}\right).$$

Theorem 20.5

Let the mixture failure rates for the multiplicative models (20.6) and (20.30) be given by relations (20.7) and (20.31), respectively, where $k > 1$.

Assume that the following quotient increases with z:

$$\frac{\pi_k(z)}{\pi(z)} = \frac{\pi\left(\frac{z}{k}\right)}{k\pi(z)} \uparrow \quad (20.32)$$

Then:

$$\lambda_{mk}(t) > \lambda_m(t);\ \forall t \in [0, \infty). \quad (20.33)$$

Proof: Although inequality (20.33) seems rather trivial at first sight, it is only valid for some specific cases of mixing (e.g., the multiplicative model). It is clear that (20.33) is always true for sufficiently small t, whereas with larger t the ordering can be different for general mixing models. Denote:

$$\Delta\lambda_m(t) = \lambda_{mk}(t) - \lambda_m(t).$$

Using definitions (20.1)–(20.2), it can be seen that, similar to the case for relation (20.20), the sign of this difference is defined by the sign of

$$\begin{aligned}
&\int_0^\infty z\bar{F}(t,z)\pi_k(z)\,dz \int_0^\infty \bar{F}(t,z)\pi(z)\,dz \\
&- \int_0^\infty z\bar{F}(t,z)\pi_k(z)\,dz \int_0^\infty \bar{F}(t,z)\pi(z)\,dz \\
&= \int_0^\infty \int_0^\infty \bar{F}(t,u)\bar{F}(t,s)[u\pi_k(u)\pi(s) \\
&\quad - s\pi_k(u)\pi(s)]\,du\,ds \\
&= \int_{\substack{0\\u>s}}^\infty \int_0^\infty \bar{F}(t,u)\bar{F}(t,s)[\pi_k(u)\pi(s)(u-s) \\
&\quad + \pi_k(s)\pi(u)(s-u)]\,du\,ds \\
&= \int_{\substack{0\\u>s}}^\infty \int_0^\infty \bar{F}(t,u)\bar{F}(t,s)(u-s)[\pi_k(u)\pi(s) \\
&\quad - \pi_k(s)\pi(u)]\,du\,ds. \quad (20.34)
\end{aligned}$$

Therefore, the sufficient condition for inequality (20.33) is condition (20.32), which is, in fact, rather crude. It is easy to verify that this condition is satisfied, for example, for the gamma and the Weibull densities, which are often used for mixing. ■

Example 20.3: Consider the same setting as in Example 20.1. Condition (20.32) is satisfied for the gamma distribution. The mixture failure rate $\lambda_m(t)$ in this case is given by relation (20.22). A similar equation obviously exists for $\lambda_{mk}(t)$, and the corresponding comparison can be performed explicitly:

$$\begin{aligned}
\lambda_{mk}(t) &= \lambda(t)\frac{E^2[Z_k]}{E[Z_k] + Var(Z_k)\Lambda(t)} \\
&= \lambda(t)\frac{k^2E^2[Z]}{kE[Z] + k^2Var(Z)\Lambda(t)} > \lambda_m(t).
\end{aligned} \quad (20.35)$$

Now we shall obtain an upper bound for $\lambda_{mk}(t)$.

Theorem 20.6

Let the mixture failure rates for the multiplicative models (20.6) and (20.30) be given by relations (20.7) and (20.31), respectively, where $k > 1$.

Then:

$$\lambda_{mk}(t) < k\lambda_m(t);\ \forall t \in (0, \infty). \quad (20.36)$$

Proof: Consider the difference $\lambda_{mk}(t) - k\lambda_m(t)$ similarly to (20.34), but in a slightly different way: $\lambda_{mk}(t)$ will be equivalently defined by the baseline failure rate $k\lambda(t)$ and the mixing variable Z (in (20.34) it was defined by the baseline $\lambda(t)$ and the mixing variable kZ). This means that:

$$\lambda_{mk}(t) - k\lambda_m(t) = k\lambda(t)(\hat{E}[Z|t] - E[Z|t]), \quad (20.37)$$

where the conditioning in $\hat{E}[Z|t]$ is different from the one in $E[Z|t]$ in the sense described. Denote:

$$\bar{F}_k(t,z) = \exp\left[-zk\Lambda(t)\right].$$

'Symmetrically' to (20.34), $\text{sign}[\lambda_{mk}(t) - k\lambda_m(t)]$ is defined by

$$\text{sign} \int_{\substack{0 \\ u>s}}^{\infty} \int_{0}^{\infty} \pi(u)\pi(s)(u-s)[\bar{F}_k(t,u)\bar{F}(t,s) - \bar{F}(t,u)\bar{F}_k(t,s)]\,du\,ds,$$

which is negative for all $t > 0$ since

$$\frac{\bar{F}_k(t,z)}{\bar{F}(t,z)} = \exp[-(k-1)z\Lambda(t)]$$

decreases with z. ■

It is worth noting that we do not need an additional condition for this bound as in the case of Theorem 20.5. Also, it is clear that $\lambda_{mk}(0) = k\lambda_m(0)$. As previously mentioned, model (20.30) defines a combination of a PH model and a frailty model. When $Z = 1$, it is an 'ordinary' PH model. In the presence of a random Z, as follows from (20.36), the observed failure rate $\lambda_{mk}(t)$ cannot be obtained as $k\lambda_m(t)$ due to the nature of the mixing.

Therefore, the PH model in each realization does not result in the PH model for the corresponding mixture failure rate.

Example 20.3 (continuation): We illustrate inequality (20.36):

$$\lambda_{mk}(t) = \lambda(t)\frac{k^2E^2[Z]}{kE[Z]+k^2Var(Z)\Lambda(t)} < \lambda(t)\frac{kE^2[Z]}{E[Z]+Var(Z)\Lambda(t)} = k\lambda_m(t).$$

20.2.2 Change Point in the Environment

Assume that there are two possible environments (stresses), $\varepsilon(t)$ and $\varepsilon_s(t)$: the baseline and a more severe one, respectively. The baseline environment for our heterogeneous population corresponds to the observed failure rate $\lambda_m(t)$ and the more severe one to $\lambda_{mk}(t)$, $k > 1$. As we did previously, assume also that the PH model for each subpopulation (for each fixed z) holds. Consider a piece-wise constant step stress with a single change point at t_1:

$$\varepsilon(t_1) = \begin{cases} \varepsilon, & 0 \le t < t_1, \\ \varepsilon_k & t \ge t_1, \end{cases} \tag{20.38}$$

where the stresses ε and ε_k correspond to the failure rates $z\lambda(t)$ and $zk\lambda(t)$, respectively ($k > 1, z \ge 0$). In accordance with the 'memoryless property' of the PH model, the stress (20.38) results in the following failure rate for each subpopulation:

$$\lambda(t, t_1, z, k) = \begin{cases} z\lambda(t), & 0 \le t < t_1 \\ kz\lambda(t) & t \ge t_1 \end{cases} \tag{20.39}$$

Denote the resulting mixture failure rate in this case as:

$$\lambda_m(t, t_1) = \begin{cases} \lambda_m(t), & 0 \le t < t_1, \\ \tilde{\lambda}_{mk}(t) & t \ge t_1, \end{cases} \tag{20.40}$$

where, similar to the previous section,

$$\tilde{\lambda}_{mk}(t_1) = k\lambda_m(t_1). \tag{20.41}$$

It is worth noting that relation (20.41) means that this model with a step stress is proportional for the mixture failure rates only at the switching point t_1. We want to prove the following inequality:

$$\lambda_{mk}(t) < \tilde{\lambda}_{mk}(t);\ \forall t \in [t_1, \infty). \tag{20.42}$$

In accordance with (20.40), consider two **initial** (for the interval $[0, \infty)$) mixing distributions: $Z_1 = Z|T_1 > t_1$, where T_1 is defined by the baseline failure rate $k\lambda(t)$ and $\tilde{Z}_1 = Z|\tilde{T}_1 > t_1$, where $\tilde{T}_1$ is defined by the baseline failure rate $\lambda(t)$. As follows from definition (20.2), the corresponding ratio

$$\frac{\tilde{\pi}(z,t_1)}{\pi(z,t_1)} = \exp[(k-1)z\Lambda(t_1)]$$

increases with z. Then inequality (20.42) follows immediately after taking the proof of Theorem 20.1 into account with obvious alterations caused by the change in the left end point of the interval from 0 to t_1.

Inequality (20.42) was graphically illustrated in *Vaupel* and *Yashin* ([20.25] Fig.10) for a specific case of a discrete mixture of two subpopulations and the Gompertz baseline failure rate. The demographic meaning of this was the following: suppose we decrease the mortality rates of the subpopulations during early life ($[0, t_1)$). Then the observed mortality rate for $[t_1, \infty)$ is *larger* than the observed mortality rate for the initial mixture without changes. In other words, early success results in more failure later on [20.25].

20.2.3 Shocks in Heterogeneous Populations

Now consider the general mixing model (20.1)–(20.2) and assume that an instantaneous shock occurs at time $t = t_1$. This shock affects the whole population: with corresponding complementary probabilities it either kills an individual or 'leaves him unchanged'. Without losing any generality, let $t_1 = 0$; otherwise a new initial mixing variable $Z|t_1$ needs to be defined and the corresponding procedure can be easily adjusted to this case. It is natural to suppose that the frailest individuals or populations (those with the largest failure rates) are more susceptible to being killed.

This setting can be defined probabilistically in the following way. Let $\pi_1(z)$ denote the frailty distribution of a random variable Z_1 after the shock and let $\lambda_{ms}(t)$ be the corresponding observed (mixture) failure rate after the shock. Assume that

$$\pi_1(z) = \frac{g(z)\pi(z)}{\int_a^b g(z)\pi(z)\,dz}, \tag{20.43}$$

where $g(z)$ is a decreasing function and therefore $\pi_1(z)/\pi(z)$ also decreases. This means that the shock performs a kind of burn-in operation [20.16] and the random variables Z and Z_1 are ordered based on the likelihood ratio [20.14, 15]:

$$Z \geq_{LR} Z_1 \tag{20.44}$$

We are now able to formulate the following result.

Theorem 20.7

Let relation (20.43), which defines the mixing density after a shock at $t = 0$ (and where $g(z)$ is a decreasing function), hold.

Also assume that the ordering given by (20.9) holds Then:

$$\lambda_{ms}(t) < \lambda_m(t);\ \forall t \in [0, \infty). \tag{20.45}$$

Proof: Inequality (20.9) is a natural ordering of the family of failure rates $\lambda(t, z)$, $z \in [0, \infty)$ and it trivially holds for the specific model (20.6). Performing all of the steps we used when obtaining relation (20.34), we finally obtain:

$$\begin{aligned}&\operatorname{sign}[\lambda_{ms}(t) - \lambda_m(t)]\\ &= sign \int_{\substack{a\\ u>s}}^{b} \int_a^b \bar{F}(t,u)\bar{F}(t,s)[\lambda(t,u)\\ &- \lambda(t,s)][\pi_1(u)\pi(s) - \pi_1(s)\pi(u)]\,du\,ds,\end{aligned}$$

which is negative due to definition (20.43) and the assumptions of this theorem. ■

At $t = 0$, for instance:

$$\lambda_m(0) - \lambda_{ms}(0) = \int_0^\infty \lambda(0,z)[\pi(z) - \pi_1(z)]\,dz.$$

In accordance with inequality (20.45), the curve $\lambda_{ms}(t)$ lies beneath the curve $\lambda_m(t)$ for $t \geq 0$. This fact seems intuitively evident, but, in fact, it is only valid due to the rather stringent conditions of this theorem. It can be shown, for instance, that replacing condition (20.44) with a weaker one of stochastic dominance, $Z_{st} \geq Z_1$, will not guarantee the ordering given in (20.45) for all t.

This result can be generalized to a sequence of shocks of the type described that occur at times $\{t_i\}$, $i = 1, 2, \ldots$

20.3 Asymptotic Behaviors of Mixture Failure Rates

20.3.1 Survival Model

The asymptotic behaviors of mixture failure rates have been studied by *Block* et al. [20.16], *Gurland* and *Sethuraman* [20.20], *Lynn* and *Singpurwalla* [20.19] and *Block* et al. [20.17], to name but a few. In *Finkelstein* and *Esaulova* [20.9] we considered the properties of $\lambda_m(t)$ as $t \to \infty$ for the multiplicative model (20.6). As $\lambda_m(t) = \lambda(t)E[Z|t]$, this product was analyzed for increasing $\lambda(t)$ and conditions implying convergence to 0 were derived, taking into account that the conditional expectation $E[Z|t]$, defined in (20.7), decreases with t. The approach taken in this section is different: we study a new lifetime model and derive explicit asymptotic formulae for mixture failure rates that generalize various specific results obtained for proportional hazards and additive hazards models. This approach also allows us to deal with the accelerated life model (ALM), which has not been studied in the literature.

We now define a class of distributions $F(t, z)$ and study the asymptotic behavior of the corresponding mixture failure rate $\lambda_m(t)$. To begin with it is more convenient to define this in terms of the cumulative failure rate $\Lambda(t, z)$, rather than in terms of $\lambda(t, z)$:

$$\Lambda(t, z) = A[z\phi(t)] + \psi(t). \tag{20.46}$$

General Assumptions for the Model (20.46):
The natural properties of the cumulative failure rate of the absolutely continuous distribution $F(t, z)$ (for $\forall z \in [0, \infty)$) imply that the functions $A(s)$, $\phi(t)$ and $\psi(t)$ are differentiable, the right hand side of (20.46) does not decrease with t and it tends to infinity as $t \to \infty$ and $A[z\phi(0)] + \psi(0) = 0$. Therefore, these properties will be assumed throughout this section, although some of them will not be needed for formal proofs.

An important additional simplifying assumption is that

$$A(s), s \in [0, \infty);\ \phi(t), t \in [0, \infty) \tag{20.47}$$

are increasing functions of their arguments and $A(0) = 0$, although some generalizations (e.g., only for ultimately increasing functions) are easily performed. Therefore, we will view $1 - \exp[-A(z\phi(t))]$, $z \neq 0$ in this chapter as a lifetime Cdf.

It should be noted that model (20.46) can be also easily generalized to the form $\Lambda(t, z) = A[g(z)\phi(t)] + \psi(t) + \eta(z)$ for some properly defined functions $g(z)$ and $\eta(z)$. However, we cannot generalize any further (at least, at this stage), and the multiplicative form of the arguments in $A[g(z)\phi(t)]$ is important to our method of deriving asymptotic relations. It is also clear that the additive term $\psi(t)$, although important in applications, provides only a slight generalization for further analysis of $\lambda_m(t)$, as (20.46) can be interpreted in terms of two components in series (or, equivalently, as two competing risks).

The failure rate, which corresponds to the cumulative failure rate $\Lambda(t, z)$, is

$$\lambda(t, z) = z\phi'(t)A'[z\phi(t)] + \psi'(t), \tag{20.48}$$

where, by $A'[z\phi(t)]$, we in fact mean $\mathrm{d}A[z\phi(t)]/\mathrm{d}[z\phi(t)]$.

Now we can explain why we start with the cumulative failure rate and not with the failure rate itself, which is common in lifetime modeling. The reason is that one can easily suggest intuitive interpretations of (20.46), whereas it is certainly not as simple to interpret the failure rate structure in the form (20.48) without stating that it just follows from the structure of the cumulative failure rate.

Relation (20.46) defines a rather broad class of survival models which can be used, for example, to model the impact of the environment on survival characteristics. The proportional hazards, additive hazards and accelerated life models, widely used in reliability, survival analysis and risk analysis, are the obvious specific cases of our relations (20.46) or (20.48):

PH (multiplicative) model:
Let

$$A(u) \equiv u,\ \phi(t) = \Lambda(t),\ \psi(t) \equiv 0.$$

Then

$$\lambda(t, z) = z\lambda(t), \quad \Lambda(t, z) = z\Lambda(t). \tag{20.49}$$

ALM:
Let

$$A(u) \equiv \Lambda(u),\ \phi(t) = t,\ \psi(t) \equiv 0.$$

Then

$$\Lambda(t, z) = \int_0^{tz} \lambda(u)\,\mathrm{d}u, \quad \lambda(t, z) = z\lambda(tz). \tag{20.50}$$

AH *model*:
Let

$$A(u) \equiv u,\ \phi(t) = t,\ \psi(t) \text{ is increasing}, \psi(0) = 0.$$

Then

$$\lambda(t, z) = z + \psi'(t), \quad \Lambda(t, z) = zt + \psi(t). \tag{20.51}$$

The functions $\lambda(t)$ and $\psi'(t)$ act as baseline failure rates in equations (20.49), (20.50) and (20.51), respectively. Note that, in all of these models, the functions $\phi(t)$ and $A(s)$ increase monotonically.

The asymptotic behaviors of the mixture failure rates for the PH and AH models have been studied for some specific mixing distributions in, for example, *Gurland* and *Sethuraman* [20.20] and *Finkelstein* and *Esaulova* [20.9]. On the other hand, as far as we know, the mixture failure rate for the ALM has only been considered at a descriptive level in *Anderson* and *Louis* [20.26].

20.3.2 Main Result

The next theorem derives an asymptotic formula for the mixture failure rate $\lambda_m(t)$ under rather mild assumptions. We use an approach related to the ideology of generalized convolutions, for example *Laplace* and *Fourier* transforms and (especially) Mellin convolutions [20.27].

Theorem 20.8

Let the cumulative failure rate $\Lambda(t, z)$ be given by the model (20.46) and the mixing pdf $\pi(z)$ be defined as

$$\pi(z) = z^{\alpha}\pi_1(z), \tag{20.52}$$

where $\alpha > -1$ and $\pi_1(z)$, $\pi_1(0) \neq 0$ is a function that is bounded in $[0, \infty)$ and continuous at $z = 0$.

Assume also that $\phi(t)$ increases to infinity:

$$\phi(t) \to \infty \quad \text{as} \quad t \to \infty \tag{20.53}$$

and that

$$\exp[-A(s)]s^{\alpha+1} \to 0 \quad \text{as} \quad t \to \infty,$$
$$\int_0^{\infty} \exp[-A(s)]s^{\alpha}\,\mathrm{d}s < \infty. \tag{20.54}$$

Then

$$\lambda_{\mathrm{m}}(t) - \psi'(t) \sim (\alpha+1)\frac{\phi'(t)}{\phi(t)}. \tag{20.55}$$

By relation (20.55) we (as usual) mean asymptotic equivalence, and we write $a(t) \sim b(t)$ as $t \to \infty$, if $\lim_{t\to\infty}[a(t)/b(t)] = 1$.

Proof: Firstly, we need a simple lemma for the Dirac sequence of functions. ■

Lemma 20.2

Let $g(z)$, $h(z)$ be non-negative functions in $[0, \infty)$ that satisfy the following conditions:

$$\int_0^{\infty} g(z)\,\mathrm{d}z < \infty, \tag{20.56}$$

and $h(z)$ is bounded and continuous at $z = 0$.

Then, as $t \to \infty$:

$$t\int_0^{\infty} g(tz)h(z)\,\mathrm{d}z \to h(0)\int_0^{\infty} g(z)\,\mathrm{d}z. \tag{20.57}$$

Proof: Substituting $u = tz$,

$$t\int_0^{\infty} g(tz)h(z)\,\mathrm{d}z = \int_0^{\infty} g(u)h(u/t)\,\mathrm{d}u.$$

The function $h(u)$ is bounded and $h(u/t) \to 0$ as $t \to \infty$, thus convergence (20.57) holds by the dominated convergence theorem. ■

We are now able to prove Theorem 20.8. The proof is straightforward, as we use definition (20.1) and Lemma 20.2.

The survival function for the model (20.46) is

$$\bar{F}(t, z) = \exp\{-[A(z\phi(t)] - \psi(t)\}.$$

Taking into account that $\phi(t) \to \infty$ as $t \to \infty$, and applying Lemma 20.2 to the function $g(u) = \exp[-A(u)]u^{\alpha}$:

$$\int_0^{\infty} \bar{F}(t, z)\pi(z)\,\mathrm{d}z = \int_0^{\infty} \exp\{-[A(z\phi(t))] - \psi(t)\}z^{\alpha}\pi_1(z)\,\mathrm{d}z$$
$$\sim \frac{\exp[-\psi(t)]\pi_1(0)}{\phi(t)^{\alpha+1}}\int_0^{\infty} \exp[-A(s)]s^{\alpha}\,\mathrm{d}s, \tag{20.58}$$

where the integral is finite due to the condition given in (20.54).

The corresponding probability density function is:

$$\begin{aligned} f(t, z) =& \{A'[z\phi(t)]z\phi'(t) \\ &+ \psi'(t)\}\exp\{-A[z\phi(t)] - \psi(t)\} \\ =& A'[z\phi(t)]z\phi'(t)\exp\{-A[z\phi(t)] \\ &- \psi(t)\} + \psi'(t)\bar{F}(t, z). \end{aligned}$$

Similarly, applying Lemma 20.2 gives:

$$\int_0^{\infty} f(t, z)\pi(z)\,\mathrm{d}z - \psi'(t)\int_0^{\infty} \bar{F}(t, z)\pi(z)\,\mathrm{d}z$$
$$= \phi'(t)\exp[-\psi(t)]\int_0^{\infty} A'[z\phi(t)]$$
$$\exp\{-A[z\phi(t)]\}z^{\alpha+1}\pi_1(z)\,\mathrm{d}z$$
$$\sim \frac{\phi'(t)\exp[-\psi(t)]\pi_1(0)}{\phi(t)^{\alpha+2}}\int_0^{\infty} A'(s)$$
$$\exp[-A(s)]s^{\alpha+1}\,\mathrm{d}s \tag{20.59}$$

Integrating by parts and using condition (20.54):

$$\int_0^{\infty} A'(s)\exp[-A(s)]s^{\alpha+1}\,\mathrm{d}s$$
$$= (\alpha+1)\int_0^{\infty} \exp[-A(s)]s^{\alpha}\,\mathrm{d}s. \tag{20.60}$$

Combining relations (20.58)–(20.60), finally:

$$\frac{\int_0^\infty f(t,z)\pi(z)\,dz}{\int_0^\infty \bar{F}(t,z)\pi(z)\,dz} - \psi'(t) \sim (\alpha+1)\frac{\phi'(t)}{\phi(t)}.$$

It is easy to see that assumption (20.52) holds for the main lifetime distributions, such as Weibull, gamma, log-normal etc. Assumption (20.53) states a natural condition for the function $\phi(t)$, which can often be viewed as a scale transformation. Conditions (20.54) mean that the Cdf $1-\exp[-A(s)]$ should not be 'too heavy-tailed' (as e.g. the Pareto distribution $1-s^{-\beta}$, for $s \geq 1, \beta-\alpha > 1$) and are equivalent to the condition that a moment of order $\alpha+1$ exists for this Cdf. The examples shown in the next subsection will clearly illustrate that these conditions are not stringent at all and can be easily met in most practical situations.

A crucial feature of this result is that the asymptotic behavior of the mixture failure rate depends only [omitting an obvious additive term $\psi(t)$] on the behavior of the mixing distribution near to zero and on the derivative of the logarithm of the scale function $\phi(t)$: $[\log \phi(t)]' = \phi'(t)/\phi(t)$. When $\pi(0) \neq 0$ and $\pi(z)$ is bounded in $[0, \infty)$, the result does not depend on the mixing distribution at all, as $\alpha = 0$!

20.3.3 Specific Models

Multiplicative (PH) Model

In the conventional notation, the baseline failure rate is usually denoted by $\lambda_0(t)$ [or $\lambda_b(t)$]. Therefore, model (20.6) reads:

$$\lambda(t,z) = z\lambda_0(t), \quad \Lambda_0(t) = \int_0^t \lambda_0(u)\,du \tag{20.61}$$

and the mixture failure rate is given by

$$\lambda_m(t) = \frac{\int_0^\infty z\lambda_0(t)\exp[-z\Lambda_0(t)]\pi(z)\,dz}{\int_0^\infty \exp[-z\Lambda_0(t)]\pi(z)\,dz}. \tag{20.62}$$

As $A(u) \equiv u, \phi(t) = \Lambda_0(t), \psi(t) \equiv 0$ in this specific case, Theorem 20.8 simplifies to:

Corollary 20.1

Assume that the mixing pdf $\pi(z), z \in [0, \infty)$ can be written as

$$\pi(z) = z^\alpha \pi_1(z), \tag{20.63}$$

where $\alpha \geq -1$ and $\pi_1(z)$ is bounded in $[0, \infty)$, continuous at $z = 0$ and $\pi_1(0) \neq 0$.

Then the mixture failure rate for the multiplicative model (20.61) has the following asymptotic behavior:

$$\lambda_m(t) \sim \frac{(\alpha+1)\lambda_0(t)}{\int_0^t \lambda_0(u)\,du}. \tag{20.64}$$

The mixture failure rate given by (20.62) can be obtained explicitly when the Laplace transform of the mixing pdf $\tilde{\pi}(t)$ is easily computed. As the cumulative failure rate increases monotonically with t, the mixture survival function is written in terms of the Laplace transform as:

$$\int_0^\infty \exp[-z\Lambda_0(t)]\pi(z)dz = \tilde{\pi}[\Lambda_0(t)].$$

Therefore, (20.62) becomes:

$$\lambda_m(t) = -\frac{(\tilde{\pi}[\Lambda_0(t)])'}{\tilde{\pi}[\Lambda_0(t)]} = -(\log \tilde{\pi}[\Lambda_0(t)])'$$

and the corresponding inverse problem can also be solved; in other words, given the mixture failure rate and the mixing distribution, obtain the baseline failure rate [20.28].

Example 20.4: As for examples 20.1 and 20.3, consider a frailty model (20.61) where Z has a gamma distribution, which, for notational convenience, is written in a slightly different form:

$$\pi(z) = \left(\frac{z}{b}\right)^{c-1} \exp\left\{-\frac{z}{b}\right\} \frac{1}{b\Gamma(c)}, \tag{20.65}$$

where $b, c > 0$.

The expected value Z is bc and the variance is b^2c. The Laplace transform of $\pi(z)$ is $\tilde{\pi}(t) = c(tb+1)^{-c}$ and therefore the mixture failure rate is given by the following expression, which is the same as (20.22):

$$\lambda_m(t) = \frac{bc\lambda_0(t)}{1 + b\int_0^t \lambda_0(u)\,du}. \tag{20.66}$$

Obviously, the asymptotic behavior of $\lambda_m(t)$ can be analyzed explicitly. Consider two specific cases.

If the baseline distribution is Weibull with $\lambda_0(t) = \lambda t^\beta$, $\beta \geq 0$, then the mixture failure rate (20.66) is

$$\lambda_m(t) = \frac{(\beta+1)\lambda bct^\beta}{(\beta+1)+\lambda bt^{\beta+1}}, \tag{20.67}$$

which converges to 0 as $t \to \infty$ because it is $\sim(\beta+1)ct^{-1}$, exactly as prescribed by formula (20.64) of Corollary 20.1 ($c = \alpha+1$).

If the baseline distribution is Gompertz with $\lambda_0(t) = \mu\exp(\beta t)$, then a simple transformations gives

$$\lambda_m(t) = \frac{\beta c\exp(\beta t)}{\exp(\beta t)+\left(\frac{\beta}{\mu b}-1\right)}. \tag{20.68}$$

If $b = \beta/\mu$, then $\lambda_m(t) \equiv \beta c$; if $b > \beta/\mu$, then $\lambda_m(t)$ increases to β/μ; if $b < \beta/\mu$, it decreases to β/μ.

It is reasonable to compare the asymptotic behaviors of (20.67) and (20.68) for the same mixing distribution (20.65). For the Weibull Cdf, the mixture failure rate converges to 0. This means that, within the framework of the multiplicative model, where the family of failure rates is ordered in z, we can still speak of convergence to the failure rate of the strongest population, defining the $z = 0$ case as a 'generalized' (or formal) strongest failure rate: $\lambda(t, 0) = 0$. However, the failure rate for a Gompertz Cdf does not converge to 0 – it converges to a constant, thus violating the principle of converging to the failure rate of the strongest population, even when formulated in a 'generalized' form! The reason for this is the sharp increase in the function $\phi(t)$, which is proportional to $\exp(\beta t)$ in the latter case.

Accelerated Life Model

In the conventional notation, this model is written as:

$$\lambda(t, z) = z\lambda_0(tz),$$
$$\Lambda_0(tz) = \int_0^{tz} \lambda_0(u)\,du. \tag{20.69}$$

Although the ALM also has a very simple definition, the presence of the mixing parameter z in the arguments make analysis of the mixture failure rate more complex than in the multiplicative case. Therefore, as mentioned previously, this model is practically unstudied. The mixture failure rate in this specific case is

$$\lambda_m(t) = \frac{\int_0^\infty z\lambda_0(tz)\exp[-\Lambda_0(tz)]\pi(z)\,dz}{\int_0^\infty \exp[-\Lambda_0(tz)]\pi(z)\,dz}. \tag{20.70}$$

The asymptotic behavior of $\lambda_m(t)$ can be described as a specific case of Theorem 20.8 with $A(s) = \Lambda_0(s)$, $\phi(t) = t$ and $\psi(t) \equiv 0$:

Corollary 20.2

Assume that the mixing pdf $\pi(z)$, $z \in [0, \infty)$ can be defined as $\pi(z) = z^\alpha\pi_1(z)$, where $\alpha > -1$, $\pi_1(z)$ is continuous at $z = 0$ and bounded in $[0, \infty)$, $\pi_1(0) \neq 0$.

Let the baseline distribution with cumulative rate $\Lambda_0(t)$ have a moment of order $\alpha+1$. Then

$$\lambda_m(t) \sim \frac{\alpha+1}{t} \tag{20.71}$$

as $t \to \infty$.

The conditions of Corollary 20.2 are not that strong and are relatively natural. Most widely used lifetime distributions have all of the moments. The Pareto distribution will be discussed in the next example.

As already stated, the conditions on the mixing distribution hold for the gamma and the Weibull distributions, which are commonly used as mixing distributions.

Relation (20.71) is really surprising, as it does not depend on the baseline distribution, which seems strange, at least at first sight. It is also dramatically different to the multiplicative case (20.64). It follows from Example 20.4 that both asymptotic results coincide in the case of the Weibull baseline distribution; this is obvious, as the ALM can only be reparameterized to end up with a PH model and vice versa for the Weibull distribution.

The following example shows other possible asymptotic behaviors for $\lambda_m(t)$ when one of the conditions of Corollary 20.2 does not hold.

Example 20.5: Consider the gamma mixing distribution $\pi(z) = z^\alpha\exp(-x)/\Gamma(\alpha+1)$. Let the baseline distribution be the Pareto distribution with density $f_0(t) = \beta/t^{\beta+1}$ $t \geq 1$, $\beta > 0$.

For $\beta > \alpha+1$ the conditions of Corollary 20.2 hold and relation (20.71) occurs. Let $\beta \leq \alpha+1$, which means that the baseline distribution doesn't have the $(\alpha+1)$th moment. Therefore, one of the conditions of Corol-

lary 20.2 does not hold. In this case:

$$\lambda_m(t) \sim \frac{\beta}{t}$$

as $t \to \infty$, which can be shown by direct integration:

$$\begin{aligned}
&\int_0^\infty z f_0(tz)\pi(z)\,dz \\
&= \int_{1/t}^\infty \frac{\beta z}{\Gamma(\alpha+1)t^{\beta+1}z^{\beta+1}} \exp(-z)z^\alpha\,dz \\
&= \frac{\beta}{\Gamma(\alpha+1)t^{\beta+1}} \int_{1/t}^\infty z^{\alpha-\beta}\exp(-z)\,dz \\
&\sim \frac{\Gamma(\alpha-\beta+1)\beta}{\Gamma(\alpha+1)t^{\beta+1}}
\end{aligned}$$

and

$$\int_0^\infty \bar{F}_0(tz)\pi(z)\,dz = \int_0^{1/t} \frac{\exp(-z)z^\alpha}{\Gamma(\alpha+1)}\,dz + \int_{1/t}^\infty \frac{\exp(-z)z^\alpha}{t^\beta z^\beta \Gamma(\alpha+1)}\,dz.$$

As $t \to \infty$, the first integral on the right-hand side is equivalent to

$$\int_0^{1/t} \frac{z^\alpha}{\Gamma(\alpha+1)}\,dz = \frac{1}{t^{\alpha+1}\Gamma(\alpha+2)}$$

and the second integral is equivalent to $\Gamma(\alpha-\beta+1)/\Gamma(\alpha+1)t^\beta$, which decreases more slowly for $\beta \le \alpha$; therefore, the sum of the two integrals is $\Gamma(\alpha-\beta+1)/\Gamma(\alpha+1)t^\beta$. Eventually:

$$\lambda_m(t) \sim \frac{\Gamma(\alpha-\beta+1)\beta}{\Gamma(\alpha+1)t^{\beta+1}} \cdot \frac{\Gamma(\alpha+1)t^\beta}{\Gamma(\alpha-\beta+1)} = \frac{\beta}{t}.$$

If $\beta = \alpha+1$, then

$$\begin{aligned}
&\int_0^\infty z f_0(tz)\pi(z)\,dz \\
&= \frac{\alpha+1}{\Gamma(\alpha+1)t^{\alpha+2}} \int_{1/t}^\infty z^{-1}\exp(-z)\,dz
\end{aligned}$$

and since

$$\int_0^{1/t} z^\alpha\,dz = o(t^{-\alpha-1}) \int_{1/t}^\infty z^{-1}\exp(-z)\,dz,$$

we obtain

$$\begin{aligned}
&\int_0^\infty \bar{F}_0(tz)\pi(z)\,dz \\
&= \frac{1}{\Gamma(\alpha+1)t^{\alpha+1}} \int_{1/t}^\infty z^{-1}\exp(-z)\,dz.
\end{aligned}$$

Therefore

$$\lambda_m(t) \sim \frac{\alpha+1}{t} = \frac{\beta}{t}.$$

and both cases can be combined into one relation

$$\lambda_m(t) \sim \frac{\min(\beta, \alpha+1)}{t}.$$

It can be shown that the same asymptotic relation holds not only for the gamma distribution, but also for any other mixing distribution $\pi(z)$ of the form $\pi(z) = z^\alpha \pi_1(z)$. If $\beta > \alpha+1$, the function $\pi_1(z)$ should be bounded and $\pi_1(0) \neq 0$.

Due to its simplicity, the asymptotic behavior of $\lambda_m(t)$ in the additive hazards model (20.51) does not warrant special attention. As $A(s) = s$ and $\phi(t) = t$, conditions (20.53) and (20.54) of Theorem 20.8 hold and the asymptotic result in (20.55) simplifies to:

$$\lambda_m(t) - \psi'(t) \sim \frac{\alpha+1}{t}.$$

21. Proportional Hazards Regression Models

The proportional hazards model plays an important role in analyzing data with survival outcomes. This chapter provides a summary of different aspects of this very popular model.

The first part gives the definition of the model and shows how to estimate the regression parameters for survival data with or without ties. Hypothesis testing can be built based on these estimates. Formulas to estimate the cumulative hazard function and the survival function are also provided. Modified models for stratified data and data with time-dependent covariates are also discussed.

The second part of the chapter talks about goodness-of-fit and model checking techniques. These include testing for proportionality assumptions, testing for function forms for a particular covariate and testing for overall fitting.

The third part of the chapter extends the model to accommodate more complicated data structures. Several extended models such as models with random effects, nonproportional models, and models for data with multivariate survival outcomes are introduced.

In the last part a real example is given. This serves as an illustration of the implementation of the methods and procedures discussed in this chapter.

The proportional hazards model has played a pivotal role in survival analysis since it was proposed by *Cox* [21.1]. This model has been widely used in many areas, such as biomedical research and engineering, for assessing covariate effects on the time to some events in the presence of right censoring. For example, when testing the reliability of an electrical instrument, the model can be used to investigate the effects of variables such as humidity, temperature, and voltage on the time to breakdown. Since time constraint might not allow us to observe the failure of every experimental unit, for some units we only know that failure did not occur up to the end of study, which is the censoring event.

Let T be the failure time, C be the censoring time, and $\boldsymbol{Z} = \{\boldsymbol{Z}_1, \cdots, \boldsymbol{Z}_p\}^T$ be a p-dimensional vector of covariates. Throughout this chapter the covariate vector $\boldsymbol{Z}$ is assumed to be time-independent, although it is straightforward to extend the theory to time-varying covariates. The failure time T might not always be observed due to censoring, and what we actually observe

are $X = \min(T, C)$, the smaller of the failure time and the censoring time, and $\Delta = I\,(T \le C)$, the indicator that failure has been observed. The dataset obtained from a failure-time study consists of n independent realizations of the triplet $(X, \boldsymbol{Z}, \Delta)$. It is usually assumed that the censoring is noninformative in that, given $\boldsymbol{Z}$, the failure and the censoring times are independent. Let $P\,(T > t \mid \boldsymbol{Z})$ be the conditional survival function, and the conditional hazard function is defined as

$$\lambda\,(t \mid \boldsymbol{Z}) = \lim_{\Delta t \downarrow 0} \frac{1}{\Delta t} P\,(t \le T < t + \Delta t \mid T \ge t, \boldsymbol{Z})\ ,$$

which is the instantaneous rate of failure at time t, given that failure has not occurred before t and the covariate vector $\boldsymbol{Z}$.

There are many ways to model the relationship between the failure time and the covariates. The proportional hazards model specifies

$$\lambda\,(t \mid \boldsymbol{Z}) = \lambda_0(t) \exp\left(\beta^T \boldsymbol{Z}\right)\ , \tag{21.1}$$

where $\lambda_0(t)$ is an unknown baseline hazard function corresponding to $\boldsymbol{Z} = (0, \cdots, 0)$, and $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)^T$ is the vector of regression coefficients.

This method does not assume a parametric distribution for the failure times, but rather assumes that the effects of the different variables on the time to failure are constant over time and are multiplicative on the hazard. The model is called the proportional hazards model since the ratio of hazards of any two experimental units is always a constant:

$$\frac{\lambda\,(t \mid z)}{\lambda\,(t \mid z')} = \frac{\lambda_0(t) \exp\left(\beta^T z\right)}{\lambda_0(t) \exp\left(\beta^T z'\right)} = \exp\left[\beta^T (z - z')\right]\ ,$$

where z and z' are the respective covariate values of the two units. This quantity is often referred to as the hazard ratio or relative risk.

The interpretation of the parameter β is similar to that in other regression models. For example, $\exp(\beta_1)$ is the hazard ratio of two study units whose values of the first covariate differ by 1 and whose values of any other covariate are the same. Usually, the goal is to make inferences about β or a subset of β to see whether a certain covariate has an effect on the survival rate or not. The baseline hazard $\lambda_0(\cdot)$ is treated as a nuisance parameter function. The proportional hazards model is considered a semiparametric model, in the sense that $\lambda_0(\cdot)$ is an infinite-dimensional parameter.

The semiparametric proportional hazards model includes the parametric Weibull model as a special case. To see this, for the Weibull distribution with density $f(t) = \alpha\lambda t^{\alpha-1} \exp(-\lambda t^{\alpha})$ and survival function $S(t) = \exp(-\lambda t^{\alpha})$, parameterize the parameter λ as $\lambda = \lambda^{'} \exp(\beta^T \boldsymbol{Z})$, then the hazard of failure given $\boldsymbol{Z}$ is

$$\lambda(t|\boldsymbol{Z}) = \lambda_0(t) \exp\left(\beta^T \boldsymbol{Z}\right)\ ,$$

where $\lambda_0(t) = \alpha\lambda^{'} t^{\alpha-1}$ is a function with two parameters, instead of the unspecified $\lambda_0(\cdot)$ in the case of the proportional hazards model. It can also be shown that the Weibull model is also a special case of the semiparametric accelerated failure-time model. In fact, the Weibull model is the most general parametric model that has both the proportional hazards and the accelerated failure-time properties. See Chapt. 12 of *Klein* and *Moeschberger* [21.2] for a detailed discussion.

21.1 Estimating the Regression Coefficients β

The partial likelihood method was introduced by *Cox* [21.3] to estimate the regression parameters β in the proportional hazards model for failure times with possible right censoring. We will first focus on the case when all failure times are distinct. When the failure time follows a continuous distribution, it is very unlikely that two subjects would fail at the same time. In reality, however, the measured time always has a discrete distribution, since it can only take values in a finite set of numbers. Thus tied failure times could happen in a real study, and special attention is needed in this situation.

21.1.1 Partial Likelihood for Data with Distinct Failure Times

Now suppose there is no tie among the failure times. Let $t_1 < \cdots < t_N$ denote the N ordered times of observed failures and let (j) denote the label of the individual that fails at t_j. Let $\mathcal{R}_j$ be the risk set at time t_j, i. e. $\mathcal{R}_j = \{i : X_i \ge t_j\}$.

The partial likelihood for the model (21.1) is defined as

$$\prod_{j=1}^{N} \frac{\exp\left(\beta^T Z_{(j)}\right)}{\sum_{i \in \mathcal{R}_j} \exp\left(\beta^T Z_i\right)}\ , \tag{21.2}$$

and the log partial likelihood is then

$$L(\beta)=\sum_{j=1}^{N}\left\{\beta^T Z_{(j)}-\log\left[\sum_{i\in\mathcal{R}_j}\exp\left(\beta^T Z_i\right)\right]\right\}.$$

The maximum partial likelihood estimate of β, $\hat{\beta}$, as proposed by *Cox* [21.3], is found by solving the score equation

$$U(\beta)=0\,,$$

where $U(\beta)=\partial L(\beta)/\partial\beta$.

The information matrix, defined as the negative of the second derivative matrix of the log likelihood, is given by

$$I(\beta)=-\frac{\partial U(\beta)}{\partial\beta}=\sum_{j=1}^{N}\left[\frac{\sum_{i\in\mathcal{R}_j}\exp\left(\beta^T Z_i\right)Z_i^{\otimes 2}}{\sum_{i\in\mathcal{R}_j}\exp\left(\beta^T Z_i\right)}-\left(\frac{\sum_{i\in\mathcal{R}_j}\exp\left(\beta^T Z_i\right)Z_i}{\sum_{i\in\mathcal{R}_j}\exp\left(\beta^T Z_i\right)}\right)^{\otimes 2}\right],$$

where $\boldsymbol{a}^{\otimes 2}=\boldsymbol{a}\boldsymbol{a}^T$ for any vector $\boldsymbol{a}$.

It can be shown that $\hat{\beta}$ is a consistent estimator for β, and $nI^{-1}(\hat{\beta})$ is a consistent estimator for the covariance matrix of $n^{1/2}(\hat{\beta}-\beta)$, where n is the number of all subjects, censored or uncensored. Thus for large samples, $\hat{\beta}$ has an approximately normal distribution with mean β and variance–covariance matrix $I^{-1}(\hat{\beta})$.

21.1.2 Partial Likelihood for Data with Tied Failure Times

In the previous section, we defined the partial likelihood for data with distinct failure times. Now we want to give several alternative partial likelihoods for data with ties between failure times.

Suppose there are N distinct observed failure times $t_1<\cdots<t_N$, and at each time $t_j(1\le j\le N)$ there are d_j observed failures. Let $\mathcal{D}_j$ be the set of all individuals who die at time t_j. Let $\mathcal{R}_j$ be the risk set at time t_j, i. e. $\mathcal{R}_j=\{i: X_i\ge t_j\}$.

When there are many ties in the data, the computation of maximum partial likelihood estimates, though still feasible, becomes time-consuming. For this reason, approximations to the partial likelihood function are often used. Two commonly employed approximations are due to Breslow and to Efron.

Breslow [21.4] suggested the following log partial likelihood for data with ties among failure times

$$L_{\mathrm{B}}(\beta)=\sum_{j=1}^{N}\left\{\beta^T\sum_{l\in D_j}Z_l-d_j\log\left[\sum_{i\in\mathcal{R}_j}\exp\left(\beta^T Z_i\right)\right]\right\}.$$

This approximation works well when there are not many ties. Another approximation of the log partial likelihood is given by *Efron* [21.5]

$$L_{\mathrm{E}}(\beta)=\sum_{j=1}^{N}\left\{\beta^T\sum_{l\in D_j}Z_l-\sum_{k=1}^{d_j}\log\left[\sum_{i\in\mathcal{R}_j}\exp\left(\beta^T Z_i\right)-(k-1)/d_j\sum_{i\in\mathcal{D}_j}\exp\left(\beta^T Z_i\right)\right]\right\}.$$

Breslow's method is easy to use and is therefore more popular, but Efron's approximation is generally the more accurate of the two. Also both likelihoods reduce to the partial likelihood when there is no tie.

21.2 Estimating the Hazard and Survival Functions

The cumulative baseline hazard function $\Lambda_0(t)=\int_0^t\lambda_0(u)\,\mathrm{d}u$ can be estimated by *Breslow* [21.6]

$$\hat{\Lambda}_0(t)=\sum_{j:\,t_j\le t}\frac{\delta_j}{\sum_{i\in R_j}\exp(\hat{\beta}^T Z_i)}\,,$$

where $\delta_j=I(T_j\le C_J)$. Note that $\hat{\Lambda}_0$ is a right-continuous step function with jumps at the observed failure times, and it is often referred to as the Breslow estimator. In the case of tied events, each of the subjects in a tie contributes its own term to the sum, and this term is the same for all subjects who failed at the specific time. This estimator can also be derived through a profile likelihood approach (*Johansen* [21.7], *Klein* and *Moeschberger* [21.2]). The baseline survival function $S_0(t)=\exp[-\Lambda_0(t)]$ can thus be estimated by $\hat{S}_0(t)=\exp[-\hat{\Lambda}_0(t)]$. The estimated survival function of an individual with covariate value z is given by

$$\hat{S}(t\mid z)=\exp\left[-\hat{\Lambda}_0(t)\mathrm{e}^{\hat{\beta}^T z}\right].$$

21.3 Hypothesis Testing

Without loss of generality, assume that we are interested in hypothesis testing involving only the first q components of the regression parameter β. Write $\beta = \left(\beta_1^T, \beta_2^T\right)^T$, where β_1 is of dimension q and β_2 is of dimension $(p-q)$. For testing the null hypothesis $\beta_1 = \beta_{01}$ against the alternative $\beta_1 \neq \beta_{01}$ for any fixed β_{01} in the presence of the unknown parameters β_2, there are three types of tests: the likelihood ratio test, the Wald test, and the score test. This type of test with $\beta_{01} = 0$ is often used in model selection procedures, testing whether a given model can be improved by including a certain additional covariate or covariate combinations.

21.3.1 Likelihood Ratio Test

The test statistic for the likelihood ratio test is given by

$$TS_{\text{LR}} = 2\left[\log L(\hat{\beta}) - \log L(\tilde{\beta})\right],$$

where $\tilde{\beta} = (\beta_{01}, \tilde{\beta}_2^T)^T$ and $\tilde{\beta}_2$ maximizes $L(\beta)$ when β_1 is fixed at β_{01}. Under the null hypothesis, the asymptotic distribution of TS_{LR} is χ_q^2.

21.3.2 Wald Test

Let $\hat{\beta} = \left(\hat{\beta}_1^T, \hat{\beta}_2^T\right)$ denote the usual maximum partial likelihood estimate of the full parameter vector $\boldsymbol{\beta} = \left(\beta_1^T, \beta_2^T\right)$, and partition the inverse of the information matrix as

$$\mathbf{I}^{-1}(\beta) = \begin{pmatrix} \mathbf{I}^{11}(\beta) & \mathbf{I}^{12}(\beta) \\ \mathbf{I}^{21}(\beta) & \mathbf{I}^{22}(\beta) \end{pmatrix},$$

where $\mathbf{I}^{11}(\beta)$ is a $q \times q$ matrix. The test statistic for the Wald test is given by

$$TS_{\text{wald}} = (\hat{\beta}_1 - \beta_{01})^T \times \mathbf{I}^{11}(\hat{\beta})^{-1}(\hat{\beta}_1 - \beta_{01}).$$

Under the null hypothesis, the asymptotic distribution of TS_{wald} is χ_q^2.

21.3.3 Score Test

Let $S_1(\beta)$ denote the vector of the first q components of the score function $S(\beta)$. The test statistic for the score test is

$$TS_{\text{score}} = S_1(\tilde{\beta})^T \times \mathbf{I}^{11}(\tilde{\beta}) S_1(\tilde{\beta}),$$

where $\tilde{\beta}$ and $\mathbf{I}_{11}(\beta)$ are defined as before. Again, the large sample distribution of the test statistic under the null hypothesis is χ_q^2.

21.4 Stratified Cox Model

The proportional hazards model can be stratified to account for heterogeneity in the baseline hazards. To achieve this, the subjects are divided into several groups with distinct baseline hazard functions and a common vector of regression coefficients β, and proportional hazards are assumed within each stratum. For a subject with covariate $\boldsymbol{Z}$ in the k-th stratum, let the hazard at time t be

$$\lambda(t \mid Z) = \lambda_k(t) \exp\left(\beta^T Z\right).$$

Within each stratum a partial likelihood function can be defined as in (21.2), and the partial likelihood for the stratified Cox model is defined as the sum of the partial likelihood functions for all strata.

21.5 Time-Dependent Covariates

The Cox model can be extended to include time-dependent covariates.

Let $\boldsymbol{Z}(t)$ be a covariate vector measured at time t. Again we assume that the censoring is noninformative in that the failure time T and the censoring time C are conditionally independent, given the history of the covariate vector $\boldsymbol{Z}^*(X)$, where $\boldsymbol{Z}^*(t) = \{Z(u) : 0 \leq u < t\}$ for any $0 \leq t \leq X$. The dataset $\left\{\left[X_i, Z_i^*(X_i), \Delta_i\right] : i = 1, \cdots, n\right\}$ is an i.i.d. sample of $\left\{\left[X, Z^*(X), \Delta\right]\right\}$. Using similar notations as in Sect. 21.1, the hazard function for T is defined as

$$\begin{aligned}\lambda\left[t \mid \boldsymbol{Z}^*(t)\right] &= \lim_{\Delta t \downarrow 0} \frac{1}{\Delta t} P\left[t \leq T < t + \Delta t \mid T \geq t, \boldsymbol{Z}^*(t)\right] \\ &= \lambda_0(t) \exp\left[\beta^T z(t)\right].\end{aligned}$$

The partial likelihood is then defined as

$$\prod_{j=1}^{N} \frac{\exp\left[\beta^T Z_{(j)}(X_{(j)})\right]}{\sum_{i\in\mathcal{R}_j} \exp\left[\beta^T Z_i(X_{(j)})\right]},$$

where, like in Sect. 21.2, (j) denotes the label of the subject with the j-th earliest observed failure time, and R_j denotes the corresponding risk set.

Though the extension of the model and partial likelihood is simple, the validity of the underlying assumption and the computation of the partial likelihood are quite complicated in practice. Extra care is needed in dealing with time-dependent covariates.

Kalbfleisch and *Prentice* [21.8] pointed out that there are two types of time-dependent covariates: external covariates, whose value do not depend on the failure process, and internal covariates, which usually carry information about the failure process. For example, when studying how long an experimental unit remains functioning, the air humidity rate is essentially external to the units work duration. But a patient's daily blood pressure is an internal time-dependent covariate, since it carries information about the health status and hence the failure time of the patient. Though the definition of the hazard function and the construction of the partial likelihood apply to both type of time-dependent covariates, it is not possible to estimate the conditional survival function when there are internal covariates.

Another problem concerns the measurement of time-dependent covariates. The calculation of partial likelihood requires that the values of any unit's time-dependent covariates be available at all failure times when it is still at risk. This cannot be achieved in general, since we can never know the failure times in advance and the information on the covariates are usually collected at predetermined time points.

One way to deal with incomplete history of time-dependent covariates is imputation, and there are several possible ways to impute the intermittent values. An ad hoc approach commonly used in practice, referred to as the LVCF method, is to impute the missing covariate at a certain time point with the nearest previous observation of the same unit. Other nonparametric approaches, like the smoothing methods, can be used to estimate the unobserved part of the time-dependent data.

If one can make the assumption that the time-dependent covariates follow certain models, for example, linear mixed effects models, several strategies can be applied, including regression calibration methods [21.9–11], joint likelihood methods, [21.12–14], and conditional score methods, [21.15].

One also needs to be aware of the possible informative censoring due to the fact that the time-dependent covariates are truncated by failure [21.16]. *Allison* [21.17] suggested avoiding using observations after the failure time, unless one is dealing with external time-dependent covariates. Failure to take into account these problems can lead to biased parameter estimates.

21.6 Goodness-of-Fit and Model Checking

21.6.1 Tests of Proportionality

A key assumption of the Cox proportional hazard model is the proportionality of the hazards. Note that the hazard function for an individual depends on the covariate values and the value of the baseline hazard. For any two individuals, it is easy to see from (21.1) that the ratio of the hazards over time will be constant. The validity of this assumption needs to be checked. Various methods can be used for this purpose.

One graphical approach to check the proportionality assumption is the log–log survival plot. We first divide all study units into several groups according to the covariate values, and then estimate the survival function within each group using the *Kaplan–Meier* method, [21.18]. If the proportional hazard assumption is satisfied, plotting the transformed survival functions, $\log\left[-\log S(t)\right]$, would result in parallel curves. This method works well with categorical covariates without many levels. For continuous predictors, one may first divide them into a few categories based on quantiles or other grouping criterion. For categorical covariates with many levels, one may want to combine them into fewer groups.

Other graphic approaches includes *Andersen* plots [21.19], *Arjas* plots [21.20], and the use of plots based on the score residuals or Schoenfeld residuals. The details of these approaches can be found in *Klein* and *Moeschberger* [21.2], Chapt. 11.

Alternatively, one can check the proportionality assumption by adding a time-dependent covariate to the model. The time-dependent covariate can be defined

as the interaction of a time-independent covariate and a function of time. If the time-dependent covariate is significant in the Cox model, it could be concluded that the effect of the time-independent covariate varies with time, and the proportional hazards assumption is violated.

21.6.2 Test of the Functional Form of a Continuous Covariate

Next we want to examine the functional form of a given covariate on the survival and see whether any transformation of the original covariate is needed. One method is based on martingale residuals.

Let $\hat{\beta}$ be the estimated regression coefficient and $\hat{\Lambda}_0(\cdot)$ be the Breslow estimator of the cumulative baseline hazard function, the martingale residual for the i-th subject is defined as

$$\hat{M}_i = \delta_i - \hat{\Lambda}_0(X_i)\exp\left(\hat{\beta}^T Z_i\right) = \delta_i - \hat{\Lambda}_i(X_i)\,.$$

It can be shown that when sample size is large, expectation of $\hat{M}_i$ is close to 0 and, for $i \neq j$, $\mathrm{cov}(\hat{M}_i, \hat{M}_j)$ is also close to 0. We also have $\sum \hat{M}_i = 0$.

When the functional form of a specific covariate needs to be examined, we first fit a Cox model with all covariates excluding the covariate to be investigated, and then plot the martingale residuals against the excluded covariate. If the plot shows an approximately linear trend, no transformation is needed and the untransformed covariate can be included in the model with the other covariates. If, however, there appears to be a certain pattern, a proper transformation of the original covariate might be needed.

Nonparametric methods can also be used to explored the nature of covariate effects on survival. Local likelihood or penalized likelihood methods with different smoothing methods have been proposed to estimate the functional form of a single covariate or a linear combination of covariates in the survival model [21.21–25].

21.6.3 Test for the Influence of Individual Observation

The influence of individual observation may be studied by the use of score residuals. We can fit the Cox model with and without the i-th observation of the data sample, and obtain the estimates $\hat{\beta}$ and $\hat{\beta}_{(i)}$, respectively. If $\hat{\beta} - \hat{\beta}_{(i)}$ is close to zero the individual observation has little influence on the estimate. We can plot this difference against the observation number to identify those influential observations.

21.6.4 Test for the Overall Fit

The overall fit of the model can be assessed using the Cox–Snell residuals, which are defined as

$$r_i = \hat{\Lambda}_0(X_i)\exp\left(\hat{\beta}^T Z_i\right), \qquad i = 1, \cdots, n\,,$$

where $\hat{\Lambda}$ is the Breslow estimator for the cumulative baseline hazard function and $\hat{\beta}$ are the estimated regression coefficients. It can be shown that, when there is no censoring and the true values of the parameters are known, $\Lambda_0(T_i)\exp\left(\beta^T Z_i\right)$ follows an exponential distribution with unit rate. Thus we can treat $\{r_i, i = 1, \ldots, n\}$ as a possibly right-censored sample of failure times from the unit exponential distribution, which has a constant hazard rate $\lambda_{\mathrm{r}}(r) = 1$ and a cumulative hazard function $\Lambda_{\mathrm{r}}(r) = r$. The failure indicator δ_i for X_i can also serve as the failure indicator for r_i. The Nelson–Aalen estimator can be used to estimate Λ_{r}:

$$\hat{\Lambda}_{\mathrm{r}}(r) = \sum_{i:\, r_i \le r} \frac{\delta_i}{\#\{r_j : r_j \ge r_i\}}\,,$$

where # counts the number of elements in a set. If the model is correct, the function $\hat{\Lambda}_{\mathrm{r}}$ would be close to the straight line $\Lambda_{\mathrm{r}}(r) = r$. Thus, plotting $\hat{\Lambda}_{\mathrm{r}}(r_i)$ against r_i will provide an assessment of the departure from the model assumptions.

21.6.5 Test of Time-Varying Coefficients

Schoenfeld residuals [21.26] can be used to test for time-varying coefficients in the Cox model. Let $Y_i(t) = I(X_i \ge t)$, be the indicator of whether unit i is still at risk at time t. For a subject who fails at time t_i, the vector of Schoenfeld residuals is defined as

$$Z_i(t_i) - \bar{Z}(t_i)\,,$$

where $\bar{Z}(t)$ is defined as

$$\bar{Z}(t) = \frac{\sum_{j=1}^{n} Y_j(t) Z_j \exp\left(\hat{\beta}^T Z_j\right)}{\sum_{j=1}^{n} Y_j(t)\exp\left(\hat{\beta}^T Z_j\right)}\,,$$

which is a weighted average of the covariate $\boldsymbol{Z}$ over all individuals at risk at time t.

Under the proportional hazards assumption, the Schoenfeld residuals should be independent of time. Therefore, a clear pattern of the Schoenfeld residuals over time implies a departure from the model assumption.

For the j-th covariate, a time-varying coefficient can be expressed as

$$\beta_j(t) = b_{0j} + b_{1j} f_j(t) ,$$

where $f_j(t)$ is a known function of time. *Grambsch* and *Therneau* [21.27] showed that the scaled Schoenfeld residuals from a Cox model have a mean of approximately $b_{1j} f_j(t)$ for the j-th covariate at time t. So the plot of the scaled Schoenfeld residuals against the event times can be used to check whether the coefficient of f_j is zero.

21.6.6 Test for a Common Coefficient Across Different Groups

To test whether the effect of a covariate on failure is identical across different groups of study units, a stratified analysis can be utilized. First, a stratified Cox model is fitted with different regression coefficients for different groups. Then another stratified Cox model is fitted with the same coefficient for all groups. The difference between the log likelihoods, which has an approximate χ^2 distribution, can be used to test for any heterogeneity in the covariate effect.

21.7 Extension of the Cox Model

21.7.1 Cox Model with Random Effects

Similarly to the case of a linear model, random effects can be added to the proportional hazards model to handle clustered or heterogeneous survival data [21.28]. Let

$$\lambda(t \mid \boldsymbol{Z}) = \lambda_0(t) \exp\left(\beta^T \boldsymbol{Z} + b^T \boldsymbol{W}\right) ,$$

where b is the random effect of the covariate vector $\boldsymbol{W}$ on survival. This model allows for a multivariate random effect with known distribution. Maximum likelihood estimates of the regression parameters, the variance components and the baseline hazard function can be obtained via the expectation maximization (EM) algorithm.

21.7.2 Nonproportional Models

Several models can be applied when one suspects that the proportionality assumption does not hold for a certain dataset. The most common among them are frailty models and cure-rate models.

Frailty models can be used to account for individual randomness in an experiment. An unobserved random variable W is added to a Cox proportional hazards model, which is assumed to follow a known distribution. The effect of W is multiplicative on the hazard: given W, the hazard rate is given by

$$\lambda(t \mid \boldsymbol{W}, \boldsymbol{Z}) = \lambda_0(t) W \exp\left(\beta^T \boldsymbol{Z}\right) .$$

With a common choice for the distribution of W, Gamma$(1, \theta)$, the marginal hazard rate given the covariate vector $\boldsymbol{Z}$ is

$$\lambda(t \mid \boldsymbol{Z}) = \frac{\lambda_0(t) \exp\left(\beta^T \boldsymbol{Z}\right)}{1 + \theta \exp\left(\beta^T \boldsymbol{Z}\right) \Lambda_0(t)} .$$

Another commonly used model for nonproportional hazards is the cure-rate model. This assumes that there are two sub-populations: cured subjects and uncured subjects. Suppose the proportion of the cured subjects is π and that of the uncured subjects is $1 - \pi$. The survival probability at t given covariates $\boldsymbol{Z}$ is then given by

$$S(t \mid \boldsymbol{Z}) = \pi S_1(\boldsymbol{Z}) + (1 - \pi) S_2(t \mid \boldsymbol{Z}) ,$$

where $S_1(\boldsymbol{Z})$ is the probability of being cured and $S_2(t \mid \boldsymbol{Z})$ represents the survival function of the uncured,

Table 21.1 Data table for the example

Time to breakdown (s)				
45 kV	40 kV	35 kV	30 kV	25 kV
1	1	30	50	521
1	1	33	134	2517
1	2	41	187	4056

71	417	1495	86100+	86420+

+ represents censoring

which is modeled as in a proportional hazards model. The cure-rate model can be used to fit failure-time data when the right tail of the survival function looks like a plateau.

21.7.3 Multivariate Failure Time Data

Sometimes an experimental unit might experience multiple failures, which could be of the same nature (e.g., same event recurring over time), or of different nature (e.g., distinct types of problems). Also, in some situations there are clustering of study units such that failure times within the same cluster are expected to be correlated. For example, pieces of equipment in the same factory might behave similarly to those in another factory.

Various methods have been developed for these kinds of multivariate failure-time data. See, for example, [21.29–33].

21.8 Example

We now use a dataset from the book by *Wayne* [21.34] as an illustration. The data came from an experiment on testing the fatigue limit for two steel specimens in two forms under different stress ratios. The data are shown in Table 21.1.

The fitting result is shown in Table 21.2. We can see that voltage has a negative effect on the failure rate. The higher the voltage is, the shorter the time to break down will be. One unit increase in voltage results in an hazard ratio of 1.27 (95% confidence interval = 1.19–1.36).

The survival function estimates for five groups of voltage are displayed in Fig. 21.1. The graph shown in Fig. 21.2 of the graph of log[-log(survival)] versus the log of survival time results in parallel straight lines, so the proportional hazard assumption is satisfied. The

22. Accelerated Life Test Models and Data Analysis

Today's consumers demand high quality and reliability in the products they buy. Accelerated life tests (ALT) are commonly used by manufacturers during product design to obtain reliability information on components and subsystems in a timely manner. The results obtained at high levels of the accelerating variables are then extrapolated to provide information about the product life under normal use conditions.

The introduction and Section 22.1 describe the background and motivations for using accelerated testing. Sections 22.2 and 22.3 discuss statistical models for describing lifetime distributions in ALT. Commonly used ALT models have two parts: (a) a statistical distribution at fixed levels of the accelerated variable(s); and (b) a functional relationship between distribution parameters and the accelerating variable(s). We describe relationships for accelerating variables, such as use rate, temperature, voltage, and voltage rate. We also discuss practical guidelines and potential problems in using ALT models. Section 22.4 describes and illustrates a strategy for analyzing ALT data. Both graphical and numerical methods are discussed for fitting an ALT model to data and for assessing its fit. These methods are thoroughly illustrated by fitting an ALT model with a single accelerating variable to data obtained from an actual ALT experiment. Extrapolation of the results at accelerated levels to normal use levels is also discussed. Section 22.5 presents statistical analysis of a wider variety of ALT data types that are encountered in practice. In particular, the examples involve ALTs with interval censoring and with two or more accelerating variables. Section 22.6 discusses practical considerations for interpreting statistical analysis of ALT data. This Section emphasizes the important role of careful planning of ALT to produce useful results. Section 22.7 discusses other kinds of accelerated tests often conducted in practice. Brief descriptions of each and specific applications in industry are also provided. Section 22.8 reviews some of the potential pitfalls the practitioner of accelerated testing may face. These are described within practical situations, and strategies for avoiding them are presented. Section 22.9 lists some computer software packages that are useful for analyzing ALT data.

Rapid developments in technology, consumer demand for highly reliable products, and competitive markets have placed pressure on manufacturers to deliver products with high quality and reliability. Similarly, there is strong pressure to shorten the concept-to-market cycle time, subject to the constraint of having a product with high reliability. Achieving these goals requires more attention to reliability early in the product design process and has lead to such programs as *design for reliability* and *design for six sigma.* As a result, there has been an increased need for upstream tests of product materials and components, often followed by subsequent testing of subsystems and even complete systems.

Customers may expect products to work properly for years or even decades. For instance, a refrigerator might be expected to work without failure for at least 10 years. Testing under normal operating conditions for reasonable lengths of time is unlikely to result in any failures and thus little information about product reliability. Hence, manufacturers perform accelerated tests (AT) on their products by exposing them to harsher conditions to generate failures and useful reliability information more quickly.

Depending on the nature of the product, life tests are accelerated by increasing product use rate or exposing the product to higher levels of accelerating variables such as temperature, pressure, and voltage. It is customary to fit a statistical model to the AT data and then extrapolate to use conditions to characterize the product's long-term performance. It is desirable that the statistical model for ATs be based on physical/chemical theory that can be used to justify the extrapolation. Operationally, however, detailed knowledge of theory relating the accelerating variables to life is not always available and the model is chosen on the basis of previous experience in similar situations.

Due to space constraints, we provide a limited discussion and description of the models and methods used in AT. For those actually involved in AT and for those who want more information, we highly recommend *Nelson* [22.1]. Other useful books with information that will complement this chapter include *Tobias* and *Trindade* [22.2] and *Meeker* and *Escobar* [22.3].

22.1 Accelerated Tests

22.1.1 Types of Accelerated Tests

During product design, manufacturers perform experiments to obtain timely information on material properties and component durability. Other experiments involving prototype systems and subsystems are used to help make product and process design decisions that will improve product robustness. Experiments are also run to support decision making in production process design. Tests during the production stage include certification of components, burn-in tests, and tests designed to monitor the production process over time. For further discussion of these issues, see *Meeker* and *Hamada* [22.4] and *Meeker* and *Escobar* [22.5]. Often these tests must be accelerated to obtain timely information.

ATs can be characterized by the nature of the response variable in the test (i. e., what can be measured or observed, relative to reliability):

- **Accelerated Life Tests ALT**
  The response in an ALT is related to the lifetime of the product. Often ALT data are right-censored because the test is stopped before all units fail. In other cases, the ALT response is interval-censored because failures are discovered at particular inspection times.
- **Accelerated Repeated Measures Degradation Tests ARMDT**

In an ARMDT, one measures degradation on a sample of units at different points in time. In general, each unit provides several degradation measurements. The degradation response could be actual chemical or physical degradation or performance degradation (e.g., drop in power output).

- **Accelerated Destructive Degradation Tests ADDT**
  An ADDT is similar to an ARMDT, except that the measurements are destructive, so one can obtain only one observation per test unit.

These different kinds of ATs can be closely related because they can involve the same underlying physical/chemical mechanisms for failure and models for acceleration. They are different, however, in that different kinds of statistical models and analyses are performed because of the differences in the kind of response.

This chapter focuses on analyses of data from ALTs. See *Meeker* and *Escobar* ([22.3], Chapts. 13 and 21) for further discussion of ARMDTs and see *Nelson* ([22.1], Chapt. 11) and *Meeker*, *Escobar*, *Kugler*, and *Kramer* [22.6] for models, methods, and examples pertaining to ADDTs.

22.1.2 Methods of Acceleration

There are different methods of accelerating tests to induce product failures more quickly. These methods vary depending on the nature of the product or material being tested.

- **Accelerate the Product Use Rate**
  This method is appropriate for products that are ordinarily not in continuous use. For example, the median life of a bearing for a certain washing machine agitator is 12 years, based on an assumed use rate of eight loads per week. If the machine is tested at 112 loads per week (16 per day), the median life is reduced to roughly 10 months.
- **Accelerate Product Aging**
  Changing environmental conditions (e.g., increasing humidity or temperature) can be used to increase the rate of chemical degradation of products such as insulating materials and adhesive bonds.
- **Accelerate by Increasing Product Stress**
  Increasing stress (e.g., voltage or pressure) on a specimen will generally cause it to fail sooner.

It is also possible to accelerate product failures by using combinations of these accelerating variables. For example, in fatigue testing one uses higher cycling rates and higher than usual levels of stress. In electro-chemical reactions, increasing voltage will also increase the rate of chemical change. Putting higher voltage stress on an insulating material may generate heat that will accelerate chemical change. In all types of acceleration, care should be taken to make sure that the underlying mechanisms and the resulting failure modes in an AT are the same as those that will affect the product in actual use.

22.1.3 Choosing an Accelerated Life Test Model

The task of finding an ALT model can be divided into two steps:

1. Choose an appropriate statistical distribution to describe lifetime at fixed levels of the accelerating variable(s). Typically the same distribution is used at all levels of stress, as would be suggested by the commonly used scale-accelerated failure-time, SAFT, model. Probability plots (i. e., plotting a nonparametric estimate on special distribution-specific probability scales) are used to help identify an appropriate distribution.
2. Choose a model to describe the relationship between the lifetime distributions and the accelerating variables. It is best if the selected model is based on physical or chemical theory, empirical considerations, or both.

These two steps are discussed in detail in Sects. 22.2 and 22.3, respectively.

As will be discussed in subsequent sections, the combination of probability plotting and maximum likelihood provides the basic statistical tools for analyzing most ALT data. Probability plots provide a convenient, intuitive method to display ALT data and assess agreement with proposed models for the data. These methods are described in detail in *Nelson* ([22.1], Chapt. 3) and *Meeker* and *Escobar* ([22.3], Chapts. 6 and 19). Maximum likelihood (ML) is the most common method of fitting an ALT model to data because it allows for censored data and because ML estimates have desirable statistical properties. The ML estimates of model parameters are those parameter values that maximize the probability of the observed data for the proposed model. The theory of ML methods has been thoroughly explored in the literature. *Nelson* ([22.1], Chapt. 5) and *Meeker* and *Escobar* ([22.3], Chapts. 8 and 19) discuss ML methods relevant to ALT data analysis. Both probability plotting and maximum likelihood methods are now widely available in commercial statistical software, as described in Sect. 22.9.

22.2 Life Distributions

In this chapter, the symbol T will denote lifetime for devices, components, systems, etc. Then, it will be assumed that T is a positive continuous random variable. The cumulative distribution function CDF for T is the probability of failure by time t (or the fraction failing by time t) and one writes $F(t) = \Pr(T \le t)$. The probability density function PDF $f(t)$ is the derivative of the CDF. That is, $f(t) = \mathrm{d}F(t)/\mathrm{d}t$. Selecting a probability distribution for lifetime is equivalent to specifying either $F(t)$ or $f(t)$.

This section describes log-location-scale probability distributions. Important members of this family include the popular Weibull and lognormal distributions. Other members of the family are described in Chapt. 4 of *Meeker* and *Escobar* [22.3]. Distributions that are other than log-location-scale (which could also be used in ALT modeling) are described in Chapt. 5 of *Meeker* and *Escobar* [22.3].

A random variable Y has a location-scale distribution if its CDF can be written as

$$F(y;\mu,\sigma) = \Pr(Y \le y) = \Phi\left(\frac{y-\mu}{\sigma}\right) ,$$

where μ is a location parameter, σ is a scale parameter, and Φ does not depend on any unknown parameters. In many reliability applications, it is assumed that $\log(T)$ has a location-scale distribution. Then T is said to have a log-location-scale distribution.

22.2.1 The Lognormal Distribution

Lifetime T has a lognormal distribution if its CDF and PDF are

$$F(t;\mu,\sigma) = \Phi_{\mathrm{nor}}\left(\frac{\log(t)-\mu}{\sigma}\right) ,$$

$$f(t;\mu,\sigma) = \frac{1}{\sigma t}\phi_{\mathrm{nor}}\left(\frac{\log(t)-\mu}{\sigma}\right) , \quad t > 0 ,$$

where Φ_{nor} and ϕ_{nor} are the standard normal (Gaussian) CDF and PDF, respectively. In particular,

$$\phi_{\mathrm{nor}}(z) = \frac{1}{\sqrt{2\pi}}\exp\left(-\frac{z^2}{2}\right) .$$

The parameters (μ,σ) are the mean and the standard deviation of $\log(T)$, respectively. Then $[\exp(\mu),\sigma]$ are, respectively, the scale and shape parameters of T. The lognormal p quantile is $t_p = \exp[\mu + \Phi^{-1}_{\mathrm{nor}}(p)\,\sigma]$. Note that $\exp(\mu)$ corresponds to the median lifetime. That is, $t_{0.50} = \exp(\mu)$.

22.2.2 The Weibull Distribution

Lifetime T has a Weibull distribution if its CDF and PDF are

$$\begin{aligned} F(t;\mu,\sigma) &= \Phi_{\mathrm{sev}}\left(\frac{\log(t)-\mu}{\sigma}\right) \\ &= 1-\exp\left[-\left(\frac{t}{\eta}\right)^{\beta}\right] \\ f(t;\mu,\sigma) &= \frac{1}{\sigma t}\phi_{\mathrm{sev}}\left(\frac{\log(t)-\mu}{\sigma}\right) \\ &= \frac{\beta}{\eta}\left(\frac{t}{\eta}\right)^{\beta-1}\exp\left[-\left(\frac{t}{\eta}\right)^{\beta}\right], \quad t > 0, \end{aligned}$$

where Φ_{sev} and ϕ_{sev} are the standard smallest extreme value SEV CDF and PDF defined by

$$\Phi_{\mathrm{sev}}(z) = 1-\exp[-\exp(z)]$$
$$\text{and} \quad \phi_{\mathrm{sev}}(z) = \exp[z-\exp(z)] ,$$

$\sigma > 0$, and $-\infty < \mu < \infty$. Here (μ,σ) are the location and scale parameters for the distribution of $\log(T)$. The expressions for the CDF and PDF above also use $\eta = \exp(\mu)$ and $\beta = 1/\sigma$, the traditional Weibull scale and shape parameters, respectively. The Weibull p quantile is $t_p = \exp\{\mu + \log[-\log(1-p)]\,\sigma\} = \eta[-\log(1-p)]^{\beta}$. Note that η is approximately the 0.63 quantile of the Weibull distribution.

The parameterization in terms of (μ,σ) is particularly convenient for lifetime regression models and is used extensively in this chapter. The (η,β) parameterization is commonly used in the engineering and statistical literature.

22.3 Acceleration Models

fitting a model to data obtained at high levels of the accelerating variables and extrapolating the results to use conditions levels. Ideally, this model should be derived from physical or chemical theory and verified empirically to justify the extrapolation. If a physical understanding of the failure mechanism is lacking, an

empirical model might be justified for extrapolation if it is based on extensive experience with how failure mechanisms relate to accelerating variables.

This section discusses basic ideas of acceleration models and some physical considerations that lead to these models. For more information on these models, see *Nelson* ([22.1], Chapt. 2) and *Meeker* and *Escobar* ([22.3], Chapt. 18).

22.3.1 Scale-Accelerated Lifetime Model

A simple, commonly used model used to characterize the effect that explanatory variables $\boldsymbol{x} = (x_1, \ldots, x_k)'$ have on lifetime T is the scale-accelerated failure-time (SAFT) model. Some of these explanatory variables are accelerating, but others may just be of interest (e.g., for product design optimization decisions). If $\boldsymbol{x}_\mathrm{U}$ denotes the ordinary use conditions, under a SAFT model, lifetime at $\boldsymbol{x}$, $T(\boldsymbol{x})$, is scaled by a deterministic factor that might depend on $\boldsymbol{x}$ and unknown fixed parameters. More specifically, $T(\boldsymbol{x}) = T(\boldsymbol{x}_\mathrm{U})/\mathcal{AF}(\boldsymbol{x})$ where the *acceleration factor* $\mathcal{AF}(\boldsymbol{x})$ is a positive function of $\boldsymbol{x}$ satisfying $\mathcal{AF}(\boldsymbol{x}_\mathrm{U}) = 1$. Lifetime is accelerated (decelerated) when $\mathcal{AF}(\boldsymbol{x}) > 1$ [$\mathcal{AF}(\boldsymbol{x}) < 1$]. Some special cases of these important SAFT models are discussed in the following sections.

Observe that under a SAFT model, the probability that failure under conditions $\boldsymbol{x}$ occurs at or before time t can be written as $\Pr[T(\boldsymbol{x}) \le t] = \Pr[T(\boldsymbol{x}_\mathrm{U}) \le \mathcal{AF}(\boldsymbol{x}) \times t]$. As described in Sect. 22.2, it is common practice to assume that the lifetime $T(\boldsymbol{x})$ has a log-location-scale distribution such as a lognormal or Weibull distribution in which μ is a function of the accelerating variable(s) and σ is constant (i. e., does not depend on $\boldsymbol{x}$). In this case,

$$F(t; \boldsymbol{x}_\mathrm{U}) = \Pr[T(\boldsymbol{x}_\mathrm{U}) \le t] = \Phi\left(\frac{\log(t) - \mu_\mathrm{U}}{\sigma}\right), \tag{22.1}$$

where Φ denotes a standard cumulative distribution function (e.g., standard normal or standard smallest extreme value) and μ_U is the location parameter for the distribution of $\log[T(\boldsymbol{x}_\mathrm{U})]$. Thus,

$$F(t; \boldsymbol{x}) = \Pr[T(\boldsymbol{x}) \le t] = \Phi\left(\frac{\log(t) - \{\mu_\mathrm{U} - \log[\mathcal{AF}(\boldsymbol{x})]\}}{\sigma}\right). \tag{22.2}$$

Note that $T(\boldsymbol{x})$ also has a log-location-scale distribution with location parameter $\mu = \mu_\mathrm{U} - \log[\mathcal{AF}(\boldsymbol{x})]$ and a scale parameter σ that does not depend on $\boldsymbol{x}$.

22.3.2 Accelerating Product Use Rate

Increasing the use rate can be an effective method of acceleration for some products. In simple situations the cycles-to-failure distribution does not depend on the cycling rate. In such situations *reciprocity holds*. Then the underlying model for lifetime is SAFT where $\mathcal{AF}(\mathrm{UseRate}) = \mathrm{UseRate}/\mathrm{UseRate}_\mathrm{U}$ is the factor by which the test is accelerated.

Use-rate acceleration may be appropriate for products such as electrical relays and switches, paper copiers, and printers, and home appliances such as toasters and washing machines. The manner in which the use rate is increased may depend on the product. For example, *Nelson* ([22.1], page 16) states that failure of rolling bearings can be accelerated by running them at three or more times the normal speed. *Johnston* et al. [22.7] demonstrated that the cycles-to-failure of electrical insulation was shortened, approximately, by a factor of $\mathcal{AF}(412) = 412/60 \approx 6.87$ when the applied AC voltage in endurance tests was increased from 60 Hz to 412 Hz.

ALTs with increased use rate attempt to simulate actual use. Thus other environmental factors should be controlled to mimic actual use environments. If the cycling rate is too high, it can cause *reciprocity breakdown*. For example it may be necessary to have test units (such as a toaster) cool down between cycles of operation. *Dowling* ([22.8], page 706) describes how increased cycle rate may affect the crack growth rate in per-cycle fatigue testing.

Reciprocity breakdown is known to occur, for example, for certain components in copying machines where components tend to last longer (in terms of cycles) when printing is done at higher rates. In such cases, the empirical power-rule relationship $\mathcal{AF}(\mathrm{UseRate}) = (\mathrm{UseRate}/\mathrm{UseRate}_\mathrm{U})^p$ is often used, where p can be estimated by testing at two or more use rates.

22.3.3 Models for Temperature Acceleration

This section describes common models that are used to describe the relationship between lifetime and temperature.

The Arrhenius Relationship for Temperature Acceleration

The Arrhenius equation is widely used to relate the rate of a chemical reaction $\mathcal{R}$ to temperature temp. This relationship can be written as

$$\mathcal{R}(\text{temp}) = \gamma_0 \exp\left(\frac{-E_a}{k_B \times \text{temp K}}\right) = \gamma_0 \exp\left(\frac{-E_a \times 11605}{\text{temp K}}\right), \quad (22.3)$$

where γ_0 and the activation energy E_a are constants that depend on material properties and test methods, $k_B = 8.6171 \times 10^{-5} = 1/11605$ is Boltzmann's constant in units of electron volts per °C, and temp K = temp °C + 273.15 is the temperature kelvin. The Arrhenius lifetime relationship is based on the view that failure occurs after there has been a critical amount of chemical reaction. Then when $\mathcal{R}$(temp) is larger, the failure will occur sooner (e.g., *Klinger* [22.9]). Empirical observations have suggested that the Arrhenius equation provides an adequate description of the relationship between product life and temperature in a variety of applications such as integrated circuits (several different kinds of failure modes), light-emitting diodes (LEDs), adhesive bonds, lubricants, incandescent bulb filaments, insulating tapes, and dielectric materials. It should be noted, however, that the nature of the failure mechanism may limit the range of temperature over which the Arrhenius relationship is adequate.

Let temp_U be the temperature at use conditions. Then the Arrhenius acceleration factor is

$$\mathcal{AF}(\text{temp}, \text{temp}_U, E_a) = \frac{\mathcal{R}(\text{temp})}{\mathcal{R}(\text{temp}_U)} = \exp\left[E_a\left(\frac{11605}{\text{temp}_U\,\text{K}} - \frac{11605}{\text{temp K}}\right)\right].$$

For simplicity, the time-acceleration factor is sometimes written as $\mathcal{AF}$(temp) instead of $\mathcal{AF}(\text{temp}, \text{temp}_U, E_a)$.

Let $\text{temp}_{Low} < \text{temp}_{High}$ be two temperature levels and define the temperature differential factor TDF

$$\text{TDF} = \left(\frac{11605}{\text{temp}_{Low}\,\text{K}} - \frac{11605}{\text{temp}_{High}\,\text{K}}\right). \quad (22.4)$$

Then, one can write

$$\mathcal{AF}(\text{temp}_{High}, \text{temp}_{Low}, E_a) = \exp(E_a \times \text{TDF}). \quad (22.5)$$

Example 22.1: Adhesive-Bonded Power Element. *Meeker* and *Hahn* [22.10] describe an adhesive-bonded power element that was designed for use at temp = 50 °C and a life test of this element is to be conducted at temp = 120 °C. Suppose that experience with this product suggested that $E_a = 0.5$. Using (22.4) and (22.5) gives TDF = 6.39 and then $\mathcal{AF}(120) \approx 24.41$ gives the acceleration factor for the chemical reaction when testing the power element at 120 °C.

Note that the Arrhenius relationship (and the assumption that the failure is directly related to the amount of material reacting) implies that the acceleration model is a SAFT model. If $T(\text{temp}_U)$ has a log-location-scale distribution with parameters μ_U and σ, then it follows from (22.2) that T(temp) also has a log-location-scale distribution with parameters $\mu = \mu_U - \beta_1 x$ and σ, where $\beta_1 = E_a$, $x = \text{TDF}$, and the TDF is computed for the temperatures $\text{temp}_U < \text{temp}$.

Nonlinear Degradation Path Models for Reaction-Rate Acceleration

As discussed earlier, when failure is caused directly by degradation, one can relate the distribution of degradation to the distribution of failure. Suppose that failure occurs when degradation reaches a certain critical level $\mathcal{D}_f$. This section discusses the situation in which degradation follows a nonlinear path (e.g., the degradation path will reach an asymptote because of a limited amount of material that is available to go into the reaction) over time. The linear path case is discussed in the next section.

The amount of degradation at time t and temperature temp is given by

$$\mathcal{D}(t; \text{temp}) = \mathcal{D}_\infty \times \left\{1 - \exp\left[-\mathcal{R}_U \times \mathcal{AF}(\text{temp}) \times t\right]\right\}, \quad (22.6)$$

where $\mathcal{R}_U$ is the rate of reaction rate at the use temperature temp_U. Note that $\mathcal{R}_U \times \mathcal{AF}$(temp) is the rate reaction at temp and $\mathcal{AF}(\text{temp}) > 1$ when $\text{temp} > \text{temp}_U$. Figure 22.1 shows the decrease in strength of adhesive bonds, as a function of time for different temperatures. In this application, $\mathcal{D}_\infty < 0$ so that, for fixed temp, $\mathcal{D}(t; \text{temp})$ is a decreasing function of t and failure occurs when $\mathcal{D}(t; \text{temp})$ falls below $\mathcal{D}_f$, say 50 N. In other applications, $\mathcal{D}_\infty > 0$, then $\mathcal{D}(t; \text{temp})$ is increasing and failure occurs once $\mathcal{D}(t; \text{temp})$ exceeds $\mathcal{D}_f$. For both cases, the lifetime T(temp) at any level temp is given by $T(\text{temp}) = T(\text{temp}_U)/\mathcal{AF}(\text{temp})$ where $T(\text{temp}_U) = -(1/\mathcal{R}_U)\log(1 - \mathcal{D}_f/\mathcal{D}_\infty)$. Note that this has the form of a SAFT model. Sufficient

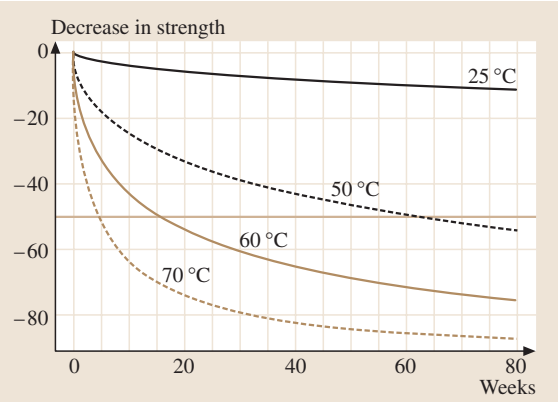

Fig. 22.1 Nonlinear decreasing degradation path at different temperatures for a SAFT model

conditions for a degradation model to be SAFT are given by *LuValle*, *Welsher* and *Svoboda* [22.11] and *Klinger* [22.9]. Under a SAFT model and a log-location-scale distribution with parameters μ and σ for $T(\text{temp}_U)$, $T(\text{temp})$ at any temp also has a log-location-scale distribution with the same σ and

$$\mu = \mu_U - \log\left[\mathcal{AF}(\text{temp})\right] = \beta_0 + \beta_1 x,$$

where $x = 11605/(\text{tempK})$, $x_U = 11605/(\text{temp}_U\text{K})$, $\beta_1 = E_a$, $\beta_0 = \mu_U - \beta_1 x_U$, and μ_U is the location parameter of the distribution of $\log(T)$ at use conditions.

Linear Degradation Path Models for Reaction-Rate Acceleration

There are situations in which a linear model can be used to approximate degradation over time. For example, when $\mathcal{R}_U \times \mathcal{AF}(\text{temp}) \times t$ in (22.6) is small enough so that $\mathcal{D}(t)$ is small compared to $\mathcal{D}_\infty$, then

$$\begin{aligned}\mathcal{D}(t;\text{temp}) &= \mathcal{D}_\infty \times \left\{1 - \exp\left[-\mathcal{R}_U \times \mathcal{AF}(\text{temp}) \times t\right]\right\} \\ &\approx \mathcal{D}_\infty \times \mathcal{R}_U \times \mathcal{AF}(\text{temp}) \times t = \mathcal{R}_U^+ \times \mathcal{AF}(\text{temp}) \times t\,,\end{aligned}$$

where $\mathcal{R}_U^+ = \mathcal{D}_\infty \times \mathcal{R}_U$. There are also practical situations (e.g., wear of automobile tires) for which a linear path adequately approximates degradation over time. In this case, $\mathcal{D}(t;\text{temp}) = \mathcal{R}_U^+ \times \mathcal{AF}(\text{temp}) \times t$ where it is assumed that $\mathcal{D}(0;\text{temp}) = 0$ and that $\mathcal{R}_U^+ \times \mathcal{AF}(\text{temp})$ is the degradation rate at condition temp.

Again, failure occurs when $\mathcal{D}(t;\text{temp})$ reaches a critical level $\mathcal{D}_f$. The equation $\mathcal{D}(t;\text{temp}) = \mathcal{D}_f$ yields the lifetime at temp, $T(\text{temp}) = T(\text{temp}_U)/\mathcal{AF}(\text{temp})$ which, again, is in SAFT form. Thus, if $T(\text{temp})$ has a log-location-scale distribution, $\mu = \beta_0 + \beta_1 x$ and σ does not depend on x (where x has the same definition given in Sect. 22.3.3).

22.3.4 Models for Voltage and Voltage–Stress Acceleration

Voltage or voltage stress can also be used to accelerate degradation and hasten product failures. Voltage measures the amount of force needed to move an electric charge between two points. Such a flow of charges produces an electrical current. Voltage stress measures voltage per unit of thickness of a dielectric. For dielectric components (e.g., capacitors and insulators), chemical degradation reduces the dielectric strength over time. Also, stronger electric fields can accelerate the growth of discontinuities, electrochemical reactions, or electromechanical changes that cause failure.

Example 22.2: Accelerated Life Test of Insulation for Generator Armature Bars. *Doganaksoy* et al. [22.12] discuss an ALT for a new mica-based insulation design for generator armature bars GAB. Degradation of an organic binder in the insulation causes a decrease in voltage strength and this was the primary cause of failure in the insulation. The insulation was designed for use at a voltage stress of 120 V/mm. Voltage-endurance tests were conducted on 15 electrodes at each of five accelerated voltage levels between 170 V/mm and 220 V/mm (i. e., a total of 75 electrodes). Each test was run for 6480 h at which point 39 of the electrodes had not yet failed. Table 22.1 gives the data from these tests. The insulation engineers were interested in the 0.01 and 0.05 quantiles of lifetime at the use condition of

Table 22.1 GAB insulation data

Voltage stress (V/mm)	Lifetime (10^3 h)
170	15 censored[a]
190	3.248, 4.052, 5.304, 12 censored[a]
200	1.759, 3.645, 3.706, 3.726, 3.990, 5.153, 6.368, 8 censored[a]
210	1.401, 2.829, 2.941, 2.991, 3.311, 3.364, 3.474, 4.902, 5.639, 6.021, 6.456, 4 censored[a]
220	0.401, 1.297, 1.342, 1.999, 2.075, 2.196, 2.885, 3.019, 3.550, 3.566, 3.610, 3.659, 3.687, 4.152, 5.572

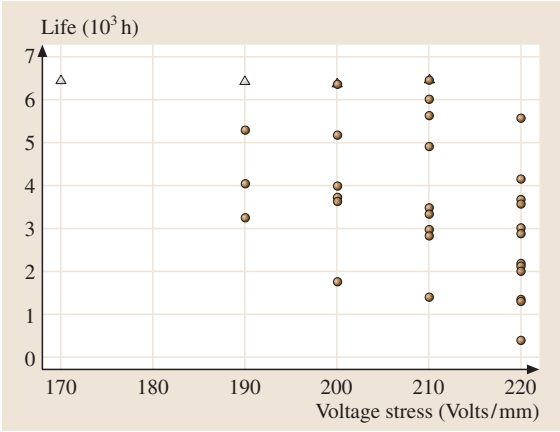

Fig. 22.2 GAB insulation data. Scatter plot of life versus voltage. Censored observations are indicated by Δ

120 V/mm. Figure 22.2 plots the insulation lifetimes against voltage stress.

Inverse Power Relationship

The inverse power relationship is frequently used to describe the effect that stresses like voltage and pressure have on lifetime. Voltage is used in the following discussion. When the thickness of a dielectric material or insulation is constant, voltage is proportional to voltage stress. Let volt denote voltage and let volt_U be the voltage at use conditions. The lifetime at stress level volt is given by

$$T(\text{volt}) = \frac{T(\text{volt}_\text{U})}{\mathcal{AF}(\text{volt})} = \left(\frac{\text{volt}}{\text{volt}_\text{U}}\right)^{\beta_1} T(\text{volt}_\text{U}) \ ,$$

where β_1, in general, is negative. The model has SAFT form with acceleration factor

$$\mathcal{AF}(\text{volt}) = \mathcal{AF}(\text{volt}, \text{volt}_\text{U}, \beta_1) = \frac{T(\text{volt}_\text{U})}{T(\text{volt})} = \left(\frac{\text{volt}}{\text{volt}_\text{U}}\right)^{-\beta_1} . \quad (22.7)$$

If $T(\text{volt}_\text{U})$ has a log-location-scale distribution with parameters μ_U and σ, then $T(\text{volt})$ also has a log-location-scale distribution with $\mu = \beta_0 + \beta_1 x$, where $x_\text{U} = \log(\text{volt}_\text{U})$, $x = \log(\text{volt})$, $\beta_0 = \mu_\text{U} - \beta_1 x_\text{U}$, and σ does not depend on x.

Example 22.3: Time Acceleration for GAB Insulation. For the GAB insulation data in Example 22.2, an estimate for β_1 is $\hat{\beta}_1 = -9$ (methods for computing such estimates are described and illustrated in Sect. 22.4). Recall that the design voltage stress is $\text{volt}_\text{U} = 120$ V/mm and consider testing at volt = 210 V/mm. Thus, using $\beta_1 = \hat{\beta}_1$, $\mathcal{AF}(210) = (210/120)^9 \approx 154$. Thus by increasing voltage stress from 120 to 210 V/mm, one estimates that lifetime is shortened by a factor of $1/\mathcal{AF}(210) \approx 1/154 = 0.0065$. Figure 22.3 plots $\mathcal{AF}$ versus volt for $\beta_1 = -7, -9, -11$. Using direct computations or from the plot, one obtains $\mathcal{AF}(210) \approx 50$ for $\beta_1 = -7$ and $\mathcal{AF}(210) \approx 471$ for $\beta_1 = -11$.

Motivation for the Inverse Power Relationship

The following description of a failure process that relates lifetime to pressure-like stresses, leading to the inverse power relationship, comes from *Meeker* and *Escobar* ([22.3], Sect. 18.4.3). Insulation units or specimens will have a characteristic dielectric strength $\mathcal{D}$. This property varies from unit to unit and degrades over time. When $\mathcal{D}$ degrades to the level of the applied voltage stress volt, a failure-causing event (e.g., short circuit or a flash-over) is triggered. Suppose one can express the dielectric strength at time t by $\mathcal{D}(t) = \delta_0 \times t^{1/\beta_1}$. Letting $\mathcal{D}(t) = \text{volt}$ and solving for t, $T(\text{volt}) = (\text{volt}/\delta_0)^{\beta_1}$. The acceleration factor for comparing lifetimes at volt and volt_U is

$$\mathcal{AF}(\text{volt}) = \mathcal{AF}(\text{volt}, \text{volt}_\text{U}, \beta_1) = \frac{T(\text{volt}_\text{U})}{T(\text{volt})} = \left(\frac{\text{volt}}{\text{volt}_\text{U}}\right)^{-\beta_1} ,$$

which agrees with (22.7).

The inverse power relationship can be used to describe cases for which the accelerating voltage increases the degradation rate. For example, suppose that degra-

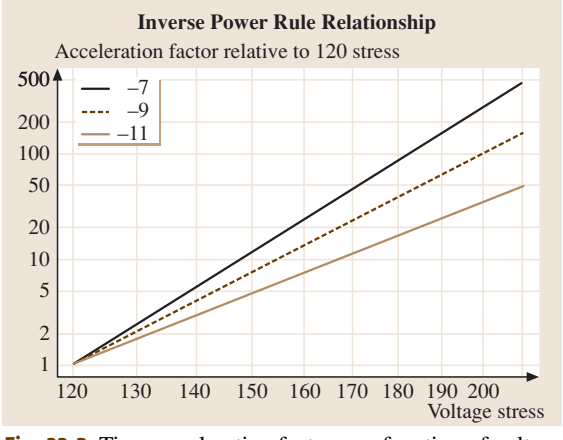

Fig. 22.3 Time-acceleration factor as a function of voltage stress and exponent $-\beta_1 = -7, -9, -11$

dation is more appropriately described by

$$\mathcal{D}(t) = \delta_0 \left[\mathcal{R}(\text{volt}) \times t\right]^{1/\gamma_1} ,$$

where $\mathcal{R}(\text{volt}) = \gamma_0 \exp\left[\gamma_2 \log(\text{volt})\right]$. Again, if failure occurs when $\mathcal{D}_\text{f} = \text{volt}$, then lifetime is

$$T(\text{volt}) = \frac{1}{\mathcal{R}(\text{volt})} \left(\frac{\text{volt}}{\delta_0}\right)^{\gamma_1} .$$

Then the acceleration factor is

$$\mathcal{AF}(\text{volt}) = \frac{T(\text{volt}_\text{U})}{T(\text{volt})} = \left(\frac{\text{volt}}{\text{volt}_\text{U}}\right)^{\gamma_2 - \gamma_1}$$

which is an inverse power relationship with $\beta_1 = \gamma_1 - \gamma_2$.

This discussion can be extended to other materials and products such as filaments of light bulbs, capacitors, roller bearings, and ball bearings. The inverse power relationship has also been used with other accelerating factors such as loading stress, cycling rate, humidity, and pressure.

22.3.5 Models for Two-or-More-Variable Acceleration

Some ALTs use two or more accelerating variables that affect the degradation process. In comparison with single-variable ALTs, in some situations, the degradation rate can be increased more effectively when two or more variables are used to accelerate the test. Many ALTs use temperature in combination with another environmental condition such as pressure, voltage, and humidity. The rest of this section describes models for these ALTs.

Extending the Arrhenius Relationship

Recall the Arrhenius equation (22.3), which gives the rate of a chemical reaction as a function of temperature. Suppose that X represents a non-thermal accelerating variable. A model for reaction rate in this situation is

$$\mathcal{R}(\text{temp}, X) = \gamma_0 \times \exp\left(\frac{-\gamma_1}{k_\text{B} \times \text{temp K}}\right) \times \exp\left(\gamma_2 X + \frac{\gamma_3 X}{k_\text{B} \times \text{temp K}}\right) , \quad (22.8)$$

where the parameters $\gamma_1 = E_\text{a}$ (the effective activation energy), γ_0, γ_2, and γ_3 are specific properties of the failure-causing chemical reaction. In (22.8), the ratio $\gamma_3 X/(k_\text{B} \times \text{temp K})$ represents possible interaction between the two accelerating variables. This model could be further extended by adding appropriate factors for other explanatory variables to the right-hand side of (22.8).

Using a SAFT formulation, one can equivalently express the extended Arrhenius relationship (22.8) in terms of the acceleration factor given by

$$\mathcal{AF}(\text{temp}, X) = \frac{\mathcal{R}(\text{temp}, X)}{\mathcal{R}(\text{temp}_\text{U}, X_\text{U})} . \quad (22.9)$$

When $T(\text{temp}_\text{U}, X_\text{U})$ has a log-location-scale distribution, (22.1), (22.8) and (22.9) imply that $T(\text{temp}, X)$ also has a log-location-scale distribution with

$$\begin{aligned}\mu &= \mu_\text{U} - \log[\mathcal{AF}(\text{temp}, X)] \\ &= \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_1 x_2 ,\end{aligned} \quad (22.10)$$

where $\beta_1 = E_\text{a}$, $\beta_2 = -\gamma_2$, $\beta_3 = -\gamma_3$, $x_1 = 11605/(\text{temp K})$, $x_2 = X$, $\beta_0 = \mu_\text{U} - \beta_1 x_{1\text{U}} - \beta_2 x_{2\text{U}} - \beta_3 x_{1\text{U}} x_{2\text{U}}$, and σ does not depend on the explanatory variables (temp, X).

Temperature–Voltage Acceleration Models

There has been a variety of approaches that have been used to model the combination of temperature and voltage acceleration. For instance, *Meeker* and *Escobar* ([22.3], Sect. 17.7) analyzed data from a study relating voltage and temperature to the failure of glass capacitors. They modeled the location parameter of log lifetime as a simple linear function of temp °C and volt. The extended Arrhenius relationship in Sect. 22.3.5 can also be used with $X = \log(\text{volt})$, as in *Boyko* and *Gerlach* [22.13]. *Klinger* [22.14] modeled the *Boyko* and *Gerlach* [22.13] data by including second-order terms for both accelerating variables.

To derive the time-acceleration factor for the extended Arrhenius relationship with temp and volt, one can follow steps analogous to those outlined in Sect. 22.3.4. Using the dielectric strength (degradation path) model at time t, $\mathcal{D}(t) = \delta_0 \left[\mathcal{R}(\text{temp}, \text{volt}) \times t\right]^{1/\gamma_1}$. Using (22.8) with $X = \log(\text{volt})$, we obtain

$$\mathcal{R}(\text{temp}, \text{volt}) = \gamma_0 \times \exp\left(\frac{-E_\text{a}}{k_\text{B} \times \text{temp K}}\right) \times \exp\left[\gamma_2 \log(\text{volt}) + \frac{\gamma_3 \log(\text{volt})}{k_\text{B} \times \text{temp K}}\right] .$$

Again, failure occurs when the dielectric strength crosses the applied voltage stress, that is, $\mathcal{D}(t) = \text{volt}$. This occurs at time

$$T(\text{temp}, \text{volt}) = \frac{1}{\mathcal{R}(\text{temp}, \text{volt})} \left(\frac{\text{volt}}{\delta_0}\right)^{\gamma_1} .$$

From this, one computes

$$\mathcal{AF}(\text{temp, volt}) = \frac{T(\text{temp}_U, \text{volt}_U)}{T(\text{temp, volt})} = \exp[E_a(x_{1U} - x_1)] \times \left(\frac{\text{volt}}{\text{volt}_U}\right)^{\gamma_2-\gamma_1} \times \{\exp[x_1 \log(\text{volt}) - x_{1U} \log(\text{volt}_U)]\}^{\gamma_3}.$$

where $x_{1U} = 11605/(\text{temp}_U\,\text{K})$ and $x_1 = 11605/(\text{temp K})$. When $\gamma_3 = 0$, there is no interaction between temperature and voltage. In this case, $\mathcal{AF}(\text{temp, volt})$ can be factored into two terms, one that involves temperature only and another term that involves voltage only. Thus, if there is no interaction, the contribution of temperature (voltage) to acceleration is the same at all levels of voltage (levels of temperature).

Temperature–Current Density Acceleration Models

d'Heurle and *Ho* [22.15] and *Ghate* [22.16] studied the effect of increased current density (A/cm^2) on electromigration in microelectronic aluminum conductors. High current densities cause atoms to move more rapidly, eventually causing extrusion or voids that lead to component failure. ATs for electromigration often use increased current density and temperature to accelerate the test. An extended Arrhenius relationship could be appropriate for such data. In particular, when T has a log-location-scale distribution, then (22.10) applies with $x_1 = 11605/\text{temp K}$, $x_2 = \log(\text{current})$. The model with $\beta_3 = 0$ (without interaction) is known as Black's equation (*Black* [22.17]).

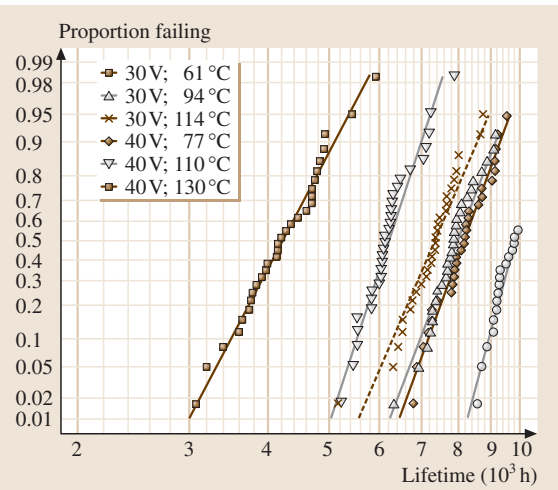

Fig. 22.4 LED device data. Lognormal multiple probability plot with lognormal ML fits for each combination of voltage/temperature

Example 22.4: Light Emitting Device (LED) Example. A degradation study on a light emitting device LED was conducted to study the effect of current and temperature on light output. A unit was said to have failed if its output was reduced to 60% of its initial value. Two levels of current and six levels of temperature were used in the test. Figure 22.4 is a probability plot of lifetimes for each combination of current and temperature. The plot suggests that the lognormal distribution is an appropriate distribution for lifetime and that increasing either temperature or current results in shorter device life.

Temperature–Humidity Acceleration Models

Relative humidity is another environmental variable that can be combined with temperature to accelerate corrosion or other chemical reactions. Examples of applications include paints and coatings, electronic devices and electronic semiconductor parts, circuit boards, permalloy specimens, foods, and pharmaceuticals. Although most ALT models that include humidity were derived empirically, some humidity models have a physical basis. For example, *Gillen* and *Mead* [22.18] and *Klinger* [22.19] studied kinetic models relating aging with humidity. *LuValle* et al. [22.20] provided a physical basis for studying the effect of humidity, temperature, and voltage on the failure of circuit boards. See *Boccaletti* et al. [22.21], *Nelson* ([22.1], Chapt. 2) *Joyce* et al. [22.22], *Peck* [22.23], and *Peck* and *Zierdt* [22.24] for ALT applications involving temperature and humidity.

The extended Arrhenius relationship (22.10)) applied to ALTs with temperature and humidity uses $x_1 = 11605/\text{temp K}$, $x_2 = \log(\text{RH})$, and $x_3 = x_1 x_2$, where RH is a proportion denoting relative humidity. The case when $\beta_3 = 0$ (no temperature–humidity interaction) is known as Peck's relationship and was used by Peck [22.23] to study failures of epoxy packing. Klinger [22.19] suggested the term $x_2 = \log[\text{RH}/(1 - \text{RH})]$ instead of $\log(\text{RH})$. This alternative relationship is based on a kinetic model for corrosion.

The Eyring Model

Fundamental work on the relationship between reaction rates and temperature, in combination with other variables, was done by Eyring in a number of important works (*Eyring*, *Gladstones*, and *Laidler* [22.25] and *Eyring* [22.26]). The Eyring model is the same as the extended Arrhenius model described in this section, except

that it has an additional factor $g(\text{temp K})$ outside of the exponential in (22.8). Usually, $g(\text{temp K}) = (\text{temp K})^p$ is used. For the purposes of using a fitted acceleration model to predict life at use conditions, for any practical values of the model parameters, this extra factor and estimating p along with E_a have no perceptible effect on the prediction. Thus the simpler Arrhenius model is what is generally used in practice. See *Meeker* and *Escobar* ([22.3], Sect. 18.3.2) and the above references for more information on the Eyring model.

22.3.6 Guidelines and Issues for Using Acceleration Models

The main objective of AT is to collect data at high levels of accelerating variables and extrapolate the results to use conditions. This section provides some guidelines and lists some common issues that arise in fitting acceleration models to ALT data.

- Whenever possible, the acceleration model should have a basis in physical or chemical theory. A careful review of previous theoretical and empirical work will often shed light on which environmental factors and degradation processes are relevant to a failure mechanism. It is highly recommended that a group of experts oversee the entire project of planning, collecting and analyzing AT data. This group should include experts with a clear understanding of the mechanical, physical and chemical nature of how the product degrades and eventually fails. This team should also include someone who is knowledgeable of the statistical aspects of planning life tests and analyzing the resulting data.
- ATs often assume a relatively simple failure mechanism or degradation process. It is possible at high levels of an accelerating variable to introduce new failure mechanisms. Acceleration could also alter other environmental factors that affect the failure mechanism. For example, *Meeker* and *Escobar* ([22.3], page 526) pointed out that ALT tests of circuit packs at higher temperatures reduced humidity, causing fewer failures than expected. Potential scenarios like these should be considered for both planning and modeling ATs.
- The main difficulty with extrapolation in ATs is that there is rarely sufficient data at lower levels of the accelerating variable to verify that the acceleration model for the failure mechanism still holds at use conditions. Thus, a good test plan minimizes the amount of acceleration while providing a statistically efficient description of the failure mechanism at use conditions. There is a large amount of work that has been done on ALT planning. For an overview of this work, see, for example, *Nelson* ([22.1], Chapt. 6) and *Meeker* and *Escobar* ([22.3], Chapt. 20 and Sect. 22.5).
- The statistical analysis of ALT data depends importantly on the acceleration model and distribution assumptions. A sensitivity analysis should be conducted to study how results (e.g., quantile and failure probability estimates) vary with changes in the assumed model and distribution. The results of such sensitivity analyses can help decision-makers understand whether model assumptions are conservative or not.

22.4 Analysis of Accelerated Life Test Data

This section discusses the statistical analysis of ALT data. First, we outline a useful strategy to follow when choosing and fitting a model to ALT data and assessing the adequacy of the fit. Then we illustrate the proposed strategy with several different ALT applications having either one or two accelerating variables.

22.4.1 Strategy for ALT Data Analysis

This section outlines some guidelines for analyzing ALT data. Suppose that groups of data were collected under several individual conditions (levels or level combinations of the accelerating variables).

1. Make a scatter plot of the lifetimes versus the explanatory variable(s) to help in the identification of an appropriate relationship or model.
2. For each individual condition, make a probability plot (*Meeker* and *Escobar*, [22.3], Chapts. 6 and 21) of the data under candidate distributions and obtain ML estimates of the parameters. A distribution provides a good fit if the plotted points fall roughly along a straight line. Check the constant-σ assumption visually by comparing the slopes of the lines in

the probability plots and statistically by comparing the estimates of σ.

3. Fit a model constraining σ to be the same at each level and compare with the unconstrained model in Step 3. This provides the basis for a formal test of constant σ.
4. Based on the previous steps, choose and fit and overall model (distribution and acceleration model).
5. Compare the overall model fit in Step 4 to the common-σ model fit in Step 3. Large discrepancies between these two models suggest an inadequate fit for the overall model.
6. Use diagnostics such as residual plots to assess the fit of the overall model and to check the model assumptions.

22.4.2 Data Analysis with One Accelerating Variable

This section describes the analysis of several different kinds of ALT data sets, following and illustrating the ALT analysis strategy outlined in Sect. 22.4.1.

ALT Data Scatter Plot

The first step is to make a scatter plot of the data and study how the accelerating variable affects the lifetime. Use a different plotting symbol to indicate censored observations.

Example 22.5: Scatter Plot of the GAB Insulation Data. Example 22.2 described a generator armature bar insulation ALT. A scatter plot of the data, given in Fig. 22.2, suggests a downward trend in lifetime as voltage stress is increased. There was heavy censoring at the lower voltage stresses. In particular, 8 out of 12 units failed at 190 V/mm and none of the 12 units failed at 170 V/mm.

Multiple Probability Plots at Individual Conditions of the Accelerating Variable

For each level (individual condition) of the accelerating variable(s), compute a nonparametric estimate of the fraction failing as a function of time and plot it on probability paper for a suggested lifetime distribution. The distribution adequately describes the data if, for each individual condition, the points lie close to a straight line. ML can be used to fit a line through the points at each level. A multiple probability plot showing these nonparametric estimates and fitted lines for all of the levels of the accelerating variable provides a convenient visual assessment of the constant-σ assumption. If the assumption is reasonable, the lines will be approximately parallel. Repeat this for different lifetime distributions.

Example 22.6: Probability Plots at Individual Conditions for the GAB Insulation Data. Figures 22.5 and 22.6 give lognormal and Weibull multiple probability plots, respectively, for the GAB insulation data. There is nothing plotted for 170 V/mm because there were no failures at this level of voltage stress. The points for each voltage stress level fall roughly along a straight line, and the lines appear to be reasonably parallel (but more parallel with the Weibull distribution). It appears that both the Weibull and the lognormal distributions pro-

	Parameter	ML estimate	Standard error	Normal-approximation 95% confidence interval
190	μ	2.49	0.44	[1.63, 3.35]
	σ	0.42	0.23	[0.14, 1.26]
200	μ	2.07	0.20	[1.68, 2.45]
	σ	0.45	0.16	[0.23, 0.89]
210	μ	1.74	0.13	[1.49, 2.00]
	σ	0.44	0.11	[0.26, 0.73]
220	μ	1.17	0.11	[0.94, 1.39]
	σ	0.42	0.09	[0.28, 0.64]

The individual maximum log likelihoods were $\mathcal{L}_{190} = -12.31$, $\mathcal{L}_{200} = -22.09$, $\mathcal{L}_{210} = -27.54$, and $\mathcal{L}_{220} = -25.05$. The total log likelihood for this model is $\mathcal{L}_1 = -86.99$

vide adequate descriptions of the GAB data. At each level of voltage stress, the Weibull distribution is fitted to the data, and estimates of μ and σ were computed by using the method of ML. Table 22.2 gives the ML estimates of μ and σ for each level of voltage stress. Table 22.2 also provides approximate standard errors and normal-approximation-based confidence intervals. The lines drawn in Fig. 22.6 represent the ML estimates of the individual CDFs (fraction failing) at each level of voltage stress.

The ML estimates of σ for all levels of voltage stress are similar. The similarities are reflected in the near-parallel CDF lines drawn in Fig. 22.6. Although details are not shown here, the maximum total log likelihood value achieved by fitting Weibull distributions with common σ (the location parameters are allowed to float) to each individual condition is $\mathcal{L}_2 = -87.01$ which is very close to the total log-likelihood $\mathcal{L}_1 = -86.99$ obtained from fitting separate Weibull distributions. This suggests that it is reasonable to assume that σ is constant across voltage stresses.

Maximum Likelihood Estimate of the ALT Model

The inverse power relationship is often used to relate the lifetime distribution of a dielectric to voltage stress. Suppose that $T(\text{volt})$, the lifetime at volt, has a log-location-scale distribution with parameters (μ, σ) and that σ does not depend on volt. Under the inverse power relationship, $\mu = \beta_0 + \beta_1 x$ where $x = \log(\text{volt})$. Fitting the model to data is accomplished by computing estimates for the parameters β_0, β_1, and σ.

Example 22.7: Maximum Likelihood Estimate of the Inverse Power Model for the GAB Insulation Data. The results of fitting the inverse power relationship Weibull model to the data are summarized in Table 22.3. A likelihood ratio test comparing with the constant-σ/floating-μ model allows a formal assessment of whether the inverse power relationship is consistent with the data. Fitting the inverse power relationship with constant σ also allows extrapolation to the use level of 120 V/mm.

Suppose that model B is obtained by imposing constraints on the parameters of model A (e.g., the constraint that the location parameters at different levels of voltage stress are related by the inverse power relationship). For $i = \text{A, B}$, let $\mathcal{L}_i$ be the maximum total log likelihood achieved by fitting model i to the data. If model B is the correct model, in large samples, the likelihood ratio statistic $\mathcal{W} = 2 \times (\mathcal{L}_\text{A} - \mathcal{L}_\text{B})$ has a χ^2_ν distribution with degrees of freedom ν equal to the difference between the number of estimated model parameters in the two models. Large values of $\mathcal{W}$ indicate evidence against the constrained model model B, relative to the

Table 22.3 GAB insulation data. ML estimates for the inverse power relationship Weibull regression model

Parameter	ML estimate	Standard error	Normal-approximation 95% confidence interval
β_0	53.39	9.46	[34.84, 71.93]
β_1	−9.68	1.77	[−13.14, −6.21]
σ	0.44	0.06	[0.33, 0.58]

The maximum log likelihood for this model is $\mathcal{L}_3 = -87.72$

unconstrained model A. The difference is statistically important at the α level if $\mathcal{W} \geq \chi^2_{(1-\alpha;\nu)}$ where $\chi^2_{(1-\alpha;\nu)}$ is the $(1-\alpha)$ quantile of the χ^2_ν distribution.

For the GAB insulation data, model A is the (unconstrained) set of Weibull distributions with common σ (five parameters), and model B is the (constrained) inverse power relationship Weibull model (three parameters). Then $\mathcal{L}_A = \mathcal{L}_2 = -87.01$, $\mathcal{L}_B = \mathcal{L}_3 = -87.72$, and $\mathcal{W} = 1.42 < \chi^2_{(0.95;2)} = 5.99$. Thus, the difference between the fits is not statistically important at the 0.05 level and the data do not provide evidence against model B.

The maximum log likelihood value attained with the lognormal distribution is -89.52, which is close to $\mathcal{L}_3 = -87.72$ for the Weibull distribution. Again, as noted earlier with the probability plots, both the Weibull and lognormal models fit the data well.

Figure 22.7 is a probability plot showing the ML fit of the inverse power relationship Weibull model to the data. It also gives the ML estimate of the fraction failing at use conditions $\text{volt}_U = 120\,\text{V/mm}$. The dashed lines give pointwise normal-approximation 95% confidence intervals for the fraction failing at use conditions. Conversely, this plot can be used to obtain an estimate and an approximate confidence interval for specified quantiles at use conditions. Figure 22.8 is a scatter plot of the GAB data with ML estimates of the 0.1, 0.5, and 0.9 quantiles at all levels of voltage stresses between 120 and 220 V/mm. The horizontal line indicates the censoring time at 6480 h. Densities (smallest extreme-value densities because time is plotted on a log scale) are shown at the voltage stresses in the experiment as well as at the use condition of 120 V/mm. Figure 22.8 suggests that it is unlikely that one would observe any failures below 170 V/mm during the ALT experiment.

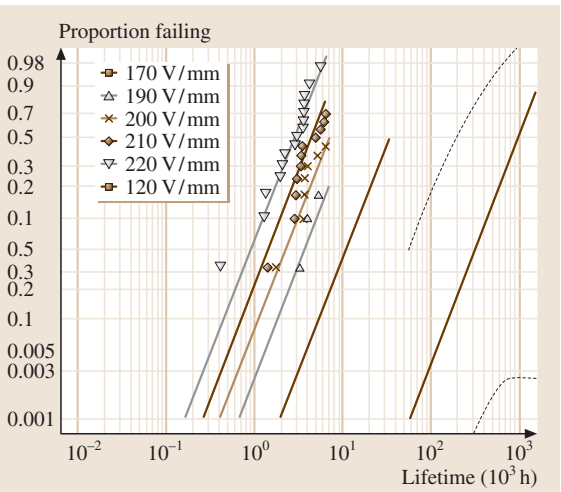

Fig. 22.7 GAB insulation data. Weibull multiple probability plot depicting the inverse power relationship Weibull regression model ML fit

Assessing Statistical Uncertainty

An estimate of the variance–covariance matrix for the ML estimates $\hat{\boldsymbol{\theta}} = (\hat{\beta}_0, \hat{\beta}_1, \hat{\sigma})'$ is

$$\widehat{\sum}_{\hat{\theta}} = \begin{pmatrix} 89.52 & -16.73 & 0.27 \\ -16.73 & 3.13 & -0.05 \\ 0.27 & -0.05 & 0.004 \end{pmatrix} . \qquad (22.11)$$

The elements of this matrix are used to compute normal-approximation confidence intervals, as described in Example 22.9. This matrix is usually available (at least as an option) as output from computer software and is useful for computing the variance of functions of the parameters (e.g., quantiles and fraction failing estimates) that may be of interest. In modern software for life data analysis, however, such computations are easy to request and printing the variance–covariance matrix is often suppressed by default.

Diagnostics and Assessing Fit of ALT Model to Data

Plots like Figs.22.7 and 22.8 can be used to assess the fit of a model to a set of data. Graphical analyses of the standardized residuals, $\exp[\log(t) - \hat{\mu}]/\hat{\sigma}$, provide additional diagnostics for judging model adequacy.

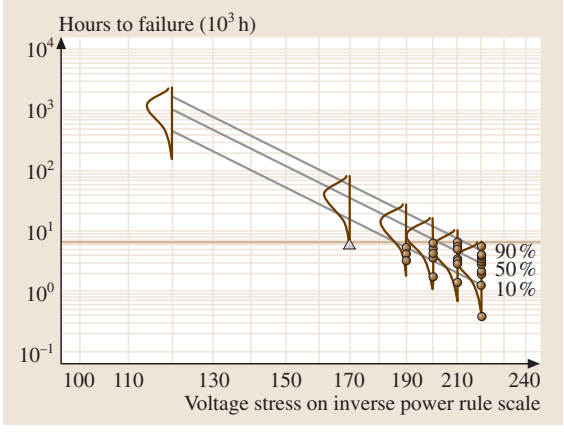

Fig. 22.8 GAB insulation data. Scatter plot showing hours to failure versus voltage stress (log–log scales) and the inverse power relationship Weibull regression model fit. Censored observations are indicated by Δ

Residuals can be plotted against the order of the test runs, fitted values, and levels of explanatory variables that are or are not in the fitted model. It is necessary to take into account the amount of censoring during interpretation. An overall assessment of the distributional assumption can be obtained by using a probability plot of the residuals.

Example 22.8: Residuals Plots for the Inverse Power Relationship Weibull Model Fit to the GAB Insulation Data. Figure 22.9 plots residuals versus fitted values. The vertical axis shows the standardized residuals. The horizontal lines are the 0.05, 0.50, and 0.95 quantiles of a standard exponential distribution (e.g., $-\log(1-0.95) = 2.996$ is the 0.95 quantile of this distribution). For the Weibull distribution, the residuals should have an approximate standard Weibull ($\mu = 0, \sigma = 1$) distribution (which is left-skewed). Thus, the Weibull distribution is appropriate if the residuals have a long lower tail. At 210 V/mm, where all of the test units failed, the residuals (first column of points in Fig. 22.9) indicate a left-skewed distribution about the center line, indicating no lack of fit of the Weibull distribution. The interpretation of the residuals is not as simple for the levels 170, 190, 200, and 210 V/mm (the last four columns of points in Fig. 22.9) because all of these levels resulted in some censored observations. The triangles (△) in Fig. 22.9 indicate lower bounds for residuals for these censored observations (i. e., the actual unobserved residuals corresponding to these points would be larger than the plotted triangles). With this in mind, there is no strong evidence of lack of fit of the Weibull distribution at these levels. Figure 22.10 is a Weibull probability plot of the residuals for all failures. The residuals fall close to a straight line, which suggests that there is no problem with the Weibull assumption.

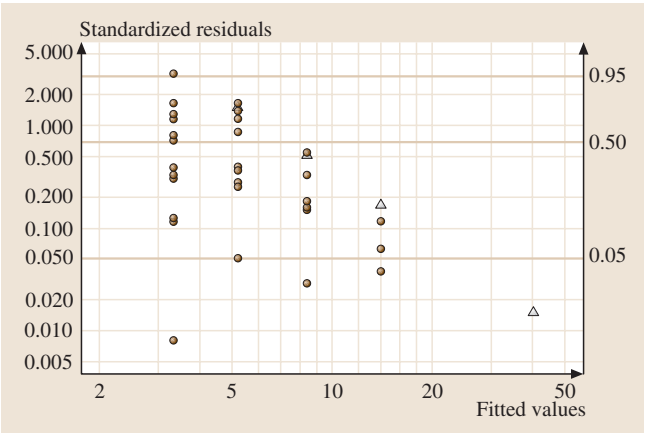

Fig. 22.9 GAB insulation data. Plot of standardized residuals versus fitted values for the inverse power relationship Weibull regression model. Censored observations are indicated by Δ

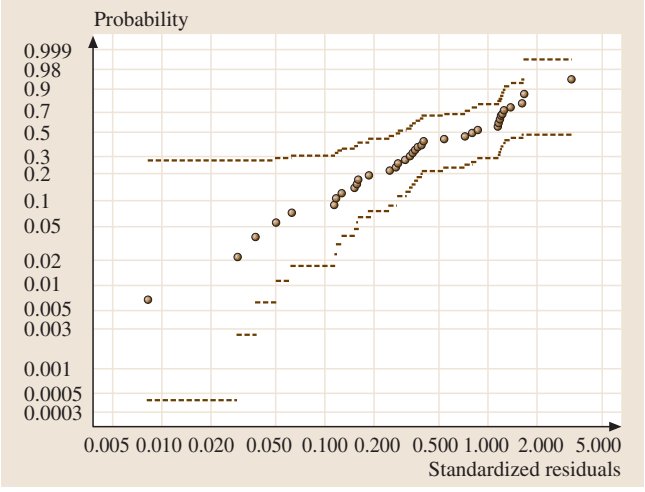

Fig. 22.10 GAB insulation data. Weibull probability plot of the standardized residuals from the inverse power relationship Weibull regression model fit

Estimation at Use Conditions and Sensitivity to Model Assumptions

It is important to quantify the statistical uncertainty in estimates from an ALT. Here, we illustrate the computation of normal-approximation confidence intervals for quantiles. See Sect. 17.4.2 of *Meeker* and *Escobar* [22.3] for a more general discussion of the methodology. The following example also contains a sensitivity analysis of the estimates with respect to the assumed distribution.

Example 22.9: ML Estimates and Confidence Intervals for Quantiles for the GAB Insulation Data Life Distribution. For the GAB experiment, it was of interest to estimate the 0.01 and 0.05 quantiles of insulation life at the 120 V/mm use condition. The ML estimate of the location parameter at 120 V/mm, computed from the ML estimates for the parameters in Table 22.3, is

$$\hat{\mu} = \hat{\beta}_0 + \hat{\beta}_1 x = 53.39 - 9.68 \log(120) = 7.07 \,.$$

The ML estimate of the log p quantile is

$$\begin{aligned} \log(\hat{t}_p) &= \hat{\mu} + \log[-\log(1-p)]\,\hat{\sigma} \\ &= 7.07 + \log[-\log(1-p)] \times 0.44 \end{aligned}$$

Table 22.4 GAB insulation data. Quantiles ML estimates at 120 V/mm

Distribution	Quantile	ML estimate	Normal-approximation 95% confidence interval
Weibull	t_{01}	154.6×10^3 h	[26.4, 907.4] $\times 10^3$ h
		17.7 y	[3.0, 103.6] y
	t_{05}	317.0×10^3 h	[51.4, 1953.0] $\times 10^3$ h
		36.2 y	[5.9, 223.0] y
Lognormal	t_{01}	254.4×10^3 h	[43.4, 1492.9] $\times 10^3$ h
		29.1 y	[5.0, 170.0] y
	t_{05}	390.8×10^3 h	[63.4, 240.9] $\times 10^3$ h
		44.6 y	[7.0, 27.5] y

with an estimated standard error $\widehat{\text{se}}_{\log(\widehat{t}_p)} = \sqrt{\widehat{\text{Var}}_{\log(\widehat{t}_p)}}$ $= \sqrt{\boldsymbol{c}' \widehat{\sum}_{\widehat{\boldsymbol{\theta}}} \boldsymbol{c}}$, where $\boldsymbol{c} = \{1, \log(\text{volt}), \log[-\log(1-p)]\}'$ and $\widehat{\sum}_{\widehat{\boldsymbol{\theta}}}$ is given in (22.11). A $100(1-\alpha)\%$ normal-approximation confidence interval for t_p is

$$\exp\left[\log(\widehat{t}_p) \pm z_{(1-\alpha/2)} \times \widehat{se}_{\log(\widehat{t}_p)}\right] = \widehat{t}_p \exp\left(\pm z_{(1-\alpha/2)} \times \widehat{se}_{\log(\widehat{t}_p)}\right) ,$$

where z_γ is the γ quantile of the standard normal distribution. Table 22.4 gives the ML estimates and 95% confidence intervals for the 0.01 and 0.05 quantiles at 120 V/mm. the data that was almost as good as the fit with the Weibull distribution. Table 22.4 also includes quantile estimates for the lognormal distribution. Although the differences between the Weibull and lognormal distribution point estimates may be judged to be large, the confidence interval for the quantile under one distribution contains the point estimate under the other. The lognormal distribution quantile estimates are optimistic relative to those for the Weibull distribution.

22.5 Further Examples

This section illustrates the use of the statistical methods, outlined in Sect. 22.4, to various other ALT applications. The examples show the fit of ALT models to interval-censored data and reliability data with two or

Table 22.5 IC device data

Temperature (°C)	Time Bounds (h) Lower	Upper	Frequency	Censoring
150	788		1	Right
150	2304		49	Right
175	788		1	Right
175	2304		49	Right
200	788		1	Right

300	1536		5	Right

more explanatory variables. These examples illustrate a wider (but not exhaustive) range of data types that arise in practice, provide more insight into how to develop ALT models, address the goals and objectives of the experiment, and study the effect of model assumptions on these aims (sensitivity analyses).

22.5.1 Analysis of Interval Censored ALT Data

Interval-censored data are common in ALT studies. Constraints on resources limit the frequency of inspection times in tests. As a consequence, engineers often fail to observe failures instantaneously, and inspection times serve as bounds for lifetimes.

Example 22.10: Analysis of Integrated Circuit Device ALT Data. Table 22.5 gives the results of an ALT for an integrated circuit (IC) device at five different levels of junction temperature. Because the diagnostic testing of each device was expensive, each unit could only be inspected a few times during the ALT. Consequently, an observation was either interval-censored (bounds for lifetime were recorded) or right-censored (lower bound for lifetime was recorded). The engineers chose inspection times that were approximately equally spaced in log time. Tests were conducted at 150, 175, 200, 250, and 300 °C on a total of 250 devices (50 at each level of temperature).

The objectives of the ALT was to quantify the long-term reliability of the ICs and to estimate the effective activation energy of the failure mechanism. In particular, the engineers involved in the study wanted to assess the hazard rate and the fraction failing by 100 000 hours at the use junction temperature of 100 °C.

Figure 22.11 is a lognormal probability plot of the data at individual conditions. There are no plots for 150, 175, 200 °C because there were no failures at these levels of temperature. The ML results for estimating the lognormal parameters at individual temperatures are given in Table 22.6. The fitted CDF lines drawn in the plot appear to be reasonably parallel. Also, the ML estimates of σ and corresponding confidence intervals do not indicate evidence against the constant-σ assumption across temperature levels. Table 22.7 gives the ML results of fitting an Arrhenius lognormal model to the IC device data. An estimate of the effective activation energy is $\widehat{E}_a = \widehat{\beta}_1 = 0.94$.

Figure 22.12 is a probability plot depicting the ML fit of the Arrhenius lognormal model to the data. It also gives the ML estimate of the fraction failing at $\text{temp}_U = 100\,°\text{C}$ with pointwise normal-approximation 95% confidence intervals. Figure 22.12 plots the ML estimates of the 0.1, 0.5, and 0.9 quantiles with the data for temperatures between 100 and 300 °C. Even though there is a large amount of statistical uncertainty, Figs. 22.12 and 22.13 both suggest that it is very unlikely that failures would occur before 100 000 hours at $\text{temp}_U = 100\,°\text{C}$.

Observing failures at two or more levels of the accelerating variable is necessary to estimate the parameters of the Arrhenius relationship. There are situations in which the activation energy E_a is specified, based

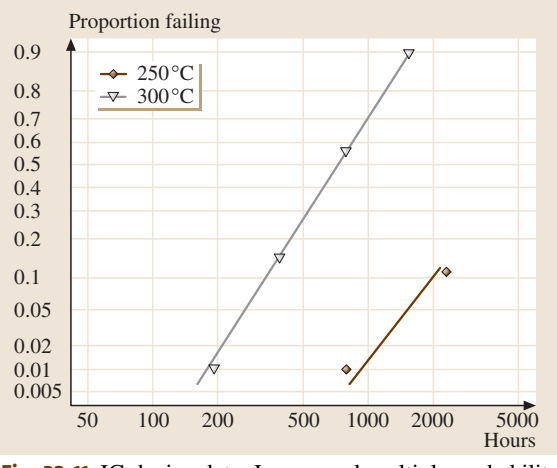

Fig. 22.11 IC device data. Lognormal multiple probability plot with individual lognormal ML fits for each temperature

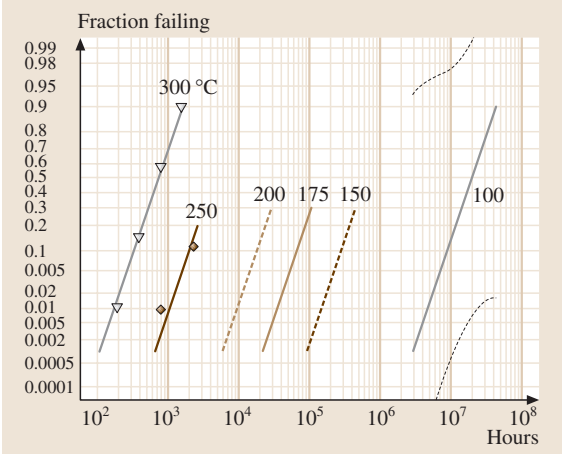

Fig. 22.12 IC device data. Lognormal multiple probability plot depicting the Arrhenius lognormal regression model ML fit

Table 22.6 IC device data. Lognormal ML estimates for each temperature

Temperature (°C)	Parameter	ML estimate	Standard error	Normal-approximation 95% confidence interval
250	μ	8.54	0.34	[7.87, 9.22]
	σ	0.74	0.25	[0.38, 1.43]
300	μ	6.58	0.20	[8.59, 9.36]
	σ	0.61	0.07	[0.48, 0.76]

The individual maximum log likelihoods were $\mathcal{L}_{250} = -26.11$ and $\mathcal{L}_{300} = -63.18$. The total log likelihood for this model is $\mathcal{L}_4 = -89.29$

Table 22.7 IC device data. ML estimates for the Arrhenius lognormal regression model

Parameter	ML estimate	Standard error	Normal-approximation 95% confidence interval
β_0	−12.45	1.95	[−16.26, −8.63]
β_1	0.94	0.09	[0.76, 1.12]
σ	0.62	0.07	[0.50, 0.77]

The maximum log likelihood for this model is $\mathcal{L}_5 = -89.45$

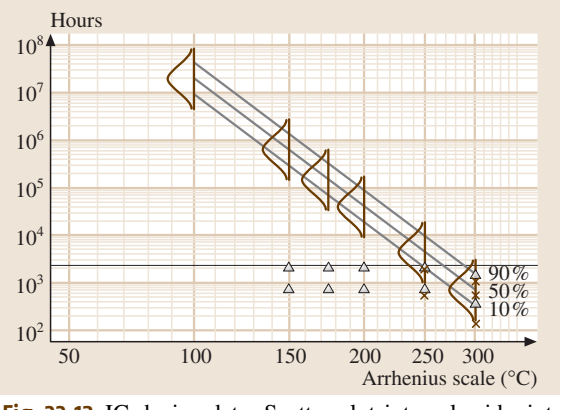

Fig. 22.13 IC device data. Scatter-plot interval midpoints failure versus °C (on an Arrhenius scale) and the Arrhenius lognormal regression model fit. Censored observations are indicated by Δ

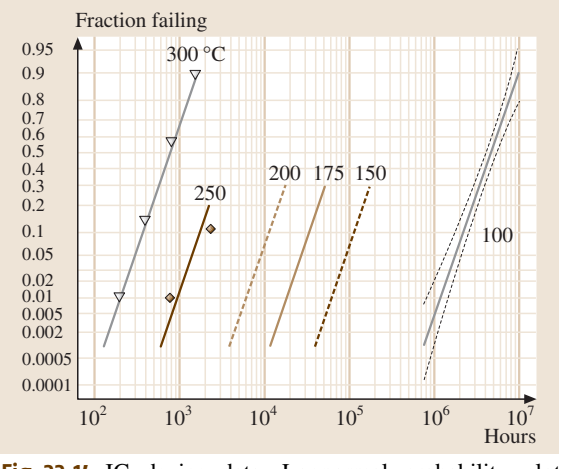

Fig. 22.14 IC device data. Lognormal probability plot showing the Arrhenius lognormal model ML estimates and 95% confidence intervals for $F(t)$ at 100 °C given $E_a = 0.8$ eV

on prior experience with the product, in which case only one temperature level with failures may suffice for estimation. For example, MIL-STD-883 [22.27] gives guidelines for conducting reliability demonstrations tests when E_a is given.

Example 22.11: Analysis of the IC Device Data when the Activation Energy is Given. Figure 22.14 is similar to Fig. 22.12, but obtained with $E_a = 0.8$ eV given. Now, the confidence intervals for the fraction failing at $\text{temp}_U = 100\,°\text{C}$ are much narrower than when E_a had to be estimated. This difference reflects a tremendous, probably unreasonable, gain in precision. Because there will be doubt about the actual value of E_a, one must exercise caution in interpreting such an analysis. Varying $\beta_1 = E_a$ over some plausible range of values provides a useful sensitivity analysis. Also a Bayesian analysis could be used when the uncertainty on E_a can be specified by a probability distribution (see *Meeker* and *Escobar* [22.3], Sect. 22.2).

22.5.2 Analysis of Data From a Laminate Panel ALT

A sample of 125 circular-holed notched specimens of a carbon eight-harness-satin/epoxy laminate panel were

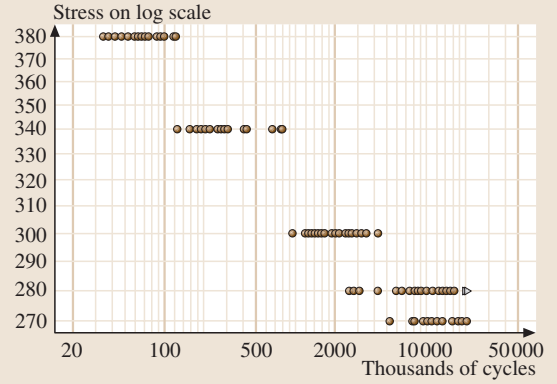

Fig. 22.15 Laminate panel data. Log–log scatter plot of life versus stress

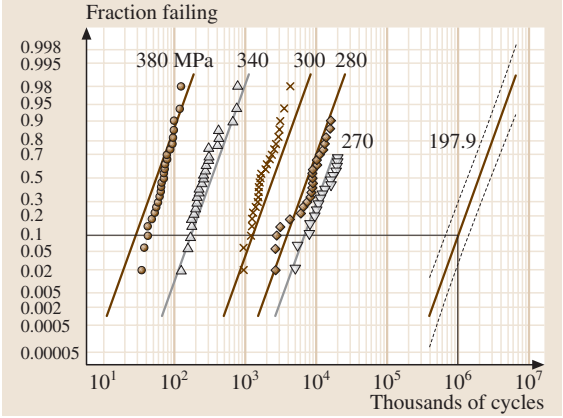

Fig. 22.16 Laminate panel data. Lognormal probability plot showing the inverse power relationship lognormal model ML fit and 95% confidence intervals for $F(t)$ at 197.9 MPa

subjected to a cyclic four-point out-of-plane bending at several levels of stress, measured in MPa. The data are from *Shimokawa* and *Hamaguchi* [22.28]. In these tests, final specimen fracture and fiber fracture occurred simultaneously. The lifetime of a specimen is the number of cycles to fracture. Figure 22.15 is a log–log scatter plot of the data. Note that the response (thousands of cycles) is plotted on the horizontal axis (the usual convention in the fatigue-fracture literature). Ten specimens were right-censored (two at 280 MPa and eight at 270 MPa). The goals of experiment were to estimate the relationship between life and stress (or the S–N curve) and a safe level of stress for a given life quantile. Figure 22.16 is a multiple lognormal probability plot of the data. The lognormal distribution appears to be appropriate here. Figure 22.15 indicates a strong linear correlation between log life and log stress. These plots suggest fitting a inverse power relationship lognormal model to the data.

Example 22.12: ML Estimate of the Inverse Power Relationship Lognormal Model for the Laminate Panel Data. For the inverse power relationship lognormal model, the parameters are $\mu = \beta_0 + \beta_1 x$ and σ, where $x = \log(\text{Stress})$. Table 22.8 gives the results of the ML estimation of β_0, β_1 and σ with the laminate panel data.

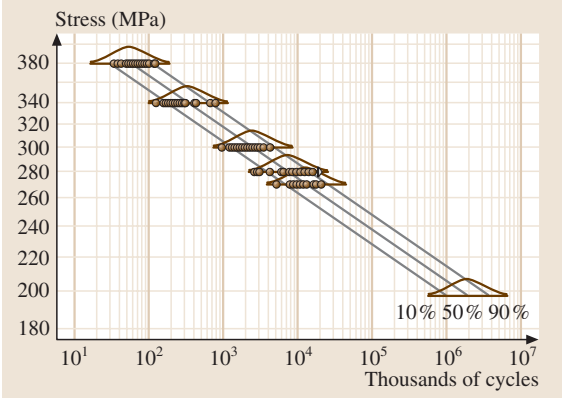

Fig. 22.17 Laminate panel data. Scatter-plot showing cycles to failure versus MPa (on a log scale) and the inverse power relationship lognormal regression model ML fit. Censored observations are indicated by Δ

Estimates of the fraction failing at the individual stress levels of the experiment are drawn in Fig. 22.16. Figure 22.17 is a scatter plot of the data with ML estimates of the 0.1, 0.5, and 0.9 quantiles. The confidence intervals for the life distribution at use conditions in this

Table 22.8 Laminate panel data. ML estimates for the inverse power relationship lognormal regression model

Parameter	ML estimate	Standard error	Normal-approximation 95% confidence interval
β_0	99.36	2.14	[95.16, 103.55]
β_1	−16.05	0.37	[−16.78, −15.32]
σ	0.52	0.04	[0.46, 0.60]
The maximum log likelihood for this model is $\mathcal{L}_6 = -898.3$			

example are much narrower, when compared to those for the IC device example shown in Fig. 22.12. This is because there is less censoring and less relative extrapolation in the inference for the laminate panel data. The median (0.50 quantile) life line in Fig. 22.17 provides the estimate of the S–N curve that was of interest to the engineers.

Example 22.13: Estimate of a Safe-Level Stress for the Laminate Panel Data. The engineers wanted to estimate a safe level of stress at which no more than 10% of the population of laminate panels would fail before 1 000 000 cycles. This involves determining the stress level at which the 0.10 quantile is 1 000 000 cycles. At any stress below this safe level of stress, the population fraction failing before 1 000 000 cycles will be more than 0.10. Using the inverse power relationship lognormal model, the safe stress level is

$$\text{safe stress} = \exp\left\{\left[\log\left(10^6\right) - 99.36 - \Phi_{\text{nor}}^{-1}(0.1) \times 0.52\right] / (-16.05)\right\} = 197.9\,\text{MPa}.$$

Figure 22.16 plots an estimate of the fraction failing (rightmost line) at this safe stress level. As seen in this plot, the stress 197.9 MPa is an extrapolation because the estimation is outside the range of the data. Of course, there is potential danger in making decisions based on this estimate, especially if the inverse power relationship lognormal model fails to hold below 270 MPa. Because the inverse power relationship is an empirical model and its use is based on past experience, it is important to perform a sensitivity analysis by computing safe-level estimates under alternative relationships. For example, the reciprocal relationship ($x = 1/\text{Stress}$) gives a model maximum log likelihood value of $\mathcal{L}_7 = -892.1$ which is larger than that from the inverse power relationship (indicating that the reciprocal model provides a better fit to the data). The estimate of the safe level of stress under the reciprocal relationship is equal to 216 MPa. This is larger (less conservative) than that under the inverse power relationship. Quantile estimates at a given stress level are also less conservative under the reciprocal relationship. That is, the estimates of life under the reciprocal relationship are longer than those under the inverse power relationship.

22.5.3 Analysis of ALT Data with Two or More Explanatory Variables

The single-variable analyses in Sects. 22.4, 22.5.1, and 22.5.2 can be extended to two or more variables (accelerated or otherwise). For example, ATs with multiple accelerating variables often use temperature in combination with humidity, pressure, and/or voltage. The goal of an AT may be to compare new and old product designs under different humidity levels, using temperature to accelerate the lifetimes. In this case, product design is a qualitative factor and the humidity range would mimic that seen in the actual application. This section illustrates the analysis of data from AT studies like these.

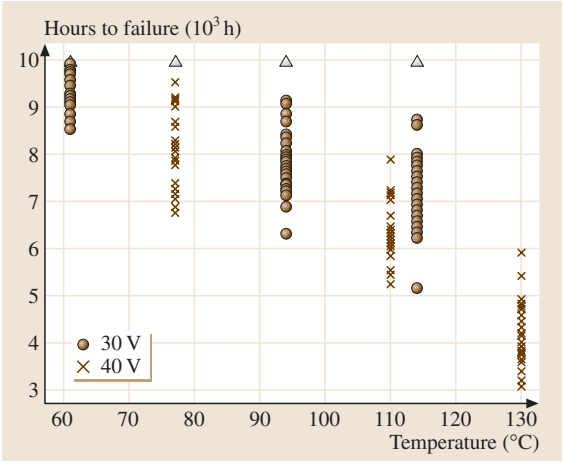

Fig. 22.18 LED device data. Scatter-plot showing hours to failure versus temperature with voltage indicated by different symbols. Censored observations are indicated by Δ

Example 22.14: Light Emitting Device Data with Accelerated Current and Temperature. Recall the LED device data from Example 22.4. The engineers were interested in the reliability of the LED at use conditions of 20 mA current and 40 °C temperature. Figure 22.18 plots the LED device data versus temperature for different levels of current. The plot suggests that failures occur earlier at higher levels of current or temperature.

The probability plot in Fig. 22.4 suggests that the lognormal distribution can be used to describe the lifetimes at each combination of current and temperature. Furthermore, because the lines are approximately parallel, it is reasonable to assume that σ is constant across individual conditions.

The inverse power (for current) and Arrhenius (for temperature) relationships are combined to model the effect that current and temperature have on lifetime. In particular, suppose that LED lifetime at volt and temp°C has a lognormal distribution with parameters μ given by

Main effects without interaction model:

$$\mu = \beta_0 + \beta_1 x_1 + \beta_2 x_2\,, \tag{22.12}$$

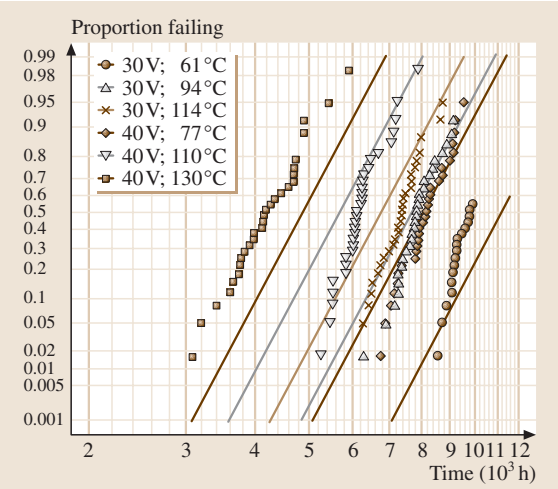

Fig. 22.19 LED device data. Multiple lognormal probability plot depicting the regression model (22.12) (without interaction) ML fit

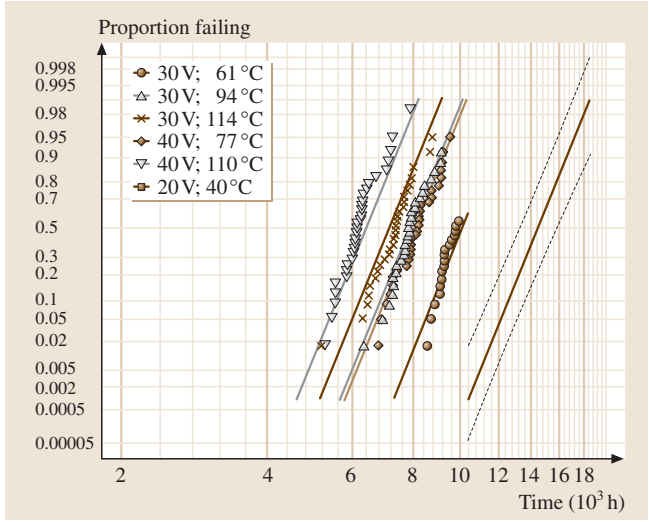

Fig. 22.20 LED device subset data. Multiple lognormal probability plot depicting the lognormal regression model (22.12) (without interaction) ML fit. The data at (40 V, 130 °C) were omitted

Main effects with interaction model:

$$\mu = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_1 x_2 \,, \qquad (22.13)$$

where $x_1 = \log(\text{volt})$, $x_2 = 11605/(\text{temp K})$, and $\beta_2 = E_a$, and σ does not depend on $\boldsymbol{x}$. Fitting the model with interaction to the data resulted in life estimates at use conditions that were shorter than those observed at the more stressful test conditions. The engineers were sure this was wrong. It turned out that the incorrect estimates were caused by the interaction term in the model. The interaction term lead to nonlinearity in the response surface and resulted in a saddle point in the surface relating μ to the transformed explanatory variables. Because this model gave nonsense results, it will not be considered any further.

The fit of the main-effects model without interaction reveals strong lack of fit at the high-level combination of volt = 40 and temp°C = 130. Figure 22.19 is a probability plot depicting the ML estimates of the fraction failing as a function of time at individual conditions. Observe that the true fraction failing as a function of time is underestimated throughout the range of data at volt = 40 and temp°C = 130. If the main-effects model were physically appropriate, it appears that it may not hold when both volt and temp are at these high levels, probably because a new failure mechanism is excited at those extreme conditions.

Table 22.9 provides the ML results for the inverse-power Arrhenius lognormal model after deleting the

	β_1	−3.96	1.21	[−6.33, −1.60]
	β_2	−0.31	0.13	[−0.57, −0.05]
	β_3	0.11	0.04	[0.04, 0.18]
	σ	0.10	0.006	[0.09, 0.12]

The maximum log likelihood values are $\mathcal{L}_8 = -173.5$ (main effects without interaction) and $\mathcal{L}_9 = -169.5$ (main effects with interaction model)

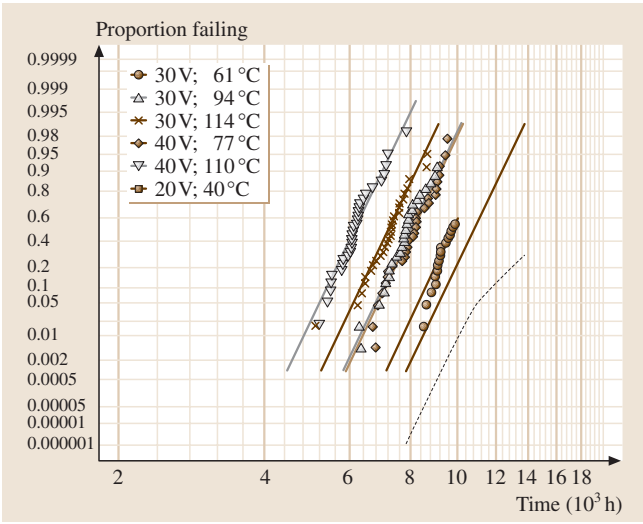

Fig. 22.21 LED device subset data. Multiple lognormal probability plot lognormal regression model (22.12) (with interaction) ML fit. The data at (40 V, 130 °C) were omitted

data at volt = 40 V and temp°C = 130 °C. Figure 22.20 shows a probability plot of the LED device subset data along with ML estimates of fraction failing as a function of time for the model without interaction.

Figure 22.20 is a lognormal probability plot of the LED device subset data along with ML estimates of fraction failing as a function of time. It also includes the ML estimate of the fraction failing as a function of time at the use conditions volt = 20 V and temp°C = 40 °C (the rightmost line). The dashed lines represent approximate 95% pointwise confidence intervals for the fraction failing as a function of time at these conditions. For this model there is much better agreement between the model and the data. Figure 22.21 is a similar multiple probability plot using the interaction model. Comparison of the models with and without the interaction term, after deleting the (40 V, 130 °C) condition, indicates some lack of fit for the model without interaction (compare the log likelihoods in Table 22.9). Predictions with the interaction model, however, are very pessimistic and much worse than had been expected by the engineers (though not as easily dismissed as the with the interaction model when fitted to the complete data set). The estimates at use conditions are highly sensitive to the model choice because of the rather large amount of extrapolation involved in computing the estimates. The engineers were uncertain as to the correct model, but felt that almost certainly the truth would lie between the two different fits shown in Figs. 22.20 and 22.21.

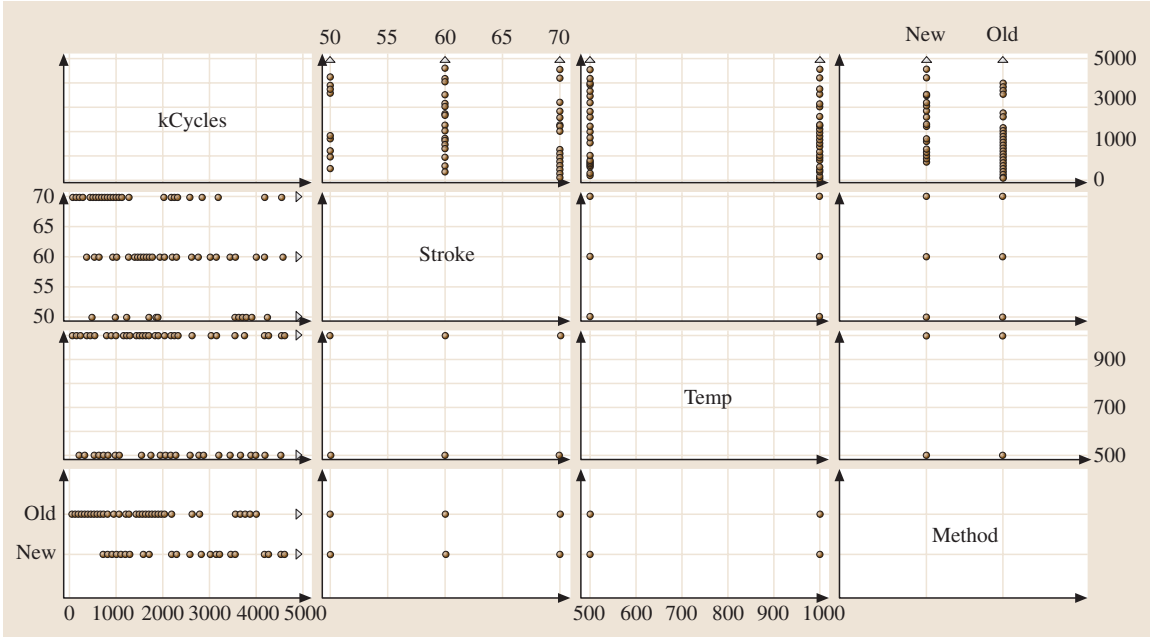

Fig. 22.22 Spring fatigue data. Scatter-plot matrix of the data

Example 22.15: An Accelerated Life Test for a Spring with Three Explanatory Variables. *Meeker*, *Escobar*, and *Zayac* [22.29] describe an experiment to compare old and new processing methods for manufacturing a spring. The experimenters used three variables, namely, stroke displacement (Stroke), processing method (Method), and temperature (temp). Springs were compressed cyclically and Stroke measured the distance that a spring was compressed. Stroke was the accelerating variable. Lifetime was measured in cycles to failure. The springs were designed to be used at Stroke= 20 mils (1 mil =1/1000 inch) and the nominal processing temperature was temp = 600 °F. The goals of the experiment were to compare the old and new processing methods, to see if temperature had an important effect on spring life, and to check if the B10 life (0.10 quantile) at use conditions was at least 500 000 kilocycles.

Meeker, *Escobar*, and *Zayac* [22.29] give the results from a 2×2×3 factorial with factors Stroke (50 mil, 60 mil, 70 mil), temp (500 °F, 1000 °F), and Method (Old, New). Each of the 12 factor combinations was replicated nine times for a total of 108 observations. All nine observations at Stroke= 60, temp = 500 °F, and Method= New were right-censored at 500 000 cycles. Figure 22.22 is a scatter-plot matrix of the Spring ALT data. It appears that on average, spring lifetimes are longer at shorter stroke, at lower temperature, and with the new processing method, respectively.

Figure 22.23 gives Weibull probability plots of the data at individual conditions (factor combinations). The plot indicates that the Weibull distribution can be used to describe the data. Moreover, the plotted lines showing the ML estimates of fraction failing as a function of time at each test condition suggest that it is reasonable to assume that σ (or, equivalently, the Weibull shape parameter β) is constant. The likelihood ratio test for homogeneity of the Weibull shape parameters provides no evidence of differences. Thus, one can assume constant σ across experimental factor combinations.

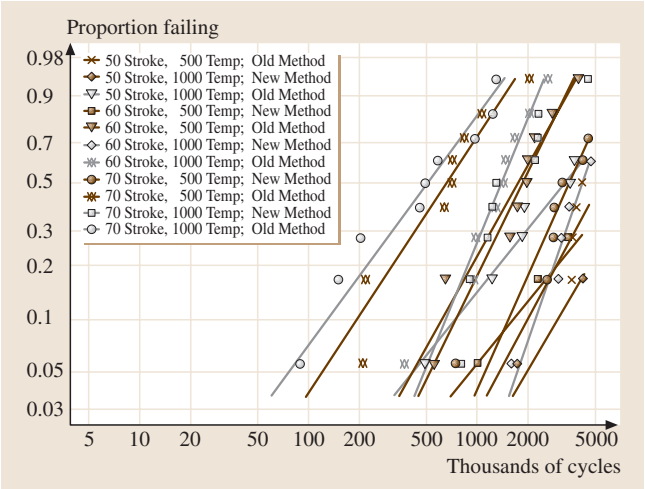

Fig. 22.23 Spring fatigue data. Weibull multiple probability plot with individual Weibull ML fits for each test condition

The model for the location parameter μ was developed as follows. Previous experience with testing similar springs suggested taking a log transformation of Stroke. On the other hand, no transformation is applied to temp because there were no prior studies involving temp (note that because temp is a processing temperature rather than a temperature driving a chemical reaction, there is no suggestion from physical/chemical theory that the Arrhenius relationship should be used). An indicator variable was used to represent the effect of the qualitative factor Method. Thus,

$$\mu = \beta_0 + \beta_1 \log(\text{Stroke}) + \beta_2\, \text{temp} + \beta_3\, \text{Method} \tag{22.14}$$

where Method = 0 for the New processing method and Method = 1 for the Old method. Terms representing factor interactions can be added to (22.14). *Meeker* et al. [22.29] extended (22.14) to include two-factor interaction terms. The likelihood-ratio test suggested,

Table 22.10 Spring fatigue data. ML estimates for the Weibull regression model

Parameter	ML estimate	Standard error	Normal-approximation 95% confidence interval
β_0	32.03	2.48	[27.16, 36.90]
β_1	−5.51	0.59	[−6.66, −4.36]
β_2	−0.000 88	0.000 27	[−0.0014, −0.000 35]
β_3	−1.27	0.15	[−1.56, −0.98]
σ	0.57	0.054	[0.47, 0.69]

The maximum total log likelihood for this model is $\mathcal{L}_{10} = -625.8$

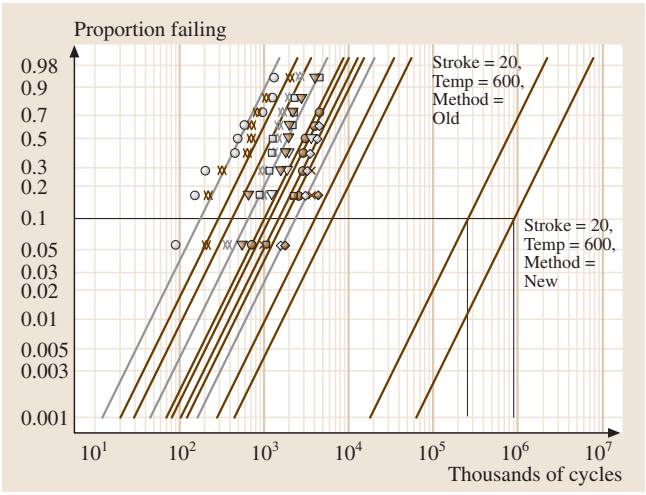

Fig. 22.24 Spring fatigue data. Weibull multiple probability plot of the Weibull regression ML fit with estimates at use conditions

however, that there was little evidence for such interactions.

Table 22.10 gives the results of fitting the Weibull model with the location parameter given in (22.14) and constant σ. For this fit, Fig. 22.24 is a probability plot showing the ML estimates for fraction failing as a function of time for each of the 12 factor combinations and for the Old and New processing methods at use conditions of Stroke = 20 mils and temp = 600 °F. We note the following:

- The estimate and confidence interval for β_1, the coefficient for Stroke, are negative, which suggests that, with temp and Method held constant, increasing Stroke shortens spring life, on average. A similar analysis shows that increasing temperature decreases the life of the units.
- The estimate for the coefficient β_3 for Method is $\hat{\beta}_3 = -1.27 < 0$ and the corresponding confidence interval excludes 0. Thus, there is evidence that switching from the Old to the New method lengthens spring life, on average. In Fig. 22.24, observe that the fraction-failing estimate for the New method is to the right (suggesting longer lives) of the fraction failing for the New method. On the average, springs under the New method last $1/\exp(\hat{\beta}_3) = 3.56$ times longer than those under the Old method. A 95% confidence interval for this factor is [2.66, 4.76] which is obtained by taking the reciprocal of the antilog of the endpoints of the confidence interval for β_3 in Table 22.10.

For a graphical comparison of quantile estimates under the two processing methods, draw horizontal lines in Fig. 22.24 that intersect the New and Old fraction-failing lines, and read off the estimates from the horizontal time axis. Estimates of the 0.10, 0.50 and 0.90 quantiles for the two processing methods under use conditions are given in Table 22.11. This table also provides estimates of the standard errors of quantile estimators and 95% normal-approximation confidence intervals. Observe that quantile estimates for the New method are 3.57 times larger than those for the Old method.

The design engineers wanted to know if the B10 life at use conditions would exceed 500 000 kilocycles. Line segments are drawn in Fig. 22.24 to indicate the B10 estimates. The Old method fails to satisfy this requirement because its B10 life estimate is 252 208 kilocycles. The estimate for the New method is 900 222 kilocycles, which does satisfy the requirement. The lower endpoint of the confidence interval is, however, below the 500 000 target. Thus, there is some doubt that the New method meets the reliability requirement.

Example 22.16: Sensitivity Analysis for the Spring Fatigue Data. Meeker et al. [22.29] studied the effect that varying model assumptions has on the analysis of the spring fatigue data. In particular, they investigated the sensitivity of the estimate of B10 life to alternative transformations of Stroke and temp, and the assumed distribution. A summary of their findings follows.

Table 22.11 Spring fatigue data. Quantiles ML estimates at (20 mil, 600 °F) for the Old and New processing methods

Processing method	Quantile	ML estimate	Standard error	Normal-approximation 95% confidence interval
Old	0.10	252 208	160 148	[72 654, 875 502]
	0.50	737 371	483 794	[203 801, 2 667 873]
	0.90	1 460 875	989 321	[387 409, 5 508 788]
New	0.10	900 221	612 067	[237 471, 3 412 619]
	0.50	2 631 947	1 855 063	[661 194, 10 476 722]
	0.90	5 214 400	3 794 441	[1 252 557, 21 707 557]

Meeker et al. [22.29] extended (22.14) to

$$\mu = \beta_0 + \beta_1 \mathrm{W} + \beta_2 \mathrm{temp} + \beta_3 \mathrm{Method}\,, \qquad (22.15)$$

where

$$\mathrm{W} = \begin{cases} \dfrac{(\mathrm{Stroke})^{\lambda} - 1}{\lambda}, & \lambda \neq 0 \\ \log(\mathrm{Stroke}), & \lambda = 0 \end{cases} \qquad (22.16)$$

and where λ was allowed to range between -1 and 2. The transformation W is known as a Box–Cox transformation, and the linear (no transformation, $\lambda = 1$) and log ($\lambda = 0$) relationships are special cases of this transformation. *Meeker* et al. [22.29] used a range of fixed values of λ and fitted by ML methods a Weibull distribution with μ in (22.15) and constant σ. They observed that, as λ moved from -1 to 2, the ML estimate of the B10 life at use conditions decreased by a factor of between 10^3 and 10^4. In particular, switching from $\lambda = 0$ to $\lambda = 1$ decreased the B10 life estimate from 900 221 kilocycles to 84 925 kilocycles. From past experience with the spring, the engineers thought that λ should be close to 0 and almost certainly less than 1. Thus, a conservative approach for designing the product using the spring as a component would be to assume that $\lambda = 1$.

Using a similar sensitivity analysis with temperature, *Meeker* et al. [22.29] observed that the estimate of B10 life was not as sensitive to temp as it was to Stroke. Increasing λ from -1 to 2 increased the B10 life estimate by no more than a factor of 1.25. They also explain that the data did not provide any information about what transformation (λ value) would be best for model fitting (because there were only two levels of temperature in the experiment).

Another sensitivity analysis involved fitting a lognormal (instead of Weibull) distribution with a location parameter given by (22.15) and constant σ. For any fixed value of λ between -1 and 2, the lognormal distribution gave more optimistic estimates of B10 life than the Weibull distribution. In particular, the lognormal estimates of B10 life were about twice as large as the Weibull estimates. This is expected because, when both distributions are fitted to the same data, the Weibull distribution is less optimistic when extrapolating in time.

22.6 Practical Considerations for Interpreting the Analysis of ALT Data

Extrapolation is an integral part of any ALT. As a result, interpretation of statistical analysis of ALT data is often a challenge. In this section, we discuss the most important issues and suggest strategies to address them.

ALTs are most effective when predicting the life for well-understood failure mechanisms for relatively simple materials or components. ALTs are less useful or there may be more restrictions for more complicated products. There are also difficulties when there are discrepancies between laboratory and field conditions. In particular, when the ALT model generates failure modes that are different from those seen in the field, the information obtained from an ALT may be difficult or impossible to interpret.

ALTs have a better chance to produce useful results if they are carefully planned with attention to obtaining information about possible failure modes from which the product or material might fail.

- Information from earlier experiences with product prototypes or similar products is important. For example, pilot studies can provide information on which environmental factors and failure modes are relevant relative to customer or field use.
- Knowledge of the physical or chemical nature of product degradation and failure is crucial in providing a basis for the statistical model to be fitted to ALT data. This could provide information on how much extrapolation is justified.
- An obvious way to limit the effect of extrapolation is to test at lower levels of the accelerating variables. Doing this, however, results in fewer observed failures, which translates into statistical estimates with larger amounts of uncertainty. For one-variable ALTs, *Meeker* and *Hahn* [22.10] provided practical guidelines for choosing ALT plans that meet practical constraints and have good statistical efficiency.

22.7 Other Kinds of ATs

Discussions up to this point pertain to ALTs where products are tested at high levels of the accelerating variables and extrapolating to assess life at use levels of these variables. Of primary interest is the life distribution with

respect to a few simple failure mechanisms. This section briefly discusses other types of ATs that are used in assessing or improving product reliability. See *Meeker* and *Escobar* ([22.3], Chapt. 19) and references therein for more detailed discussion of these tests and other references.

22.7.1 Continuous Product Operation Accelerated Tests

In this type of AT, tests are performed on the complete system. Such tests are useful because, in addition to testing individual components, the tests can catch problems with component interfaces that cannot be tested in low-level ALTs. In these tests, a sample of product is tested on a more or less continuous basis to accelerate failure mechanisms. Applications include accelerated testing of engines (e.g., in automobiles, motorcycles, lawn equipment, washing machines) and refrigerator compressors. Caution is taken to avoid damage to the system that would not occur in actual product use (e.g., overheating or melted parts due to extreme temperatures). In automobile engine testing, there is one test standard in which the engine is run continuously and another in which the engine is cycled on and off continuously. This is because the two different ATs will tend to generate different kinds of failures.

22.7.2 Highly Accelerated Life Tests

In highly accelerated life tests HALT, products are operated under extremely high levels of variables such as temperature (−90 °C to 190 °C), vibration (up to 60 Grms), and other stresses directly related to system operation. These tests are used to identify failure modes and determine product operational limits. It is generally agreed that these tests provide little or no information about product life at use conditions. This is because the results of the tests usually lead to product design changes. HALTs are typically performed on solid-state electronics, but, with proper equipment, they can be applied to other products as well. *Confer* et al. [22.30] remarked that HALTs can be used to inspect lots of incoming components and to screen products by burn-in. At extremely high levels of the stressing variables, the failure-mechanism model may no longer hold or the system experiences some damage. Thus, precautions must be taken to avoid these effects. See, for example, *McLean* [22.31] and *Hobbs* [22.32] for more information on HALT methods.

22.7.3 Environmental Stress Tests

These tests are closely related to HALTs in that the main objective is to identify reliability issues quickly (e.g., product design flaws) and address them while in the product-development stage. Different authors have different names for this type of test. One is stress–life (STRIFE) tests in which one or two prototypes are aggressively tested to produce failures quickly. Most common STRIFE tests involve temperature and vibration that are cycled in increasing amplitudes throughout the test. *Nelson* ([22.1], pages 37–39) refers to such tests as 'elephant tests.' He described tests of ceramic cookware exposed to cycles of high and low temperature until failure. Failures occurring in these tests are often due to design flaws in the product. Thus, this type of test allows engineers to identify design flaws and fix them while in the design stage. Also, the engineers must determine if failures due to these flaws would occur in actual to avoid unnecessary product redesign. *Nelson* ([22.1], pages 38–39) describes an example where a transformer was redesigned to eliminate a failure mode that was discovered in an elephant test. Years later it was realized that none of the transformers with the old design ever failed from this failure mode; the expensive redesign had been unnecessary.

Nelson ([22.1], Chapt. 1) and *Meeker* and *Escobar* ([22.3], pages 519–520) give more detailed discussions of issues related to environmental stress tests.

22.7.4 Burn-In

Early failures (infant mortality) are the most common problem with electronic products. Defective components, sometimes called freaks, comprise a small fraction of all products and are caused by manufacturing defects. Burn-in involves operating the units at higher that usual levels of accelerating variables for a specific length of time to screen out such defects. For example, burn-in of products such as integrated circuits involve testing units at high levels of temperature and humidity. Units that survive this burn-in period are then put into service. This type of test is expensive because it is essentially a 100% inspection of products. Also, the longer the burn-in period, the more defective items are identified. Tradeoffs between these and other considerations are studied to determine the length of the burn-in period. *Jensen* and *Petersen* [22.33] describe some of the engineering issues related to burn-in. *Kuo* et al. [22.34] discuss statistical and economic issues of burn-in.

22.7.5 Environmental Stress Screening

Environmental stress screening (ESS) methods were developed to improve traditional burn-in tests. It has been suggested that ESS is less expensive and more effective in detecting defectives from the product population. In ESS, products are tested at milder, but more complex, stress processes than in burn-in tests. The methodology has been developed mostly along engineering considerations. The goal is still to screen out defectives without causing damage to the systems. It is widely used in consumer, industrial, and military electronics manufacturing. *Nelson* ([22.1], pages 39–40) provided references regarding ESS military standards and more in-depth discussions of ESS.

22.8 Some Pitfalls of Accelerated Testing

This section reviews potential difficulties one may face in the analysis and interpretation of ALT data. See *Meeker* and *Escobar* [22.35] for a more detailed discussion of these pitfalls.

22.8.1 Failure Behavior Changes at High Levels of Accelerating Variables

It is possible that failure mechanisms at high levels of the accelerating variables may not be the same as those at low levels. High levels of the accelerating variables could induce failure modes that have not been identified beforehand or which may not occur in normal use of the product. Such failure modes can be direct results of physical changes brought on by extreme stressing (e.g., at high temperatures product parts could warp or melt). Also, even with the same failure mechanism, the assumed relationship between life and the accelerating variable(s) may not be valid at higher levels. For example, in a voltage-accelerated ALT, the relationship between log(Life) and log(volt) may not be linear at higher levels of volt.

Previously unrecognized failure modes could still be accounted for in the data analysis by regarding failures caused by them as right-censored with respect to the failure mode of primary interest. This approach, however, requires the assumption of independent failure modes. *Nelson* ([22.1], Chapt. 7) discusses methods for analyzing failure data with competing failure modes, but the failure modes at the higher levels of the accelerating variables restrict the amount of information that will be available on the mode of interest. If possible, the investigator should establish limits on the accelerating variables within which only the primary failure mode occurs and the assumed ALT model holds.

In some applications there will be an effort to eliminate a particular failure mode that is seen only at higher levels of stress. This would be done to make it possible to study another failure mode of primary interest more effectively.

22.8.2 Assessing Estimation Variability

Estimates from ALTs will contain statistical uncertainty due to having only a limited amount of data. It is unsafe to base product-design decisions on point estimates alone. Instead, conclusions from data analysis should account for statistical uncertainty by using confidence intervals. Such confidence intervals provide a range of plausible values for quantities of interest. All of our examples have presented such confidence intervals. Recall the analysis of the GAB insulation data in Example 22.2. Estimates and corresponding pointwise 95% confidence intervals for the fraction failing at $\text{volt}_U = 120$ are shown in Fig. 22.7. The confidence interval for the probability of failure before 5×10^5 h is [0.0017, 0.94]. This interval is too wide to be of any practical value. There are ways to reduce statistical uncertainty (reduce confidence interval width). In general, one could, for instance, increase the sample size, observe more failures by testing at higher stress levels, or reduce the amount of extrapolation. One could also use prior information to fix the values of model parameters that would normally be estimated from data, if there is good information about such parameters. Recall the analyses of the IC device data in Examples 22.10 and 22.11. In the first analysis, all model parameters, including the activation energy E_a, were estimated and pointwise confidence intervals for the fraction failing at use condition temp $= 100\,^\circ\text{C}$ are given in Fig. 22.12. Figure 22.14 is a similar plot for the second analysis with E_a fixed at 0.8 eV, resulting in much narrower confidence intervals. Of course, conclusions from an analysis like that shown in Fig. 22.14 could be misleading if E_a were to be misspecified. *Meeker* and *Escobar* ([22.3], Sect. 22.2) discuss applications of Bayesian analysis

where prior distributions are set up to reflect information about model parameters.

It is important to recognize that the uncertainty reflected in confidence intervals does not include the error (bias) that results from fitting an incorrect model (and strictly speaking, no statistical model is exactly correct). More extrapolation will exacerbate the problem. So, it is important to do sensitivity analysis to study the effect that changes in the model assumptions will have on the results. For example, one could study how estimates and confidence intervals change when the form of the stress-life relationship and/or distribution is changed, as was done in several of the examples in this chapter.

22.8.3 Degradation and Failure Measured in Different Time Scales

In certain applications, lifetime is measured in different time scales (e.g., cycles or hours to failure) depending on which factors affect the degradation process. Often, time scales are determined by how the product is actually used. Incandescent light bulb burn time drives a filament-evaporation process, leading to eventual failure. One way to speed up time is by increasing voltage. The bulb is operated continuously and lifetime is measured in hours of operation. Also, turning a light bulb on and off produces mechanical shocks that can cause the initiation and growth of fatigue cracks within the filament. Bulb life in this case might be measured in on–off cycles. Testing bulbs continuously at higher voltages does not simulate the on–off cycling effect. Thus, predictions based on a simple model with only one time scale will not accurately describe light bulbs that fail through a combination of burn time and on–off cycles.

22.8.4 Masked Failure Modes

In some situations, higher levels of the accelerating variable can produce a new failure mode, not ordinarily seen at use conditions. This new failure mode can mask the failure mode of interest. If the new failure mode is not recognized (because engineers naively think they are the same and do not check), the resulting conclusions will be highly optimistic relative to the truth. See *Meeker* and *Escobar* ([22.3], Fig. 19.22) for an illustration and further discussion.

22.8.5 Differences Between Product and Environmental Conditions in Laboratory and Field Conditions

For accurate prediction of failure behavior in the field, it is necessary that laboratory conditions be similar to those in the field, and that units tested in the laboratory be similar to products in actual use. Laboratory conditions are not always similar to field conditions. For example, in a life test of a circuit pack, accelerated levels of temperature resulted in lower humidity levels. This in turn inhibited corrosion, which was the primary cause of failure in the field. Thus, there were more failures in the field than were predicted by the data analysis. Laboratory tests should have controlled both temperature and humidity levels. Also, laboratory tests are generally carefully controlled, while in actual use, the environment may be highly variable.

There are various points in the process from prototype development to product manufacture at which product-building inconsistencies could occur. Technicians may build prototypes to be used in testing in a manner that is different from the way an assembly line builds the final product. For example, products with epoxy have to be cured for a certain length of time in an oven. Uncured epoxy can be highly reactive and may cause corrosion and lead to premature failure. It is possible that the units are effectively cured in the lab, but not in the factory assembly line. ALT tests will likely predict failure behavior that is more optimistic than that in the field. Raw materials and instruments could also vary. It is also possible, because of identified design flaws, to modify the product design several times throughout the process. Any inconsistencies in how a product is built will most likely cause disagreements between laboratory and field results.

22.9 Computer Software for Analyzing ALT Data

Nelson ([22.1], pages 237–240) provides a table listing software packages for analysis of ALT data by maximum likelihood methods (which has been updated in the 2004 paperback edition). The table provides the packages' features and specific capabilities. Commercially available statistical software such as SAS JMP [22.36], SAS [22.37], MINITAB [22.38], and S-PLUS [22.39] have procedures specifically for ALT data analysis.

ALTA [22.40] is a software package specifically for ALT analysis.

All of the analyses in this chapter were done with S-PLUS Life Data Analysis (SPLIDA) by *Meeker* and *Escobar* [22.41]. SPLIDA runs on top of S-PLUS. Special features for some plots were created by modifying SPLIDA functions and using S-PLUS annotation tools. SPLIDA consists of special S-PLUS functions and GUIs, and is available for download from http://www.public.iastate.edu/~splida/. The SPLIDA download also contains files with all of the data sets from this chapter, as well as many other example data sets, including all examples from *Meeker* and *Escobar* [22.3] and many from *Nelson* [22.1].

23. Statistical Approaches to Planning of Accelerated Reliability Testing

This chapter presents a few statistical methods for designing test plans in which products are tested under harsher environment with more severe stresses than usual operating conditions. Following a short introduction, three different types of testing conditions are dealt with in Sects. 23.2, 23.3, and 23.4; namely, life testing under constant stress, life testing in which stresses are increased in steps, and accelerated testing by monitoring degradation data. Brief literature surveys of the work done in these areas precede presentations of methodologies in each of these sections.

In Sect. 23.2, we present the conventional framework for designing accelerated test plans using asymptotic variance of maximum likelihood estimators (MLE) derived from the Fisher information matrix. We then give two possible extensions from the framework for accelerated life testing under three different constant stress levels; one based on a nonlinear programming (NLP) formulation so that experimenters can specify the desired number of failures, and one based on an enlarged solution space so that the design of the test plan can be more flexible in view of the many possible limitations in practice. These ideas are illustrated using numerical examples and followed by a comparison across different test plans.

We then present planning of accelerated life testing (ALT) in which stresses are increased in steps and held constant for some time before the next increment. The design strategy is based on a target acceleration factor which specifies the desired time compression needed to complete the test compared to testing under use conditions.

Using a scheme similar to backward induction in dynamic programming, an algorithm for planning multiple-step step-stress ALT is presented.

In Sect. 23.4, we consider planning problems for accelerated degradation test (ADT) in which degradation data, instead of lifetime data, are used to predict a product's reliability. We give a unifying framework for dealing with both constant-stress and step-stress ADT. An NLP model which minimizes cost with precision constraint is formulated so that the tradeoff between getting more data and the cost of conducting the test can be quantified.

Technology and market forces have created generation after generation of highly reliable products. For most products, it is no longer feasible to test products/components in the usual manner at their design conditions as the time needed to obtain sufficient failure information so as to understand the products' behaviors and to quantify their reliability is prohibitively long. In applications where safety and mission success are critical, accelerated reliability testing (ART) is commonly deployed to quantify products' reliability. The basic idea of ART is to achieve time compression so that failure information can be precipitated within a reasonable

test duration. To achieve the requisite time compression, products are tested either under a harsher environment or under more intensive usage than the usual use condition. For many products which are always on, only the former is feasible and will be dealt with in this chapter.

One of the important issues in ART is how to plan a test by determining the testing time, stress levels, sample sizes for different stress levels, etc., so as to achieve cost saving and/or efficiency. Good planning does not only lead to shorter test time or fewer test specimens or both; but more importantly; a good test plan will result in a more precise estimate for the reliability measure of interest, which could be critical, in some cases, in meeting a design or customer specification.

In this chapter, we present test plans for three types of acceleration tests, namely, constant-stress accelerated life test, step-stress accelerated life test and accelerated degradation test, in the following three sections, respectively. A quick review of the literature in each of these areas will first be presented at the beginning of the respective sections. The statistical approach for planning these experiments will then follow. At the end of each section, a numerical example will be given to illustrate the application of the planning methodology.

23.1 Planning Constant-Stress Accelerated Life Tests

The most commonly adopted ART is the constant-stress accelerated life test (CSALT) which comprises multiple sub-samples tested at different but fixed stress levels, at which time-censored failure times are recorded. For ease of administration, commonly used CSALT test plans consist of equally spaced test stresses, each with the same number of test specimens. Such standard plans are highly inefficient for estimating product reliability at the design stress as fewer failures are expected at lower stress levels unless the test duration is much longer than other higher stress levels. Pioneering work by *Chernoff* [23.1] and *Meeker* and *Nelson* [23.2] proposed statistically optimal plans for constant-stress ALT which involved only two stress levels. As a result, these plans, though statistically optimal, cannot be used to validate the assumed stress–life relationship. To remedy this problem, *Meeker* and *Hahn* [23.3] proposed the use of a 4:2:1 allocation ratio for low-, middle- and high-stress levels and gave the optimal low-stress level by assuming that the middle stress is the average of the high- and low-stress levels. An alternative approach is to set equally spaced stress levels with equal allocations as in *Nelson* and *Kielspinski* [23.4] and *Nelson* and *Meeker* [23.5]. The main reason for using a predetermined allocation and middle stress is that the statistically optimal plan only involves two stress levels once the stress–life relation is given. *Nelson* [23.6] provides a comprehensive treatment of these plans and thus they will not be presented in this chapter.

Another approach adopted by *Yang* [23.7] and *Yang* and *Jin* [23.8] to overcome this problem is to add test constraints involving expected minimum number of failures to be observed at the mid-stress levels. The resulting plan is sensitive to the value of the constraint for expected minimum number of failures as it indirectly determines the mid-stress levels and corresponding sample allocation. *Tang* [23.9] imposed constraints that limit the probability of having probability plots with best-fit lines crossing at the lower tails. In this way, the stress levels and their corresponding sample allocations are best suited to infer whether the shape parameters are indeed different at different stress levels. Motivated by the fact that the mid-stress level is meant for validating the assumed stress–life model, *Tang* et al. [23.10] considered test plans in which the mid-stress level will have the least influence on the slope of the stress–life relationship plot. Although these plans are more robust, variances of the estimates at design stress for these compromised plans may be much higher than those under the two-stress-level optimum plans. To address this, *Tang* and *Yang* [23.11] proposed a graphical approach for planning multiple constant-stress-level ALT so that the uncertainty involved for some estimate of interest is not worse than that of a statistical optimum plan by a margin determined by the experimenter before the test. Recently, *Tang* and *Xu* [23.12] presented a general framework for planning ALT. We shall summarize these plans in this Section and provide a simple comparison.

There are many other papers in statistical planning of CSALT that are not presented here. Most of the work has been summarized in *Nelson* [23.6] and *Meeker* and *Escobar* [23.13]. A comprehensive bibliography is given in *Nelson* [23.14]. For example, *Meeter* and *Meekers* [23.15] presented optimal plans involving a nonconstant shape parameter, in the case of Weibull distribution, and *Tang* et al. [23.16] gave optimal plans involving a failure-free life represented by a location parameter.

Notations and Assumptions

S_d, S_i, S_h	Stress (design, i, high) levels, $i = 1, 2, \ldots, h-1$
ξ_i	$\frac{S_i - S_h}{S_d - S_h}$: normalized stress levels, $i = 1, 2, \ldots, h$, so that $\xi_h = 0, \xi_d = 1$
π_i	Proportion of units tested at ξ_i
n	Total sample size
n_i	Actual number of test units needed at ξ_i
h	Total number of stress levels; also denotes the high stress level
τ_i	Censoring time at low S_i, $i = 1, 2, \ldots, h$
$\mathbf{F}$	Fisher information matrix for the plan with a unit of n independent observations
σ	Scale parameter
μ	Location parameter of the smallest extreme value distribution
μ_D, μ_H	μ (design, highest test stress)
p_i	Probability that units tested at ξ_i fail before τ_i
m	A maximum bound
γ_i	Expected number of failure at stress ξ_i
Avar[log(t)]	Asymptotic variance of natural logarithm of the estimate of a fixed percentile of interest t
$\hat{t}_{0.43}$	The estimate of the 43rd percentile of the time to failure; which is also the maximum likelihood estimation (MLE) of the mean life of the smallest extreme value distribution at design stress

23.1.1 The Common Framework

For ease of discussion and comparison, the common assumptions and framework of these plans are:

1. The lifetime follows a Weibull distribution of which the natural logarithm of life, $y = \ln(t)$, has a smallest extreme-value distribution with a reliability function given by
$$R(y) = \exp\left\{-\exp\left[(y-\mu)\Big/\sigma\right]\right\} \quad -\infty < y < +\infty\,, \tag{23.1}$$
where μ is the location parameter and σ is the scale parameter.
2. The scale parameter does not depend on the stress level and;
3. The location parameter is a linear function of the transformed stress:
$$\mu(\xi) = \alpha + \beta\,\xi\,, \tag{23.2}$$
where, α, β are unknown parameters to be estimated from test data.
4. For planning purpose, the initial guess values for σ, p_D and p_H are given.
5. Test units allocated to ξ_i are tested simultaneously until τ_i.
6. The highest test stress is specified.
7. The test stresses are above the design stress.
8. The measure of statistical precision is given by the asymptotic variance of the MLE of the mean life of the smallest extreme value distribution, which is the 43rd percentile ($\hat{t}_{0.43}$), at design stress.

For test conducted at three stress levels, the above variance is given by:

$$\begin{aligned} y_{\text{var}} &= \text{Avar}\left[\hat{t}_{0.43}(1)\right] \\ &= [1\,,1\,,-0.577\,22]\mathbf{F}^{-1}[1\,,1\,,-0.577\,22]'\,, \end{aligned} \tag{23.3}$$

where $\mathbf{F}$ is the Fisher information matrix for the plan given below

$$\mathbf{F} = \frac{n}{\sigma^2}\begin{pmatrix} M_{11} & M_{12} & M_{13} \\ M_{21} & M_{22} & M_{23} \\ M_{31} & M_{32} & M_{33} \end{pmatrix}\,,$$

$$M_{11} = \sum_{i=1}^{3} \pi_i A(\psi_i)\,,$$

$$M_{22} = \sum_{i=1}^{3} \pi_i \xi_i^2 A(\psi_i)\,,$$

$$M_{33} = \sum_{i=1}^{3} \pi_i C(\psi_i)\,,$$

$$M_{12} = M_{21} = \sum_{i=1}^{3} \pi_i \xi_i A(\psi_i)\,,$$

$$M_{13} = M_{31} = \sum_{i=1}^{3} \pi_i B(\psi_i)\,,$$

$$M_{32} = M_{23} = \sum_{i=1}^{3} \pi_i \xi_i B(\psi_i)\,,$$

$$A(\psi_i) = 1 - \exp\left\{-\exp\left[(\psi_i - \theta)\Big/\sigma\right]\right\}\,,$$

$$
\begin{aligned}
B(\psi_i) = & \int_0^{\exp(\psi_i)} \ln(w) w \exp(-w)\,\mathrm{d}w \\
& + \left(\exp\left\{-\exp\left[(\psi_i-\theta)\big/\sigma\right]\right\}\right) \\
& \times \psi_i \exp(\psi_i)\,, \\
C(\psi_i) = & 1-\exp\left\{-\exp\left[(\psi_i-\theta)\big/\sigma\right]\right\} \\
& + \int_0^{\exp(\psi_i)} \ln^2(w) w \exp(-w)\,\mathrm{d}w \\
& + \left(\exp\left\{-\exp\left[(\psi_i-\theta)\big/\sigma\right]\right\}\right) \\
& \times \psi_i^2 \exp(\psi_i)\,, \\
\psi_i = & \left[\tau_i - (\alpha+\beta S_H)\right]\big/\sigma\left[\beta\,(S_D - S_H)\right]\big/\sigma\,.
\end{aligned}
$$

Note that, usually, the standardized asymptotic variance, $\mathrm{Svar} = \mathrm{Avar}^*(n/\sigma^2)$ is used in optimization.

23.1.2 Yang's Approach

Yang [23.7] formulated a constrained nonlinear programme to obtain an optimal test plan. He allowed for varying censoring time at different stress levels and aimed to minimize the total test duration while achieving statistical efficiency and robustness. The objective function to be minimized consists of a weighted sum of the standardized asymptotic variance and the product of the test duration at the lowest stress level and the sum of test duration; i. e.

$$
\begin{aligned}
&\text{Minimize: } \omega\,\mathrm{AVar}\left[\log(t_{0.43})\right] + (1-\omega)\tau_1 \sum_i \tau_i\,, \\
&\qquad 0 \le \omega \le 1\,, \\
&\text{Subject to: } \tau_i > \tau_j \quad \text{for } i < j\,, \\
&\qquad \sum_i \pi_i = 1\,; \\
&\qquad \xi_i > \; xi_j > \xi_h = 0 \quad \text{for } i < j\,, \\
&\qquad n\pi_i p_i \ge \gamma_i \quad \text{for all } i\,.
\end{aligned}
\tag{23.4}
$$

Yang [23.7] presented the solution for four stress levels, i. e. $h = 4$, and $\gamma_i = 10$ for all i. He transformed the above into an unconstrained optimization using a penalty-function approach to obtain nearly optimal plans. A similar approach is given in *Yang* and *Jin* [23.8] with 3 stress levels, known as the three-level best-compromised test plan, where the middle stress is the average of the low and high stresses.

23.1.3 Flexible Near-Optimal Plans

In the above plans, the inclusion of additional stress levels will give rise to less-precise estimates compared to the statistically optimal two-level CSALT. For better management of risk in planning ALT, it would be useful to know the extent by which the variance of the percentile of interest is inflated. For practical implementation, test plans should also be sufficiently flexible, in that some range of stress levels and the corresponding allocations are provided instead of stipulating specific stress levels and allocations. In the following, we present flexible near-optimal plans proposed by *Tang* and *Yang* [23.11] that provides the flexibility while limiting the loss in precision. For simplicity, we assume that the censoring time at all stress levels are identical, i. e. $\tau_i = T$ for all i.

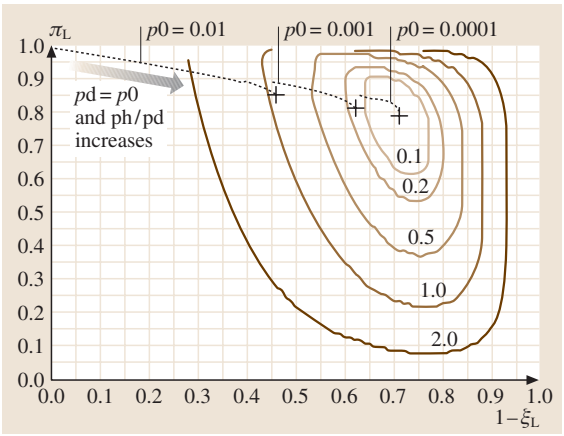

Fig. 23.1 Solution space of a two-stress-level CSALT

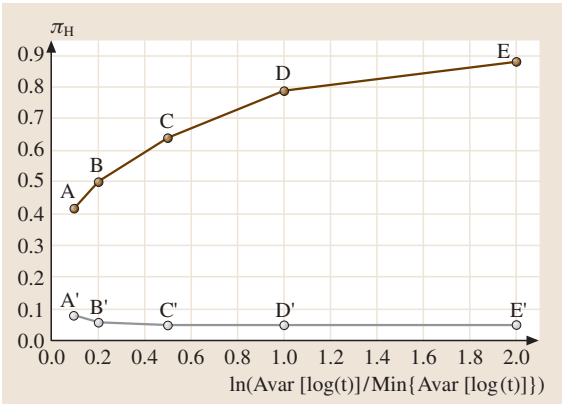

Fig. 23.2 Feasible region of π_H for different values of m in (23.5)

Consider a solution of two-stress-level CSALT depicted in Fig. 23.1. The statistically optimal solutions specify the low stress level (ξ_L) and the corresponding allocation (π_L), which are marked by "+" for different p_d. A possible approach in enlarging the solution space is to consider combinations of (ξ_L, π_L) such that the following ratio is restricted to a maximum bound tolerable, say m:

$$\ln\left(\frac{\mathrm{Avar}\left[\log(t)\right]}{\mathrm{Min}\left\{\mathrm{Avar}\left[\log(t)\right]\right\}}\right) \le m\ . \tag{23.5}$$

Figure 23.1 depicts the contours that enclosed (ξ_L, π_L) for m ranging from 0.1–2.

This principle of enlarging the solution space can be generalized to 3SCSALT. In the following, we give a step-by-step description on how a contour plot of the solution space for 3SCSALT is constructed.

1. For different combinations of p_d and p_h, the statistically optimal 2SCSALT plan with the optimal value of π_H can be determined. By allowing the value of m in (23.5) to vary, a range of π_H as a function of m can easily be determined. The results are depicted in Fig. 23.2 for m= 0.1, 0.2, 0.5, 1.0, 2.0.
2. For each value of π_H, the solution space of ξ_M and ξ_L can be obtained using the same criterion as in (23.5). An example for $\pi_H = 0.15$ is given in Fig. 23.3 for m= 0.1, 0.2, 0.5, 1.0, 2.0. Interestingly, the solution space of ξ_M and ξ_L is enclosed in an approximately right-angled triangle sharing the common slope of 1 as $\xi_L > \xi_M$.
3. As one would usually like to ensure that ξ_L and ξ_M are sufficiently far apart, the preferred solution will be at the vertex of the right angle. Tracing the vertices for different values of m, the various combinations of ξ_L and ξ_M form a straight line, as depicted in Fig. 23.2.
4. Repeated applications of this procedure for different values of π_H result in a plot depicting the solution space of ξ_L and ξ_M of 3SCSALT, as shown in Fig. 23.4. In Fig. 23.4, we use the boundary values of π_H marked by A, B, C, D, E, A', B', C', D' and E' in Fig. 23.2, and some intermediate values of π_H (0.13, 0.18, 0.25, 0.33) to generate the corresponding lines that give the preferred solutions of ξ_L and ξ_M for different values of m.
5. The contours of various setting of m (0.1, 0.2, 0.5, 1, 2) are superimposed on these lines so that ξ_L and ξ_M can be read off by interpolation between the lines of π_H for a given m value.

To determine π_L and π_M, since the main purpose of having a middle stress is to validate the stress life model, one may prefer minimum allocation to the middle stress such that there are sufficient failures to detect nonlinearity, if it exists. In this case, π_M is given by

$$\pi_M = \frac{\gamma_m}{n F_M(T)}\ , \tag{23.6}$$

where γ_M is the minimum number of failures expected under the middle stress level, and $F_M(T)$ is the prob-

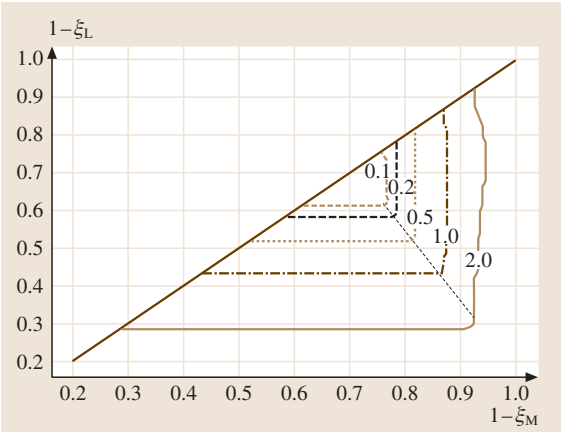

Fig. 23.3 Solution space for the middle and low stress levels for $\pi_H = 0.15$

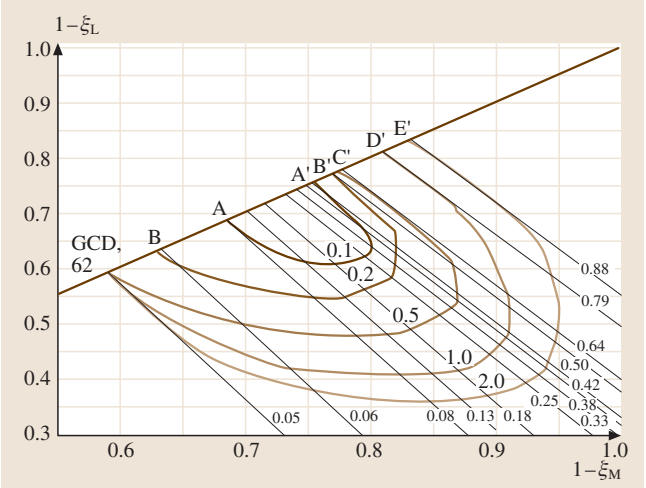

Fig. 23.4 Contour plots of the solution space for 3SCSALT

ability of failure by the end of the test at the middle stress.

Alternatively, as suggested by *Tang* [23.9], a good planning strategy is to set the centroid of the lower and middle stress levels, weighted by their respective allocation, in a near-optimal 3SCSALT plan equal to the optimal low stress in the statistical optimal plan, i. e.

$$\frac{\xi_{3M}\pi_{3M}+\xi_{3L}\pi_{3L}}{\pi_{3M}+\pi_{3L}}=\xi_{2L}^{*}$$

$$\Rightarrow \xi_{3M}\pi_{3M}+\xi_{3L}\pi_{3L}$$

$$=\xi_{2L}^{*}\left(1-\pi_{H}^{*}\right), \qquad (23.7)$$

where the subscript numbers 3 and 2 represent the number of stresses under which the test plans are designed, superscript "*" means optimal values; note that $\pi_{3H}=\pi_{H}^{*}$.

In summary, the steps in obtaining a 3SCSALT test plan are:

- For the given inputs, solve for the optimal π_{H}^{*}.
- For a given value of m, obtain ξ_{L} and ξ_{M} from Fig. 23.4 by interpolation between the lines of π_{H} to that corresponds to the optimal π_{H}.
- Compute π_{M} from (23.6) or (23.7) noting that $\pi_{L}=1-\pi_{M}-\pi_{H}$.

23.1.4 Numerical Example

In this section, we give an example to show the procedure for planning a three-stress-level CSALT given that $p_d=0.0001$, $p_h=0.9$ and $n=300$, $T=300$, $\sigma=1$, and $m=0.1$. These give rise to $\mu_H=4.8698$ and $\mu_D=14.9148$.

1. Solve for the statistically optimal plan: $\xi_{2L^*}=0.29$ and $\pi_H=0.21$. (see Fig. 23.1)
2. From Fig. 23.4, with $\pi_H=0.21$ and $m=0.1$, $\xi_L=0.38$ and $\xi_M=0.22$.
3. From (23.6), since $\mu(\xi_M)=7.0795$ and $F(300)=0.223$, assuming that $\gamma_M=21$, we have $\pi_M=0.314$ and $\pi_L=0.477$.
4. Alternatively, from (23.7), we have $0.22(0.79-\pi_L)+0.38\pi_L=0.29\times0.79$ which gives $\Rightarrow \pi_L=0.35$, $\pi_M=0.44$.

Since the low stress levels are determined with $m<0.1$, the resulting asymptotic variances should be less than 1.1 times the best achievable variance. Note that the sample allocation ratio is approximately 5:3:2, which is quite different from the 4:2:1 recommended by *Meeker* and *Hahn* [23.3]. Despite the lower allocation to the low stress level, the expected number of failures is about 8–10 at the lower stress in these plans, which is sufficient to make some meaningful statistical inference.

23.2 Planning Step-Stress ALT (SSALT)

The simplest form of SSALT is a partially ALT considered by *Degroot* and *Goel* [23.23] in which products are first tested under use condition for a period of time before the stress is increased and maintained at a level throughout the test. This is a special case of a simple SSALT where only two stress levels are used. Much work has been done in this area and literature appeared before 1989 has been covered by *Nelson* [23.6], which has a chapter devoted to step-stress and progressive-stress ALT assuming exponential failure time. A survey

Table 23.1 A summary of the characteristics of literature on optimal design of SSALT

Paper	Problem addressed	Input	Output	Lifetime distribution
Bai et al. [23.17]	Planning two-step SSALT	p_d, p_h	Optimal hold time	Exponential
Bai, *Kim* [23.18]	Planning two-step SSALT	p_d, p_h, shape parameter	Optimal hold time	Weibull
Khamis, *Higgins* [23.19]	Planning three-step SSALT without censoring	All parameters of stress–life relation	Optimal hold time	Exponential
Khamis [23.20]	Planning m-step SSALT without censoring	All parameters of stress–life relation	Optimal hold time	Exponential
Yeo, *Tang* [23.21]	Planning m-step SSALT	p_h and a target acceleration factor	Optimal hold time and lower stress	Exponential
Park, *Yum* [23.22]	Planning two-step SSALT with ramp rate	p_d, p_h, ramp rate	Optimal hold time	Exponential

of the subsequent work from 1989 has been given in *Tang* [23.24]. A summary of the work relating to optimal design of SSALT is presented in Table 23.1. The term optimal usually refers to minimizing the asymptotic variance of the log(MTTF), where MTTF is the mean time to failure, or that of a percentile at use condition. As we can see from Table 23.1, with the exception of *Bai* and *Kim* [23.18], all this work deals with exponential failure time. This is due to simplicity as well as practicality, as it is hard to know the shape parameter of the Weibull distribution in advance.

23.2.1 Planning a Simple SSALT

We first consider a two-level SSALT in which n test units are initially placed on S_1. The stress is changed to S_2 at $\tau_1 = \tau$, after which the test is continued until all units fail or until a predetermined censoring time T. For simplicity, we assume that, at each stress level, the life distribution of the test units is exponential with mean θ_i, and that the linear cumulative exposure model (LCEM) of *Nelson* [23.6] applies.

The typical design problem for a two-step SSALT is to determine the optimal hold time, with a given low stress level. In the following, we shall give the optimal plan that includes both optimal low stress and hold time as in *Yeo* and *Tang* [23.21].

The Likelihood Function

Under exponential failure time and LCEM assumptions, the likelihood function under simple step-stress is

$$L(\theta_1, \theta_2) = \prod_{j=1}^{n_1}\left[\frac{1}{\theta_1}\exp\left(-\frac{t_{1,j}}{\theta_1}\right)\right] \times \prod_{j=1}^{n_2}\left[\frac{1}{\theta_2}\exp\left(-\frac{t_{2,j}-\tau}{\theta_2}-\frac{\tau}{\theta_1}\right)\right] \times \prod_{j=1}^{n_c}\exp\left(-\frac{\tau}{\theta_1}-\frac{T-\tau}{\theta_2}\right), \quad (23.8)$$

where the notations are defined as follows:

- n_i number of failed units at stress level S_i, $i = 1, 2, \ldots, h$,
- n_c number of censored units at S_h (at end of test),
- $t_{i,j}$ failure time j of test units at stress level S_i, $i = 1, 2, \ldots, h$,
- θ_i mean life at stress S_i, $i = 1, 2, \ldots, h$,
- τ_i hold time at low stress levels S_i, $i = 1, 2, \ldots, h-1$,
- T censoring time.

MLE and Asymptotic Variance

The MLE of $\log(\theta_0)$ can be obtained by differentiating the log-likelihood function in (23.8):

$$\log\left(\theta_0\hat{}\right) = \frac{\log\left(\frac{U_1}{n_1}\right) - (1-\xi_1)\log\left(\frac{U_2}{n_2}\right)}{\xi_1}, \quad (23.9)$$

where

$$U_1 = \sum_{j=1}^{n_1} t_{1,j} + (n-n_1)\cdot\tau\,;$$

and

$$U_2 = \sum_{j=1}^{n_2}\left(t_{2,j}-\tau\right) + (n-n_c)\cdot(T-\tau)\,.$$

From the Fisher information matrix, the asymptotic variance of the MLE of the log(mean life) at the design stress is:

$$V(\xi_1, \tau) = \frac{\left(\frac{1}{\xi_1}\right)^2}{1-\exp\left(-\frac{\tau}{\theta_1}\right)} + \frac{\left(\frac{1-\xi_1}{\xi_1}\right)^2}{\exp\left(-\frac{\tau}{\theta_1}\right)\left[1-\exp\left(-\frac{1-\tau}{\theta_2}\right)\right]}\,. \quad (23.10)$$

To obtain the optimal test plan, we need to express (23.10) in terms of ξ_1,τ, and other input variables. To do this, we need to assume a stress–life relation. For illustration, suppose the mean life of a test unit is a log-linear function of stress:

$$\log(\theta_i) = \alpha + \beta S_i\,, \quad (23.11)$$

where α, β ($\beta < 0$) are unknown parameters. (This is a common choice for the life–stress relationship because it includes both the power-law and the Arrhenius relation as special cases.) From the log-linear relation of the mean in (23.11), we have

$$\frac{\theta_2}{\theta_1} = \left(\frac{\theta_2}{\theta_0}\right)^{\xi_1} = \exp(\beta\xi_1)\,.$$

And since $p_h = 1-\exp\left(-\frac{1}{\theta_2}\right)$, it follows that $V(\xi, \tau)$ is given by:

$$V(\xi_1, \tau) = \frac{\left(\frac{1}{\xi_1}\right)^2}{1-(1-p_h)^{\omega}} + \frac{\left(\frac{1-\xi_1}{\xi_1}\right)^2}{(1-p_h)^{\omega}\left[1-(1-p_h)^{1-\tau}\right]}\,, \quad (23.12)$$

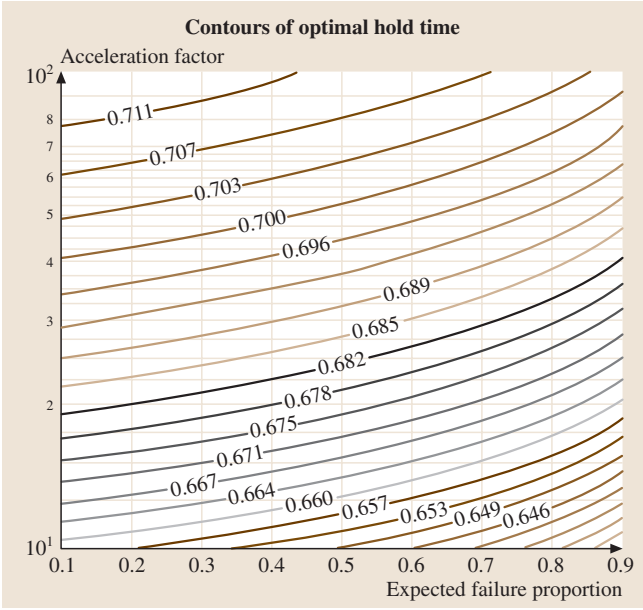

Fig. 23.5 Contours of optimal hold time at low stress for a two-step SSALT. For a given (p, ϕ), the optimal hold time can be read off by interpolation between the contours

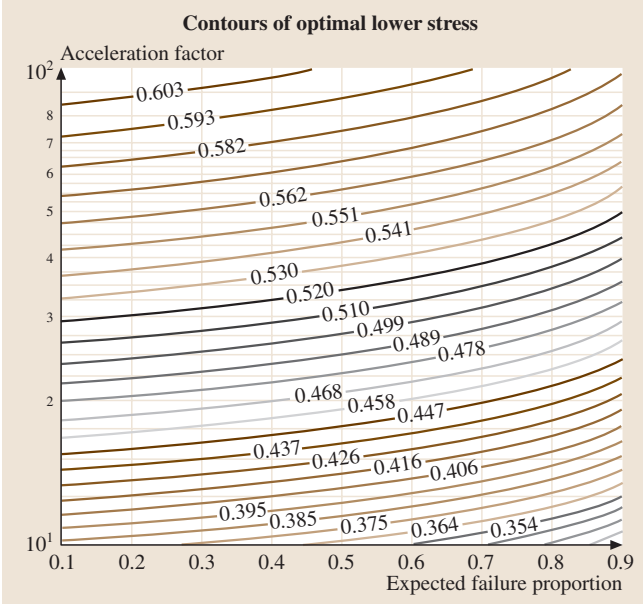

Fig. 23.6 Contours of optimal low stress level for a two-step SSALT. For a given (p, ϕ), the optimal low stress can be read off by interpolation between the contours

where

$$\omega \equiv \tau \left(\frac{\theta_2}{\theta_0}\right)^{\xi_1} = \tau \left[\exp\left(\beta\xi_1\right)\right].$$

As β is unknown, another input variable is needed. We propose using the target acceleration factor (AF) as it is a measure of the amount of extrapolation and a time-compression factor. AF is easier to estimate compared to the commonly used probability of failure at design stress. Given the time constraint that determines the maximum test duration and some guess of the test duration if the test were conducted at use condition, the target AF, denoted by ϕ, is given by the ratio of the two, i. e.

$$\phi = \frac{\text{time to failure at design stress}}{\text{time to failure under test plan}} . \tag{23.13}$$

For exponential lifetime under the LCEM assumption, the equivalent operating time for the test duration T at the design stress given is by $\theta_0 \left(\frac{\tau}{\theta_1} + \frac{T-\tau}{\theta_2}\right)$. As a result, the AF is:

$$\phi = \frac{\tau\frac{\theta_0}{\theta_1} + (T-\tau)\frac{\theta_0}{\theta_2}}{T} . \tag{23.14}$$

From the log-linear stress–life relation in (23.11), without loss of generality, let $S_0 = 0$, $S_1 = x$, $S_2 = 1$, $T = 1$. Then, (23.14) becomes:

$$\phi = (1-\tau)\exp\left(-\beta\right) + \tau\exp\left(-\beta x\right) . \tag{23.15}$$

The optimal low stress and the corresponding hold time can be obtained by solving the following constrained nonlinear programme (NLP):

$$\text{min: } V(x,\tau) = \frac{\left(\frac{1}{1-x}\right)^2}{1-(1-p_h)^{\omega}} + \frac{\left(\frac{x}{1-x}\right)^2}{(1-p_h)^{\omega}\left[1-(1-p_h)^{1-\tau}\right]}$$

$$\text{subject to: } (1-\tau)\exp\left(-\beta\right) + \tau\exp\left(-\beta x\right) = \phi , \tag{23.16}$$

where $x = 1-\xi_1$.

The results are given graphically in Figs. 23.5, 23.6, with (p_h, ϕ) on the x–y axis, for ϕ ranging from 10–100 and p ranging from 0.1–0.9. Figure 23.5 shows the contours of the optimal normalized hold time τ and Fig. 23.6 gives the contours of the optimal normalized low stress (x). Given a pair of (p_h, ϕ) the simultaneous

optimal low stress and hold time can be read from the graphs.

Both sets of contours for the optimal hold time and the optimal low stress show an upward convex trend. The results can be interpreted as follows. For the same p, in situations where the time constraint calls for a higher AF, it is better to increase the low stress and extend the hold time at low stress. For a fixed AF, a longer test time (so that p increases) will result in a smaller optimal low stress and a shorter optimal hold time.

23.2.2 Planning Multiple-Step SSALT

To design optimal plans for multiple-step SSALT, we adopt a similar idea as in CSALT where the low stress level and its sample allocation are split into two portions. As all units are tested in a single step-stress pattern, the analogy of the sample allocation in a CSALT is the hold time in a SSALT. As a result, for a three-step SSALT, the hold time at the high stress level is kept at $(1-\tau)$ while the hold time at low stress is split into two for the additional intermediate stress level. In doing so, we need to ensure that after splitting the optimal low stress of a two-step SSALT into two stress levels, the AF achieved in the newly created three-step SSALT is identical to that the original two-step SSALT. Since the high stress and its hold time remain intact, the AF contributed by the first two steps of the three-step SSALT must be the same as that contributed by the low stress in the original two-step SSALT. In essence, given the target AF and p_h, we first solve the optimal design problem for a two-step SSALT. Then, a new target AF corresponding to the AF contributed by the low stress of the optimal two-step SSALT is used as input to solve for a new two-step SSALT; which, after combining with the earlier result, forms a three-step SSALT. To achieve the new target AF, the resulting middle stress will be slightly higher than the optimal low stress. The new two-step SSALT uses this middle stress as the high stress and the optimal τ as the test duration. The optimal hold time and low stress for a three-step SSALT can be solved using (23.16).

The above procedure can be generalized to m steps SSALT which has $m-1$ cascading stages of two-step SSALT, as it has the structure of a typical dynamic programme. The number of steps corresponds to the stage of a dynamic programme and the alternatives at each stage are the low stress level and test duration.

For example, in a three-step SSALT having two cascading stages of simple SSALT, the results of stage 1 of the simple SSALT gives the optimal low stress level and its hold time. At stage 2, this low stress level is split into a simple SSALT that maintains the overall target AF. As a result AF is one of the state variables which is additive under LCEM; i. e. the new target AF for stage 2 is the AF contributed by the low stress in stage 1. From (23.15), the AF contributed by the low stress is given by

$$\phi' = \tau \ \exp(-\beta x)\,. \tag{23.17}$$

To solve the stage 2 NLP, this target AF needs to be normalized by the hold time, τ, due to change to time scale; i. e. the normalized AF, ϕ_2 at stage 2 is given by:

$$\phi_2 = \phi'/\tau = \exp(-\beta x)\,. \tag{23.18}$$

Note that, to meet the above target AF, the middle stress level x_m should be higher than the optimal low stress in stage 1. As a result, p_2, the expected proportion of failure at x_m during τ will also increase. At the same time, for consistency, we need to ensure that β of the stress life model is identical to that obtained in stage 1. These variables are interdependent and can only be obtained iteratively. The algorithm [23.24] that iteratively solves for p_2, x_m, that results in the same β is summarized as follows.

1. Compute $p_2^{(0)}$, the expected proportion of failure at the low stress level of stage 1:

$$\begin{aligned} p_2^{(0)} &= 1-\exp\left(-\frac{\tau}{\theta_x}\right) \\ &= 1-\exp\left\{-\tau\log\left(\frac{1}{1-p}\right)\right. \\ &\quad \left.\times\exp\left[\beta\,(1-x)\right]\right\}. \end{aligned} \tag{23.19}$$

2. Solve the constrained NLP in (23.16) to obtain $\left(\tau^*_{(1)}, x^*_{(1)}, \beta^*_{(1)}\right)$.
3. Compute the new middle stress $x_\mathrm{m}^{(1)}$

$$x_\mathrm{m}^{(1)} = \beta^*_{(1)} \Bigg/ \left[\log\left(\frac{\log\left(\frac{1}{1-p_2^{(0)}}\right)}{\tau\log\left(\frac{1}{1-p}\right)}\right) + \beta^*_{(1)}\right], \tag{23.20}$$

4. Update p_2 using $x_\mathrm{m}^{(1)}$:

$$\begin{aligned} p_2^{(1)} &= 1-\exp\left\{-\tau\log\left(\frac{1}{1-p}\right)\right. \\ &\quad \left.\times\exp\left[\beta\left(1-x_\mathrm{m}^{(1)}\right)\right]\right\}. \end{aligned} \tag{23.21}$$

5. Repeat steps 2 to 4, with $\left(p_2^{(1)}, \phi_2\right)$, $\left(p_2^{(2)}, \phi_2\right)$, $\left(p_2^{(3)}, \phi_2\right), \ldots$ until $\left|\beta^*_{(k)} - x_\mathrm{m}^{(k)}\beta\right| < \varepsilon$, for some prespecified $\varepsilon > 0$.

Suppose that $\left(\tau^*_{(k)}, x^*_{(k)}, \beta^*_{(k)}\right)$ are the solutions of the scheme. The new optimal low stress and hold time can be computed by combining the results from stages 1 and 2 to form the optimal plan for a three-step SSALT ($h = 3$) as follows:

$$x_1 = x_{\mathrm{m}}^{(k)} \cdot x^*_{(k)}\ ,\ \ x_2 = x_{\mathrm{m}}^{(k)}\ ,\ \ \tau_1 = \tau \cdot \tau^*_{(k)}\ ,\ \ \tau_2 = \tau\ . \tag{23.22}$$

In general, the above scheme can be carried out recursively to generate test plans for multiple-step SSALT.

23.2.3 Numerical Example

Suppose that a three-step SSALT test plan is needed to evaluate the breakdown time of insulating oil. The high and use stress levels are 50 kV and 20 kV, respectively, and the stress is in log(kV). The total test time is 20 h. It is estimated that the reliability is about 0.1 under 50 kV for 20 h ($p = 0.9$) and the target acceleration factor $\phi = 50$.

Solving (23.16) gives $\beta = 4.8823$, $\tau_2 = 0.6871$ and $x = 0.5203$. Using these as the inputs for the next stage, we have $\tau_1 = 0.4567$; $x_1 = 0.2865$ and $x_2 = 0.6952$. As a result, the voltages for conducting the SSALT are

$$\begin{aligned} S_1 &= \exp\left[S_0 + x_1(S_h - S_0)\right] \\ &= \exp\left\{\log(20) + 0.2865 \times \left[\log(50) - \log(20)\right]\right\} \\ &= 26.0\,\mathrm{kV}\ , \\ S_2 &= \exp\left[S_0 + x_2(S_h - S_0)\right] \\ &= \exp\left\{\log(20) + 0.6952 \times \left[\log(50) - \log(20)\right]\right\} \\ &= 37.8\,\mathrm{kV}\ . \end{aligned}$$

And the switching times for the lowest and the middle stress are

$$\begin{aligned} t_1 &= \tau_1 20 = 9.134\,\mathrm{h} = 548.0\,\mathrm{min}\ ; \\ t_2 &= \tau_2 20 = 13.74\,\mathrm{h} = 824.5\,\mathrm{min}\ . \end{aligned}$$

The three-step SSALT starts the test at 26 kV and holds for 548 min, then increase the stress to 37.8 kV and holds for another 276 min (=824.5–548), after which the stress is increased to 50 kV until the end of the test.

23.3 Planning Accelerated Degradation Tests (ADT)

For reliability testing of ultra-high-reliability products, ALT typically ends up with too few failures for meaningful statistical inferences. To address this issue, accelerated degradation tests (ADT), which eliminate the need to observe actual failures, were proposed. For successful application of ADT, it is imperative to identify a quantitative parameter (degradation measure) that is strongly correlated with product reliability and thus will degrade over time. The degradation path of this parameter is then synonymous to performance loss of the product. The time to failure is usually defined as the first passage time of the degradation measure exceeding a prespecified threshold.

Planning of ADT typically involve specifying the stress levels, sample size, sample allocations, inspection frequencies and number of inspections for a constant-stress ADT (CSADT). More samples and frequent inspections will result in more accurate statistical inferences; but at a higher testing cost. So there is a tradeoff between the attainable precision of the estimate and the total testing cost. *Park* and *Yum* [23.25] and *Yu* and *Chiao* [23.26] used precision constraints for optimal planning. *Boulanger* and *Escobar* [23.27] and *Yu* and *Tseng* [23.28] also derived cost functions according to their test procedures. *Wu* and *Chang* [23.29] and *Yang* and *Yang* [23.30] presented CSADT plans such that the asymptotic variance of a percentile of interest is minimized while the testing cost is kept at a prescribed level. *Tang* et al. [23.31] gave SSADT plans in which the testing cost is minimized while fulfilling a precision constraint. *Park* et al. [23.32] gave an SSADT plan with destructive inspections. *Yu* and *Tseng* [23.33] presented a CSDT plan in which the rate of degradation follows a reciprocal Weibull distribution.

23.3.1 Experimental Set Up and Model Assumptions

For simplicity, we consider an ADT, be it a CSADT or SSADT, with two stress levels. Some descriptions and assumptions are as follows:

1. The test stress X_k is normalized by $X_k = \frac{S_k - S_0}{S_2 - S_0}$, $k = 0, 1, 2$, in which the S_k are functions of the applied stresses. With such a transformation, $X_0 = 0 < X_1 < X_2 = 1$.
2. A total sample size is n of which n_k are assigned to the stress level X_k, so that the relationship between

n and n_k can be expressed by:

$$n = \begin{cases} \sum_{k=1}^{2} n_k & \text{for CSADT} \\ n_k & \text{for SSADT} \end{cases} . \tag{23.23}$$

3. The test duration at stress X_k is τ_k, and the stopping time of the whole test is T. The relationship between T and τ_k is:

$$T = \begin{cases} \text{maximum}(T_1, T_2) & \text{for CSADT} \\ \sum_{k=1}^{2} T_k & \text{for SSADT} \end{cases} . \tag{23.24}$$

4. For each unit i, let $D_{i,1}, D_{i,2}, \ldots D_{i,j}$ be the recorded degradation values, which are the differences between the initial and current value of the degradation measurement at the preset time points $t_{i,1}, t_{i,2}, \ldots t_{i,j}, t_{i,0} = 0 < t_{i,1} < t_{i,2} < \ldots < t_{i,j} < \ldots t_{i,L} = T$; each item is measured L_1 times at X_1 and L_2 times at X_2. The total number of inspections is $L = L_1 + L_2$. Given the number of inspections, all samples are inspected simultaneously at equal interval Δt so that the stress-changing time is $T_1 = L_1 \Delta t$ and the experiment stopping time is $T = L\Delta t = (L_1 + L_2)\,\Delta t$.
5. The degradation is governed by a stochastic process $[D_k(t), t \geq 0]$ with drift $\eta_k > 0$ and diffusion $\sigma_k^2 > 0$ at X_k. We assume that the degradation increments follow a normal distribution, i. e. $\Delta D_{i,j} \sim N\left(\eta_k \Delta t_{i,j}, \sigma^2 \Delta t_{i,j}\right)$ with probability distribution function (PDF)

$$f\left(\Delta D_{i,j}\right) = \frac{1}{\sqrt{2\pi}\sqrt{\Delta t_{i,j}\sigma^2}} \exp \times \left(-\frac{\left(\Delta D_{i,j} - \Delta t_{i,j}\eta_k\right)^2}{2\Delta t_{i,j}\sigma^2} \right) \tag{23.25}$$

in which the drift is stress-dependent, and is given by:

$$\eta_k = a + bX_k \tag{23.26}$$

and the diffusion remains constant for all stresses:

$$\sigma_k^2 = \sigma^2 , \tag{23.27}$$

where a, b and σ^2 are unknown parameters that need to be pre-estimated either from engineering handbooks or other ways before experiment planning.

6. Only degradation increments are measured throughout the test. This assumption is mild since the products in ADT are always highly reliable and normally no physical failures occur.

The above model is applicable to stress-drift relations that can be linearized as in (23.26). For example, for degradation induced by humidity, (23.26) may be the result after taking logarithm of the rate of reaction versus the logarithm of the relative humidity. In the case of the Arrhenius model, the reaction rate is an exponential function of the stress factor (= 1/absolute temperature); taking logarithms on both sides of the equation results in a linear function between the log(Drift), which is η_k, versus the stress factor (= 1/absolute temperature).

23.3.2 Formulation of Optimal SSADT Plans

Here, we follow *Tang* et al. [23.31], in which an optimal SSADT plan is obtained such that the total test expense is minimized while the probability that the estimated mean lifetime at use stress locates within a predescribed range of its true value should not be less than a precision level p. For simplicity, the decision variables are the sample size and the number of inspections at each stress level, which also determine the test duration for a given inspection interval. The context of discussion can be generalized to that of a CSADT plan by noting that

$$\pi_k = \begin{cases} \frac{n_k}{n} & \text{for CSADT} , \\ \frac{T_k}{T} & \text{for SSADT} . \end{cases} \tag{23.28}$$

$$q_k = \begin{cases} \frac{T_k}{T} & \text{for CSADT} , \\ \frac{n_k}{n} & \text{for SSADT} . \end{cases} \tag{23.29}$$

For CSADT, $q_1 = 1, 0 < q_2 \leq 1$, while $q_k = 1$ for SSADT. With this definition, the proportion of sample allocation in CSADT is analogous to the holding time in SSADT. This is consistent with the analogy between CSALT and SSALT.

Precision Constraint in SSADT Planning

Suppose that the mean lifetime at use condition, $\mu(X_0)$, is of interest in our planning. To obtain an estimate close to its true value with a certain level of confidence, we impose a precision constraint by limiting the sampling risk in estimating $\mu(X_0)$ with its MLE, i. e. $\widehat{\mu}(X_0)$, to be reasonably small. Mathematically, this can be expressed as follows:

$$\Pr\left[\frac{\mu\,(X_0)}{c} \leq \widehat{\mu}\,(X_0) \leq c\mu\,(X_0) \right] \geq p\,, \tag{23.30}$$

where $c > 1$ and p are given constants. The asymptotic variance of $\widehat{\mu}\,(X_0)$ is needed for further explanation of (23.30). From (23.25), the log-likelihood for an individual degradation increment $D_{i,j}$ is

$$\ln L_{i,j} = -\frac{1}{2}\ln(2\pi) - \frac{1}{2}\ln\left(\Delta t_{i,j}\right) - \ln\sigma - \frac{U_{i,j}^2}{2}\,, \tag{23.31}$$

where

$$U_{i,j} = \frac{\left(\Delta D_{i,j} - \Delta t_{i,j}\eta_k\right)}{\sqrt{\Delta t_{i,j}}\sigma}\,, \begin{cases} k=1 & \text{if } j \le L_1\,, \\ k=2 & \text{otherwise}\,. \end{cases}$$

Hence, the log-likelihood function for all degradation increments of n items is given by

$$\ln L = \sum_{i=1}^{n}\sum_{j=1}^{L}\ln L_{i,j}\,. \tag{23.32}$$

Given the degradation critical value D_c, $\mu\,(X_0)$ is given by the ratio of this threshold value over drift at use condition:

$$\mu\,(X_0) = D_c/\eta_0 = D_c/a\,. \tag{23.33}$$

Let $\left\{\widehat{a}, \widehat{b}, \widehat{\sigma}\right\}$ be the MLE of $\{a, b, \sigma\}$, then, by the invariant property, the MLE of $\mu\,(X_0)$ is given by:

$$\widehat{\mu}\,(X_0) = D_c/\widehat{\eta_0} = D_c/\widehat{a} \tag{23.34}$$

Then the asymptotic variance of $\widehat{\mu}(X_0)$ can be obtained by:

$$\text{Avar}\left[\widehat{\mu}(X_0)\right] = \widehat{h}'\mathbf{F}^{-1}\widehat{h}\,, \tag{23.35}$$

where $h = \left(\frac{\partial\widehat{\mu}(X_0)}{\partial a}, \frac{\partial\widehat{\mu}(X_0)}{\partial b}, \frac{\partial\widehat{\mu}(X_0)}{\partial\sigma}\right)'$, and $\boldsymbol{F}$ is a Fisher information matrix displayed as follows, in which the caret ($\widehat{\ }$) indicates that the derivative is evaluated at $\{a\,, b\,, \sigma\} = \left\{\widehat{a}\,, \widehat{b}\,, \widehat{\sigma}\right\}$. We make use of $E\left(U_{i,j}\right) = 0$ and $\text{Var}\left(U_{i,j}\right) = 1$

$$\boldsymbol{F} = \begin{pmatrix} E\left(-\frac{\partial^2\ln\tilde{L}}{\partial a^2}\right) & E\left(-\frac{\partial^2\ln\tilde{L}}{\partial a\partial b}\right) & E\left(-\frac{\partial^2\ln\tilde{L}}{\partial a\partial\sigma}\right) \\ & E\left(-\frac{\partial^2\ln\tilde{L}}{\partial b^2}\right) & E\left(-\frac{\partial^2\ln\tilde{L}}{\partial b\partial\sigma}\right) \\ \text{symmetrical} & & E\left(-\frac{\partial^2\ln\tilde{L}}{\partial\sigma^2}\right) \end{pmatrix}$$

$$= \frac{n}{\widehat{\sigma}^2}\begin{pmatrix} L\Delta t & \Delta t\sum_{k=1}^{2}X_k L_k & 0 \\ & \Delta t\sum_{k=1}^{2}X_k^2 L_k & 0 \\ \text{symmetrical} & & 2L \end{pmatrix}.$$

Thus we have

$$\text{Avar}\left[\widehat{\mu}(X_0)\right] = \frac{\widehat{\sigma}^2}{n}\frac{D_c^2}{\widehat{a}^4}\left(\frac{\sum_{k=1}^{2}X_k^2 L_k}{L\Delta t\sum_{k=1}^{2}X_k^2 L_k - \Delta t\left(\sum_{k=1}^{2}X_k L_k\right)^2}\right). \tag{23.36}$$

Because the MLE is asymptotically normal and consistent, for large n, approximately we have

$$\widehat{\mu}\,(X_0) \sim N\left\{\left[\mu\,(X_0)\right]\,,\ \text{Avar}\left[\widehat{\mu}\,(X_0)\right]\right\}, \tag{23.37}$$

which can be rewritten as

$$\frac{\widehat{\mu}(X_0)}{\mu(X_0)} \sim N\left(1\,, \frac{\widehat{\sigma}^2}{n\widehat{a}^2}Q\right). \tag{23.38}$$

From (23.30), we have

$$\Pr\left(\frac{1}{c} \le \frac{\widehat{\mu}(X_0)}{\mu(X_0)} \le c\right) \ge p\,. \tag{23.39}$$

This translates into the precision constraint

$$\Phi\left(\frac{(c-1)\sqrt{n}}{\frac{\widehat{\sigma}}{\widehat{a}}\sqrt{Q}}\right) - \Phi\left(\frac{\left(\frac{1}{c}-1\right)\sqrt{n}}{\frac{\widehat{\sigma}}{\widehat{a}}\sqrt{Q}}\right) \ge p\,,\ c > 1\,, \tag{23.40}$$

where $\Phi(\cdot)$ is the cumulative distribution function (CDF) of the standard normal distribution and

$$Q = \frac{\sum_{k=1}^{2}X_k^2 L_k}{L\times\Delta t\times\sum_{k=1}^{2}X_k^2 L_k - \Delta t\times\left(\sum_{k=1}^{2}X_k L_k\right)^2}. \tag{23.41}$$

Cost Function in SSADT Planning

Typical cost components for testing consists of:

1. Operating cost, which mainly comprises the operator's salary and can be expressed as $\Delta t(C_{o1}L_1 + C_{o2}L_2)$, where C_{ok} is the salary of the operator per unit of time at X_k.
2. Measurement cost, which includes the cost of using measuring equipments and the expense of testing materials. Because depletion of equipments at higher stress is more severe than that at lower stress, measurement cost can be generated as $n(C_{m1}L_1 + C_{m2}L_2)$, where C_{mk} is the cost per measurement per device at X_k.

3. Sample cost, which is related to the number of samples, and can be formulated as $C_d n$, where C_d is the price of an individual device.

So, the total cost (TC) of testing is:

$$\begin{aligned} &TC\,(n\,,\,L_1\,,\,L_2|X_1\,,\,\Delta t) \\ &= \Delta t\,(C_{o1}L_1 + C_{o2}L_2) \\ &\quad + n\,(C_{m1}L_1 + C_{m2}L_2) + C_d n\,, \\ &C_{ok} > 0\,,\, C_{mk} > 0\,,\, C_d > 0\,. \end{aligned} \tag{23.42}$$

In some experiments, the lower test stress can be fixed because of practical limitations. For example, the temperature of a test oven can only be adjusted within a small range or even fixed at some particular values. Given the lower stress X_1, the two-step-stress ADT planning problem is to determine the sample size n, number of inspections L_1 and L_2. The problem is formulated as:

$$\begin{aligned} &\text{Min: TC}\,(n\,,\,L_1\,,\,L_2|X_1\,,\,\Delta t) \\ &\quad = \Delta t\,(C_{o1}L_1 + C_{o2}L_2) \\ &\quad\quad + n\,(C_{m1}L_1 + C_{m2}L_2) + C_d n\,, \\ &\quad\quad C_{ok} > 0\,,\, C_{mk} > 0\,,\, C_d > 0\,; \\ &\text{s.t.: } \Phi\left(\frac{(c-1)\cdot\sqrt{n}}{\frac{\tilde{\sigma}}{\tilde{a}}\cdot\sqrt{Q}}\right) - \Phi\left(\frac{(\frac{1}{c}-1)\cdot\sqrt{n}}{\frac{\tilde{\sigma}}{\tilde{a}}}\cdot\sqrt{Q}\right) \\ &\quad\quad \geq p\,,\;\; c > 1\,. \end{aligned} \tag{23.43}$$

Due to the simplicity of the objective function and the integer restriction on the decision variables, the solution can be obtained by complete enumerations or using search methods given in *Yu* and *Tseng* [23.28].

23.3.3 Numerical Example

In this example, the operating temperature of a light-emitting diode (LED) in use condition is 25 °C. Historical experience indicates that the highest temperature that will not affect the failure mechanism is 65 °C. The lower test stress is set at 45 °C, which can be normalized by

$$\begin{aligned} X_1 &= \frac{S_1 - S_0}{S_2 - S_0} \\ &= \frac{1/(45+273) - 1/(25+273)}{1/(65+273) - 1/(25+273)} \\ &= 0.53\,. \end{aligned}$$

This normalization is consistent with the Arrhenius model in which stress takes the reciprocal of temperature.

To set the inspection time interval, we refer to a similar CSADT plan conducted at 25 °C in *Yu* and *Chiao* [23.26], which suggested an optimal inspection time interval of 240 h. Here, in view of adopting a higher stress, Δt should be shorter as the degradation rate is higher. Here, $\Delta t = 120$ h to capture more degradation information. The operation and measurement coefficients are set at $C_{o1} = 0.3\,,\, C_{o2} = 0.4\,,\, C_{m1} = 4$ and $C_{m2} = 4.5$.

Here the c and p values represent the dependence on sampling risk. Smaller sampling risk implies smaller c and relatively larger p and vise versa. As an illustration, we present the case of $c = 2$, $p = 0.9$ by setting $\tilde{\sigma} = 10^{-4}$ (which is comparable with the value used in *Yu* and *Chiao* [23.26]).

Substitute this information into (23.42) and (23.43), we have:

$$\begin{aligned} &\text{Min:}\quad \text{TC}\,(n\,,\,L_1\,,\,L_2) \\ &\qquad = 120\cdot(0.3\cdot L_1 + 0.4L_2) \\ &\qquad\quad + n\cdot(4L_1 + 4.5L_2) + 86n \\ &\text{s.t.:}\quad \Phi\left(\frac{\sqrt{n}}{100\sqrt{Q}}\right) - \Phi\left(\frac{-\frac{1}{2}\sqrt{n}}{100\sqrt{Q}}\right) \geq 0.9\,, \end{aligned}$$

where $Q = 0.53^2 L_1 + L_2/120\big[(L_1+L_2)(0.53^2 L_1 + L_2) - (0.53L_1 + L_2)^2\big]$.

This plan puts 16 samples at 45 °C for 3240 h, after which the temperature is increased to 65 °C and held for 720 h before the end of the test. Measurements are taken at 120 h interval.

23.4 Conclusions

In this chapter, literature surveys and statistical approaches for planning three types of accelerated reliability testing, namely, constant-stress accelerated life tests, step-stress accelerated life tests and step-stress accelerated degradation tests, are presented. We only focus on literature concerning the above three problems since the 1990s. A more comprehensive survey can be obtained from *Nelson* [23.14]. The general approach taken in solving for the optimal plan is to derive the asymptotic variance (or its approximation) of a percentile of interest at use condition and minimize it subject to a set of constraints. The constraints either

help to define the logical solution space or help to narrow the solution space for ease of finding the solution. For more general considerations, the approach presented in *Tang* and *Xu* [23.12] can be adopted to generalize the current models so that other objectives and constraints can be incorporated.

24. End-to-End (E2E) Testing and Evaluation of High-Assurance Systems

U. S. Department of Defense (DoD) end-to-end (E2E) testing and evaluation (T&E) technology for high-assurance systems has evolved from specification and analysis of thin threads, through system scenarios, to scenario-driven system engineering including reliability, security, and safety assurance, as well as dynamic verification and validation. Currently, E2E T&E technology is entering its fourth generation and being applied to the development and verification of systems in service-oriented architectures (SOA) and web services (WS). The technology includes a series of techniques, including automated generation of thin threads from system scenarios; automated dependency analysis; completeness and consistency analysis based on condition–event pairs in the system specification; automated test-case generation based on verification patterns; test-case generation based on the topological structure of Boolean expressions; automated code generation for system execution as well as for simulation, automated reliability assurance based on the system design structure, dynamic policy specification, analysis, enforcement and simulation; automated state-model generation; automated sequence-diagram generation; model checking on system specifications; and model checking based on test-case generation. E2E T&E technology has been successfully applied to several DoD command-and-control applications as well civilian projects.

The Department of Defense (DoD) end-to-end testing and evaluation (E2E T&E) project started in 1999 when the DoD was involved in the largest testing project ever, i.e, year 2000 (Y2K) testing. During Y2K testing, it was discovered that, even though DoD had many testing guidelines, most of them only addressed unit testing, and few were available for integration testing, but Y2K testing involved mainly integration testing, and thus needed E2E T&E guidelines.

Even though many techniques, such as inspection and program verification, are available for evaluating system reliability and quality, testing was and is the primary means for reliability and quality assurance. Furthermore, in practice, integration testing is often the most time-consuming and expensive part of testing. It is common to find software development projects with 50–70% of effort on testing, and 50–70% of the testing effort on integration testing. A review of the literature on integration testing shows that most integration testing techniques are either a methodology, such as incremental integration, top-down, and bottom-up integration [24.1], or are based on specific language or design structures of the program under test [24.2–5]. These techniques are useful, but are applicable to software written using the related techniques only. For example, an integration testing technique for an object-oriented (OO) program using Java may not be applicable to the testing of a legacy program using the common business-oriented language (COBOL). It may not be applicable to a C++ program because Java has no pointers but C++ does.

Due to these considerations, DoD initiated a project on E2E T&E in 1999 [24.6], intended to verify the interconnected subsystems as well as the integrated system. E2E T&E is different from module testing where the focus is on individual modules and is similar to, yet different from, integration testing where the focus is on the interactions among subsets of modules. Since 1999, E2E T&E has evolved from thin-thread specification and analysis, to scenario specification and analysis, and to scenario-driven system engineering (SDSE), and from SDSE to testing and verification of web services (WS) in a service-oriented architecture (SOA).

This paper is organized as following. Section 24.1 covers the history and evolution of E2E T&E and scenario specification. Section 24.2 presents an overview of the third and fourth generations of E2E T&E techniques. Section 24.3 elaborates static analyses, including model checking, completeness and consistency (C&C) analyses, and test-case generation. Section 24.4 presents automated test execution by distributed agents and how simulation of concurrent scenarios can be executed. Section 24.5 discusses policy specification and enforcement, which can be used to enforce safety and security policies, as well as dynamic verification and validation. Section 24.6 presents the reliability model for dynamic reliability assurance. Section 24.7 outlines the application of E2E T&E in SOA. Finally, Sect. 24.8 concludes this paper.

24.1 History and Evolution of E2E Testing and Evaluation

This section briefly describes the evolutionary development of the new generations of E2E T&E. Table 24.1 depicts the four generations of E2E T&E, their application periods, and the signature techniques in each generation.

24.1.1 Thin-Thread Specification and Analysis – the First Generation

The genesis of the DoD E2E T&E is thin-thread specification and analysis. This is based on the lesson learned from DoD Y2K testing. At that time, it was discovered that the DoD did not have an integration testing guideline that could be used for a variety of applications written in a variety of programming languages. Most existing integration techniques are either mainly of high-level concepts (such as those that used an incremental manner to perform integration testing) or are applicable to specific design structures or programming languages only, e.g., an integration testing techniques for object-oriented (OO) programs. Thus, there is an immediate need for an integration testing guideline that can be used by a majority of DoD organizations and services.

While no such DoD integration testing guidelines are available, it was discovered that most DoD organizations used the concept of thin threads to perform integration testing. A thin thread is essentially an execution sequence that connects multiple systems during system exercise and execution, and most organizations reported their Y2K testing effort in terms of the number of thin threads successfully executed and tested. In other words, thin threads were successfully used as the

Table 24.1 Evolution of E2E T&E techniques

Generations	Application period	Signature techniques
First	1999–2002	Thin thread specification and analysis techniques
Second	2001–2003	Scenario specification, analysis, and pattern verification techniques
Third	2003–present	Scenario specification and analysis, Scenario-driven system engineering, including reliability, security, and risk analysis; modeling and simulation
Fourth	2004–present	Scenario specification and analysis, and scenario-driven system engineering in service-oriented architecture with dynamic composition and recomposition

principal technique for Y2K integration testing. Integration testing based on thin threads has many advantages including:

- Thin threads are independent of any application;
- Thin threads are independent of any programming languages;
- Thin threads are also independent of any specific design structure;
- Thin threads can be used early during system development and late during system integration testing; and
- Thin threads can be easily understood by a vast number of DoD engineers. Thus, a DoD integration testing based on thin threads becomes a viable candidate for an integration guideline.

However close examination of DoD Y2K testing effort also revealed some important weakness of thin threads:

- Most thin threads were specified without a consistent format or using a localized format. In other words, different groups used different formats to specify thin threads;
- Most thin threads were developed manually and placed in an Excel file and thus were rather expensive to develop and maintain;
- The number of thin threads needed for successful integration testing was not known and thus some organizations used an extensive number of thin threads (such as thousands of thin threads) while some used only few (such as four to five) for a large application;
- The quality of thin threads was not easy to determine as they were developed manually and verified manually.

Thus, the first step of DoD E2E T&E focuses on the following issues:

1. The development of a consistent format for specifying thin threads. Because many thin threads share certain commonality with other thin threads, the DoD E2E guideline also suggests the organization of thin threads into a hierarchical thin-thread tree with related thin threads grouped together as a sub-tree in the thin-thread tree;
2. The development of a tool so that thin threads can be analyzed to ensure that these thin threads meet the minimum requirements;
3. The development of a guideline to determine the number of thin threads needed for an application; specifically, assurance-based testing (ABT) was developed to determine the number of thin threads needed for a certain system quality.

This first-generation DoD E2E T&E also assumes that each individual, participating system has been tested before they are subject to the DoD integration testing.

Several related techniques to thin threads have also been developed, including functional regression testing [24.7], automated dependency recognition and analysis, risk analysis, and test coverage based on specification of thin threads. Three versions of the DoD E2E tools have been developed and experimented with in the period 1999–2002. This experimentation showed that, once the thin-thread tree is specified, it is straightforward to develop test cases to run the integrated system.

24.1.2 Scenario Specification and Analysis – the Second Generation

During 2001–2002, experimentation of the DoD thin-thread tools revealed several serious shortcoming of thin threads:

- The number of thin threads needed is often too large to be manually developed even if an automated support tool is available; and
- Many thin threads differ only slightly from each other as they addressed the same similarity features and functionality of the application.

These shortcomings are due to the fact that each thin thread represents a specific execution sequence while a typical DoD application may have numerous execution

sequences. Thus, it is expensive and time-consuming to specify these thin threads even with automated tool support. To address these problems, it was discovered that it is possible to add control constructs such as *if-then-else* and *while* into thin threads. However, adding these constructs will change the meaning of thin threads because such a modified thread no longer represents one execution sequence, but multiple execution sequences. In other words, the modified thread is no longer a thin thread as defined by the DoD Y2K testing project, and the modified thread is called a scenario, for lack of an alternative, better names.

DoD E2E T&E is changed from the specification and analysis of thin threads to the specification and analysis of system scenarios; furthermore, techniques are developed so that thin threads will be automatically generated once system scenarios are specified. The fact that thin threads can be automatically generated from E2E scenarios makes them different from unified modeling language (UML) use cases. While UML use cases also describe system scenario from an external point of view, a use case does not need to be able to generate thin threads for testing, furthermore the E2E system scenarios can be used early in the development life cycle as well as late for integration testing and regression testing.

The original DoD E2E T&E techniques, such as automated dependency recognition and analysis, test coverage, risk analysis, functional regression testing, are modified so that they are applicable to the E2E system scenarios. Furthermore, several versions of tools were developed to support scenario specification and analysis.

Experiments with second-generation DoD E2E T&E were carried out on several projects, including a testing project for a high-availability communication processor. The requirements of a sample telecommunication processor were first translated into system scenarios, then the tool automatically generate a large number of thin threads from these scenarios, and finally an engineer developed test cases based on the thin threads generated. It was discovered that translating the original requirements into system scenarios is much easier than specifying the thin threads from the same requirements, and generating test cases from the thin threads generated is straightforward. The engineers involved in these experimentation also expressed the advantage of this approach over their current approach. It was much more difficult to develop test cases from the system requirements using their current approach, and the DoD E2E approach is much more structural and rigorous while saving them time and effort in developing test cases. In conclusion, second-generation DoD E2E T&E achieved its original goal of assisting test engineers to perform integration testing efficiently and effectively.

Several other new techniques were developed and discovered:

1. The system scenarios can be specified formally and subjected to a variety of formal analyses, not just the dependency analysis and risk analysis developed in the first generation of the E2E tool.
2. Systems often exhibit patterns in their behavior and these patterns can be rather useful for automated test-script generation.
3. As the developers of DoD E2E T&E always suspected, E2E techniques can also be useful in design and analysis rather than for integration testing only. This was confirmed in early 2003, and after hearing the briefing of the E2E T&E, a DoD organization started using the E2E T&E techniques for specifying and analyzing its command-and-control system.

Formalized scenario specification

The system scenario in DoD E2E T&E can be formalized in two ways: the first concerns the elements in the scenario, while the second concerns the process aspect of the scenario. The first aspect is formalized using the the actor, condition, data, action, timing, and event (ACDATE) model [24.8]. Using the ACDATE model, the specification of the software under development is described by its five model elements and their relationships.

- An **actor** is a model element that represents a system or its component with a clear boundary that interacts with other actors.
- A **condition** is a predicate on data used to determine the course of a process taken by actors. Conditions can be preconditions and post-conditions representing external and internal conditions and situations. Internal conditions represent the states of all system objects of interest, and external conditions can be network and database connections
- A **data** is an information carrier that represents the internal status of actors.
- An **action** is a model element that represents an operational process to change the internal status of an actor. Actions are performed when the preconditions are satisfied and events occur. Typically an action is
  a brief atomic computation such as
  – Assignment: sets the value of a variable,

  - Call: calls an operation on a target object,
  - Create: creates a new object,
  - Destroy: destroys an object,
  - Return: returns a value to a caller.
  - Send: generates an event, outgoing data,
  - Terminate: self-destruction of the owning object.
- The **timing** is an attribute of an actor, data, condition, event and action or behavioral model elements that describe their static or dynamic time information.
- An **event** is a model element that represents an observable occurrence with no time duration. Events can be internal and external occurrences that impact on, or are generated by, system objects such as incoming data (inputs), external action, and internal method call/message.

Once the specification of the software under development is represented by these five components and their relationships, the execution steps can be constructed using control constructs such as *if-then-else* and *while-do*, as shown in the following example. Figure 24.1 illustrates a simple scenario: "when both the driver and passenger door are locked, if remote controller is pressed for unlock, then the driver door will be opened", in the design of a car alarm system. In this scenario, five actors, one condition, one data, and one action are used.

Once the system scenario are specified, model checking, test-case generation, automated code generation, policy-enforcement-based dynamic testing, and simulation can be performed.

An important attribute is that scenarios can be specified in a hierarchical manner. The tester can first specify system scenarios at the highest level of abstraction. Once obtained, scenarios can be decomposed to show low-level details. This process can continue until scenarios are detailed enough for the T&E purpose. Furthermore, scenarios can be organized in a scenario tree where a group of related scenarios form a high-level scenario group [24.9, 10]. This feature is useful for testing an system of systems (SoS) because it often has subcomponents that interact with each other, and some of these components are legacy systems while others may be new systems that have just been introduced. Organizing system scenarios in a hierarchical manner facilitates test reuse and matches the hierarchical structure of the SoS.

Pattern Analysis

Even though a system may have hundreds of thousand scenarios, it may have only a few scenario patterns. For example, a commercial defibrillator has hundreds of thousand of scenarios, however, most (95%) of these scenarios can be classified into just ***eight*** scenario patterns [24.11]:

- Basic pattern (40%),
- Key-event-driven pattern (15%),
- Timed key-event pattern (5%),
- Key-event time-sliced pattern (7%),
- Command–response pattern (8%),
- Look-back pattern (6%),
- Mode-switch patten (8%), and
- Interleaving pattern (6%).

This provides an excellent opportunity for rapid verification because scenarios that belong to the same pattern can be verified using the same mechanism, except perhaps with different parameters such as timing and state information. This can save significant time and effort for implementation of test scripts.

}
```
Action

Data

Fig. 24.1 A sample scenario in the ACDATE language. Once the system scenarios are specified, model checking, test-case generation, automated code generation, policy-enforcement-based dynamic testing, and simulation can be performed

For example, suppose a system has 7000 scenarios, and if 15% of these scenarios belong to a specific pattern, these 1050 (7000×0.15) scenarios can be tested using the same verification software with individualized parameters. Thus, the productivity gain can be significant and industrial application of this approach showed that 25–90% effort reduction is possible [24.12].

Another significant advantage of this approach is the size reduction achieved using this approach. Industrial applications and experiments have indicated that the average length of code for test scripts reduced from 1380 lines of code (LOC) per scenario to 143 LOC per scenario using this approach, corresponding to a size reduction of 89.6%. If we assume that an expert test engineer can develop 1000 LOC of test script each week, the effort reduction achieved by using this approach is significant.

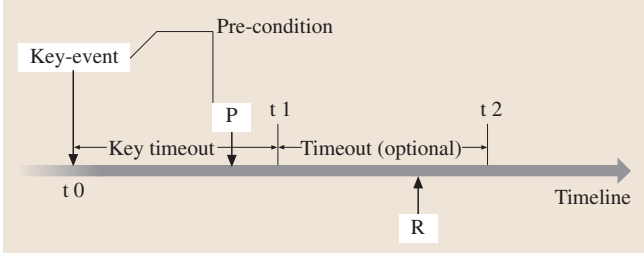

Fig. 24.2 Timed key-event-driven requirement pattern

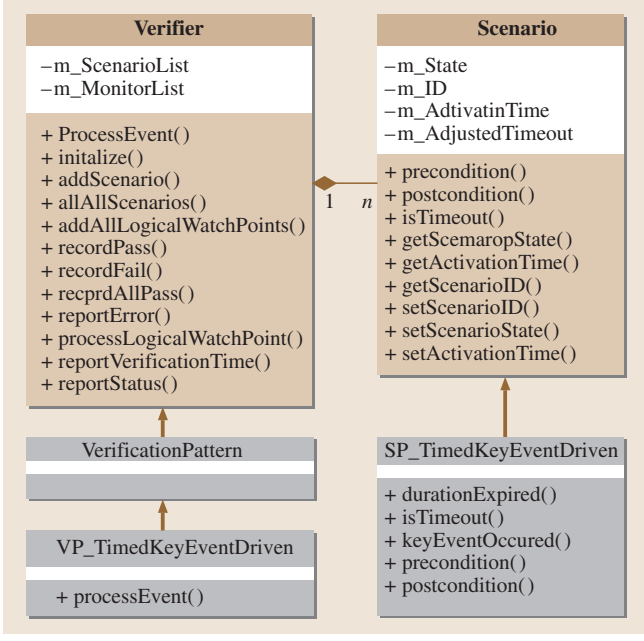

Fig. 24.3 Class diagram of the timed key-event-driven requirement pattern

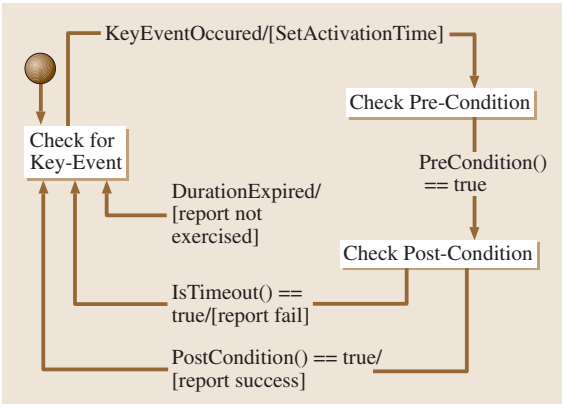

Fig. 24.4 Timed key-event-driven verification pattern

The following illustrate this concept for a timed key-event pattern.

Figure 24.2 shows a timed key-event-driven scenario pattern that includes two timing constraints for three events:

- Within the duration from t0 to t1 and after the key event, if event P occurs, then event R is expected to occur before t2.

As a typical example in an implantable defibrillator, when the device detects a heart problem, the capacity must be charged before it can apply a therapy to the patience, and this scenario shows three events (detection, capacity charged, and therapy applied), and the timing constraints between these three events.

Timed key-event verification patterns.
Name. Timed key-event-driven verification pattern
Description. The timed key-event-driven verification pattern is used to verify requirements that can be represented using the timed key-event-driven scenario pattern shown in Fig. 24.3. It provides an interface to decide if the duration has expired.
Verification state machine. Unlike the basic verification pattern, which starts checking the pre-condition right away, the verification process here checks the pre-condition within the *duration* after the key event occurs. The verifier can report "*not exercised*" if it failed to verify the pre-condition within this duration. Figure 24.4 shows an example of the timed key-event-driven verification pattern.

24.1.3 Scenario-Driven System Engineering – the Third Generation

Once system scenarios are formalized and experimented, DoD realized another need, i. e., can DoD E2E technology be useful for system engineering and system development? Traditional system engineering focuses on the following aspects:

- Reliability analysis;
- Safety analysis;
- Security analysis;
- Simulation, including distributed simulation and code generation;
- Verification and validation (V&V).

The DoD E2E already focused on V&V, and thus the quest is to extend the E2E technology to address the other aspects of system engineering. The rest of the paper will focus on

- Distributed simulation and code generation will be discussed in Sect. 24.4;
- Safety analysis: traditional safety analysis includes event analysis, event sequence and fault-tree analysis, while modern safety analysis includes static model checking and dynamic simulation analysis using executable policies. Model checking will be discussed in Sect. 24.1 and policy specification and enforcement will be discussed in Sect. 24.6;
- The DoD E2E security analysis is based on specification security policies and uses the simulation to evaluate the system vulnerability by verifying the security policies at runtime. These will be discussed in Sects. 24.4 and 24.6.
- Reliability analysis: it turns out that system scenarios are useful for both static and dynamical reliability analyses, and this will covered in Sect. 24.6.

24.1.4 E2E on Service-Oriented Architecture – the Fourth Generation

Currently, E2E T&E technology is being applied to the emerging SOA and web services (WS) platforms where more dynamic features are required, including dynamic composition, recomposition, configuration, reconfiguration, V&V, reliability assurance, ranking of WS, and methodologies that assess the WS. The fourth generation of E2E T&E has the same basic techniques but is implemented on a different software architecture. The basic techniques in the third and fourth generations of E2E T&E will be discussed in Sects. 24.3–24.7 and the SOA-specific techniques will be presented in Sect. 24.8.

24.2 Overview of the Third and Fourth Generations of the E2E T&E

This section outlines the major components of the basic techniques in the third and fourth generations of the E2E T&E. As shown in Fig. 24.5, the development process starts from the user requirements, which

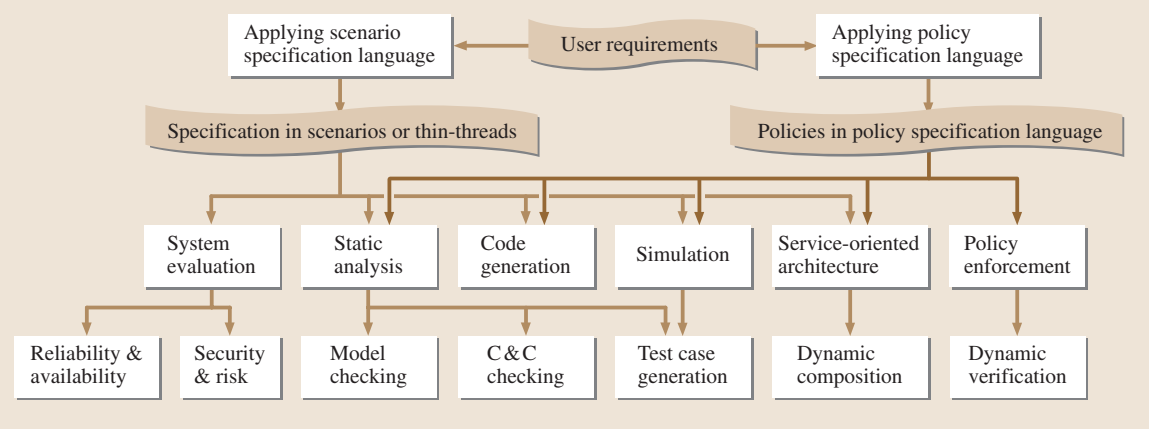

Fig. 24.5 The overall development and E2E T&E

is then formalized into the specification in the ACDATE scenario language, consisting of a sequence of actors, conditions, data, actions, timings, and events. Because scenarios are developed directly from the requirements, they are independent of any programming languages, design techniques, or development processes, such as the waterfall model, or agile development processes such as extreme programming [24.13].

Based on the scenario specification, static analysis, automated code generation, simulation, and system evaluation can be performed. E2E T&E also supports the service-oriented architecture (SOA) where software components are defined by standard interfaces that allow dynamic composition of new services based on existing services. On the other hand, the policies can be extracted from the user requirements and presented in a policy specification language. A policy-based system can be developed and policies are used to verify the behavior of the system dynamically. Static analysis, simulation, and code generation can be applied on policy specification.

Static analysis. Once the system is specified in scenarios, various analysis techniques [24.9, 14, 15] can be used to statically analyze the specification, for example, model checking and C&C. These analyses help the designer to make informed and intelligent decision in the requirement and design phases of project development [24.7, 13, 15]. In other words, the E2E T&E tool can be used early in the life cycle, during, and throughout the rest of the life cycle, including during operation and maintenance. Several methods can be applied to perform model checking, for example, Berkeley lazy abstraction software verification tool (BLAST) [24.16] developed at the University of California at Berkeley and C&C analysis [24.11]. In the process of model checking, both positive and negative test cases can be generated [24.17]. The positive test cases are used to test if the system generates correct output for valid inputs, while the negative test cases are used to test if the system does not generate an undesired output. An undesired output is one that could cause an undetected error or an unacceptable consequence.

The E2E process also supports rapid test-case generation by classifying system scenarios into patterns, where each pattern has a corresponding test case that can be parameterized to test all the system scenarios belong to the pattern. This approach promotes test-case reusability and reduces the cost of test-script generation significantly [24.18]. This approach has been used successfully to test commercial real-time safety-critical embedded medical devices such as pacemakers and defibrillators.

Code generation. Once the model is verified, the automated code-generation tool can be applied to generate the executable directly from the scenario specification. Code generation can also be performed in the simulation framework.

Simulation. Simulation is a practical way to prove the design idea and assess the performance of complex systems dynamically [24.19]. The traditional simulation is done in a specify-and-code or model-and-code manner, which means that, in the simulation process, engineers first construct the target system model and then develop the simulation code to run the simulation. This approach is expensive and inflexible. The automated code generation in E2E T&E environment can perform model-and-run or specify-and-run simulation. In other words, once the scenario model is constructed, no additional simulation coding effort is needed to run the simulation. Even the real target system's code can be automatically generated from the system model with little or no human involvement, because the same automated code-generation tool is applied to generate the real system code and simulation code. In E2E simulation, once scenarios are available, the system is executed in a simulation environment by tracing the conditions and actions in the scenarios. Simulation can be used together with other analyses to prove the ideas and features of the system design. For example, simulation can be used together with timing analysis to determine if the system satisfies the timing requirements. Furthermore, multiple scenarios can be simulated at the same time to determine the interaction of these scenarios. The E2E tool supports distributed test execution by providing the architecture with a test master and test agents. The test master is responsible for managing test scenarios and test scripts, and sending test commands to test agents for remote execution. Test agents are responsible for sending test commands to the system under test for test execution, collecting and data analysis, and for reporting test results to the test master.

Policy enforcement and dynamic verification. A policy-based system allows the requirements and the specification to be modified dynamically. The typical application of a policy-based system is in dynamic safety and security enforcement where the safety and security of a system can change from time to time. A policy-based system is also useful when the system is dealing

with a dynamically changing environment or the functional requirements can change from time to time. For example, the initial system has been programmed for an application temperature range of 0–100 degrees. If the range is later extended to 0–150 degrees, a policy-based implementation does not need to modify the program code and regenerate the executable code. Only the policy data need be updated and reloaded. Policy enforcement can be applied as a dynamic V&V method. In fact, many functional requirements of a system can be extracted as policy requirements. For example, array index range checking, probability value range checking, and execution-order checking can be written as policies. As a result, policy enforcement can dynamically check the validity of computing. Policy enforcement is particularly useful in detecting bugs that are difficult to catch during unit testing and those with complicated interactions due to concurrent threads and processes in simulation.

System evaluation. E2E T&E supports both static and dynamic analyses of reliability, availability, security, risk, timing, usage, dependency, and the effectiveness of test cases. The evaluation results can be applied immediately to guide subsequent testing. For example, according to the number of faults each test case detects, the effectiveness of the test cases can be ranked dynamically. In subsequent testing, the more effective test cases will be applied first in testing. The reliability evaluation results can be applied in selecting components that need to be replaced dynamically.

Service-oriented architecture. The service-oriented architecture (SOA) considers a software system consisting of a collection of loosely coupled services. These services can make use of each other services to achieve their own desired goals and end results. Simple services can cooperate in this way to form a complex service. Technically, a service is the interface between the producer and the consumer. From the producer's point of view, a service is a function that is well defined, self-contained, and does not depend on the context or state of other functions. In this sense a service is often referred to as a service agent. The services can be newly developed applications or just wrapped around existing legacy software to give them new interfaces. From the consumer's point of view, a service is a unit of work done by a service provider to achieve desired end results for a consumer. The next generation of E2E T&E will deal with SOA and composition and recomposition, dynamic configuration and reconfiguration of software systems. Initial investigations have been performed [24.14, 17, 20, 21].

24.3 Static Analyses

To ensure the correctness of the specification, static analysis will be performed, including model checking and C&C analysis. Test cases can be generated in the process of static analysis.

24.3.1 Model Checking

Model checking has been proposed recently to facilitate software testing following the idea that model checking verifies the model while testing validates the correspondence between the model and the system. One of the most promising approaches was proposed at the University of California at Berkeley using BLAST [24.16]. The BLAST model checker is capable of checking safety temporal properties, predicate-bound properties (in a form that asserts that, at a location l, a predicate p is true or false), and identify dead code. BLAST abstracts each execution path as a set of predicates (or conditions) and then these predicates are used to generate test cases to verify programs. This approach is attractive because it deals with code directly rather than the state model used in traditional model checking [24.22]. Thus, the BLAST approach is better suited for software verification than traditional model checking. However, BLAST does not handle currency and its test-case generation is targeted mainly on the positive aspects of testing. Negative aspects such as near misses are not handled. In our E2E T&E framework, many scenarios may be active at the same time, and it is necessary to verify that concurrent execution of these scenarios will not cause the system to deviate from its intended behavior. We extend the BLAST approach to suit the scenario specification in three ways: (1) instead of using the source code to drive model checking, we use our scenario modeling language for model checking. The control-flow automata used by BLAST resembles the workflow model derived by the control constructs in the scenario language; (2) we rely on the conditional or unconditional output, effect, and precondition in each thin thread to construct their essential inner control logic; and (3) we enhance

BLAST to handle concurrent executions of processes in the ACDATE language [24.17].

24.3.2 Completeness and Consistency Analysis

Software requirements are often incomplete, inconsistent, and ambiguous. The specification based on the requirements may have inherited the faults. Faults introduced in this stage of development have been shown to be difficult and more expensive to correct than faults introduced later in the life cycle. C&C analysis on specification aims to eliminate requirement- and specification-related faults. As shown in Fig. 24.6, the process starts from converting user requirements into a ACDATE scenario specification; extracting condition and event (CE) combinations from the specification; performing a completeness analysis to identify all the missing CE combinations; performing consistency analysis to check if the CE combinations are consistent with each other; and identifying the set of scenarios that need to be modified to make the system reliable and robust. More specifically, these steps are explained as follows.

1. Derive system scenarios from the system requirements: formalize system scenarios using the ACDATE model, which includes elements (actor, condition, data, action, timing and event) and the relations among them.
2. Parse each scenario and extract the combinations of conditions and events: from the ACDATE model, the CE combinations are automatically extracted. The CE combinations are partitioned into independent components where each component does not interact or related to the others. Two scenarios are independent of each other if there is no way for them to interact or influence each other. For example, two scenarios that share a common condition are considered related, and the related relationship is transitive. By exhaustively examining the transitive relationships, one can determine if two scenarios are independent of each other.
3. Perform C&C analysis on CE combinations: once the CE combinations are obtained in step 2, consistency analysis on CE combinations is performed and completeness analysis on CE combinations is then performed to identify those missing CE combinations.
4. Construct patching scenarios to eliminate those missing CE combinations. Using an Karnaugh-map analysis, we can aggregate a large number of missing CE combinations into a smaller set of equivalent CE combinations. From these CE combinations, we can develop patching scenarios to cover the missing condition.
5. Classify each patching scenario into one of the three categories: (1) incorporate it as a functional scenario; (2) treat it as an exception with an exception handling; or (3) consider it as a do not care item, based on the nature of the application. In the first case, the covering scenario is indeed an intended behavior but missed in the specification, in the second case the covering scenario is not intended and should be masked out in the specification.
6. Amend the scenario specification using the C&C analysis results: use the results in step 5 to patch the scenario specification automatically.
7. Inform the user about the amendment of the specification and seek amendment of the requirements from the user.

The C&C analysis process is an iterative and incremental process. After each amendment, the C&C process should be repeated to ensure that the amendment does not introduce new consistency. Tools have

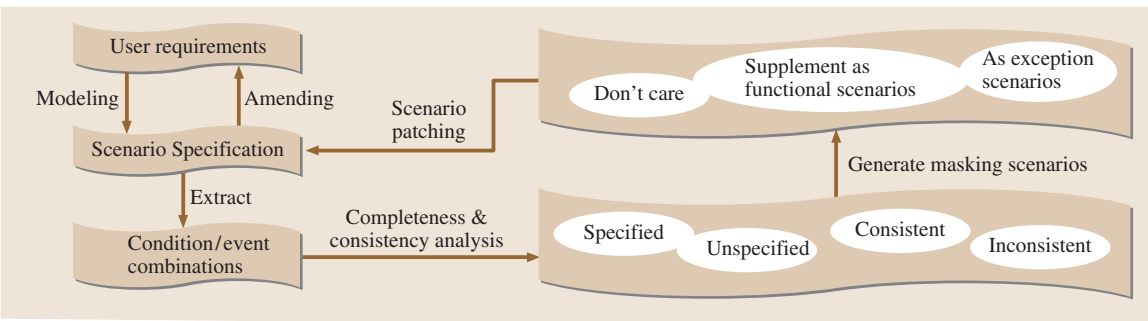

Fig. 24.6 The process of C&C analysis

been developed to perform steps 2–6 automatically. Experiments with the tools in several large, industrial applications have been carried out and the results indicate that the process described above is feasible and scalable to large applications.

24.3.3 Test-Case Generation

Test-case generation techniques can be greatly enhanced by comprehensive formal C&C analysis followed by test-case generation based on Boolean expressions [24.11]. An important distinction of this approach is that test-case generation is based on the quantitative Hamming distance. All previous approaches, including modified condition/decision coverage (MC/DC) and MUMCUT [24.23], were based on user experience and intuition. Exploring the topological hypercube structure of Boolean expressions can easily reveal the faults not discoverable by previous approaches. Furthermore, these two mechanisms can be completely automated, thus saving significant effort and time. After the Boolean-expression generation, the Swiss-cheese test-case-generation tool can be applied to obtain both positive and negative test cases.

The Swiss-cheese (SC) approach is an efficient iterative algorithm developed based on C&C analysis [24.17]. It can identify most error-sensitive positive test cases and most critical negative test cases. Given the Boolean expressions that represent the system specification, the algorithm first maps the Boolean expressions into a multidimensional Karnaugh map called a polyhedron. The algorithm then iteratively identifies all boundary cells of the polyhedron and selects the most error-sensitive test cases among all the boundary cells. The more neighboring negative test cases (degree of vertex – DoV) a boundary cell has, the more error-sensitive it is. The last step is post-checking, which tries to identify critical negative test cases within the polyhedron. For each negative test case, the term Hamming distance (HD) is used to define the minimum different Boolean digits between it and any boundary cells. The HD of all boundary cells is 0. The smaller the HD is, the more critical a negative test case is. It is shown in this paper that negative test cases can detect more failures. The SC approach uses the most critical negative test cases first to test a program, and then randomly chooses the remaining test cases.

24.4 E2E Distributed Simulation Framework

Traditional simulation methodologies adopt a model-code-run approach, such as that used in the Institute of Electrical and Electronics Engineers (IEEE) modeling and simulation (M&S) high-level architecture (HLA) [24.24] and other popular simulation frameworks, which means that the engineers must create a model of the target system, develop the simulation code based on the model, and then run the simulation code, as discussed in GALATEA [24.25]. The E2E scenario-based modeling and simulation framework pro-

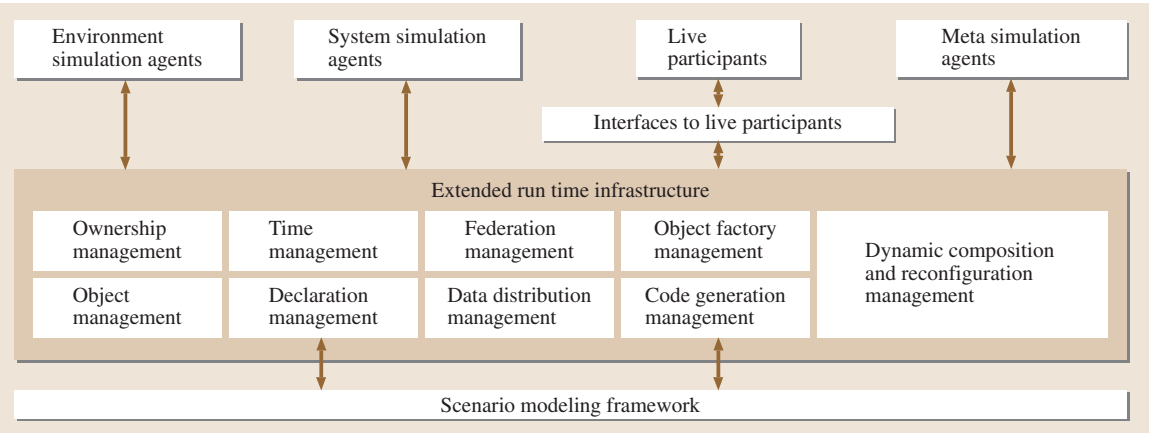

Fig. 24.7 Simulation framework architecture

vides a model-and-run paradigm for simulation. In other words, once the model is available, the model is directly executed for simulation without manual simulation-code development. The simulation code is automatically generated from the system scenario specification. Before the code is generated, the model can be evaluated using existing E2E analysis techniques such as C&C analysis to ensure that the model is correct. Furthermore, the simulation run can be dynamically verified using a formal policy specification.

24.4.1 Simulation Framework Architecture

Figure 24.7 shows the E2E T&E simulation framework running on an SOA, based on software agents. According to the definition in [24.26, 27], a software agent is "an autonomous computer program that operates on behalf of something or someone else" and can "be viewed as a self-contained, concurrently executing thread of control that encapsulates some state and communicates with its environment and possibly other agents via some sort of message passing". The agents here serve as an entity that is capable of carrying out the simulation task and performing a variety of analyses. Both the agents and the simulation framework are designed according to an object-oriented layout to support distribution (of objects/agents), modularity, scalability, and interactivity [24.25], as demanded by the IEEE HLA specification [24.24].

The E2E simulation framework integrates the concepts and tools that support modeling and simulating systems under the distributed, interactive, continuous, discrete, and synthetic focuses. The simulation framework consists of:

- The ACDATE scenario language and the framework that allows the construction of the system models.
- The on-demand automated dynamic code generator that supports rapid and automated simulation/real system-code generation such that simulation can be carried out once the system model is ready. No additional programming effort is needed. The *execution* here means that the real system components' execution is involved in the system simulation, i. e. end-to-end simulation including the end hardware-in-the-loop and man-in-the-loop.
- Simulation agents that carry out the simulation tasks and form a simulation federation (in the HLA sense) serve as the simulator for the whole system. These agents can be geographically distributed on computers that are interconnected via a local-area and/or wide-area network [24.19].
- An extended runtime infrastructure to support the agents' work. As required in [24.28], the simulation here is separated from the target system model, which makes the simulation framework flexible and generic.

As discussed in [24.24], traditional simulation techniques should be extended to support interactive simulation of a number of programs executing in heterogeneous and distributed computers that interact with each other through communication networks and are managed by a distributed operating system. The IEEE has provided the HLA framework to allow the development of a standard simulation framework with many different simulation components, which is used as a reference for the design of our framework. Figure 24.7 shows the architecture of our simulation framework. As can be seen, the scenario modeling framework provides the scenario specifications of the target systems. The extended runtime infrastructure separates the simulator (which consists of the agents and/or the live participants) from the target system model and provides the necessary runtime support for the simulator.

24.4.2 Simulation Agents' Architecture

The E2E T&E simulation framework is object-oriented, agent-based, discrete-event-driven, distributed, and real-time. In object-oriented terms, E2E simulation is based on the integrated ACDATE scenario model, which is based on SoS/SOA and the object-oriented modeling methodology. Each component in the system is modeled as a specific object–actor that has interfaces (actions), behaviors (scenarios) and constraints (policies). The simulation is carried out by a set of simulation agents. The agents are the most important elements in our simulation framework.

An agent can simulate either a single actor or multiple actors. Two agents may or may not reside in the same computation site. Agents can talk with each other via standard communication protocols. The behavior of a simulation agent is determined by the SoS/SOA scenario model of the actors simulated on this simulation agent. Based on the system's scenario model, it is clear how an actor will behave to some outside stimulus either from the environment or from some other agents under given conditions. The outside stimuli are modeled as discrete events that can be received and processed by an actor. Once an event arrives at an actor, the ac-

tor will put it into its waiting queue. How the events in the waiting queue are processed depends on the actor's scenario model, i. e. if the system is modeled as a multi-tasking actor, any incoming event can be processed as long as there is enough resource. If the system is modeled as a single-tasking actor, an incoming event can be processed only if no other task is scheduled to use the processor, and so on. Due to some uses of the framework for decision-making, one simulation run should finish before a given deadline, if required.

The simulation can be formally described as follows. Simulation of an actor A_i starts from the point when an event $E_{i,k}$ arrives at A_i. At the point, A_i will pick up scenario $\text{Scnr}_{i,w}$, which describes the behavior of A_i in response to $E_{i,k}$ and sends $\text{Scnr}_{i,w}$ to a scenario simulation/execution engine, as shown in Fig. 24.8. The scenario simulation engine will then interpret $\text{Scnr}_{i,w}$ and perform the following:

- Check current system condition, which includes the A_i own conditions $\{C_{i,i1}, C_{i,i2}, \ldots, C_{i,im}\} \in \{C_{i,0}, C_{i,1}, \ldots, C_{i,Mi}\}$ and/or other actors' conditions as guard conditions.
- Based on the system condition and chosen scenario $\text{Scnr}_{i,w}$, the simulation engine will choose an execution path which includes a series of actions $\{\text{Act}_{i,v1}, \text{Act}_{i,v2}, \ldots, \text{Act}_{i,vn}\}$.
- The scenario simulation engine will carry out the chosen actions, whose semantics are also specified using scenarios. Thus, whether an action can be successfully performed also depends on the system conditions at that point. An action may change the owner actor's status by changing the values of the data owned by the actor; or emit a new event either to other actors or to its owner actor.
- Agents' states will be changed accordingly as the actions are performed, which is reflected in the data-changing function: Act: $D \rightarrow D_0$, where D is the set of data values before the action Act is performed, where D_0 is the set of data values after the action Act is performed.

Events are the only channel through which different actors can communicate with each other. An event can carry parameters to provide more information for the receiver to make decision on how to respond to the incoming event. Simulation agents used here contain versatile communication capability, which is implemented by the communication component of each agent, and thus an agent can be exposed to the outside world as a traditional transmission control protocol/internet protocol (TCP/IP) service, a dedicated network component,

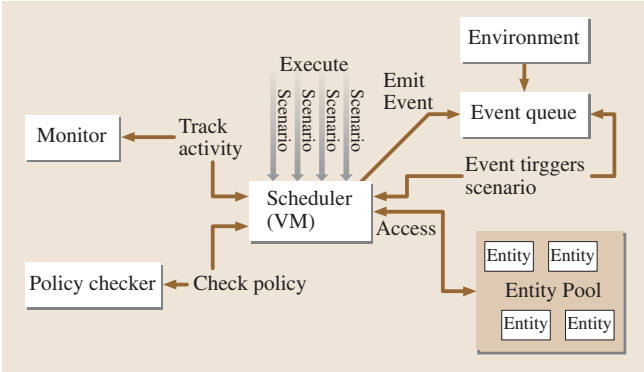

Fig. 24.8 Simulation engine inside a distributed simulation agent

or more generally a web service. In the latter case, as each simulation agent is exposed as a web service, it is easy for the simulation users to perform the simulation tasks on the internet.

There are three major types of simulation agents: environment simulation agents, system simulation agents and meta-agents. By separating the environment simulation agents and system simulation agents, it is easy to study the target system's behaviors under different environments without touching the target system model and simulation, which only requires a change to different environment simulation agents in the simulation. Meta-agents are agents that monitor and coordinate the whole simulation. With the help of these meta-agents, engineers can easily know what is going on in the distributed simulation from a global point of view. These meta-agents can also help perform dynamic analyses that involve more than one participating simulation agents such as the generation of overall system behavior.

24.4.3 Simulation Framework and Its Runtime Infrastructure (RTI) Services

The simulation extended runtime infrastructure is an extension and enhancement of high level architecture/runtime infrastructure (HLA/RTI) [24.24], which serves as a design reference for our simulation framework's runtime infrastructure. The major improvements are the automated ACDATE/scenario code generation and deployment management, event management on SOA, and automated simulation runtime reconfiguration and recomposition. With the help of these services, our simulation framework is capable of providing on-demand simulation, which means that the simulation code can be dynamically obtained and used for simulation from the dynamic code generator whenever it is

demanded by the users; as well as dynamic simulation reconfiguration.

In contrast to traditional HLA/RTI services, which are exposed as traditional remote procedure call (RPC) methods using the user datagram protocol (UDP)/TCP, the services provided by our simulation framework can be exposed as either RPC-like service using binary communication data via TCP, or WS using simple object access protocol (SOAP) messages to carry communication data via the hypertext transfer protocol (HTTP).

Managing events in SOA

The simulation framework is developed on top of an SOA, and thus it can reuse resources on SOA, a lot of benefits can be obtained. One of these is that a simulation agent does not need to know the existence of other simulation agents. Simulation framework RTI will provide an event-space service (ESS) to facilitate communication among simulation agents, as shown in Fig. 24.9. The services provided by ESS include:

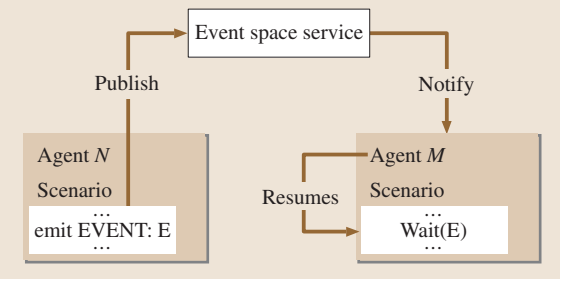

Fig. 24.9 Event publishing and notification example

- Event registration
  - Event publishing registration: before sending out any event, agents must register what events they will send out with the ESS.
  - Event subscription registration: an agent must subscribe the interested events before it can actually know that the event happens.
- Event publishing: agents can emit events using ESS
- Event notification: ESS can notify the occurrence of events to those agents that have subscribed the events.

Automated Simulation Code Generation and Deployment

The simulation code is generated based on the scenario specification, which includes the ACDATE definition and scenario description, as shown in Fig. 24.10. Each ACDATE element will be translated into an object with the attributes defined in the specification. Instrumentation code will be inserted into the objects to interface with the monitor and policy checker. Each scenario will be translated into a procedure that is basically a sequence of operations on the ACDATE objects or emitting events. Similarly, instrumentation code will be inserted into the procedure so that the procedure can interface with the scheduler to schedule concurrent execution and the event queue for emitting new events.

Table 24.2 shows a sample simulation code automatically generated with instrumentation code that interfaces with the scheduler, event queue, monitor, and policy checker.

Simulation framework provides two base components for scenario code generation: BaseACDATE

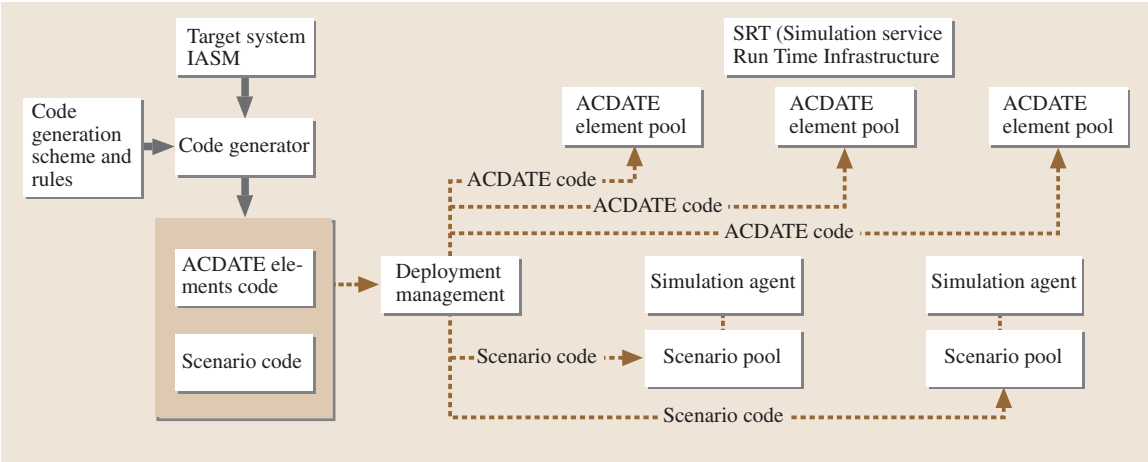

Fig. 24.10 Automated simulation-code generation and deployment

Table 24.2 Automatically generated code example

```
public override void ScnrFunc()// a scenario
 . . . . . .
{
Condition_4 condition4 = new Condition_4();// obtain ACDATE elements
Action_5 action5 = new Action_5();
Data_2 data2 = new Data_2();
e = newSimRunTimeLogArgs(SimRunTimeLogArgs.LogTypes.ScnrPreStatement,2,
1, 0, "Before Step 1 in scenario 6");
this.OnPreScnrStatementEventHandler(this, e);
data2.SetValue(1); // data2's value is now changed to integer 1
e = newSimRunTimeLogArgs(SimRunTimeLogArgs.LogTypes.DataWrite,
2, 1, 0, "After Step 1 in scenario 6");
// interface to instrumentations such as policy checker embedded here
this.OnPostScnrStatementEventHandler(this, e);
System.Windows.Forms.MessageBox.Show("Agent 1 - Step 1 done");
e = newSimRunTimeLogArgs(SimRunTimeLogArgs.LogTypes.SchedulingFlag,
System.Threading.Thread.CurrentThread.GetHashCode(), 1, 0, "Calling
Scheduling");
this.OnSchedulingEventHandler(this, e);
System.Threading.Thread.CurrentThread.Suspend();// interface to simula-
tion scheduler
 . . . . . .
}
```

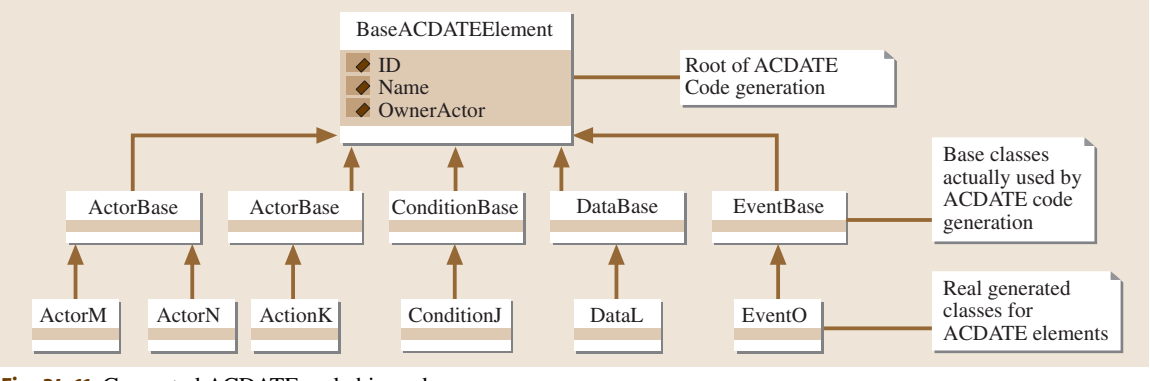

Fig. 24.11 Generated ACDATE code hierarchy

(Fig. 24.11) and BaseScenario (Fig. 24.12). The BaseACDATE component contains all the base class definitions for the ACDATE elements in the scenario. The BaseScenario component provides the base class for the scenario specification in the scenario model while referencing the used ACDATE elements' information in the BaseACDATE component.

For different system simulations, different simulation code will be automatically generated based on the target system's scenario model. The generated code is divided into two major categories of components: ConcreteACDATE and ConcreteScenarios. ConcreteACDATE here does not mean a single component but a collection of components holding

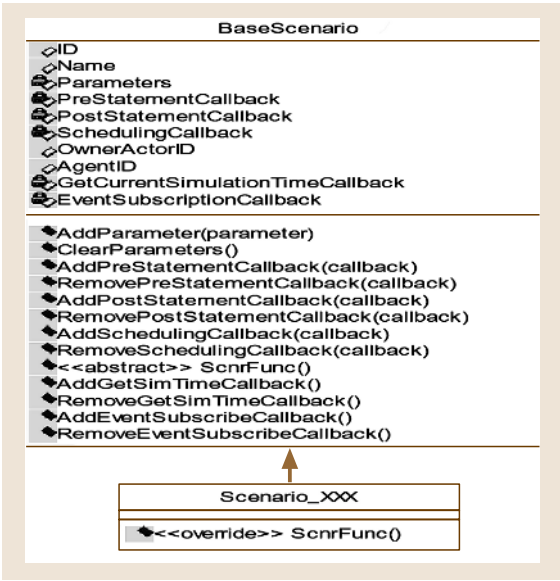

Fig. 24.12 Generated scenario code hierarchy

the generated code for the concrete ACDATE elements in the target system's scenario model. Similarly, ConcreteScenarios is a collection of components holding the concrete scenario code of the target system's scenario model, with only references to the related ConcreteACDATE components. Each generated component has its own deployment configuration document, based on which the deployment management will deploy the simulation code properly. More details of automated simulation code generation will be discussed in later sections.

At simulation runtime, with different simulation code loaded, the simulation agents can simulate different target systems while keeping the simulation agents themselves untouched.

In a distributed simulation system, simulation deployment is an important issue. Traditionally simulation deployment is done manually, which is time-consuming and error-prone, especially for large simulation systems. Simulation deployment can be formally specified and then be automated. As has been discussed, with different target system models (code) loaded, the simulation agents can perform different simulation tasks. Machine understandable simulation deployment specification [in extensible markup language (XML)] will be provided. Service RTI will provide a dynamic model (code) load/unload service based on the simulation deployment specifications.

Automated Simulation Reconfiguration and Recomposition

For a large-scale distributed simulation, a single failure may corrupt the whole simulation if the failure point is critical (a single point of failure). It is important to organize the simulation services (agents) distributing across the internet to form a functional simulator, which can make use of the unutilized computation power. With the policy and dynamic reconfiguration service (DRS), the simulation framework should be able to see the change of system behavior when a new policy becomes effective during simulation without shutting down the system.

Dynamic simulation composition and reconfiguration management involves the following issues:

- Automated simulation-agent deployment and discovery
- Automated simulation-agent status monitoring and failure detection
- Automated dynamic simulation code generation
- Automated dynamic simulation configuration generation
- Automated dynamic simulation deployment and redeployment.

A simulation agent knows nothing about the target system until the corresponding simulation code is loaded into the agent. With different simulation code loaded, the simulation is capable of simulating different target systems. The simulation agent can also unload the previously loaded simulation code component and reload a new set of simulation code components to simulate another target system. In this sense, the real components of a functional simulation are the dynamically and automatically generated simulation distributed across the network.

The first problem one may face is how the dynamically generated simulation code components can know where the counterparts and the runtime infrastructure services are. This can be solved with using a dynamically and automatically generated configuration of the simulation. With any given simulation topology, users can specify where and how a simulation should be deployed. A configuration document will then be automatically generated for each dynamically and automatically generated simulation code component based on the users' deployment requirements, such that each simulation code component can know where to obtain the required resources and services, as well as how to communicate with the runtime infrastructure services and its counterparts. This has been introduced in previous sections.

The automatically generated simulation code components along with their configuration documents are deployed based on the deployment configuration documents to set up the simulation agents properly with the help of the automated deployment management services, as shown in Fig. 24.13.

During the simulation, the status-monitoring services continuously monitor the status of the simulation agents involved. Once the failure of a simulation agent is detected, the runtime infrastructure will try to discover an available simulation agent and perform the code and configuration generation again for the alternative agent. The new simulation agent is then loaded with the simulation code and configuration and the simulation is resumed. Using automated simulation composition and deployment, users can also easily change the deployment of the simulation anytime. However, in these cases all the unfinished work on the crashed simulation agents will all be lost, if it has not been saved.

There is another scenario in which dynamic simulation reconfiguration can be used: on-the-fly model changing and continuous simulation. Users can change the target system model during the simulation without restarting the simulation to reflect the effect of model modification.

Once the target system model has been changed, based on the original users' deployment requirements and the status of the simulation agents, the automated simulation deployment service can determine which agents are affected by the model modification. The simulation code components and configuration documents are then regenerated based on the modified model. Once the affected simulation agents enter a safe state where unloading and reloading simulation code components will not affect other running simulation agents, the automated simulation deployment service will unload and reload the simulation agents with the modified simulation code components. Before the simulation components are unloaded, the status of the simulation agents is saved. The saved information is used to restore the original agents after the new simulation code components are reloaded. In this way, the users' simulation will not be interrupted by the model modification.

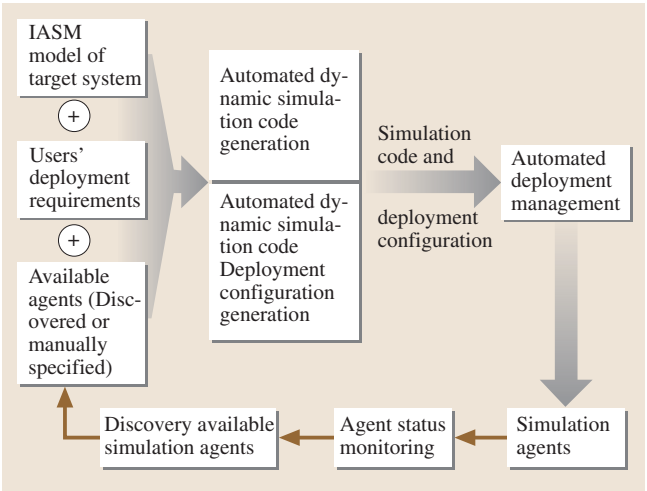

Fig. 24.13 Automated simulation reconfiguration and recomposition

24.5 Policy-Based System Development

Policies have been increasingly used in computing systems for specifying constraints on system status and system behaviors. A *policy* is a statement of the intent of the policy maker or the administrator of a computing system, specifying how he or she wants the system to be used [24.29]. Usually, policies are hard-coded into the system implementation, For instance, if a policy states that "passwords must be at least eight characters long", there must exist a snippet of code in the system implementation that checks the length of passwords. Hard-coded policies can cause major problems for the system such as:

- It is difficult and expensive to update.
  Whenever a policy needs to be changed (e.g. the system administrator wants to reduce the minimum length of valid passwords from eight characters long to five characters long), the whole system has to be shut down, and the code has to be modified, recompiled, and redeployed. The process is lengthy and significantly increases an organization's operating expenses. Shutting down a mission-critical system, in most cases, is prohibitive and may cause disastrous consequences to the mission.
- It is difficult to manage.
  Hard-coding policies do not separate policy specification from system implementation. Policies are spread throughout the system implementation. If a policy maker wants to know how many policies

there are in the system, or what are the policies that are defined for the role of supporting arms coordinator, there is no easy way to find the answers.

In the past decade, a number of *policy specification languages (PSLs)* have been proposed [24.29–33]. PSLs provide a simple and easy-to-use syntax to specify policies separately from the system implementation. A user interface can provide a means for policy makers to specify and manage policies. A policy engine can interpret and enforce policies at runtime rather than at compilation time, which allows policies to be dynamically added, removed, updated, and enabled or disabled.

24.5.1 Overview of E2E Policy Specification and Enforcement

Figure 24.14 shows the simulation environment that we developed for highly developed systems. When developing such systems, V&V needs to be performed at each step of the development. First, the system requirement is translated into the formal specification. The specification is verified by a C&C check. After several iterations of verification, the final specification is obtained. Test cases are generated from the specification. An automated code-generation tool generates the executable for simulation. This process has been reported in [24.17].

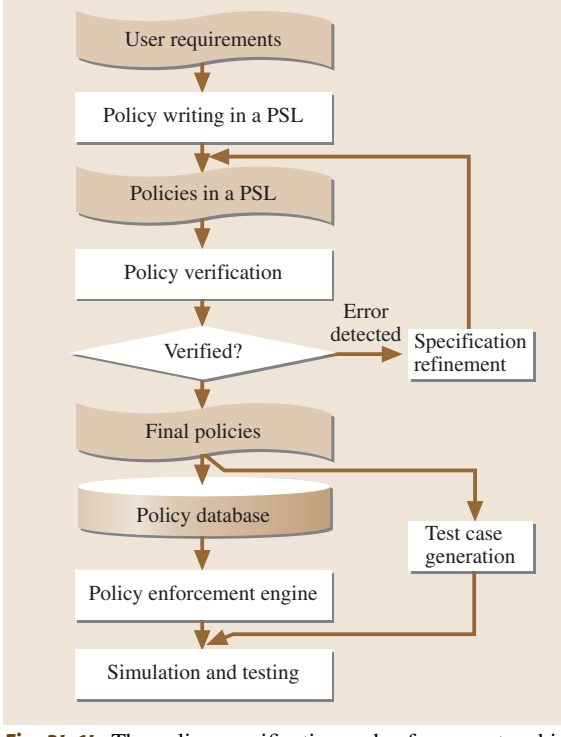

Fig. 24.14 The policy specification and enforcement architecture

Independently of the development processes, the policies are extracted from the requirements and then written in a policy specification language (PSL). Similarly to the specification, the policies are verified by a C&C check to detect any incomplete and inconsistent policies. After the policies pass the verification, they will be stored in a policy database. Test cases that dynamically check C&C can be generated from the final policies. During the course of simulation execution, a policy-enforcement engine dynamically loads the policies from the policy database, interprets them, and enforces them at runtime. Since the policy engine dynamically interprets and enforces policies, policies can be easily changed (added, removed, updated, and enabled/disabled) on-the-fly at any time.

This paper not only makes use of the flexibility of policies, but also applies policies as a dynamic V&V method. In fact, many functional requirements of a system can be extracted as policy requirements. For example, array index range check, probability value range check, and execution orders can be written as policies. As a result, the policy enforcement can dynamically check the validity of computing. Policy enforcement is particularly useful in detecting those bugs that are difficult to catch during unit testing and those with complicated interactions due to concurrent threads and processes in simulation. Note that traditional testing suffers from the need to set up the environment to a given state and run the program to see if the program behaves as intended, which is time-consuming and difficult. Policy is a good way of ensuring the simulation program is correct because an engineer can specify any kinds of policies that need to be enforced to see if the simulation program performs correctly. Another advantage of using simulation to run policies is that simulation can run extensive cases to ensure extensive coverage. Thus, we can have both static and dynamic coverage, e.g., how many times a specific set of scenarios have run, and how many times a specific scenarios will happen, and how many of these scenarios are performed correctly.

24.5.2 Policy Specification

We designed the policy specification and enforcement language (PSEL) that covers obligation policies, authorization policies and system constraints. A policy editor

and a graphical policy-management interface have been developed for policy input. Obligation policies and authorization policies are defined on roles rather than on individual actors. A role represents a management position and the responsibilities and rights associated with that management position. Actors are assigned to roles according to their management positions. Since actors take particular roles in an organization, policies specified on a role will in turn apply to actors who take this role.

Obligation policies define a role's responsibilities, specifying what actions a role must or must not take under a condition. *Positive obligation policies* are event–condition–action (ECA) rules with the semantics that: on receiving a triggering event E, a role R must perform the action A if condition C is true. For instance, the policy "on receiving the call for fire, the supporting arms coordinator must issue a fire order" should be defined as a positive obligation policy, since it specifies the responsibility of actors who take the supporting arms coordinator role.

Negative obligation policies forbid a role from performing action A if condition C is true. For instance, the policy "If a main battle tank can shoot, it must not reject the fire order" should be defined as a negative obligation policy. If violated, the policy enforcer will inform the system simulator of the detection of the policy violation. The system simulator will perform the compensation action that is intended to minimize the consequences caused by the policy violation. Table 24.3 gives the syntax and examples of obligation policies.

Authorization policies define a role's rights to perform actions, specifying which actions are allowed or prohibited for the role under a certain circumstance. In PSEL, authorization policies are specified and enforced through access control models. Currently, two access control models are supported in PSEL: the Bell–LaPadula (BLP) model and the role-based access control model.

Bell–LaPadula (BLP) model [24.34] is a mandatory access control model widely used in military and government systems. It controls information flow and prevents information from being released to unauthorized persons. The BLP model defines four ordered *security levels*: Unclassified < Confidential < Secret < Top Secret. Security levels are then assigned to actors and data. An actor's security level is called the *security clearance*; data's security levels are called the *security classification*. Each action in the system has a subject (an actor) that performs the action, data (objects) on which the action is performed, and an accessing attribute that indicates the nature of this action (read, write, both, or neither).

The BLP model defines two access rules. The *no-read-up* rule applies to all actions whose accessing attributes are read. It specifies that an actor is not allowed to read data if the actor's security clearance is lower than the data's security classification. For instance, the observer in the special operations forces (SOF) team, with a security clearance of confidential, is not allowed to read (attribute: read) the target destroyed report (security classification: secret). The no-read-up rule prevents unauthorized persons from reading information they are not supposed to read. The *no-write-down* rule applies to all actions whose accessing attributes are write. It specifies that an actor is not allowed to write data if the actor's security clearance is higher than the data's security classification. The no-write-down rule prevents actors with higher security clearance from accidentally

Table 24.3 Examples of obligation policies

Policy type	Syntax	Example

Positive obligation policy	MUSTDO {
	definedOn ROLE

	do ACTION
	on CONDITION
	}
		MUSTDO {
		definedOn ROLE:SupportingArmsCoordinator
		triggeredByEVENT:ReceiveCFF
		do ACTION:IssueFireOrder
		on CONDITION:
		}

Negative obligation policy	MUSTNOTDO {
	definedOn ROLE
	do ACTION
	on CONDITION
	perform COMPENSATION
	}
		MUSTNOTDO {
		definedOn ROLE:MainBattleTank
		do ACTION:MBTRejectMission
		on CONDITION:MainBattleTankCanShoot
		perform COMPENSATION:Warning
		}

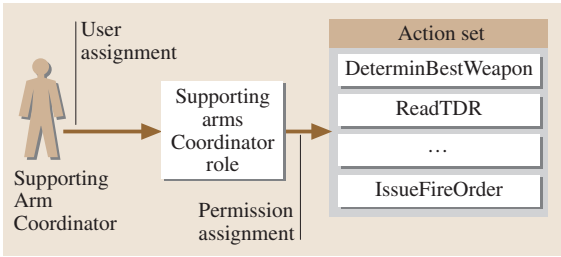

Fig. 24.15 The RBAC model

writing classified information to an unclassified media, so that unauthorized persons can read the information.

The *role-based access control (RBAC)* model [24.35–37] has been increasingly implemented in various systems, due to its policy-neutral nature. As shown in Fig. 24.15, in RBAC a group of roles are defined according to the semantics of a system. Actors are then assigned to roles according to their management position in this system. A set of actions are then assigned to a role, giving it the permissions to perform these actions. PSEL also supports a role hierarchy. *A role hierarchy* represents the superior and subordinate relationships among roles, allowing a superior role to obtain all permissions of its subordinate roles automatically. *Role delegation* is also supported, which enables a role to temporarily transfer its permissions to other roles, and for them to be revoked at a later time.

The access rule defined in the RBAC model is simple: an action A is allowed if

- there exists a role R, such that A.owner takes R, and
- R has permission to perform A.

For instance, the supporting arms coordinator (who takes the supporting arms coordinator role) is allowed to issue the fire order. Figure 24.16 shows the graphical user interface for role-based authorization policy specification.

System constraints define constraints on system status and behaviors that must hold in the system execution or simulation. *System constraints on data* specify that data must or must not be within a certain range. For example, the policy that "the distance between the SOF team and the surface-to-surface missile (SSM) launcher must be $\geq$ 3000 feet at all times" is a system constraint on data. *System constraints on actions* are currently temporal logic on actions. Examples could be "action DetermineBestWeapon must occur before action InputFireOrder" or "the call for fire (CFF) command can

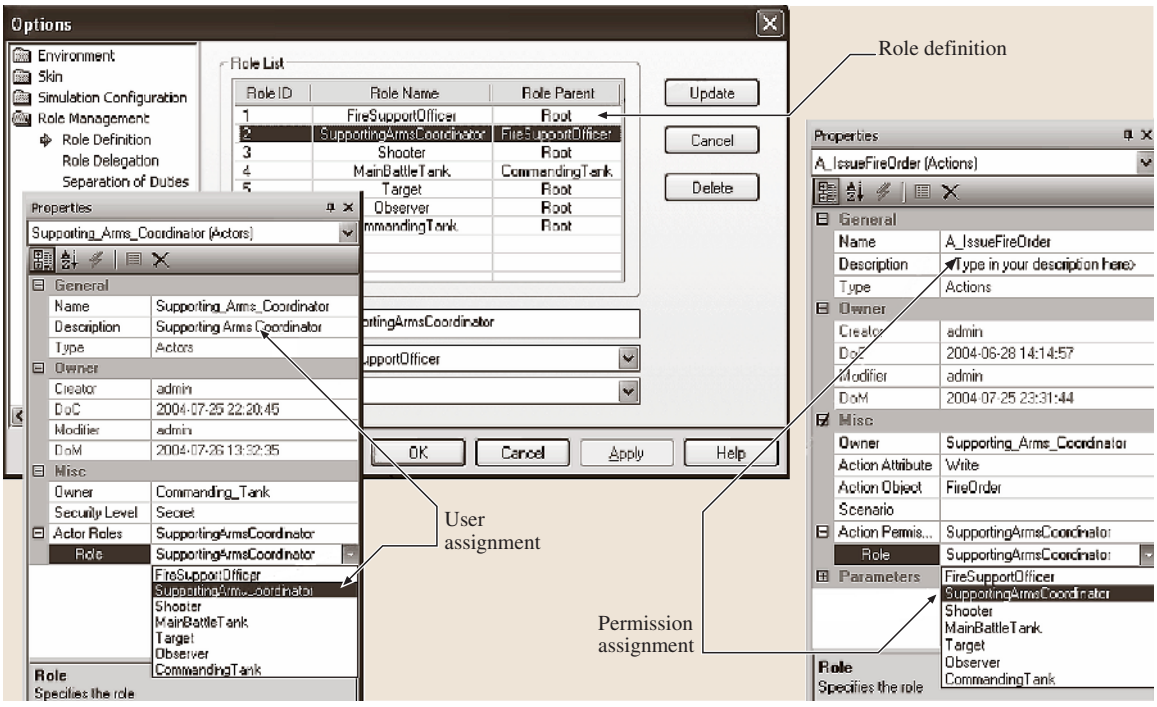

Fig. 24.16 Graphical user interface for role-based authorization-policy specification

Table 24.4 Examples of specifying system constraints

Policy type	Syntax	An example

System constraints on data	MUSTBE / MUSTNOTBE {
	appliedTo DATA
	status EXPRESSION
	on CONDITION
	perform COMPENSATION
	}
		MUSTBE {
		appledTo DATA:SOFTeamDistanceFromSSM
		status EXPRESSION:">=3000"
		on CONDITION:TRUE
		perform COMENSATION:SOFRetreat
		}

System constraints on actions	MUSTBE / MUSTNOTBE {
	do ACTION:Operator
	(action parameters)
	on CONDITION:TRUE
	perform COMPENSATION
	}
		MUSTBE {
		do ACTION:Sequence
		(ACTION:DetermineBestWeapon
		ACTION:InputFireOrder)
		on CONDITION:TRUE
		perform COMPENSATION:Warning }

be issued only once". Currently, the following temporal logic operators are supported by our ACDATE-based policy framework:

- Concurrency (A, B): A, B occur concurrently;
- Sequence (A, B, C): A, B, C occur in this sequence;
- Order (A, B, C): A, B, C occur in this order consecutively;
- Either (A, B): either A occurs or B occurs, but not both;
- Exist (A): A must occur;
- Once (A): A must occur once, and only once.

Conditions are associated with system constraints, specifying when these policies are to be enforced. In addition, compensation actions are defined in a system constraint. When policy violation is detected, associated compensation actions will be performed by the simulator to minimize the consequences brought about by policy violation. Table 24.4 gives syntax examples of specifying system constraints.

24.5.3 Policy Enforcement

Policies are enforced in the course of system simulation. In the initialization phase of system simulation, the policy enforcer will load policies out of the policy database and register them with the system simulator according to their semantics. Policies are registered so that the system simulator knows when to trigger policy enforcement. The system simulator triggers the policy enforcer when a registered event occurs, a registered action is performed, or a registered datum is modified. The policy enforcer will enforce relevant policies attached to these registered events, actions, or data, and return the results of enforcement back to the system simulator.

Policy enforcement can be classified into three categories: policy checking, policy execution, and policy compensation. *Policy checking* verifies if policy violations are detected when actions are performed or data are changed. *Policy execution* executes the action defined in the policy when receiving the triggering events. *Policy compensation* executes the compensation action defined in the policy when policy checking detects a policy violation. All checkable policies come with a compensation action.

Only positive obligation policies are executable policies. The other types of policies (e.g. negative obligation policies, all authorization policies and all system constraints) are all checkable policies. *Executable policies* influence the paths of system simulation through the actions defined in them. When the triggering event occurs, executable policies registered to this event will be enforced, and the action specified in the policy specification will be executed by the system simulator. *Checkable*

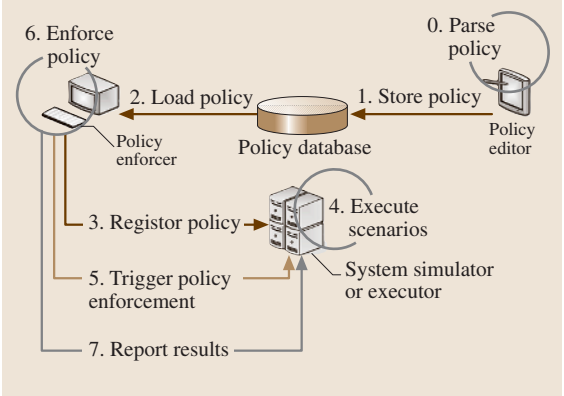

Fig. 24.17 The policy enforcement framework

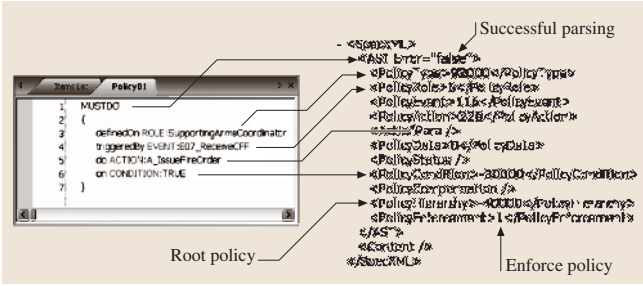

Fig. 24.18 Policy parsing

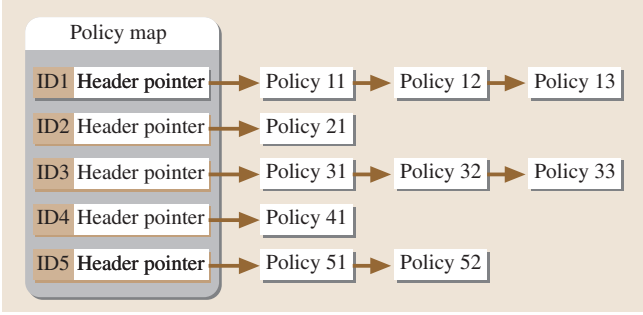

Fig. 24.19 Policy map

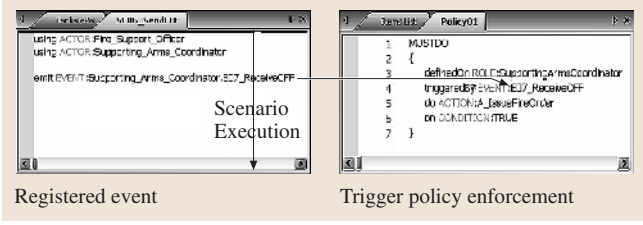

Fig. 24.20 Policy enforcement triggering – event

policies can also influence the paths of the system simulation through compensation actions. When data are changed or actions are performed, checkable policies registered to the data or actions will be enforced. If policy violations are detected, the compensation action specified in the policy specification will be executed by the system simulator.

Figure 24.17 illustrates the policy enforcement framework. After ACDATE elements are defined and policies are extracted, policies are specified in the policy editor, which parses policies for correctness, C&C, and stores them in the policy database. During the initialization phase of simulation, the policy enforcer loads policies from the policy database, interprets them and registers them with the system simulator. While the simulator executes system scenarios, it triggers the policy enforcement when registered events occur, registered actions are performed, or registered data are changed. The policy enforcer checks or executes policies and returns the results to the simulator. Based on the returned results, the simulator determines what the next system scenarios are.

The policy editor parses policies for correctness and C&C. On successful parsing, the policy editor translates policies into XML and stores them in the policy database. The policy parser is implemented by: another tool for language recognition (ANTLR). According to the policy syntax, ANTLR creates an abstract syntax tree (AST) for each policy. Policy elements (roles, actions, condition, etc.) are extracted by traversing the tree, and translated to the XML representation, as shown below. The XML representation of a policy is then stored in the policy database as a string. Figure 24.18 shows an example policy parsing.

The purpose of policy registration is to let the system simulator know when policy enforcement should be triggered. In our ACDATE-based policy framework, three out of the six ACDATE elements can trigger policy enforcement: event, action, and data. Events occurrences will trigger the enforcement of positive obligation policies; action performances will trigger the enforcement of negative obligation polices, authorization policies, and system constraints on actions; data changes will trigger the enforcement of system constraints on data, as shown in Table 24.5.

To improve performance, a policy map is created, mapping a particular event, action or data to a list of relevant policies to which it is registered, as shown in Fig. 24.19. All policies registered to a particular action,

Table 24.5 Policy registration

Policy type	Authorization policy	Positive obligation policy	Negative obligation	System constraints on data	System constraints on action
Event		X			
Action	X		X		X
Data				X	

event or datum form a linked list. The linked list and the identification (ID) of the action, event or datum are then organized as a policy map. When policy enforcement is triggered, the policy enforcer locates the policy linked list of a particular action, event or datum, and enforces all policies in the list.

After policies have been registered, the simulator initializes the data and starts running the system scenarios. The simulator keeps an eye on the simulation of system scenarios, and triggers the policy enforcement by invoking the EnforcePolicy method in the policy enforcer whenever an event is triggered, an action is performed or a datum is changed. Figure 24.20 shows an example where a triggering event causes a policy enforcement execution. The policy enforcer enforces all relevant policies, records all violations in the policy log, and returns the policy log back to the system simulator.

When policy enforcement is triggered, the simulator invokes the EnforcePolicy method in the policy enforcer, passing the ID of the event, action or datum that triggered the policy enforcement. On being triggered, the policy enforcer looks into its policy map, maps the ID to a list of policies to which it has been registered, and enforces them one by one. Authorization policies are not registered in the policy map, and they are enforced before obligation policies and system constraints are enforced. When policies are being

```
bool CPolicyEnforcer::PolicyEnforcer(const long lEntityID)
{
    // lEntityID is the ID of the entity that triggers policy enforcement
    // An Entity could be an event, action, or data
    if (GetEntityType(lEntityID) == ACTION_TYPE)
    {
        Verify whether this action is allowed by RLP  Model;
        Verify whether this action is allowed by RBAC Model;
    }

    deque<CPolicy*> pDequePolicy = m_mapPolicyMap.Find(lEntityID);
    for (size_t i = 0; i < pDequePolicy.size(); i++)
    {
        bool bPassed = true;
        CPolicy* pPolicy = pDequePolicy[i];

        switch(pPolicy->m_lPolicyType)
        {
        case POLICY_MUST_DO:
            bPassed = PolicyCheckMustDo(pPolicy, lEntityID);
            break;
        case POLICY_MUST_NOT_DO:
            bPassed = PolicyCheckMustNotDo(pPolicy, lEntityID);
            break;
        case POLICY_MUST_BE:
            bPassed = PolicyCheckMustBe(pPolicy, lEntityID);
            break;
        case POLICY_MUST_NOT_BE:
            bPassed = PolicyCheckMustNotBe(pPolicy, lEntityID);
            break;
        }

        if (!bPassed)
        {
            Record Policy Violations;
        }
    }

    if (no policy violations) return true;
    return false;
}
```

enforced, all violations are recorded into a policy log that is returned to the simulator. The EnforcePolicy method returns a Boolean value indicating whether policy violations are detected. Figure 24.21 gives the policy enforcement algorithm.

24.6 Dynamic Reliability Evaluation

Software reliability has been defined as the probability that no failure occurs in a specified environment during a specified (continued) exposure period. Existing software reliability models assess reliability statically in the development process. The E2E T&E perform dynamic evaluation at runtime using a software reliability model that is integrated into the ACDATE scenario model. Figure 24.22 illustrates the development and operation processes using this model.

From the scenario specification, the atomic components can be identified and a data collector is instrumented around each atomic component, which collects runtime failure data during testing and operation. Based on the collected data, the reliability of both components and the SoS can be assessed. The rest of the section explains the major components in this reliability assurance process.

24.6.1 Data Collection and Fault Model

An SoS may consist of many subsystems or components and it is hard to exactly distinguish their contributions to the overall reliability of the SoS due to the anfractuous dependency relations among them. A component may consist of several subcomponents, in which case its reliability can be computed analytically, provided the reliability of each subcomponent is known. The breakdown can be continued to each subcomponent. However it must end somewhere when the component is either indivisible or it is not worthwhile dividing it further. We then consider these components as black boxes or atomic components in our reliability model. In other words, the reliability of an atomic component is not the result of (but an input to) our reliability model.

Although the decision on what component shall be treated as a black box is truly application-dependent,

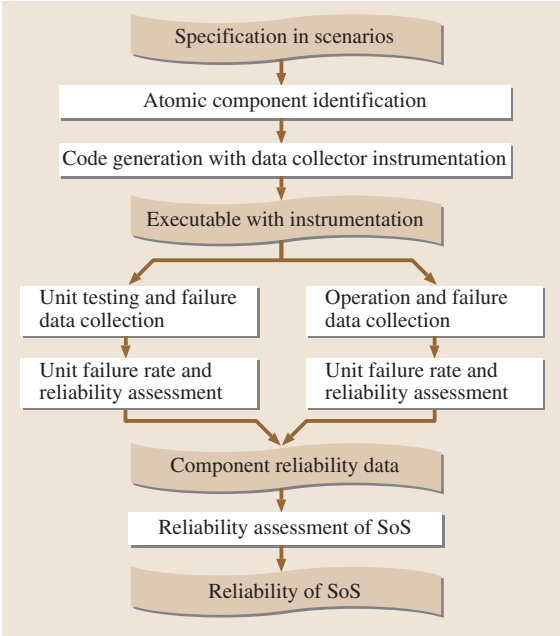

Fig. 24.22 Dynamic reliability assurance

we propose three general principles to curb arbitrariness and strengthen the rationale for our reliability model.

Granularity principle: a finer granularity can lead to more accurate evaluation results but may increase the complexity of the computation. Basically there is a trade-off between granularity and accuracy and their balance depends on the specific application and its requirements.

Perceptible principle: if a component is treated as a *white box*, the opposite of a black box, then the dependencies among all its subcomponents that have an effect on reliability will be modeled explicitly and hence be accounted for during the reliability computation. If the dependency is neither clear nor completely modeled, then the result of the computation will be biased.

Continuous principle: a component is a white box only if its super-component is a white box. It is of no benefit if a black box has a subcomponent as a white box since the reliability of a black box is not computed.

The perceptible principle and the continuous principle define the *effective domain* of the ACDATE scenario model. Inside the domain, everything is explicitly modeled and hence is a white box, while a component outside the domain is a black box. Code that is either manually developed or automated generated based on the model represents its effective domain in the system.

The black box, which is outside the effective domain of the model, can be further categorized as follows:

- Operation on hardware through a device driver;
- A system call provided by the operating system;
- A method or attribute in the programming platform, e.g., the vector class in Java, C# or C++ standard template library (STL);
- A method or attribute in a library provided by a third party;
- Input from a human operator;
- A component in a remote location.

Different types of black boxes incur different reliability estimations, which will be detailed in the next subsection.

Figure 24.23 illustrates the effective domain, where a circle is a white box, a disk is a black box, a line is a dependency relation, and a dashed line is an unclear dependency relation.

To collect failure data, each function call to an atomic component is replaced by a wrapper call that collects failure data related to the atomic component.

Assume a call to an atomic component is atomfun(p1, p2, . . . , pn), where atomfun is the function name, and p1, p2, . . . , pn are the parameters. In the data collector instrumentation stage in Fig. 24.22, the function call is replaced by a wrapper function call: dataanalyzer(atomfun, p1, p2, . . . , pn).

The data collector function is:

```
dataanalyzer(atomfun, p1, p2, . . . , pn)
{
Increment the execution counter;
Find the specification of atomfun;
Verify the legitimacy of p1, p2, . . . , pn;
Call atomfun(p1, p2, . . . , pn);
```

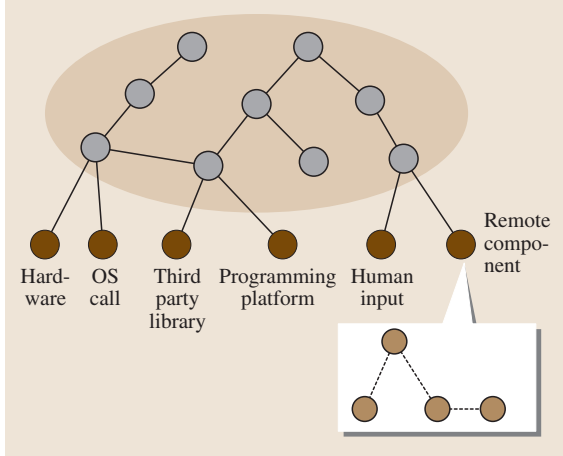

Fig. 24.23 Identification of atomic components in an SoS

Verify the legitimacy of results;
Handle exceptions;
If results fail, report a failure;
}

The data collector performs acceptance testing on the inputs and outputs of the atomic component and maintains following data in a local log file:

- The execution counter keeps track of how many times the atomic component has been called.
- The failure counter counts how many failures have been detected.
- Failure types: incorrect data, exceptions, and crash, etc.

The local log file associated with the data collector automatically synchronizes with a central database that records data related to all atomic components. The synchronization can be performed in the testing stage, in the development process, and during the operational stage after the software is delivered to the client. Online error reporting during the operational stage can also help the developers to design patches and updates of the software. The execution number of each atomic component collected during the operational stage can be used to determine the execution profile of the software.

For each atomic component, the following data items are maintained in the database:

- Versions: recording the date and time of each modification/error correction performed on the atomic component. Each error correction results in a new version of the component;
- Number of executions between two error corrections;
- Number of failures between two error corrections;
- Numbers of each failure type.

Table 24.6 Reliability definition of ACDATE entities

ACDATE	Reliability of the ACDATE entity
	The *probability* that the:
Actor	– actor presents the expected behavior
Condition	– condition presents the expected Boolean value
Data	– data presents the expected value
Action	– action presents the expected behavior
Timing	– action completes in given time frame
Event	– event is sent or received successfully
Scenario	– scenario presents the expected behavior
System	– system presents the expected behavior

These data can be used to estimate the reliability of the components. In the next subsection, we will apply the input domain-based reliability growth model to estimate the reliability of each atomic component.

An incorrect output of a program is a failure. A program contains errors if it can produce a failure when certain input cases are applied. The size of an error is the ratio of the number of inputs that can detect the error (cause a failure) and the total number of valid inputs.

According to the input domain-based reliability growth model [24.38, 39], the failure data stored in the central database can be used to estimate the error sizes $\Theta_1, \Theta_2, \ldots, \Theta_k$ and the failure rates $\lambda_1, \lambda_2, \ldots, \lambda_n$ of the errors in each atomic component between two error corrections. The error sizes and failure rates between error corrections can be used to estimate the final failure rate λ of each atomic component.

The failure rate and the total number of executions associated with each atomic component is the input to the structural reliability model to be discussed in the remaining part of the paper.

24.6.2 The Architecture-Based Reliability Model

In the previous subsection, we evaluated the reliability of atomic components. In this subsection, we evaluate the reliability of an SoS consisting of multiple systems, each of which is considered an atomic component. The model can be generalized to evaluate a system or a subsystem in a system, with the knowledge of the reliability of its components, operational profile, and the architecture of the system. The architecture determines the contribution of the reliability of each atomic component to that of the overall system. Hence the approach is named the architecture-based reliability model [24.40].

First we give the definition of a component's reliability and present our assumptions; then we discuss how the architecture affects the propagation of reliability; finally, we derive the formulas that compute the reliability.

We base our reliability model on the ACDATE scenario model, which describes the structure of a system using model entities *actors*, *conditions*, *data*, *actions*, *timing*, and *events*, and the behavior of a system using *scenarios*. The ACDATE scenario model models the general computing process.

The *reliability* definitions of ACDATE entities and scenarios are summarized in Table 24.6.

The assumptions of our reliability are

1. Assignment assumption: the assignment operation introduces no new failure.
2. Condition assumption: the condition fails when any data that constitutes the condition fails.
3. Acyclic dependency assumption: there is no cyclic dependency among ACDATE entities.

The system behaviors are specified by a few system-level scenarios and the reliabilities of those system-level scenarios will contribute to that of the system. Different scenarios may have different execution rates (the operational profile), which determine the weight of the contributions.

A scenario is a sequence of activities connected by four operators: *sequence*, *choice*, *loop* and *concurrency*. Each *activity* is a data assignment, exchanging an event, doing an action, or executing a sub-scenario. Hence the reliability of data, events, actions and sub-scenarios will contribute to that of a scenario. The choice and loop operator are associated with one or more conditions that determine the branches to take. Hence the reliability of conditions also contributes to that of a scenario. Moreover, the *true/false* rate of each condition will affect the reliability of the scenario through the choice and loop operators (formulas will be presented later).

Each top-level scenario would be invoked by an *external* event. Hence, the occurrence rates of external events determine the operational profile of top-level scenarios. A scenario may emit an *internal* event, whose sole function is to resume or invoke the execution of a sub-scenario. Hence, the occurrence rates of internal events will affect the operational profile of sub-scenarios (in addition to direct calling from other scenarios). The occurrence rates of internal events can be determined by that of external events invoking top-level scenarios, and the control flow of those scenarios that emit internal events.

To summarize, assuming that we know the reliability of each scenario and the occurrence rate of each external event (and hence internal events), we can evaluate the reliability of the system following the formula:

$$Rel_{\text{system}} = \left[\sum (w_i * Rel_{\text{scenario\_}i})\right] / \sum (w_i) ,$$

where w_i is the execution rate of the corresponding scenario. In the following we present the calculation of the reliability of a scenario.

The reliability of data is determined by that of its storage method, which is modeled as atomic components (memory, external database, file system, etc.), and hence is known. The reliability of actions is known if it is atomic (e.g., a system call), or is that of the sub-scenario that implements it. The reliability of events is determined by that of the communication link (atomic component) and hence is known.

Following assumption 1, the reliability of assignment is that of the right-hand-side data. Hence we know the reliability of each activity in a scenario.

If several activities are connected by a sequence operator, then the overall reliability follows the formula:

$$Rel_{\text{sequence}} = \prod Rel_{\text{activity\_}i} ,$$

where $Rel_{\text{activity\_}i}$ is the reliability of each activity that participates in the sequence. If several activities are connected by a concurrency operator and all of them are replicas, then the overall reliability follows the formula:

$$Rel_{\text{concurrency}} = 1 - \prod (1 - Rel_{\text{activity\_}i}) .$$

Otherwise, it is the same as the sequence, since any failure results in the failure of the overall concurrency. For the loop operator, the formula is:

$$Rel_{\text{loop}} = (Rel_{\text{cond\_set}} \cdot Rel_{\text{block}})^{Pt} ,$$

where $Rel_{\text{cond\_set}}$ is the reliability of the condition set associated with the loop operator, Rel_{block} is the reliability of the block of activities enclosed in the loop operator, and Pt is the expected number of loops. We will discuss $Rel_{\text{cond\_set}}$ later. For the choice operator, the formula is

$$Rel_{\text{choice}} = Rel_{\text{cond}_{\text{set}}} \cdot \left(Pt \cdot Rel_{\text{true\_block}} + (1 - Pt) \cdot Rel_{\text{false\_block}}\right) ,$$

where Pt is the probability that the condition set evaluates as *true*. Since a scenario consists of only these four types of operators, we can calculate its reliability following these formulas. The reliability of a condition is determined by the data that constitute the condition, or is known if the condition is atomic (e.g., a system call). Following assumption 2, if a condition consists of several data, its reliability is the product of the reliabilities of all the data. We omit the deduction process due to the space restriction and only present the final formulas here:

$$Rel_{\text{cond\_set}} = 1 - \sum ProTop_{c(m,o)} ,$$

where each $ProTop_{c(m,o)} = \sum ProTop_{\{c\}o}$

Table 24.7 The most reliable services and their forecast

Components	Reliability	Forecast probability	Adjusted probability
RainForecast	0.764	18 % heavy rain	33.1%
TempForecast	0.98	31 % extreme temp	31.76 %
WindForecast	0.90	23 % strong wind	28.4 %

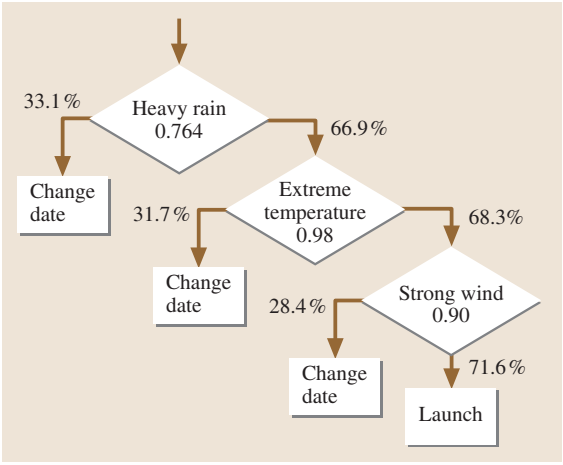

Fig. 24.24 Decision making

Each $ProTop_{\{c\}o}$ is calculated by the following formulas:

$$ProTop_{\{c\}o} = Rel_{\{c\}o} \cdot \left(ProTF_{\{c\}o} + ProFT_{\{c\}o}\right) \cdot Prob_{remv} ,$$

$$Rel_{\{c\}o} = \prod(1 - Rel_{Ck}) \cdot \prod(Rel_{Cl}) ,$$

where Rel_{Ci} is the reliability of the i-th condition in the condition set. Each condition set is evaluated in disjunction normal form (DNF), whose Boolean value may be dominated by a true disjunct. $Prob_{remv}$ is used to compensate for possible domination and is defined as the probability that the disjunct evaluates to be false. $ProTF_{\{c\}o}$ and $ProFT_{\{c\}o}$ are the probabilities that a condition incorrectly changes from *true* to *false*, or from *false* to *true*, respectively, and are determined by the condition's reliability.

24.6.3 Applications

This subsection uses an example to illustrate the applications of the proposed dynamic software reliability model. Assume a space agency plans to launch a satellite on a specific date and from a specific location. Among other constraints, the launch is heavily dependent on the weather conditions at the launch location, including rain, wind, and temperature. Three independent weather services are used, offering RainForecast, TempForecast, and WindForecast, respectively. The forecasts are given with their probabilities. The reliabilities based on the history of the services, their forecast probabilities (component outputs), and the adjusted probabilities based on the reliability and the forecast probabilities are given in Table 24.7.

To decide whether to change the launch date based on the weather forecasting information, the space agency then constructed a system based on the components. The reliability of the system and the final decision of whether to launch the satellite can then be assessed by the process shown in Fig. 24.24. The numbers in the diamond boxes are the reliabilities of each component. The numbers on the branches are the probabilities forecasted by the best service. The decision is based on these two factors.

24.6.4 Design-of-Experiment Analysis

Design of experiment (DOE) is an engineering technique [24.41] that can be used to determine the extent of the impact of the parameters (factors) of a model on the final results. This subsection applies DOE to analyze the impact of the reliability of the components on the reliability of the SoS.

There are three factors in the example, the reliabilities of (A) RainForecast, (B) TempForecast, and (C) WindForecast. We use two-level DOE techniques, i. e., we use high and low values of each factor: RainForecast (70%, 90%), TempForecast (90%, 99%) and WindForecast (85%, 95%). In our experiment, the three-factor and two-level design generated the analysis of variance (ANOVA) table shown in Table 24.8.

The F-value represents the significance of the impact of a model and its components. In general, if a com-

Table 24.8 ANOVA significance analysis

Source	F-value	Prob > F-value
Model	$1.421 \times 10^{+5}$	< 0.0001
A (RainForecast)	$3.898 \times 10^{+5}$	< 0.0001
B (TempForecast)	$2.2943 \times 10^{+4}$	< 0.0001
C (WindForecast)	$1.3558 \times 10^{+4}$	< 0.0001

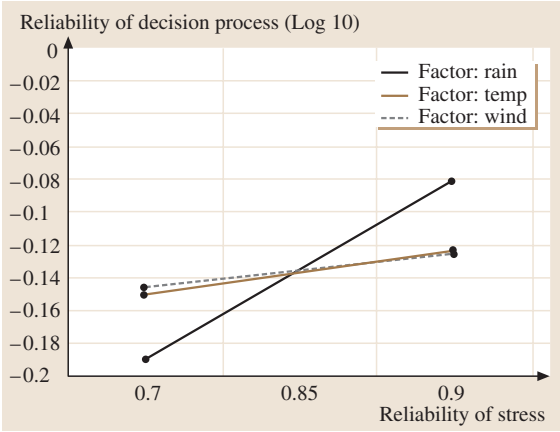

Fig. 24.25 Impact of components

ponet generates a significance value (Prob > F-Value) of less than 0.05, the impact of the component is significant. For example, the F-value $1.421 \times 10^{+5}$ for the overall model in the table implies that the model is significant. There is only a 0.01% chance that the an F-value of this size could occur for this model due to noise.

The experimental results in Table 24.8 also show that the F-values and significances of RainForecast, TempForecast, and WindForecast are all less than 0.0001, and thus they are all significant model components.

DOE can be used to compare the significances among the components. Figure 24.25 shows the impacts of the three components on the overall reliability in our example. As can be seen, the higher the component reliability, the higher the overall reliability. However, the impact of the RainForecast service is much more significant than that of the others. This suggests that the space agency should pay more attention to the quality of the rain-forecast service provider.

24.7 The Fourth Generation of E2E T&E on Service-Oriented Architecture

Service-oriented architecture (SOA) and web services (WS) are emerging technologies that may change the way computer software is designed and used. Many industrial standards have been defined in the past few years to facilitate and regulate the development of WS. However, there are still a number of barriers preventing WS from being widely applied or being used as the platform for trustworthy and high-assurance systems. *Sleeper* identified five missing pieces of WS technology: reliability, security, orchestration, legacy support, and semantics [24.42]. Among these five issues, reliability is the least addressed and probably most difficult, for the following reasons:

- WS are based on an unreliable and open internet infrastructure, yet they are expected to be trustworthy.
- WS have a loosely coupled architecture, yet they are expected to collaborate closely and seamlessly.
- WS can be invoked by unknown parties with unpredictable requests, and thus WS must be robust.
- WS involve runtime discovery, dynamic binding with multiple parties, including middleware and other WS, and runtime composition using existing WS. Thus, WS must support dynamic and runtime behaviors.
- WS must support dynamic configuration and reconfiguration to support fault-tolerant computing.
- WS must support dynamic composition and recomposition to cope with the changing environment and changing requirements.
- WS involve concurrent threads and object sharing. It is difficult to test concurrent processes.

We propose an integrated collaborative and cooperative WS development process to achieve high-assurance computing. The process is implemented in a framework consisting of three major modules dealing with the construction, publishing, and testing of WS.

As shown in Fig. 24.26, the WS cooperative and collaborative computing (WSC3) framework consists of three modules: cooperative WS construction; publishing; and testing, assessment, and ranking (WebStrar). The framework can be used by service requestors, service providers, as well as researchers experimenting with WS.

As an example, the arrows and numbers in Fig. 24.26, which outline cooperation scenarios between the components, are explained as follow.

1. The WS construction module, in the process of dynamically constructing a composite WS based on existing WS, requests information from the WS publishing module.
2. The publishing module provides required information, including the specification and interface of using the WS.

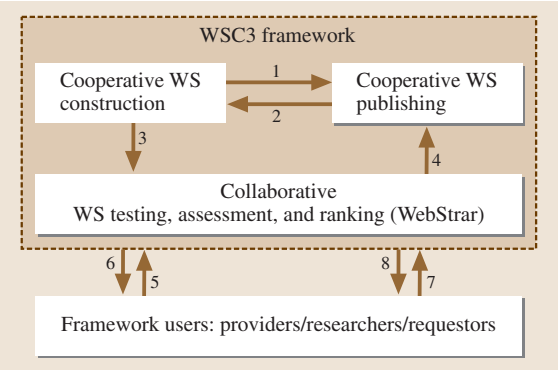

Fig. 24.26 WS cooperative and collaborative computing framework

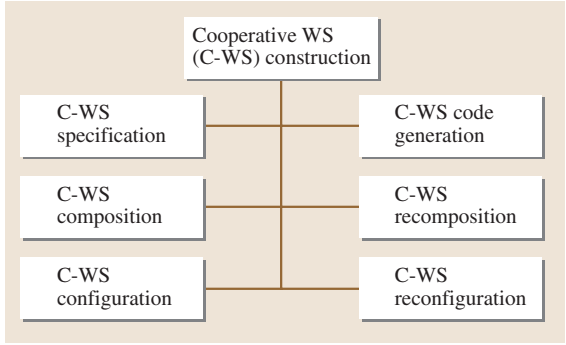

Fig. 24.27 Cooperative WS construction

3. After a composite WS is constructed, the construction module submits the WS to the WebStrar module for rigorous testing.
4. If the WS passes the test, it will be registered with the publishing module and a new WS is available for online access.
5. A WS provider or a researcher submits their WS for publication or testing. The WS will be tested by the WebStrar module rigorously based on the test scripts submitted by the provider as well as the test scripts generated by WebStrar. Sharing the test scripts represents collaboration between the framework and WS providers and researchers.
6. The framework publishes the WS and informs the WS provider if the submitted WS passes the test.
7. A WS requestor requests a service. The requestor can request testing before using a WS. It can use the test scripts provided by the framework or submit their own test scripts. Sharing the test scripts represents collaboration between the framework and WS requestors. WS requestors can also access the reliability data and ranking information of published WS.
8. The framework processes and responds to the WS requestor.

In the following three subsections, we elaborate the three modules in the WSC3 framework, respectively.

24.7.1 Cooperative WS Construction

Figure 24.27 elaborates the cooperative WS construction module in Fig. 24.26. This module has six components.

The cooperative WS specification component provides guidelines and tools for users to write WS specifications in a specification language, e.g., in OWL-S. The component will then use WebStrar to perform a consistency and completeness (C&C) check on the specification.

Once the specification passes the check, the code-generation component can automatically generate the executable code. The WS generated in this way is atomic, because its implementation detail is not accessible to the users. All WS submitted by WS providers are also atomic.

The cooperative WS composition component provides automated high-level WS composition based on existing atomic WS and their specifications.

The recomposition component can reconstruct a composite WS if the requirement and specification are changed. Composition and recomposition components construct WS based on the functional requirement while the configuration and reconfiguration components deal with the management of redundant resources and the reliability of WS. The configuration component adds redundant structure into composite WS to meet the reliability requirements while the reconfiguration component maintains redundancy after the environment is changed, for example, if some WS become faulty or unavailable.

24.7.2 Cooperative WS Publishing and Ontology

This section elaborates the cooperative WS publishing module in Fig. 24.26. Current WS publishing is based on the universal description, discovery, and integration (UDDI) technique. The UDDI discovery part is based on simple term/text matching, which does not have the intelligent to find synonyms and semantically related terms. For example, if the phrase "red wine" is searched, terms like Cabernet Sauvignon and Merlot should be found too.

Table 24.9 Cooperative versus traditional ontology

	Traditional ontology	Cooperative ontology
Test scripts	Does not include test scripts	Include test scripts and execute these test scripts at runtime
Nonfunctional property	Use certain terms to represent the value of these nonfunctional properties, such as performance and security.	Use test scripts to present the nonfunctional properties. Translate the nonfunctional properties to the measurable features.
Behavior constraints	Allow specification of the constraints, but not their execution at runtime	Execute the constraints at runtime to check if the assigned services match the constraints.
Interface	Does not include the interface information in the description	Use specific test scripts to present the interface constraints

OWL-S and Protégé are recent projects that support ontology description. Ontology defines the basic terms and relations comprising the vocabulary of a topic area as well as the rules for combining terms and relations to define extensions to the vocabulary [24.43]. This represents knowledge about a domain and describes specific situations in the domain [24.44]. Dynamic composition and recomposition need to discover WS at runtime over the internet, add them to the ontology domain, and then compose a WS at runtime.

Current ontology methods do not include the verification process. In our cooperative WS publishing module, we integrated the collaborative verification and validation (CV&V) process into the ontology by including the necessary test scripts in the ontology domain. When a WS is chosen for composition, recomposition, configuration, or reconfiguration, the stored test scripts will be immediately applied to test the WS. This integrated ontology with CV&V is called cooperative ontology. Table 24.9 compares and contrasts cooperative and traditional ontology.

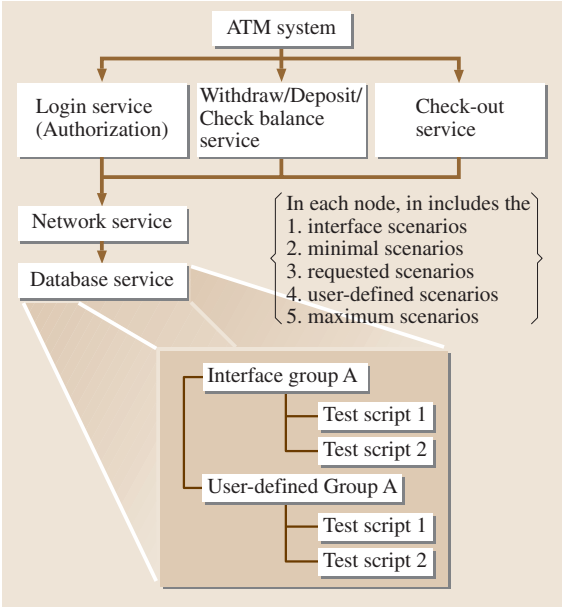

Fig. 24.28 ATM services tree example

The ontology-based architecture plays a key role in runtime WS composition. Runtime verification can choose different levels of test scripts to verify the services found. To further explain the idea, a simple automatic teller machine (ATM) example is used here. Assume the ATM offers login, balance-checking, withdrawal, deposit, and logout services.

The service tree of the cooperative ontology representing the ATM composite WS is given in Fig. 24.28. Each node has a service interface definition, a number of service constraints and service scenarios, and user-specific requirements described using test scripts. For instance, if we want to choose a login service that supports a specific character set [&*^%] in the user name, the user-defined test script can be:

Execute Register("abc&^%123", "123456");*

If this test script fails, the services found do not conform to the requirement and will be rejected. As discussed before, there are multiple levels of test scripts, which include the interface test scripts. In the service tree specification, the internal relations among test scripts are also important to support dynamic service composition and recomposition.

24.7.3 Collaborative Testing and Evaluation

The WS composed using the process in Fig. 24.29 will be tested, assessed and ranked. Figure 24.4 depicts the module that tests and assesses the reliability of the WS and assures the tools involved. The solid arrows indicate that a component can be decomposed into several subcomponents, while the dotted arrows indicate the data flow between components. WebStrar itself is a framework supporting the development of trustworthy WS

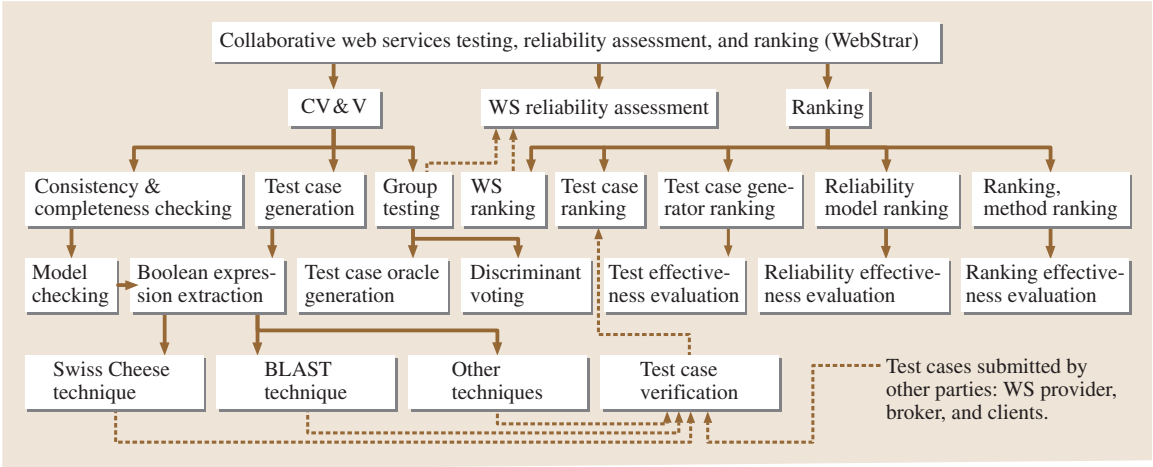

Fig. 24.29 Collaborative testing, assessing, and ranking

(http://asusrl.eas.asu.edu/srlab/projects/webstrar/index.htm). This section explains the individual techniques developed and to be developed in this framework. At the top level, WebStrar consists of three components: CV&V, WS reliability assessment, and ranking.

The idea of CV&V is to involve all parties (WS providers, brokers, and clients) in verifying and validating the WS, because the WS provider does not have full information on how their WS will be used by clients and brokers in user-composed composite WS [24.45, 46]. Before test-script generation, the consistency and completeness of the WS specification in OWL-S or web services description language (WSDL) will be checked through model checking or other methods, which may detect inconsistent conditions or incomplete coverage of the requirements [24.17]. Once the specification passes this check, Boolean expressions can be extracted, which can be used for test-script generation. Different techniques can be applied here; we have applied the Swiss cheese [24.17] and BLAST [24.16] techniques in our experiments. The system-generated test scripts, along with the test scripts provided by other parties, will be verified for correctness and ranked according to their effectiveness at detecting faults in WS.

Group testing is a key technique developed to test the potentially large numbers of WS available on the internet [24.46]. WS with the same specification can be tested in groups and the results are compared by a discriminant voter, which can identify correct and faulty output based on the majority principle. The majority results are used as the oracles for future testing.

Reliability assessment of WS is different from that of traditional software. WS reliability models do not have access to the WS source code. WS reliability can only be assessed at runtime because WS can be composed and modified (recomposed) at runtime. A group-testing-based dynamic reliability model has been developed to assess WS reliability [24.40]. Reliability is one of the criteria used to rank WS. Other criteria include security, performance, real-time ability, etc.

WebStrar allows researchers and WS providers to submit their models and tools for evaluation and ranking. WebStrar supports ranking of test scripts in terms of fault-detection capacity, test-script generation algorithms in terms of generation of effective test scripts, reliability models in terms of the accuracy of their assessment results, and ranking models themselves in terms of ranking accuracy.

24.8 Conclusion and Summary

E2E T&E technology was initially developed for DoD command-and-control systems and later applied in various industrial projects. It was initially designed as an integrated testing technology and later developed

into a full development technology spanning requirements; specification; model checking; code generation; test-case generation; testing; simulation; policy specification and enforcement; and reliability, security, and risk enforcement and assessment. All these techniques are coherently based on the scenario specification. From the software architecture point of view, E2E T&E technology has evolved from centralized architecture, through distributed agent architecture, to service-oriented architecture.

E2E T&E technology has been successfully applied in several DoD command-and-control projects where high-assurance computing is required and in several civilian projects including embedded systems in business networks. The application of the technology and its tools dramatically reduce the development cycle of the end systems and increase their dependability.

Systems developed using E2E T&E technology have the following attributes and features.

The developed systems are flexible and can adapt to changing environments. Some important attributes of *adaptability* include *speed*, *scalability*, *reusability*, *partitioning*, and *integration*. In general, the system is adaptive as it supports rapid development; is scalable from small applications to large applications; has many reusable tools that can produce reusable components; and has an integrated process.

The E2E T&E development process is fast because it includes tools that perform all jobs automatically where possible. It generates test cases automatically from the system specification and policy specification. It generates an executable automatically, and performs distributed test execution automatically. The evaluation process is also automatic.

The E2E T&E process is scalable because it can apply to large as well as small applications. The scenarios used in the E2E process are hierarchical and thus can apply to the hierarchical structure of a large SoS or a small subsystem.

The E2E T&E process has many reusable tools, including the scenario specification tool, the test-case management tool, the scenario simulation tool, and the distributed test-execution tool. One of the key benefits of the E2E tool is that specified scenarios are highly reusable and can be easily changed. System scenarios keep on changing as new requirements become known and new technology is introduced during system development; changing system scenarios with the E2E tool is much easier than redeveloping scenarios by hand. In most cases, new scenarios are developed by changing existing scenarios, and changing scenarios using the E2E tool with dependency analysis is easier than starting from scratch without any tool support. Furthermore, once new scenarios are specified, they can be automatically analyzed by various techniques such as timing analysis, and new test scripts can be rapidly generated and executed.

E2E T&E tightly integrates system analysis and modeling with integration testing because the same techniques, i. e., scenarios, can be used for both system analysis as well as integration testing. The importance of testing has recently being emphasized by agile development processes such as extreme programming. While testing is one of their main techniques, agile processes do not have such tight integration between system analysis and testing as the DoD E2E T&E. Tight integration changes the way systems are developed; instead of performing *requirement-driven testing* only, the E2E process calls for *test-based requirement analysis*. In other words, the requirements should be developed in a way that can be used for rapid integration testing (by automated test-script generation, verification patterns, and distributed test execution) and evaluation (by various analyses and simulation). In fact, E2E T&E supports a test-based development process from requirements to operation and maintenance, and such a process is compatible with agile development processes or incremental development.

25. Statistical Models in Software Reliability and Operations Research

Statistical models play an important role in monitoring and control of the testing phase of software development life cycle (SDLC). The first section of this chapter provides an introduction to software reliability growth modeling and management problems where optimal control is desired. It includes a brief literature survey and description of optimization problems and solution methods.

In the second section a framework has been proposed for developing general software reliability models for both testing and operational phases. Within the framework, pertinent factors such as testing effort, coverage, user growth etc. can be incorporated. A brief description of the usage models have been provided in the section. It is shown how a new product sales growth model from marketing can be used for reliability growth modeling. Proposed models have been validated on software failure data sets.

To produce reliable software, efficient management of the testing phase is essential. Three management problems viz. release time, testing effort control and resource allocation are discussed in Sects. 25.2 to 25.4. The operations research approach, i. e. with the help of the models, optimal management decisions can be made regarding the duration of the testing phase, requirement and allocation of resources, intensity of testing effort etc. These optimization problems can be of interest to both theoreticians and software test managers. This chapter discusses both of these aspects viz. model development and optimization problems.

A scientific way of solving decision-making problems arising in large and complex systems involves the construction of a model (usually a mathematical model) that represents the character of the problem. Modeling can be the most practical way of studying the behavior of such systems. A model exhibits relationships between quantitative variables under a definite set of assumptions that portray the system. It allows experimentation with different alternative courses of actions and facilitates the use of sophisticated mathematical techniques and computers for the purpose. Mathematical models have proved to be useful for understanding the structure and functioning of a system, predicting future events and prescribing the best course of actions under known constraints. The success and popularity of operations research, a problem-solving approach started with the above philosophy as its basic working principle, has demonstrated the utility of mathematical modeling. One of the fields where mathematical modeling, particularly stochastic modeling, has been applied widely is

reliability. Stochastic modeling in reliability theory has continued to be an area of extensive research for more than four decades. The subject has traditionally been attached to hardware systems. But with ever increasing use of computers in present times software reliability has also emerged as a discipline of its own. This chapter endeavors to develop new mathematical models for software reliability evaluation and propose methods for efficient management of the testing phase.

The last decade of the 20th century will be noted in history for the incredible growth in information technology. The proliferation of the Internet has gone far beyond even the most outrageously optimistic forecasts. Consequently computers and computer-based systems have invaded every sphere of human activity. As more systems are being automated mankind's dependence on computers is rapidly increasing. Though this technology revolution has made our lives better, concern for safety and security has never been greater. There are already numerous instances where the failure of computer-controlled systems has led to colossal loss of human lives and money. Computer-based systems typically consist of hardware and software. Quality hardware can now be produced at a reasonable cost but the same cannot be said about software. Software development consists of a sequence of activities where perfection is yet to be achieved. Hence there is every possibility that fault can be introduced and can remain in a software. A fault occurs when a human makes a mistake, called an error, in performing some software activity. These faults can lead to failures with catastrophic results. Therefore a lot of emphasis is put on avoiding the introduction of faults during software development and to remove dormant faults before the product is released for use.

The testing phase is an extremely important component of the software development life cycle (SDLC), where around half the developmental resources are consumed. In this phase the software product is tested to determine whether it meets the requirement. It is endeavored to remove faults lying dormant in the software. The theory developed in this chapter primarily addresses the testing phase. The only way to verify and validate the software is by testing. The software testing involves running the software and checking for unexpected behavior of the software output. A successful test can be considered to be one that reveals the presence of latent faults. During testing, resources such as manpower and time are consumed. A very specialized kind of manpower is required for test-case generation, running the test cases and debugging. Time is also a very important resource as software cannot be tested indefinitely and there is always pressure to release the software as early as possible. With the increasing importance of cost and time during software development, efficient management of the testing phase becomes a high-priority issue for an organization. Therefore it is important to understand the failure pattern and faults causing these failures. The chronology of failure occurrence and fault removal can be utilized to provide an estimate of software reliability and the level of fault content. A software reliability model is a tool that can be used to evaluate the software quantitatively, develop test status and monitor the change in reliability performance [25.1]. Numerous software reliability growth models (SRGMs), which relate the number of failures (faults identified) and execution time (CPU time/calendar time), have been discussed in the literature [25.2–9]. These models are used to predict fault content and the reliability of software. The majority of these models can be categorized as nonhomogeneous Poisson process (NHPP) models as they assume a NHPP model to describe the failure phenomenon [25.3,6,8,10]. New models exploit the mean-value function of the underlying NHPP by proposing new forms for it; this chapter takes this modeling approach. Moreover the expected behavior of the users of the software has also been included in the modeling process.

Large software systems contain several million lines of code. The sheer size of the product presents unique problems in terms of the ability of the software designers to achieve software quality rapidly. the testing phase, which consumes the largest portion of software development resources, poses formidable challenges. Manpower from diverse background are involved in the testing process. It is this phase where a closer interaction with the users is a must. It is a fact that if software is tested for a longer period it would result in an increase in reliability. But the cost of testing also increases. Very often test managers work under tight schedules and with limited resources. Therefore, to produce reliable software, efficient management of the testing phase is required. Three such management problems viz. the release-time problem, the testing effort control problem and the resource allocation problem are discussed in this chapter.

To know when to stop testing is a pertinent question during the testing phase. If the time of release of the software for operation can be forecasted beforehand it can help management immensely. The predictive ability of SRGMs can provide a scientific answer. The release time should be an optimal tradeoff between cost and reliability. Due to the obvious importance of the problem it has received a lot of attention from re-

searchers [25.3, 8, 11–16]. In this chapter this problem has been chosen as the first illustration of the application of the methods of operations research in software reliability engineering. The usage-based SRGMs have been applied in more realistic mathematical programming formulations of the problem. Often the target reliability level is fixed for release time during the testing of software. Using SRGMs the reliability of the software can be forecasted for any future time. If it is found that the target cannot be achieved, the testing effort needs to be accelerated. The additional resource requirements can be calculated using

SRGMs [25.17–19]. In Sect. 25.3 we discuss the above testing effort control problem and provide a new solution method through an SRGM specially developed for the purpose. Optimal resource allocation is a problem that bothers all decision makers. Hence the literature in this area is very rich. Many operations researchers are working on new allocation problems arising in systems that are changing due to the proliferation of technology. Module testing in the testing phase is one such activity where optimal resource allocation can be important for obtaining reliable software [25.17, 20, 21]. In this chapter the mathematical programming approach has been suggested for the solution of this problem.

The objective of this chapter is to highlight the importance of modeling and optimization in software reliability engineering. The first part is devoted towards model development and, thereafter, three illustrations of optimization and control are provided.

25.1 Interdisciplinary Software Reliability Modeling

A commercial software developer endeavors to make its software product popular in the market by providing value to its customer and thus generating goodwill. Apart from satisfying customers by meeting all their requirements and attaching additional features, the developer at the same time makes constant efforts to build bug-free software. As manual systems are increasingly being automated, a failure due to software can lead to loss of money, goodwill and even human lives. The competition in the commercial software market is intense and, because of the nature of the applications involved, purchasers look for quality in terms of the reliability of the software. Therefore software developers lay special emphasis on testing their software.

During the testing phase, test cases that simulate the user environment are run on the software and any departure from the specifications or requirements is called a failure and an effort is made immediately to remove the cause of that failure (a fault in the software). Testing goes on until the management is satisfied with the reliability of the software. But software cannot be tested exhaustively within a limited time period. This is the reason why we often hear about failures of software in operation and sometimes even in safety-critical systems. These failures are caused by faults that remain even after testing. Hence it is important to study how these failures occur in the user phase. Selling a software is not a one-off deal. It involves cultivating long-term relationship with the purchasers. Many of the developers come up with newer versions of their software after the launch of their product. These new versions can contain codes of the previous version with some additional modules and modifications. Moreover, some developers give warranties on their products. Hence any fault that is reported by the user is corrected. If the number of faults remaining in the software can be estimated to a reasonable accuracy it can give the management a useful metric to be used for decision making under the situations discussed above. Mathematical modeling can help in developing such a metric.

SRGMs have been widely used to estimate the reliability of software during testing. Many authors have even tried to extend them to represent the failure phenomenon during the operational phase, typically used in the software release-time problem [25.3, 15, 16]. But this approach is not correct when usage of software is different from during testing, which is actually the case for most commercial software packages. Testing is done under a controlled environment. Testing resources such as manpower and consumed (computer) time can be measured and extended further into the future. Mathematical models have been proposed for testing effort itself but they are not suitable for measuring the usage of software in the market. The intensity with which failures would manifest themselves during operational use is dependent upon the number of times the software is used and not much has been done in the literature for this situation [25.21]. An attempt has been made in this chapter to model reliability growth, linking it to the number of users in the operational phase. In this chapter we propose a framework for model development for the operational phase, which can also connect the testing phase, thus providing a unique approach to modeling both the testing and operational phases.

Kenny [25.21] proposed a model to estimate the number of faults remaining in the software during its operational use. He has assumed a power function to represent the usage rate of the software. Though Kenny argues that the rate at which the commercial software is used is dependent upon the number of users, the model proposed by him can fail to capture the growth in the number of users of a software product. A mathematical model to capture the growth of users is integrated into the proposed software reliability growth model.

Although commercial software products have been on the market for two decades, identifying the target customers with certainty is impossible. Hence a product, which may be similar in many respect to another one when launched in the market, behaves as a new product or innovation. The Bass model for innovation diffusion [25.22] in marketing has satisfactorily been used for this dynamic market of software products [25.23]. This model explicitly categorizes the customers into innovators and imitators. Innovators have independent decision-making abilities whereas imitators make the purchase decisions after getting first-hand opinion from a user. Here it is assumed that purchasers or users whose number with respect to time can be modeled as an innovation diffusion phenomenon are those who can report a failure caused by the software to the developer. Such a model can correctly describe the growth of users in terms of:

1. a slow start but a gain in growth rate,
2. a constant addition of users,
3. a big beginning and tail off in the usage rate, as pointed out by *Kenny* [25.21].

The model can also describe the situation where a much-hyped product when launched in a market does not fare according to expectation. Once the number of users of the software is known, the rate at which instructions in the software are executed can be estimated. The intensity with which failures would be reported depends upon this usage. The models developed in the software reliability engineering literature can now be used to model the fault exposure phenomenon.

Another important factor that affects software reliability immensely is testing coverage, but very few attempts have been made in the literature to include its impact [25.24, 25]. With the running of test cases and corresponding failure-removal processes during the testing phase, more portions of the software, paths, functions are tested. However, it is also a fact that software cannot be tested exhaustively. As testing coverage increases software becomes more reliable. Hence testing coverage is very important for both software test managers as well as users of the software. The model developed in this chapter for both the testing and operational phases also takes this factor into account, which is another novel feature of the chapter.

Notations:

$m, m(t)$: Expected number of faults identified in the time interval $(0,t]$ during the testing phase.

$\hat{m}, \hat{m}(t)$: Expected number of faults identified in the time interval $(0,t]$ during the operational phase.

$e, e(t)$: Expected number of instructions executed on the software in the time interval $(0,t]$.

$W, W(t)$: Cumulative testing effort in the time interval $(0,t]$; $\frac{\mathrm{d}}{\mathrm{d}t}W(t) = w(t)$.

a: Constant representing the number of faults lying dormant in the software at the beginning of testing.

$p, p(W(t))$: Testing coverage as a function of time testing effort.

$\alpha, \beta, \delta, \gamma$: Constants.

g, h, k, i, j: Constants.

$k_i, i = 1, \ldots, 9$: Constants.

$\bar{W}$: Constant representing the saturation point for the growth of users of the software.

T: Release time of the software.

$m^*(t)$: Number of failures reported during the operational phase, $t > T$.

q: Factor by which the operational usage rate differs from the testing rate per remaining faults.

$R_{\mathrm{te}}(x|t)$: Reliability of the software during the testing phase, $t < T$.

$R_{\mathrm{op}}(x|t)$: Reliability of the software during the operational phase, $t > T$.

C_1, C_2: Costs of testing per unit time and removing a fault, respectively, during the testing phase.

C_3: Cost of a failure and removing it during the operational phase.

T_{s}: Scheduled delivery time of the software.

$p_{\mathrm{c}}(t)$: Penalty cost $\begin{cases} 0, & t \le T_{\mathrm{s}} \\ p_{\mathrm{c}}.t & \text{otherwise} \end{cases}$.

T_{w}: Warranty period of the software.

25.1.1 Framework for Modeling

As discussed in the Introduction, several quantitative measures of growth in reliability of software during the testing phase have been proposed in the literature and several of these can be classified as NHPP models [25.3, 8, 9]. These NHPP models are based on the assumption that 'Software failures occur at random times during testing caused by faults lying dormant in the software'. The assumption appears true for both the testing and operational phases. Hence NHPP models can be used to describe the failure phenomenon during both of these phases. The counting process $\{N(t), t \geq 0\}$ of an NHPP is given as follows.

$$\Pr[N(t) = k] = \frac{[m(t)]^k}{k!} \mathrm{e}^{-m(t)}, \quad k = 0, 1, 2,$$
$$\text{and } m(t) = \int_0^t \lambda(x)\,\mathrm{d}x . \tag{25.1}$$

The intensity function $\lambda(x)$ (or the mean-value function $m(t)$) is the basic building block of all the NHPP models existing in the software reliability engineering literature. These models assume diverse testing environments such as the distinction between failure and removal processes, learning of the testing personnel, the possibility of imperfect debugging and error generation etc. In models proposed by *Yamada* et al. [25.26] and *Trachtenberg* [25.27], the effect of the intensity of testing effort on the failure phenomenon has been studied. Faults if present in the software are exposed when the software is run. During the testing phase, test cases are run and in the operational phase the software is used by the user. Hence the rate at which failures would occur depends upon its usage (i. e. testing effort during testing or number of users in the operational phase [25.21]). Hence SRGMs should incorporate the effect of usage. But this may give rise to more complication and confusion as a number of functions exist in the literature that describes the testing effort or user growth with time. In this chapter an attempt has been made to address this problem. A general framework for model development has been proposed here. Using the basic building blocks of this framework SRGMs for both testing and operational phases can be developed with ease. The proposed approach is based upon the following basic assumptions.

1. Software failure phenomenon can be described by an NHPP. Software reliability growth models of this chapter are the mean-value functions of NHPP.
2. The number of failures during testing/operation is dependent upon the number of faults remaining in the software at that time. It is also dependent upon the rate of testing coverage.
3. Testing coverage increases due to testing effort.
4. As soon as a failure occurs the fault causing that failure is immediately identified. Identified faults are removed perfectly and no additional faults are introduced during the process.
5. The number of instructions executed is a function of testing effort/number of users.
6. Testing effort/number of users is a function of time.

Using the above assumptions the failure phenomenon can be described with respect to time as follows [25.21, 27]:

$$\frac{\mathrm{d}m}{\mathrm{d}t} = \frac{\mathrm{d}m}{\mathrm{d}e}\frac{\mathrm{d}e}{\mathrm{d}W}\frac{\mathrm{d}W}{\mathrm{d}t} . \tag{25.2}$$

We discuss below individually each component (fraction) on the right-hand side of the above expression.

Component 1

During testing instructions are executed on the software and the output is matched with the expected results. If there is any discrepancy a failure is said to have occurred. Effort is made to identify and later remove the cause of the failure. The rate at which failures occur depends upon the number of faults remaining in the software [25.10]. As the coverage of the software is increased more faults are removed. The rate at which additional faults are identified is directly dependent upon the rate at which software is covered through additional test cases being run [25.24, 25]. It is also dependent upon the size of the uncovered portion of the software. Based on these facts the differential equation for fault identification/removal can be written as:

$$\frac{\mathrm{d}m}{\mathrm{d}e} = k_1 \frac{p'}{c-p}(a-m) , \tag{25.3}$$

where p' is the rate (with respect to testing effort) with which the software is covered through testing, c is the proportion of total software which will be eventually covered during the testing phase, with $0 < c < 1$. If c is closer to 1, one can conclude that test cases were efficiently chosen to cover the operational profile. For a logistic fault removal rate we can assume the following

form for $\frac{p'}{c-p}$:

$$\frac{p'}{c-p} = \frac{g}{1+h\mathrm{e}^{-gW}} \,. \tag{25.4}$$

$$\text{Hence, } p(W) = c\frac{1-\mathrm{e}^{gW}}{1+h\mathrm{e}^{-gW}} \,. \tag{25.5}$$

Testing coverage is directly related to testing effort, because with more testing effort we can expect to cover a larger portion of the software. Testing effort can be modeled as a function of time, which will be discussed later in this chapter.

Component 2

The second component of expression (25.2) relates the number of instructions executed with the testing effort or the number of users of the software. For the sake of simplicity we assume it to be constant

$$\frac{\mathrm{d}e}{\mathrm{d}W} = k_2 \,. \tag{25.6}$$

Substituting (25.3) and (25.6) into (25.2) we have

$$\frac{\mathrm{d}m}{\mathrm{d}t} = k_1\frac{g}{1+h\mathrm{e}^{-gW}}(a-m)k_2\frac{\mathrm{d}W}{\mathrm{d}t} \,. \tag{25.7}$$

In the next section the mathematical models for the software testing effort (component 3 of (25.2)) are discussed.

25.1.2 Modeling Testing Effort

The resources that govern the pace of testing for almost all software projects [25.6] are

1. Manpower, which includes
   - Failure-identification personnel,
   - Failure-correction personnel.
2. Computer time

In the literature, either the exponential or Rayleigh function has been used to explain the testing effort. Both can be derived from the assumption that, the testing effort rate is proportional to the testing resources available.

$$\frac{\mathrm{d}W(t)}{\mathrm{d}t} = c(t)[\alpha - W(t)] \,, \tag{25.8}$$

where $c(t)$ is the time-dependent rate at which testing resources are consumed with respect to remaining available resources. Solving (25.8) under the initial condition $W(0) = 0$, we get

$$W(t) = \alpha\left\{1 - \exp\left[\int_0^t c(x)\,\mathrm{d}x\right]\right\} \,. \tag{25.9}$$

When $c(t) = c$, a constant

$$W(t) = \alpha\left(1 - \mathrm{e}^{-ct}\right) \,. \tag{25.10}$$

If $c(t) = ct$, (25.8) gives a Rayleigh-type curve

$$W(t) = \alpha\left(1 - \mathrm{e}^{-ct^2/2}\right) \,. \tag{25.11}$$

Huang et al. [25.28] developed an SRGM, based upon an NHPP with a logistic testing-effort function. The cumulative testing effort consumed in the interval $(0, t]$ has the following form

$$W(t) = \frac{p}{1+r\mathrm{e}^{-lt}} \,. \tag{25.12}$$

Where p, r and l are constants. SRGMs with logistic testing-effort functions provide better results on some failure data sets.

Yamada et al. [25.29] described the time-dependent behavior of testing-effort expenditure by a Weibull curve while proposing an SRGM of

$$W(t) = \alpha\left(1 - \mathrm{e}^{-\beta t^k}\right) \,. \tag{25.13}$$

Exponential and Rayleigh curves become special cases of the Weibull curve for $k = 1$ and $k = 2$ respectively. To study the testing-effort process, one of the above functions can be chosen. In the following section we develop an SRGM where the fault-detection rate is a function of the testing effort and can have one of the forms discussed above.

25.1.3 Software Reliability Growth Modeling

Any one of the testing-effort models can be substituted in (25.7) to obtain a general software reliability growth model. Equation (25.7) can be written as follows

$$\frac{(\mathrm{d}m/\mathrm{d}t)}{(\mathrm{d}W/\mathrm{d}t)} = k\frac{g}{1+h\mathrm{e}^{-gW}}(a-m) \,, \tag{25.14}$$

where, $k = k_1k_2$. Equation (25.14) is a first-order linear differential equation. Solving it with the initial conditions $m(0) = 0$ and $W(0) = 0$ we have,

$$m[W(t)] = a\frac{\left(1+h\mathrm{e}^{-gW(t)}\right)^k - (1+h)\mathrm{e}^{-gkW(t)}}{\left(1+h\mathrm{e}^{-gW(t)}\right)^k} \,. \tag{25.15}$$

Next it is shown how a similar modeling approach can be used to obtain a failure-count model for the operational phase.

This SRGM is flexible and general in nature. For different parameter values it can reduce to many well-known SRGMs. *Pham* et al. [25.30] have proposed an alternative approach for the development of a general, flexible SRGM, though the impact of testing coverage was not explicitly considered in their model development. Moreover the modeling approach of this chapter can be extended to the operational phase, as shown next.

25.1.4 Modeling the Number of Users in the Operational Phase

During the operational phase failures are reported by the users. Software developers remove faults that cause these failures in future releases of the software. The number of failure reports can depend on the number of users of the software. As the usage grows so does the number of failure reports. Hence usage during the operational phase plays a similar role as testing effort during the testing phase. The failure-count model for the operational phase is based upon the following assumptions:

1. The number of unique failure reports and corresponding fault removals of the software during the operational phase can be described by an NHPP.
2. The number of failures during operation is dependent upon the number of faults remaining in the software. It is also directly proportional to the size of the uncovered portion (at the completion of the testing phase) of the software and the volume of instructions executed.
3. Once a failure is reported, the same failure report by other users is not counted. The SRGM developed can be interpreted as a failure-count model. The debugging process by the developer is assumed to be perfect.
4. The volume of instructions executed is related to the number of users.
5. The number of users of the software is a function of time.

Using the above assumptions the fault-removal phenomenon during the operational phase can be described as a function of time as follows:

$$\frac{\mathrm{d}\hat{m}}{\mathrm{d}t} = [1 - p(T)]\frac{\mathrm{d}\hat{m}}{\mathrm{d}e}\frac{\mathrm{d}e}{\mathrm{d}W}\frac{\mathrm{d}W}{\mathrm{d}t}\,, \tag{25.16}$$

where T is the release time of the software, $[1 - p(T)]$ is the size of the uncovered portion of the software and its value is known at the time of release of the software, $\hat{m}$ is the mean-value function of the failure-count model for the operational phase, i. e., the expected number of faults removed during the operational phase. The other three fractions of the right-hand side of (25.16) can be modeled similarly to the process followed in Sect. 25.1.1. Now fault removal is directly dependent on the number of instructions executed. It is also a fact that additional faults are removed during code checking for failure-cause isolation, but these faults may not have caused failures. *Kapur* and *Garg* [25.31] have discussed this phenomenon. Based upon these arguments the following expression can be written

$$\frac{\mathrm{d}\hat{m}}{\mathrm{d}e} = \left(k_4 + k_5\frac{\hat{m}}{a_1}\right)(a_1 - \hat{m})\,, \tag{25.17}$$

where k_4 is the rate at which remaining faults cause failures. It is a constant, as each one of these faults has an equal probability of causing failure. k_5 is the rate at which additional faults are identified without causing any failures; it is a constant, but also depends upon the number of faults already identified. $a_1 = [a - m(T)]$ is the number of faults present in the software when it was released for use (test time T).

During the debugging process some of the faults might be imperfectly removed and can cause failure in future. If this factor is introduced into the model, (25.17) can be modified as follows:

$$\frac{\mathrm{d}\hat{m}}{\mathrm{d}e} = \left(k_4 + k_5\frac{\hat{m}}{(a_1 + \hat{m})}\right)\left[(a_1 + k_6\hat{m}) - \hat{m}\right]. \tag{25.18}$$

In the above expression k_6 is the rate of imperfect debugging. But finding a closed-form solution for (25.18) is difficult. Therefore we can assume a logistic rate function as discussed (25.17),

$$\frac{\mathrm{d}\hat{m}}{\mathrm{d}e} = \left(\frac{i}{1 + j\,\mathrm{e}^{-it}}\right)(a_1 - k_7\hat{m})\,, \tag{25.19}$$

where, $k_7 = 1 - k_6$. Moreover, assuming that the number of instructions executed is a constant with respect to usage growth, the following expression, which is similar to (25.6), can be written.

$$\frac{\mathrm{d}e}{\mathrm{d}W} = k_8\,. \tag{25.20}$$

25.1.5 Modeling the User Growth

Kenny [25.21] used the power function to describe the growth in the user population of a software

$$W(t) = \frac{t^{(k+1)}}{(k+1)} \,. \tag{25.21}$$

$W(t)$ here is the number of users of the software in the operational phase at time t. The function can correctly describe the users growth in terms of

1. a slow start but a gain in growth rate,
2. a constant addition of users,
3. a big beginning and tail off in the usage rate.

However, in the marketing literature, the power function is seldom used for the purpose as described above. One of the reasons may be that the parameters of the function are not amenable to interpretation. The growth in the number of users with respect to time can also be described by the Bass model [25.22] of innovation diffusion. To apply the Bass model it is assumed that there exists a finite population of prospective users who, with time, increasingly become actual users of the software (no distinction is made between users and purchasers here as the Bass model has been successfully applied to describe the growth in number of both of them). In each period there will be both innovators and imitators using the software product. The innovators are not influenced in their timing of purchase by the number of people who have already bought it, but they may be influenced by the steady flow of nonpersonal promotion. As the process continues, the relative number of innovators will diminish monotonically with time. Imitators are, however, influenced by the number of previous buyers and increase relative to the number of innovators as the process continues.

The combined rate of first purchasing of innovators and imitators are given by the term $\left(\alpha + \beta \frac{W(t)}{\bar{W}}\right)$ and increases through time because $W(t)$ increases through time. In fact the rate of first purchasing is shown as a linear function of the cumulative number of previous first purchasers. However, the number of remaining nonadopters, given by $\left[\bar{W} - W(t)\right]$ decreases through time. The shape of the resulting sales curve of new adopters will depend upon the relative rate of these two tendencies. If a software product is successful, the coefficient of imitation is likely to exceed the coefficient of innovation i. e. $\alpha < \beta$. On the other hand, if $\alpha > \beta$, the sales curve will fall continuously.

The following mathematical model, known as the Bass model [25.22] in the marketing literature, describes this situation.

$$\frac{\mathrm{d}W(t)}{\mathrm{d}t} = \left(\alpha + \beta \frac{W(t)}{\bar{S}}\right)\left[\bar{S} - W(t)\right] . \tag{25.22}$$

The solution of (25.22) for $W(t=0)$ is

$$W(t) = \bar{W}\frac{1 - \exp[-(\alpha+\beta)t]}{1 + (\beta/\alpha)\exp[-(\alpha+\beta)t]} \,. \tag{25.23}$$

Givon et al. [25.23] have used the modified version of this model to estimate the number of licensed users as well as users of pirated copies of the software. Though it can be reasonably assumed that it is the licensed-copy holders who would report the failures, (25.23) can be used to find the expected number of users at any time during the life cycle of the software. If the new software is expected to go through the same history as some previous software (very likely for versions of the same software) the parameters of an earlier growth curve may be used as an approximation.

The derivative of (25.23) to be used in expression (25.16) has the following form

$$\frac{\mathrm{d}W(t)}{\mathrm{d}t} = \bar{W}\frac{\beta[1 + (\beta/\alpha)]\exp[-(\alpha+\beta)t]}{\left\{1 + (\beta/\alpha)\exp[-(\alpha+\beta)t]\right\}^2} \,. \tag{25.24}$$

After substitution of all the components, (25.16) is a first-order linear differential equation. Solving it with the initial condition $m(t=0) = 0$ we have,

$$\hat{m}(t) = \frac{a_2}{k_9}\left[1 - \left(\frac{(1+j)\mathrm{e}^{-\mathrm{i}W(t)}}{1 + j\,\mathrm{e}^{-\mathrm{i}W(t)}}\right)^{k_9}\right] , \tag{25.25}$$

where $a_2 = k_8 a_1[1 - p(T)]$ and $k_9 = k_7 k_8[1 - p(T)]$.

25.1.6 Estimation Methods

The testing-effort data or the data pertaining to the number of users (or usage) of a software can be collected in the form of testing effort/usage, $w_k(- < w_1 < w_2 < \ldots < w_n)$ consumed in time $(0, t_i]$; $i = 1, 2, \ldots, n$. Then the testing-effort model/usage growth model parameters can be estimated by the method of least squares as follows

$$\text{Minimize} \sum_{i=1}^{n} \left(W_i - \hat{W}\right)^2 \tag{25.26}$$

subject to $\hat{W}_n = W_n$ (i. e. the estimated value of the testing effort is equal to the actual value).

To estimate the parameters of the SRGMs obtained through (25.15) and (25.25), the method of maximum likelihood (MLE) is used [25.3, 6, 8]. The fault-removal

Table 25.1 Fitting of testing effort data

Data sets	α	β	k	R^2
DS-1	2669.9	0.000773	2.068	0.99

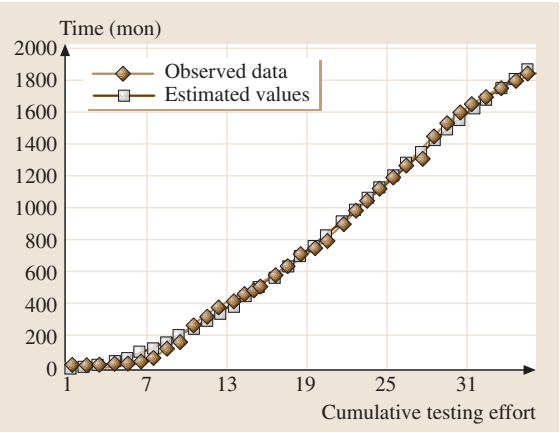

Fig. 25.1 Fitting of the effort curve (DS-1)

data is given in the form of cumulative number of faults removed, y_i in time $(0, t_i]$. Thus the likelihood function is given as

$$L[a_1, a_2, b_o, b_r, q|(y_i, W_i)] = \prod_{i=1}^{n} \frac{[m(t_i) - m(t_{i-1})]^{y_i - y_{i-1}}}{(y_i - y_{i-1})!} e^{-[m(t_i) - m(t_{i-1})]} . \quad (25.27)$$

25.1.7 Numerical Illustrations

To validate the models four real software failure data sets have been chosen. The first two were collected during the testing phase of software while the third and fourth data sets are based on failure reports of software in operational use.

Data set 1 (DS-1): The data are cited from *Brooks* and *Motley* [25.11]. The fault data set is for a radar system of size 124 KLOC (kilo lines of code) tested for 35 months, in which 1301 faults were identified.

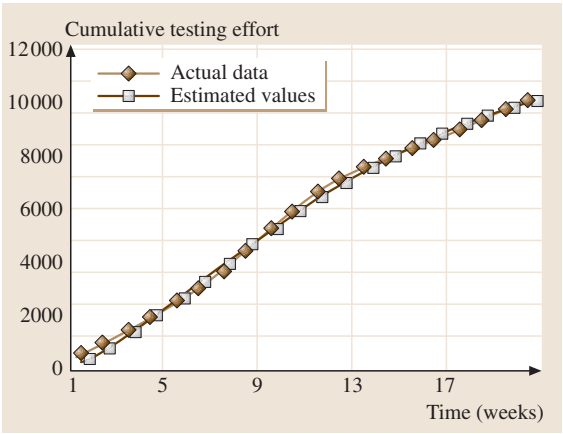

Fig. 25.2 Fitting of the testing effort curve (DS-2)

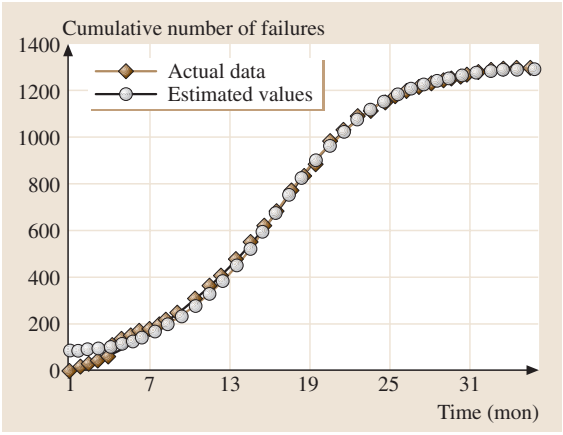

Fig. 25.3 Fitting of the failure curve (DS-1)

Data set 2 (DS-2): The data set pertains to release 1 of the tandem computer project cited in [25.30]. The software test data is available for 20 weeks, during which 100 faults were identified.

In both cases the Weibull function (25.13) gave the best fit to the testing-effort data. The results are presented in Table 25.1 and the curve fits are depicted in Figs. 25.1 and 25.2, respectively.

The estimation results for the parameters of SRGM (25.15) have been summarized in Table 25.2 and are graphically presented in Figs. 25.3 and 25.4.

Table 25.2 Parameter estimation of the SRGM

Data set	a	H	g	k	R^2
DS-I	1305	4.46445	0.003173	1.0363	0.996

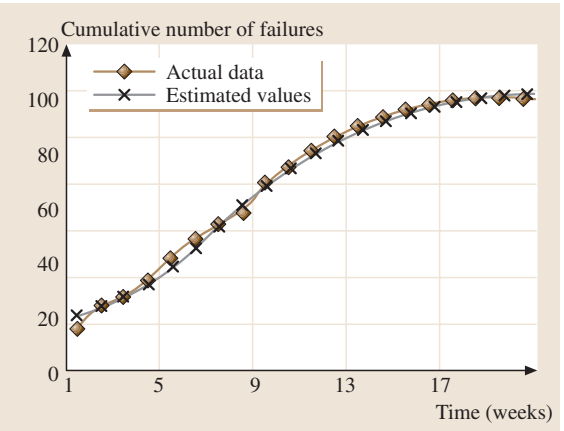

Fig. 25.4 Fitting of the failure curve (DS-2)

Next we estimate the parameters of SRGMs obtained from equation (25.25) and using usage growth functions (25.21) and (25.23). The following data set has been chosen for illustration.

Data set 3 (DS-3): This failure data set [25.32] is for an operating system in its operational phase. The software consists of hundreds of thousands of delivered object code instructions. 112 faults were reported during the observation period of around five months. The Bass model (25.23) could best describe the usage data and hence was chosen. Using the estimated values, the rest of the parameters of the model were estimated. The estimation results are summarized in Table 25.3 and are depicted in Figs. 25.5 and 25.6.

25.2 Release Time of Software

It is important to know when to stop testing. The optimal testing time is a function of many variables: software size, level of reliability desired, personnel availability, market conditions, penalty cost due to delay in delivery of the product and penalties of in-process failures. If the release of the software is unduly delayed, the software developer may suffer in terms of penalties and revenue loss, while premature release may cost heavily in terms of fault removals to be done after release and may even harm the manufacturer's reputation. Software release-time problems have been classified in different ways. One of them is to find the release time such that the cost incurred during the remaining phases of the life cycle (consisting of the testing and operational phases) of the software is minimized [25.3, 15]. This problem can also be alternatively defined in terms of maximizing gain, where gain is defined as the difference in cost incurred when all faults are removed during the operational phase as against the cost when some faults are removed during the testing phase and others are removed during the operational phase. It can be proved that maximizing gain is the same as minimizing cost. Some

release-time problems are based upon reliability criteria alone. Models that minimize the number of remaining faults in the software or the failure intensity fall under this category [25.3]. Release-time problems have also been formulated for minimizing cost with minimum reliability requirements or maximizing reliability subject to budgetary constraints [25.3]. The bicriterion release policy simultaneously maximizes reliability and minimizes cost subject to reliability and resource constraints. In all these formulations software reliability growth models play a very important role due to their predictive ability. It is a fact that the longer software is tested, the higher its reliability. But it cannot be tested indefinitely, due to time and cost factors. With increasing cost, there is also a loss of opportunity in earning profit. Again software can have scheduled delivery time and the developer may have to pay high penalty costs due to a delay in delivery. Hence an optimal tradeoff between cost and reliability is required to find the termination time of testing. All the costs mentioned above are minimized subject to some constraints. These constraints are primarily related to a certain minimum level of testing reliability. The cost and reliability functions are discussed in detail later in this section.

The Cost Function

Cost functions discussed in the literature include costs of testing, removing faults during testing and that of failures and removals during the operational phase. As testing is done under a controlled environment, costs pertaining to testing, removing faults, documentation etc. can be estimated, but difficulty arises in quantifying the cost of a failure at the user end. As a way out a more realistic approach of warranty cost is being considered [25.33]. In release-time problems, costs of failure and removal of a fault occurring during a limited warranty period immediately after release need also to be included. Failure during the operational phase also amounts to loss of goodwill for the developer. Hence, in the cost function, failures after testing are counted and costs for their removal are estimated. Cost due to delay in delivery [25.34] is normally included in the overall software development cost. Release-time problems should include their affect. The cost function can takes the following form:

$$C(T) = c_1 T + c_2 m(T) + c_3 m^*(T + T_w) + p_c(T) \,. \tag{25.28}$$

It is assumed above that the costs of removing faults during testing and operation are constants: c_2 and c_3, respectively. The functional forms for $m(T)$ and $m^*(T + T_w)$ are also required. SRGMs have been used for $m(T)$ and the model that best describes the reliability growth during the testing phase needs to be chosen. To estimate the number of failures in the warranty period, models for the operational phase should be used. A typical cost function with an S-shaped reliability growth curve can take the form (or a part of it) of the curve, as shown in Fig. 25.7.

In the release-time problems discussed in the literature, it has been assumed that failures will occur in the operational phase in the same manner as they do during testing [25.15]. Though the testing environment is designed such that it best represents the operational phase, the intensity of use of the software may differ. It is shown below how the simple Goel–Okumoto model [25.10] can be modified for the purpose. For the failure phenomenon of software in operational phase, the following differential equation is proposed:

$$\frac{\mathrm{d}}{\mathrm{d}t} m^*(t) = b_1 [a_1 - m^*(t)] \,, \quad t > T \,. \tag{25.29}$$

This equation is based on the assumption that failures during the operational phase are dependent on the number of faults remaining in the software at and after the time of release. Again the rate at which failures will occur with respect to the remaining faults is dependent on perceived usage of the software during this period. It is also assumed that upon a failure the corresponding fault is to be removed, at least during the warranty period. Our primary interest during this phase is to count the failures, as this directly translates to very high costs on account of risk, loss of goodwill and removal of faults or replacement of the entire software. The number of faults remaining in the software at time T is,

$$a_1 = [a - m(T)] = a - m(T) \,. \tag{25.30}$$

It is expected that there would be no fault generation during debugging in this phase. It is also assumed that the

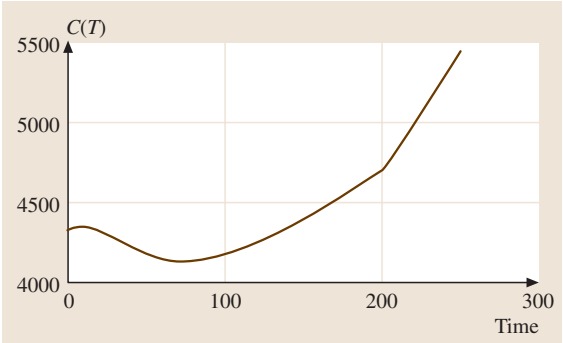

Fig. 25.7 The cost function

usage in the operational phase differs from that during the testing phase by a constant factor q. Hence the new rate is $b_1 = bq$. If $q = 1$, the intensity of use of the software during both these phases is similar. For $q < 1$ ($q > 1$) the software is expected to be used less (more) intensely during the operational phase. The solution of the differential equation (25.29) with the initial condition $m^*(T) = 0$ is

$$m^*(t) = a_1 \left[1 - e^{-b_1(t-T)}\right], \quad t > T, \qquad (25.31)$$

where $m^*(t)$ represents the expected number of failures in operational phase by time 't'. It is assumed that the failure phenomenon is still governed by an NHPP but with a new mean-value function.

Reliability Functions

Reliability expressions for NHPP software reliability models can easily be derived [25.6, 8, 10]. Software reliability is defined as the probability that the software operates failure-free for a specified time interval, on the machines for which it was designed, with the condition that the last failure occurred at a known time epoch. If the fault-detection process follows an NHPP then it can be shown that the software reliability at time t for a given interval $(t, t+x)$ is given by,

$$R_{te}(x|t) = e^{-[m(t+x)-m(t)]}. \qquad (25.32)$$

Software reliability at time 't' during the user phase is defined as the probability of nonoccurrence of failure in the interval $(t, t+x]$, $x \geq 0$, $t > T$; in the operational environment. The definition is similar to the definition for the testing phase. A mathematical expression for the same can be derived using the SRGM (25.31) and the NHPP assumption. The following expressions results [25.6, 22].

$$R_{op}(x|t) = e^{-[m^*(t+x)-m^*(t)]}, \quad t > T. \qquad (25.33)$$

The reliability curves for different values of q for a particular data set are given in Fig. 25.8. It is also observed that, for particular values of a, b and p, the operational reliability curve lies above the testing reliability curve i. e. $R_{op}(x|t) \geq R_{te}(x|t)$, $t \in [0, \infty)$ when $q = 1$. This result agrees with that derived in [25.16] when testing and operational profiles are identical.

25.2.1 Release-Time Problem Formulations

The release-time problem of software is to find a testing termination time T^* from an optimal tradeoff between cost and reliability. Many optimization problems

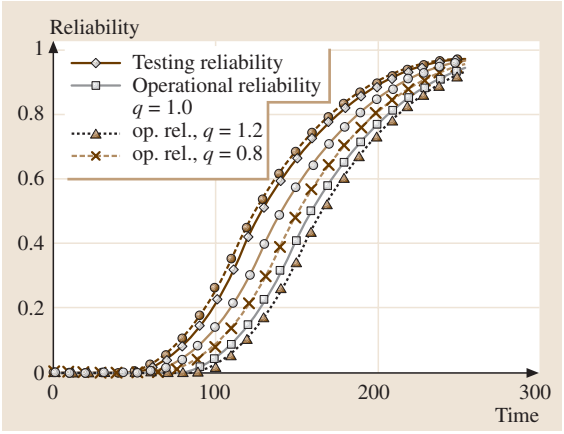

Fig. 25.8 Reliability curves for various q

have been formulated in the literature for this purpose [25.13, 15, 16, 33–36]. These problems select one or more functions from the lists of objective functions and constraints.

Objectives

(O1) Cost function: minimize $C(T)$;
(O2) Reliability functions:

1. Maximize $R_{te}(x|t)$,
2. Maximize $R_{op}(x|t)$.

Constraints

(C1) Budget constraint: $C(T) \leq B$;
(C2) Reliability constraints:

1. $R_{te}(x|t) \geq R_t$,
2. $R_{op}(x|t) \geq R_o$.

Where R_t and R_o are minimum reliability requirements for the testing and operational reliabilities respectively. In Table 25.4 some release-time problem formulations [25.3, 8] have been presented.

(R1) is the easiest problem formulation and is applicable for routinely developed software for which requirements are well defined. (R2) should be chosen for safety critical systems, where reliability is of utmost importance. (R4) is the most general problem formulation but is the most difficult to solve. A number of methods, including visual inspection of the cost curve, calculus, nonlinear programming, dynamic programming and neural networks etc. [25.3, 12, 15, 36], have been applied to find the optimal solution. Optimization software packages can also be used for this purpose.

Table 25.4 Release-time problems

Release time problem	Objective(s)	Constraints(s)
(R1) Cost criterion	Cost function (O1)	None
(R2) Reliability criterion	Reliability functions (O2-a) and (O2-b)	Reliability constraints (C2-a) and (C2-b)
(R3-A) Cost-reliability critera	Cost function (O1)	Reliability constraints (C2-a) and (C2-b)
(R3-B) Reliability-cost critera	Reliability functions (O2-a) and (O2-b)	Budget constraint (C1)
(R4) Bicriterion release criteria	Cost function (O1) Reliability functions (O2-a) and (O2-b)	Budget constraint (C1) Reliability constraints (C2-a) and (C2-b)

25.3 Control Problem

Before the release of software, a target reliability level is fixed. A reliable estimate of the fault content of software can also be obtained. Hence the management may desire to remove a certain percentage of it before release. But during the testing phase it is frequently realized that this may not be achievable for a number of reasons, such as inadequacy of the testing effort, inefficiency of the testing team etc. Hence, there is a need to increase the fault-removal rate. The problem of accelerating fault removal to achieve a certain reliability level or to a remove a certain percentage of total fault content of software is known as the testing-effort control problem. *Yamada* and *Ohtera* [25.19] took the software reliability growth modeling approach to solve this problem. In this section a new method to accelerate fault removal using SRGMs is proposed.

Additional Notations Used in this Section

α: Total testing resources to be eventually consumed, a constant;
$W_o(t)$: Cumulative testing effort on failure observation;
$W_r(t)$: Cumulative testing effort on fault removal;
$m_f(t)$: Number of failures observed in $(0, t]$;
b_o, b_r: Constants of proportionality, denoting rates of failure observation and fault removal, respectively;
m^*: Number of faults desired to be removed in time $(0, T_2]$;
$W(t - T_1)$: $W(t) - W(T_1)$, T_1 is the time duration;
a_1: $a - m(T_1)$;
a_2: $a - m_f(T_1)$.

25.3.1 Reliability Model for the Control Problem

The management of a software development project has time schedules for testing and release of software, but it is ignorant about the number and nature of faults lying dormant in it before the testing is actually done. SRGMs help in this regard after testing has been carried out for a certain period. The estimated parameters of the selected SRGM provide information about the number of faults remaining and the efficiency of the testing effort. Hence the expected number of faults that will be removed at any time in the future can be forecasted if the effort follows a known pattern. Frequently, management aspires to a reliability level at release that can be interpreted in terms of remaining number of faults. When the forecasted number of faults falls below the desired number, the testing effort needs to be controlled [25.18]. One obvious method (method I) is to increase the intensity of the testing effort through the employment of more manpower, computer time etc. But with limited resources available, this may not be feasible. Here it is shown how fault removal can also be accelerated by manipulating the allocation of testing resources to the two processes of failure observation and fault removal (method II). The models developed earlier in this chapter do not distinguish between fault identification and removal phenomenon. For the solution of the control problem we use the following SRGM.

The software testing phase aims to observe the failure process and remove the cause of the failure (the removal process). It is observed that different amounts of testing resources are consumed by each of these

processes. In SRGMs developed in the literature, the time-dependent behavior of the testing effort and the consequent reliability growth has been studied.

Yamada et al. [25.37], have given an SRGM incorporating the time lag between failure observation and fault removal. *Kapur* et al. [25.3] developed an S-shaped SRGM based on an NHPP to model the relationship between fault removal and testing effort. The cumulative testing effort was taken as a weighted sum of resources spent on fault observation and removal processes. We modify these SRGMs here. It is a common experience that, during early stages of testing, a large number of failures are observed, while the corresponding fault removals are lower. On the other hand, during later stages of testing, failures are harder to observe. Hence the failure-detection and the fault-removal processes should be studied distinctly.

Let $q_o(t)$ and $q_r(t)$ be the proportions of testing effort used on the failure-observation and fault-removal processes i. e. $q_o(t) = \frac{W_o(t)}{W_o(t)+W_r(t)} = \frac{W_o(t)}{W(t)}$ and $q_r(t) = \frac{W_r(t)}{W(t)}$. Then $q_o(t)+q_r(t) = 1$. If we assume $q_o(t) = q$ and $q_r(t) = (1-q)$, where q is a constant lying between 0 and 1. Then $qW(t)$ denotes the testing effort on failure observation and $(1-q)W(t)$, the effort on fault correction in the interval $(0, t]$. The NHPP-based SRGM developed below is based on the following assumptions:

1. No new faults are introduced into the software system during the testing phase.
2. The rate of fault removal to the current testing effort on removal is proportional to the number of identified faults that are yet to be removed at that instant.

The assumptions take the form of the following differential equations

$$\frac{m_f'(t)}{qw(t)} = b_o\,[a - m_f(t)]\ , \tag{25.34}$$

$$\frac{m'(t)}{(1-q)w(t)} = b_r\,[m_f(t) - m(t)]\ . \tag{25.35}$$

Solving the above system of equations with the initial conditions $m_f(t=0) = 0$ and $m(t=0) = 0$, we get

$$m(t) = a\left\{1 - \frac{1}{-b_o q + b_r(1-q)} \times \left[b_r(1-q)\mathrm{e}^{-b_o q W(t)} - b_o q\,\mathrm{e}^{-b_r(1-q)W(t)}\right]\right\}. \tag{25.36}$$

Equation (25.36) represents the cumulative number of faults removed, with respect to the testing effort consumed in the interval $(0, t]$. The time-dependent testing-effort function can have any of the forms presented in the preceding subsection. The removal function (25.36) is an S-shaped growth curve, because of the time lag between failure observation, the removal of the corresponding fault and the nature of the effort function.

For $q = 1$, the model reduces to the exponential model due to *Goel* and *Okumoto* [25.10]. In this case the process consists of a single step, i. e. faults are removed as soon as they are identified. With increasing $(1-q)$, the effort on removal increases. Hence the SRGM (25.36), captures the severity in faults present in a software. The model has been validated on actual software reliability data sets [25.17].

25.3.2 Solution Methods for the Control Problem

Method I

Suppose that software has been tested for time T_1 and it is to be released by time T_2, $T_2 > T_1$. Using the test data for the interval $(0, T_1]$ the parameters of the SRGM (25.36), can be statistically estimated. The testing effort in this interval is $W(T_1)$ and the corresponding number of faults that have been removed is $m(T_1)$. Based on the estimates of parameters, the number of faults expected to be removed by time T_2 is,

$$m(T_2) = a\left\{1 - \frac{1}{-b_o q + b_r(1-q)} \times \left[b_r(1-q)\mathrm{e}^{-b_o q W(T_2)} - b_o q\,\mathrm{e}^{-b_r(1-q)W(T_2)}\right]\right\} \tag{25.37}$$

The difference $[m(T_2) - m(T_1)]$ is the number of faults that is expected to be removed in the interval $(T_1, T_2]$. Often the management aspires to a level of reliability for the software at the time of release, which can be translated in terms of the number of faults (m^*) that it

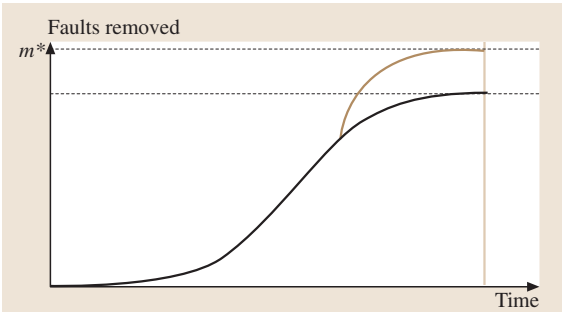

Fig. 25.9 Testing effort control

desired to be removed. If $m^* > m(T_2)$, the fault-removal rate has to be increased. This control problem is depicted in Fig. 25.9.

First the testing effort required to remove $[m^* - m(T_2)]$ faults in the time interval $(T_1, T_2]$ is calculated. Using the assumptions for the SRGM (25.36), the following expression results for $m(t)$, $t > T_2$

$$m(t) = m(T_1) + a_1\left(1 - \mathrm{e}^{-b_\mathrm{r}(1-q)W(t-T_1)}\right) - \frac{a_2 b_\mathrm{r}(1-q)}{-b_\mathrm{o}q + b_\mathrm{r}(1-q)} \times \left(\mathrm{e}^{-b_\mathrm{o}qW(t-T_1)} - \mathrm{e}^{-b_\mathrm{r}(1-q)W(t-T_1)}\right) . \tag{25.38}$$

In the above equation if m^* is substituted for $m(t)$ and W^* for $W(t-T_1)$, the following expression results,

$$m^* = m(T_1) + a_1\left\{1 - \mathrm{e}^{-b_\mathrm{r}(1-q)W^*}\right\} - \frac{a_2 b_\mathrm{r}(1-q)}{-b_\mathrm{o}q + b_\mathrm{r}(1-q)} \times \left\{\mathrm{e}^{-b_\mathrm{o}qW^*} - \mathrm{e}^{-b_\mathrm{r}(1-q)W^*}\right\} . \tag{25.39}$$

With the values of $m^*, m(T_1), a_1, b_o, a_2, b_r$ and q being known, equation (25.39) can be solved numerically to obtain the value of W^*, i. e. the amount of additional resources needed.

Method II

An alternative way to achieve the desired fault-detection level is to change the allocation factor of resources to be spent on the failure-identification and fault-removal processes. During the early stages of the testing phase a large number of failures may be observed, while the corresponding fault-removal rate is lower. This is due to the latency time needed by the removal team to cope with the workload. In this case it is reasonable to allocate resources in order to increase the testing effort of the failure-removal team, which may stimulate removal. On the other hand, during the late stages of testing, failures may be hard to identify and the removal team would have had enough time to remove most of the faults. Thus the fault removal will slow down, due to the lower number of failure observations. Hence it is more logical to assign more resources to the failure-identification team. Again during the later stages of testing it may happen that most of the failures had already been identified but not removed. Ideally the testing effort should now be concentrated on removal.

As discussed above, removal can be accelerated through proper allocation of resources. The optimal proportion of resources to be allocated to the failure-identification process, q^* to remove m^* faults can be found by solving the following equation numerically

$$m^* = m(T_1) + a_1\left(1 - \mathrm{e}^{-b_\mathrm{r}(1-q^*)W(T_2-T_1)}\right) - \frac{a_2 b_\mathrm{r}(1-q^*)}{-b_\mathrm{o}q^* + b_\mathrm{r}(1-q^*)} \times \left(\mathrm{e}^{-b_\mathrm{o}q^*W(T_2-T_1)} - \mathrm{e}^{-b_\mathrm{r}(1-q^*)W(T_2-T_1)}\right) . \tag{25.40}$$

The proportion of testing effort to be spent on fault removal during the time interval $(T_1,T_2]$ is $(1-q^*)$. In the following section, the results derived through the two methods are illustrated numerically.

In the literature only method I has been proposed for the control problem, but frequently management has to deal with limited testing resources. Method II, which increases fault removal through proper segregation of resources, can provide a solution. Moreover, following this method, testing can be done more efficiently by constantly monitoring the effort and fault removal and then allocating the optimal proportion of resources to the testing teams [25.38]. The control problem and the solution methods can be further refined. There can be an upper limit other than the initial fault content on the number of faults that can be removed by changing the allocation factor. Again the sensitivity analysis of the parameters with respect to the estimates and the optimal solution can provide further insight into the optimal allocation of testing resources. An early release of software is always desirable, but this should not undermine its quality. Also with a limited budget, decision making on the duration of testing becomes complicated. Hence cost–reliability criteria for the release of software and control of the testing effort should be jointly considered.

25.4 Allocation of Resources in Modular Software

Large software consists of modules. Modules can be visualized as independent pieces of software performing predefined tasks, mostly developed by separate teams of programmers and sometimes at different geographical locations. These modules are later integrated to form complete software. In module testing, each module is

tested independently and the software environment is simulated [25.39]. Typically this phase consumes 25% of the total development effort. In this phase the objective is to remove the maximum number of faults lying dormant in the modules. Though no conclusion can be drawn on system reliability at this stage, it is definitely enhanced with each fault removal. However, the testing has to be concluded within a specified time, which calls for proper allocation of limited resources among modules. This gives rise to the management problem of maximization of total fault removal within a finite time period or testing resource budget. In this section, we have formulated it as a mathematical programming problem. Again all modules are not equally important neither do they contain an equal number of faults. The severity of a fault in each module can also differ. In the light of this we have proposed another mathematical programming problem in that section. To arrive at a solution to this problem a mathematical relationship between testing resource consumption and fault removal is required. SRGMs have been used as a tool to monitor the progress of the testing phase by quantifying various reliability measures of the software system such as reliability growth, remaining number of faults, mean time between failures, testing effort etc. One approach is due to *Musa* et al. [25.6], where they have assumed that the resource consumption isan explicit function of the number of faults removed and calendar time. We develop a new model for the testing effort, which is solely dependent upon fault removal. The mathematical model is based upon the marginal testing effort function (MTEF), is defined as the effort required to remove an additional fault at any time. MTEFs are different in each module, depending on the severity of the faults in it, and using them we determine the optimal allocation of testing resources among modules; this has never been used before for optimal allocation of resources.

Using a simpler form of the MTEF a closed-form solution for optimal allocation of testing resource is obtained. It is very important to give a plausible form, but, as seen in another optimization problem, when more practical constraints are added to the same problem, no closed-form solution could be obtained. The problem is then solved as a nonlinear programming problem using a software package.

Additional Notations for this Section

m_i: Number of faults removed in the *i-th* module;
c_i: Cost of unit testing effort in the *i-th* module;
α_i: Relative importance of module i, $\sum_{i=1}^{N} \alpha_i = 1$;
$w(m)$: Marginal testing effort when m faults have been removed;
$W(m)$: Cumulative testing effort when m faults have been removed;
$W_i(m)$: Cumulative effort to remove m faults in the *i-th* module;
$w_i(m)$: Marginal testing effort function in the *i-th* module;
B: Total testing resource available; budget;
r_i: Minimum number of faults desired to be removed in the *i-th* module;
N: Number of modules;
k', p, q, k: Constants of proportionality;
p_i, q_i, k_i: Parameters of marginal testing effort function for the *i-th* module;
a_i: Number of faults in the *i-th* module;
d_i: $c_i k_i$;
δ, γ: Probability of imperfect (perfect) debugging, $0 \le \delta, \gamma \le 1$;
δ_i, γ_i: Probability of imperfect (perfect) debugging, $0 \le \delta_i, \gamma_i \le 1$.

25.4.1 Resource-Allocation Problem

Consider software with 'N' modules. During module testing each module is tested independently. We assume that the modules have a finite number of faults and we aspire to remove the maximum number of them. Testing resources such as manpower and computer time are used and the management has to allocate limited testing resources among the modules. This problem of optimal allocation of testing resources among modules can be formulated as a mathematical programming problem, which is given below.

$$\text{maximize} \quad \sum_{i=1}^{N} m_i \,,$$

subject to

$$\sum_{i=1}^{N} c_i W_i(m_i) = B \,. \tag{25.41}$$

Kubat and *Koch* [25.18] have used SRGMs and through the method of Lagrangian multipliers have obtained solution to the above problem. However, this method does not rule out the possibility of negative allocation of resources to some modules. To correct this, algorithms that are similar in nature have been proposed in these

papers; they sequentially give zero allocations to these modules and distribute the values among the others. But this proposition is also not suitable, as testing cannot be stopped abruptly. As a way out, management can decide upon some minimum number of faults that it expects to remove from each module.

All modules of software are not equally important. The relative importance of modules can be determined based upon the frequency with which modules are expected to be called for execution in the actual user environment. Accordingly weights can be attached to each module. Incorporating this, the optimization problem above (25.41) can be reformulated as

$$\text{maximize} \quad \sum_{i=1}^{N} \alpha_i m_i$$

subject to

$$m_i \geq r_i \,, \quad i = 1, \ldots, N \,,$$
$$\sum_{i=1}^{N} c_i W_i(m_i) = B \,. \tag{25.42}$$

A functional relationship between the testing effort and fault removal is needed before we solve (25.41) or (25.42). SRGMs can be used for this purpose. We adopt the reverse approach and develop a model for resource consumption vis-à-vis fault removal in the next section.

25.4.2 Modeling the Marginal Function

Most SRGMs depict reliability growth with reference to execution time. Only a few SRGMs incorporate the effect of a time-dependent testing-effort pattern. Testing-effort components such as manpower utilization are dependent on the outcome of testing. Hence how the resources are consumed with each failure and removal attempt is a very important factor during decision making on resource allocation. Therefore we formulate an MTEF that gives a functional relationship between testing and fault removal. The time factor is not explicitly present in the model. Marginal testing effort (MTE) is the amount of effort required to remove an additional fault at any given time. Hence, if m faults have already been removed from the software, the MTE is the testing effort required to remove the $(m+1)$-th fault. We propose a mathematical relationship between the MTE and the number of faults removed based upon the assumption that the MTE is inversely proportional to the remaining faults in the software, i. e. the more faults we remove, the greater effort would be required to remove the next fault.

Mathematically this can be written as

$$w(m) = \frac{k'}{a-m} \tag{25.43}$$

$$\text{and} \quad W(m) = k' \ln \frac{a}{a-m} \,. \tag{25.44}$$

In this expression it is also implicitly assumed that the software contains a finite number of faults at the initiation of testing, that fault removal is perfect and that no new faults are introduced in the process. These assumptions are similar to those used by *Goel* and *Okumoto* [25.10] for their SRGM, i. e. the rate of fault removal is proportional to the remaining faults at any given time. The SRGM is with respect to execution time and it is the mean-value function of the underlying stochastic process described by an NHPP. As the optimization problems being studied in this chapter are with respect to testing resource consumption, MTEF is better suited for our purpose. But the variability in the nature of relationship between the variables i. e. resource consumption and fault removal needs to be captured in a MTEF. It should also include the effect of learning on the testing team. With each additional fault removed, some more faults lying on the execution path are removed and the testing team also gains insight into the software. To incorporate this, we assume that, the MTE is also inversely proportional to a linear function of the number of faults removed. Hence (25.44) can be written as,

$$w(m) = \frac{k}{(p+qm)(a-m)} \tag{25.45}$$

$$\text{and} \quad W(m) = \frac{k}{p+aq} \ln \frac{a(p+qm)}{p(a-m)} \,. \tag{25.46}$$

A higher value of q denotes a higher rate of learning of the testing team and implies a growth rate in the MTE. In expression (25.45) it is assumed that, on a failure, the fault causing that failure is immediately removed with unit probability. Though every care is taken to correct the cause of a failure, the possibility of imperfect debugging and fault generation cannot be ruled out [25.3, 6, 40]. If the fault remains, even after debugging, then it is said to be imperfectly debugged. New faults can also be introduced during the removal process. In both ways the fault content enhances the chance of failure in future. As this phenomenon is a reality, the MTEF should ideally contain the effect of imperfect debugging and fault generation. We modify (25.45) through the assumption that the number of faults imperfectly debugged and generated during the debugging phenomenon is dependent

upon the number of removal attempts already made. The following expression results from these assumptions:

$$w(m) = \frac{k}{(p+qm)} \frac{1}{(a+\delta m - m)} = \frac{k}{(p+qm)} \frac{1}{(a-\gamma m)}, \tag{25.47}$$

$$W(m) = \frac{k}{p\gamma + aq} \ln \frac{a(p+qm)}{p(a-\gamma m)}. \tag{25.48}$$

The modules of a piece of software are independent pieces of software themselves. Hence the least-squares method suggested above can be used to estimate the parameters of the MTEFs of the different modules. For this it is required that modules have already been tested for some time and data pertaining to failures and resource consumption has been recorded.

25.4.3 Optimization

During module testing, modules are tested independently, i. e. the testing teams are different. Again each module can be visualized as independent software and hence distinct MTEFs can be used to describe their testing resource consumption. After the modules have been tested for some time, the parameters of the MTEF viz. a_i, p_i, q_i, k_i can be estimated. Based upon these estimates optimal allocation of resources among modules can be calculated.

Using the MTEF (25.44), the optimization problem (25.41) can be formulated as

$$\text{maximize} \sum_{i=1}^{N} m_i$$

$$\text{subject to} \sum_{i=1}^{N} c_i k_i \ln \frac{a_i}{a_i - m_i} = B. \tag{25.49}$$

We can solve this problem by the method of Lagrangian multipliers. Defining the Lagrange function as

$$L(m_1, m_2, \ldots, m_N, \theta) = \sum_{i=1}^{N} m_i - \theta \left(\sum_{i=1}^{N} c_i \int_0^{m_i} \frac{k_i}{a_i - x} \mathrm{d}x - B \right), \tag{25.50}$$

we get the following optimality conditions

$$\frac{c_i k_i}{a_i - m_i} = \text{constant} \quad \forall i \tag{25.51}$$

$$\text{and} \sum_{i=1}^{N} c_i k_i \ln \frac{a_i}{a_i - m_i} = B. \tag{25.52}$$

After some algebraic simplifications, from (25.52) and (25.52) we obtain

$$W_i^* = \frac{B - \ln \prod_{i=1}^{N} \left(\frac{a_j d_i}{d_j a_i} \right)^{d_j}}{\sum_{j=1}^{N} \frac{d_j}{d_i}}, \quad i = 1, \ldots, N. \tag{25.53}$$

Which is the optimal allocation of testing resources for the *i-th* module in terms of B, a_i and d_i. We have used here the simplest among the MTEFs proposed above. Though obtaining closed-form solution such as (25.53) is always desirable, arriving at one becomes nearly impossible if (25.41) is made more complex. Even with the other two MTEFs in (25.45) and (25.47) the method of Lagrangian multipliers does not directly provide a solution. As the objective here is to highlight the use of marginal effort modeling in allocation problems, we formulate these optimization problems as nonlinear programming problems that could be solved by any of the known methods.

In the solution obtained through (25.53) some modules can receive zero allocations. Hence the minimum number (percentage) of faults that are desired to be removed from each module should be added as a constraint, as in (25.42). Consider the following optimization problem where (25.45) and (25.47) have been substituted into the problem (25.42).

$$\text{Maximize} \sum_{i=1}^{N} \alpha_i m_i$$

subject to

$$m_i \geq r_i, \quad i = 1, \ldots, N,$$

$$\sum_{i=1}^{N} \frac{c_i k_i}{p_i + a_i q_i} \ln \frac{a_i(p_i + q_i m_i)}{p_i(a_i - m_i)} = B. \tag{25.54}$$

With the MTEF (25.47) the resource constraint takes the following form (25.55), the objective function and the other constraint remaining the same in the problem:

$$\sum_{i=1}^{N} \frac{c_i k_i}{p_i \gamma_i + a_i q_i} \ln \frac{a_i(p_i + q_i m_i)}{p_i(a_i - \gamma_i m_i)} = B. \tag{25.55}$$

Equations (25.54) and (25.55) are nonlinear programming problems and any of the standard methods can be used to solve them. But when the number of modules increases, deriving the solution manually becomes difficult. We have solved the problem above with

the help of a software a packages for higher numbers of modules. Once the optimal m_i are found, they can be substituted into (25.44) or (25.48) to find the optimal allocation of resources to the modules. Optimization techniques such as dynamic programming and fuzzy mathematical programming have also been used by the authors for solving more complex resource-allocation problems [25.20, 41].

26. An Experimental Study of Human Factors in Software Reliability Based on a Quality Engineering Approach

In this chapter, we focus on a software design-review process which is more effective than other processes for the elimination and prevention of software faults in software development. Then, we adopt a quality engineering approach to analyze the relationships among the quality of the design-review activities, i.e., software reliability, and human factors to clarify the fault-introduction process in the design-review process.

We conduct a design-review experiment with graduate and undergraduate students as subjects. First, we discuss human factors categorized as predispositions and inducers in the design-review process, and set up controllable human factors in the design-review experiment. In particular, we lay out the human factors on an orthogonal array based on the method of design of experiments. Second, in order to select human factors that affect the quality of the design review, we perform a software design-review experiment reflecting an actual design process based on the method of design of experiments. To analyze the experimental results, we adopt a quality engineering approach, i.e., the Taguchi method. That is, applying the orthogonal array $L_{18}(2^1 \times 3^7)$ to the human-factor experiment, we carry out an analysis of variance by using the signal-to-noise ratio (SNR), which can evaluate the stability of the quality characteristics, discuss effective human factors, and obtain the optimal levels for the selected predispositions and inducers.

Further, classifying the faults detected by design-review work into descriptive-design and symbolic-design faults, we discuss the relationships among them in more detail.

Software faults introduced by human errors in development activities of complicated and diverse software systems have resulted in many system failures in modern computer systems. Since these faults are related to the mutual relations among human factors in such software development projects, it is difficult to prevent such software failures beforehand in software production control. Additionally, most of these faults are detected and corrected after software failure occurrences during the testing phase.

If we can make the mutual relations among human factors [26.1, 2] clear, then we expect the problem of software reliability improvement to be solved. So far, several studies have been carried out to investigate the relationships among software reliability and human factors by performing software development experiments and providing fundamental frameworks for understand-

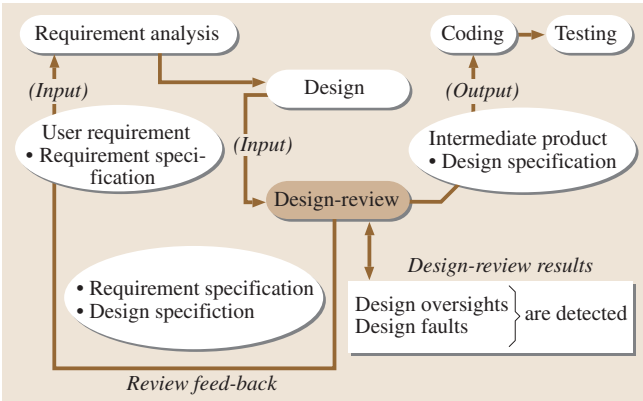

Fig. 26.1 Inputs and outputs in the software design process

ing the mutual relations among various human factors; see [26.3, 4].

In this chapter, we focus on a software design-review process that is more effective than other processes for the elimination and prevention of software faults. Then, we adopt a quality engineering approach [26.5, 6] to analyze the relationships among the quality of the design-review activities, i. e., software reliability, and human factors to clarify the fault-introduction process in the design-review process.

Furthermore, classifying the faults detected by the design-review work into descriptive-design and symbolical-design faults, we discuss the relationships among them.

26.1 Design Review and Human Factors

26.1.1 Design Review

The inputs and outputs for the design-review process are shown in Fig. 26.1 The design-review process is the intermediate process between the design and coding phases, and has software requirement specifications as inputs and software design specifications as outputs. In this process, software reliability is improved by detecting software faults effectively [26.7].

26.1.2 Human Factors

The attributes of the software designers and the design-process environment are related through the design-review process. Therefore, human factors that influence the design specification are classified into two kinds of attributes as follows [26.8–11] (Fig. 26.2):

1. Attributes of the design reviewers (predispositions)
   The attributes of the design reviewers are those of the software engineers who are responsible for the design-review work, for example, the degree of understanding of the requirement specifications and design methods, the aptitude of the programmers, their experience of and capability for software design, the volition of achievement of software design, etc. Most of these are psychological human factors which are considered to contribute directly to the quality of software design specification.
2. Attributes of the design-review environment (inducers)
   In terms of design-review work, many kinds of influential factors are considered, such as the learning level of design methods, the type of design methodologies, physical environmental factors for the software design work, e.g., temperature, humidity, noise, etc. All of these influential factors may indirectly affect the quality of the software design specification.

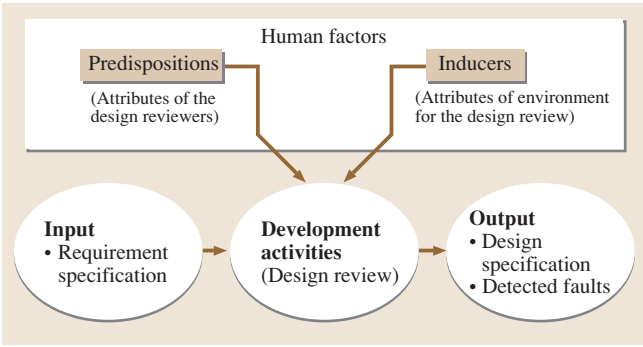

Fig. 26.2 A human-factor model including the predispositions and inducers

26.2 Design-Review Experiment

26.2.1 Human Factors in the Experiment

In order to discover the relationships between the reliability of the software design specification and the human factors that influence it, we have performed a design-review experiment by selecting five human factors, as shown in Table 26.1, as control factors concerned with the review work.

- BGM (background music) of classical music in the review-work environment (inducer A)
  Design-review work for detecting faults requires concentrated attentiveness. We adopt a BGM of classical music as a factor of the work environment that maintains review efficiency.
- Time duration of design-review work (inducer B)
  In this experiment, we set the subjects design-review work to be completed in approximately 20 min. We adopt three time durations for software design-review work, such as 20 min, 30 min and 40 min.
- Check list (inducer E)
  We prepare a check list (CL), which indicates the matters to be noticed in the review work. This factor has the following three levels: detailed CL, common CL, and without CL.
- Degree of understanding of the design method (predisposition C)
  Predisposition C of the two predispositions is the degree of understanding of the design method R-Net (requirements network). Based on preliminary tests of the ability to understand the R-Net technique, the subjects are divided into the following three groups: high, common, and low ability.
- Degree of understanding of the requirement specification (predisposition D)
  Predisposition D of the two predispositions is the degree of understanding of the requirement specification. Similarly to predisposition C, based on preliminary tests of geometry ability, the subjects are divided into the following three groups: high, common, and low ability.

26.2.2 Summary of Experiment

In this experiment, we conduct an experiment to clarify the relationships among human factors affecting software reliability and the reliability of design-review work by assuming a human-factor model consisting of predispositions and inducers, as shown in Fig. 26.2. The actual experiment has been performed by 18 subjects based on the same design specification of a triangle program which receives three integers representing the sides of a triangle and classifies the kind of triangle that these sides form [26.12]. We measured the capability of the 18 subjects in terms of their degree of understanding of the design method and the requirement specification by using preliminary tests before the design of experiment. Furthermore, we seeded some faults in the design specification intentionally. We then executed this design-review experiment in which the 18 subjects detected the seeded faults.

We performed the experiment using the five control factors with three levels, as shown in Table 26.1, which are assigned to the orthogonal array $L_{18}(2^1 \times 3^7)$ of the design of experiment, as shown in Table 26.3.

Table 26.1 Controllable factors in the design-review experiment

	Control factor	Level		
		1	2	3
A	BGM of classical music to review-work environment (inducer)	A_1: yes	A_2: no	–
B	Time duration of design-review work (minute) (inducer)	B_1: 20 min	B_2: 30 min	B_3: 40 min
C	Degree of understanding of the design method (R-Net technique) (predisposition)	C_1: high	C_2: common	C_3: low
D	Degree of understanding of the requirement specification (predisposition)	D_1: high	D_2: common	D_3: low
E	Check list (indicating the matters that require attention in the review work) (inducer)	E_1: detailed	E_2: common	E_3: nothing

26.3 Analysis of Experimental Results

26.3.1 Definition of SNR

We define the efficiency of the design review, i. e., the reliability, as the degree that the design reviewers can accurately detect correct and incorrect design parts for a design specification containing seeded faults. There exists the following relationship among the total number of design parts, n, the number of correct design parts, n_0, and the number of incorrect design parts containing seeded faults, n_1:

$$n = n_0 + n_1 \,. \tag{26.1}$$

Therefore, the design parts are classified as shown in Table 26.2 by using the following notation:

n_{00} = the number of correct design parts detected accurately as correct design parts,
n_{01} = the number of correct design parts detected by mistake as incorrect design parts,
n_{10} = the number of incorrect design parts detected by mistake as correct design parts,
n_{11} = the number of incorrect design parts detected accurately as incorrect design parts,

Table 26.2 Input and output tables for the two kinds of error

(i) Observed values

Input \ Output	0 (true)	1 (false)	Total
0 (true)	n_{00}	n_{01}	n_0
1 (false)	n_{10}	n_{11}	n_1
Total	r_0	r_1	n

(ii) Error rates

Input \ Output	0 (true)	1 (false)	Total
0 (true)	$1-p$	p	1
1 (false)	q	$1-q$	1
Total	$1-p+q$	$1-q+p$	2

where the two kinds of error rate are defined by

$$p = \frac{n_{01}}{n_0} \,, \tag{26.2}$$

$$q = \frac{n_{10}}{n_1} \,. \tag{26.3}$$

Table 26.3 Controllable factors in the design-review experiment

Experiment	Control factors								Observed values				SNR (dB)
						Error							
No.	*A*	*B*	*C*	*D*	*E*	*e*	*e*	*e*	n_{00}	n_{01}	n_{10}	n_{11}	
1	1	1	1	1	1	1	1	1	110	1	2	16	8.404
2	1	1	2	2	2	2	2	2	108	3	10	8	−0.515
3	1	1	3	3	3	3	3	3	109	2	16	2	−6.050
4	1	2	1	1	2	2	3	3	111	0	2	16	10.008
5	1	2	2	2	3	3	1	1	107	4	4	14	2.889
6	1	2	3	3	1	1	2	2	104	7	11	7	−4.559
7	1	3	1	2	1	3	2	3	111	0	4	14	8.104
8	1	3	2	3	2	1	3	1	106	5	8	10	−0.780
9	1	3	3	1	3	2	1	2	110	1	11	7	2.099
10	2	1	1	3	3	2	2	1	110	1	11	7	2.099
11	2	1	2	1	1	3	3	2	106	5	4	14	2.260
12	2	1	3	2	2	1	1	3	105	6	12	6	−4.894
13	2	2	1	2	3	1	3	2	105	6	10	8	−2.991
14	2	2	2	3	1	2	1	3	108	3	15	3	−5.784
15	2	2	3	1	2	3	2	1	105	6	10	8	−2.991
16	2	3	1	3	2	3	1	2	109	2	2	16	6.751
17	2	3	2	1	3	1	2	3	107	4	4	14	2.889
18	2	3	3	2	1	2	3	1	103	8	9	9	−3.309

Considering the two kinds of error rate, p and q, we can derive the standard error rate, p_0 [26.6] as

$$p_0 = \frac{1}{1+\sqrt{\left(\frac{1}{p}-1\right)\left(\frac{1}{q}-1\right)}} \,. \tag{26.4}$$

Then, the signal-to-noise ratio based on (26.4) is defined by [26.6]

$$\eta_0 = -10\log_{10}\left(\frac{1}{(1-2p_0)^2}-1\right) \,. \tag{26.5}$$

The standard error rate, p_0, can be obtained from transforming (26.5) by using the signal-to-noise ratio of each control factor as

$$p_0 = \frac{1}{2}\left(1-\frac{1}{\sqrt{10^{(-\frac{\eta_0}{10})}+1}}\right) \,. \tag{26.6}$$

26.3.2 Orthogonal Array $L_{18}(2^1 \times 3^7)$

The method of experimental design based on orthogonal arrays is a special one that requires only a small number of experimental trials to help discover the main factor effects. In traditional research [26.4, 8], the design of experiment has been conducted by using the orthogonal array $L_{12}(2^{11})$. However, since the orthogonal array $L_{12}(2^{11})$ is applied for grasping the factor effect between two levels the human factors experiment, the middle effect between two levels cannot be measured. Thus, in order to measure it, we adopt the orthogonal array $L_{18}(2^1 \times 3^7)$, which can lay out one factor with two levels (1, 2) and seven factors with three levels (1, 2, 3), as shown in Table 26.3, and dispense with $2^1 \times 3^7$ trials by executing 18 experimentally independent experimental trials each other. For example, as for experimental trial no. 10, we executed the design-review work under the conditions A_2, B_1, C_1, D_3, and E_3, and obtained a computed SNR of 2.099 dB from the observed values $n_{00} = 110$, $n_{01} = 1$, $n_{10} = 11$, and $n_{11} = 7$.

Additionally, the interaction between two factors can be estimated without sacrificing a factor. Any pair of human factors are partially mixed with the effect of the remaining factors. Therefore, we have evaluated the large effects of highly reproducible human factors because the selected optimal levels of the relatively large factor has a larger effect than that of the smaller one.

Considering these circumstances, we can obtain the optimal levels for the selected inhibitors and inducers efficiently by using the orthogonal array $L_{18}(2^1 \times 3^7)$.

26.4 Investigation of the Analysis Results

26.4.1 Experimental Results

The experimental results for the observed values of the design parts discussed in Sect. 26.3.1 in the software design specification are shown in Table 26.3. The SNR data calculated using (26.5) are also shown in Table 26.3.

26.4.2 Analysis of Variance

The result of the analysis of variance for the observed correct and incorrect design parts is shown in Table 26.4 by using the SNR data, as shown in Table 26.3. In Table 26.4, f, S, V, F_0, and ρ represent the degree of freedom, the sum of squares, the unbiased variance, the unbiased variance ratio, and the contribution ratio, respectively, for performing the analysis of variance. In order to obtain the precise analysis results, the check list factor (factor E) is pooled with the error factor (factor e). We then performed the analysis of variance based on the new pooled error factor (factor e').

26.4.3 Discussion

As a result of the experimental analysis, the effective control factors such as the BGM of classical music to review-work environment (factor A), the duration of the design-review work (factor B), the degree of understanding of the software design method (Factor C), and the degree of understanding of the requirement specification (factor D) were recognized. In particular, factors A and B are mutually interacting.

We then find that our experience from actual software development [26.8] and the experimental result above based on a design review are equivalent. Table 26.5 shows the comparisons of SNRs and standard error rates. The improvement ratio of the reliability of design review is calculated as 20.909 dB [i. e. 33.1% measured in the standard error rate in (26.4) from (26.5)] by using the SNR based on the optimal condition (A_1, B_3, C_1, D_1) of the control factors, such as A, B, C, and D, whose effects are rec-

Table 26.4 The result of analysis of variance using the SNR

Factor	f	S	V	F_0	ρ (%)
A	1	36.324	36.324	10.578*	7.4
B	2	33.286	16.643	4.847*	5.9

○: pooled, *: 5% level of significance,
**: 1% level of significance

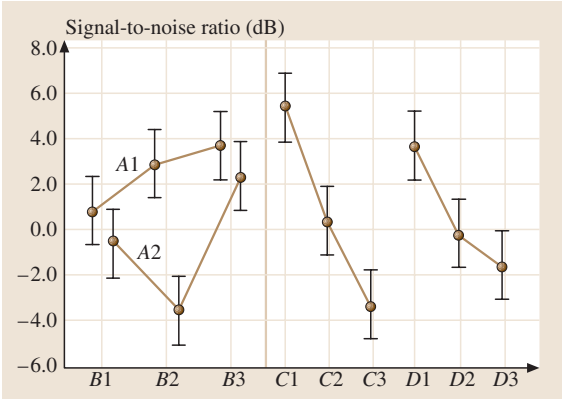

Fig. 26.3 Estimation of significant factors

ognized in Fig. 26.3. Therefore, it is expected that a quantitative improvement in the reliability of design review can be achieved by using these control factors.

26.5 Confirmation of Experimental Results

Table 26.6 shows the optimal and worst levels of the control factors for the design-review discussed in Sect. 26.4. Considering the circumstances, we conduct an additional experiment to confirm the experimental results using the SNR.

26.5.1 Additional Experiment

We focus on the effect of faults detected under the optimal conditions of the design-review work. As for the design of experiment discussed in Sect. 26.2, the design specification is for the triangle program reviewed by 18 subjects. We measured both their degree of understanding of the design method and their degree of understanding of the requirement specification by preliminary tests before the design of the additional experiment.

We also seeded some faults into the design specification intentionally. We then executed the same design-review experiment discussed in Sect. 26.2.2 under the same review conditions (the optimal levels for the selected predispositions). Additionally, we confirmed that the selected predispositions divided by the preliminary tests were consistent with the optimal levels of the two inducers.

The experimental results for the observed values of correct and incorrect design parts and the preliminary tests are shown in Table 26.7 with the SNR data calculated using (26.5).

26.5.2 Comparison of Factorial Effects Under Optimal Inducer Conditions

Figure 26.4 shows the optimal levels of the control factors of the design review based on the additional experiment. If both inhibitors are at the high state, the fault-detection rate is improved. Additionally, Table 26.8 shows a comparison of the SNRs and standard error rates between the optimal levels for the selected inducers. The improvement ratio of the reliability of the design review

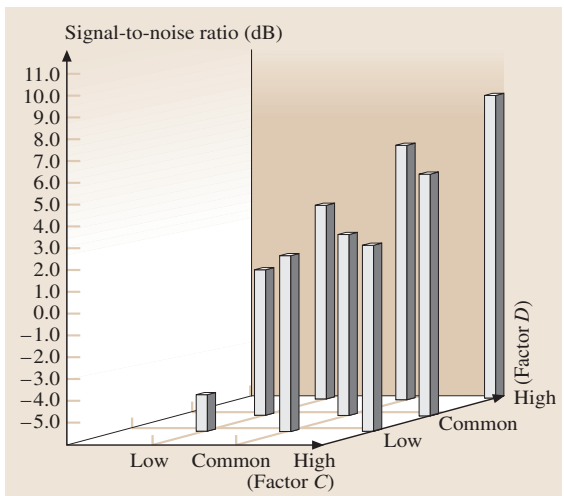

Fig. 26.4 The comparison of factorial effects

	High	Low	
Signal-to-noise ratio (dB)	10.008	−3.510	Δ 13.518
Standard error rates (%)	2.3	22.3	Δ 20.0

is calculated as 13.518 dB (i. e. 20.0% measured in the standard error rate) by using the signal-to-noise ratio based on the optimal conditions of the control factors, such as A, B, C, and D, whose effects are recognized in Fig. 26.4. Thus, we can confirm that the optimal levels of the two inducers are consistent with the optimal levels of the two predispositions C and D divided by the preliminary tests.

26.6 Data Analysis with Classification of Detected Faults

26.6.1 Classification of Detected Faults

We can distinguish the design parts as follows to be pointed out in the design review as detected faults into descriptive-design and symbolical-design parts, denoted by R_1 and R_2, respectively.

- Descriptive-design faults
  The descriptive-design parts consist of words or technical terminologies which are described in the design specification to realize the required functions. In this experiment, the descriptive design faults are algorithmic, and we can improve the quality of the design specification by detecting and correcting them.
- Symbolical-design faults
  The symbolical-design parts consist of marks or symbols which are described in the design specification. In this experiment, the symbolical-design faults are notation mistakes, and the quality of the design specification cannot be improved by detecting and correcting them.

26.6.2 Data Analysis

The experimental results for the observed values classified into the two types of design parts discussed in Sect. 26.6.1 are shown in Table 26.9. The SNR data calculated through (26.5) are also shown in Table 26.9.

A result of the analysis of variance for the descriptive-design parts is shown in Table 26.10, and that for the symbolical-design parts shown in Table 26.11, based on the SNR data shown in Table 26.9. Figure 26.5 shows the effect for each level in the control factor that affects the design-review result based on the SNR calculated from the observation values.

Descriptive-Design Faults

In design-review work, the effective review conditions for correcting and removing algorithmic faults are BGM of classical music, "yes(A_1)" and design-review time, "40 minutes(B_3)". The reviewer's capability, the degree of understanding of the design method (R-Net Technique), "high(C_1)", and that of the require-

ment specification, "high(D_1)", are derived as optimal conditions.

Symbolic-Design Faults

In design-review work, the optimal condition for effective review conditions for correcting and removing notation mistakes is that the degree of understanding of the requirement specification is "high(C_1)".

26.6.3 Data Analysis with Correlation Among Inside and Outside Factors

Furthermore, classifying the detected faults as due to the outside factor R and the inside control factors A, B, C, D, and E, as shown in Table 26.9, we can perform the analysis of variance. Here, the outside factor R has two

levels, corresponding to descriptive-design parts (R_1) and symbolical-design parts (R_2).

As a result of the analysis of variance, by taking account of correlation among inside and outside factors, we can obtain Table 26.12. There are two kinds of errors in the analysis of variance: e_1 is the error among the experiments of the inside factors, and e_2 is the mutual correlation error between e_1 and the outside factor. In this analysis, since there was no significant effect by performing F-testing for e_1 with e_2, F-testing for all factors was performed using e_2. As a result, the significant control factors, such as the degree of understanding of the

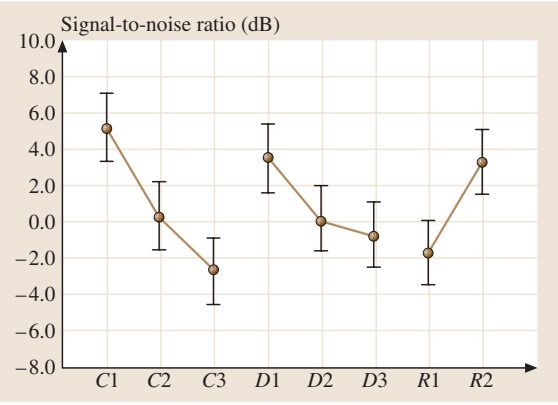

Fig. 26.6 The estimation of significant factors with correlation among inside and outside factors

design method (factor C), the degree of understanding of the requirement specification (factor D), and the classification of the detected faults (factor R), were recognized. Figure 26.6 shows the effect of the factor for each level in the significant factors that affect the design-review work.

As a result of the analysis, in the inside factors, only factors C and D are significant and the inside and outside factors are not mutually interacting. That is, it turns out that the reviewers with a high degree of understanding of the design method and a high degree of understanding of the requirement specification can review the design specification efficiently regardless of the classification of the detected faults. Moreover, the result that the outside factor R is highly significant, i. e., the descriptive-design faults are detected less effectively than the symbolic-design faults, can be obtained. That is, although it is a natural result, it is difficult to detect and correct the algorithmic faults which would lead to an improvement in quality rather than the notation mistakes. However, it is important to detect and correct the algorithmic faults as this is an essential problem for quality improvement in design-review work. Therefore, in order to increase the rate of detection and correction of algorithmic faults, which would lead to quality improvement, before design-review work it is necessary to make reviewers understand fully the design technique used to describe the design specification and the contents of the requirement specifications.

27. Statistical Models for Predicting Reliability of Software Systems in Random Environments

After a brief overview of existing models in software reliability in Sect. 27.1, Sect. 27.2 discusses a generalized nonhomogeneous Poisson process model that can be used to derive most existing models in the software reliability literature. Section 27.3 describes a generalized random field environment (RFE) model incorporating both the testing phase and operating phase in the software development cycle for estimating the reliability of software systems in the field. In contrast to some existing models that assume the same software failure rate for the software testing and field operation environments, this generalized model considers the random environmental effects on software reliability. Based on the generalized RFE model, Sect. 27.4 describes two specific RFE reliability models, the γ-RFE and β-RFE models, for predicting software reliability in field environments. Section 27.4 illustrates the models using telecommunication software failure data. Some further research considerations based on the generalized software reliability model are also discussed.

Many software reliability models have been proposed to help software developers and managers understand and analyze the software development process, estimate the development cost and assess the level of software reliability. Among these software reliability models, models based on the nonhomogeneous Poisson process (NHPP) have been successfully applied to model the software failure processes that possess certain trends such as reliability growth or deterioration. NHPP models are very useful to predict software failures and software reliability in terms of time, and to determine when to stop testing and release the software [27.1].

Currently most existing NHPP software reliability models have been carried out through the fault intensity rate function and the mean-value functions $m(t)$ within a controlled operating environment [27.2–13]. Obviously, different models use different assumptions and therefore provide different mathematical forms for the mean-value function $m(t)$. Table 27.1 shows a summary of several existing models appearing in the software reliability engineering literature [27.14]. Generally, these models are applied to software testing data and then to make predictions of software failures and reliability in the field. The underlying assumption for this application is that the field environments are the same as, or close to, a testing environment; this is valid for some software systems that are only used in one environment throughout their entire lifetime. However, this assumption is not valid for many applications where a software program may be used in many different locations once it is released.

The operating environments for the software in the field are quite different. The randomness of the field environment will affect software failure and software reliability in an unpredictable way. *Yang* and *Xie* [27.15] mentioned that the operational reliability and testing reliability are often different from each other, but they assumed that the operational failure rate is still close to the testing failure rate, and hence that the difference between them is that the operational failure rate decreases with time, while the testing failure rate remains constant. *Zhang* et al. [27.16] proposed an NHPP software reliability calibration model

Table 27.1 Summary of NHPP software reliability models [27.14]

Model name	Model type	MVF [$m(t)$]	Comments
Goel–Okumoto (G–O)	Concave	$m(t) = a(1 - e^{-bt})$ $a(t) = a$ $b(t) = b$	Also called exponential model
Delayed S-shaped	S-shaped	$m(t) = a[1 - (1 + bt)e^{-bt}]$ $a(t) = a$ $b(t) = \frac{b^2 t}{1+bt}$	Modification of G–O model to obtain S-shape
Inflection S-shaped SRGM	Concave	$m(t) = \frac{a(1-e^{-bt})}{1+\beta e^{-bt}}$ $a(t) = a$ $b(t) = \frac{b}{1+\beta e^{-bt}}$	Solves a technical condition with the G–O model. Becomes the same as G–O if $\beta = 0$
HD/G–O model	Concave	$m(t) = \log\left[(e^a - c)/(e^{a e^{-bt}} - c)\right]$	Same as G–O when $c = 0$
Yamada exponential	Concave	$m(t) = a\left(1 - e^{-r\alpha(1-e^{(-\beta t)})}\right)$ $a(t) = a$ $b(t) = r\alpha\beta e^{-\beta t}$	Attempts to account for testing effort
Yamada Rayleigh	S-shaped	$m(t) = a\left(1 - e^{-r\alpha(1-e^{(-\beta t^2/2)})}\right)$ $a(t) = a$ $b(t) = r\alpha\beta t e^{-\beta t^2/2}$	Attempts to account for testing effort
Yamada imperfect debugging model (1)	S-shaped	$m(t) = \frac{ab}{\alpha+b}(e^{\alpha t} - e^{-bt})$ $a(t) = a e^{\alpha t}$ $b(t) = b$	Assumes exponential fault-content function and constant fault-detection rate
Yamada imperfect debugging model (2)	S-shaped	$m(t) = a(1 - e^{-bt})(1 - \frac{\alpha}{b}) + \alpha a t$ $a(t) = a(1 + \alpha t)$ $b(t) = b$	Assumes constant fault-introduction rate α and constant fault-detection rate
PNZ model	S-shaped and concave	$m(t) = \frac{a}{1+\beta} e^{-bt}\left[(1 - e^{-bt})(1 - \frac{\alpha}{b}) + \alpha a t\right]$ $a(t) = a(1 + \alpha t)$ $b(t) = \frac{b}{1+\beta e^{-bt}}$	Assumes introduction rate is a linear function of testing time, and the fault-detection rate function is nondecreasing and inflexion S-shaped
Pham–Zhang model	S-shaped and concave	$m(t) = \frac{1}{1+\beta e^{-bt}}\left[(c + a)(1 - e^{-bt}) - \frac{a}{b-\alpha}(e^{-\alpha t} - e^{-bt})\right]$ $a(t) = c + a(1 - e^{-\alpha t})$ $b(t) = \frac{b}{1+\beta e^{-bt}}$	Assume constant introduction rate is exponential function of testing time, and the error-detection function is nondecreasing with an inflexion S-shaped model

by introducing a calibration factor. This calibration factor, K, obtained from software failures in both the testing and field operation phases will be a multiplier to the software failure intensity. This calibrated software reliability model can be used to assess and adjust the predictions of software reliability in the operation phase.

Instead of relating the operating environment to the failure intensity λ, in this chapter we assume that the effect of the operating environment is to multiply the unit failure-detection rate $b(t)$ achieved in the testing environment using the concept of the proportional hazard approach suggested by *Cox* [27.17]. If the operating environment is more liable to software failure, then the unit fault-detection rate increases by some factor η greater than 1. Similarly, if the operating environment is less liable to software failure, then the unit fault-detection rate decreases by some positive factor η less than 1.

This chapter describes a model based on the NHPP model framework for predicting software failures and evaluating the software reliability in random field environments. Based on this model, developers and engineers can further develop specific software reliability models customized to various applications.

Notations	
$R(t)$	Software reliability function
η	Random environmental factor
$G(\eta)$	Cumulative distribution function of η
γ	Shape parameter of gamma distributions
θ	Scale parameter of gamma distributions
α, β	Parameters of beta distributions
$N(t)$	Counting process which counts the number of software failures discovered by time t
$m(t)$	Expected number of software failures detected by time t, $m(t) = E[N(t)]$
$a(t)$	Expected number of initial software faults plus introduced faults by time t
$m_1(t)$	Expected number of software failures in testing by time t
$m_2(t)$	Expected number of software failures in the field by time t
$a_1(t)$	Expected number of initial software faults plus introduced faults discovered in the testing by time t
a	Number of initial software faults at the beginning of testing phase, is a *software parameter* that is directly related to the software itself
T	Time to stop testing and release the software for field operations
a_F	Number of initial software faults in the field (at time T)
$b(t)$	Failure detection rate per fault at time t, is a *process parameter* that is directly related to testing and failure process
p	Probability that a fault will be successfully removed from the software
q	Error introduction rate at time t in the testing phase
MLE	Maximum likelihood estimation
RFE-model	Software reliability model subject to a random field environment
γ-RFE	Software reliability model with a gamma distributed field environment
β-RFE	Software reliability model with a beta distributed field environment
NHPP	Non-homogeneous Poisson process
SRGM	software reliability growth model
HD	Hossain–Ram
PNZ	Pham–Nordman–Zhang
G–O	Goel–Okumoto
NHPP	nonhomgeneous Poisson process
MLE	maximum likelihood estimation
RFE	random field environment

27.1 A Generalized NHPP Software Reliability Model

A generalized NHPP model studied by *Zhang* et al.[27.7] can be formulated as follows:

$$m'(t) = \eta b(t)[a(t) - pm(t)] \,, \tag{27.1}$$

$$a'(t) = q \cdot m'(t) \,, \tag{27.2}$$

where $m(t)$ is the number of software failures expected to be detected by time t. If the marginal conditions are given as $m(0) = 0$ and $a(0) = a$, then for a specific environmental factor η, the solutions to (27.1) and (27.2) are, given in [27.7], as follows

$$m_\eta(t) = a \int_0^t \eta b(u) \mathrm{e}^{-\int_0^u \eta(p-q)b(\tau)\mathrm{d}\tau} \mathrm{d}u \,, \tag{27.3}$$

$$a_\eta(t) = a \left[1 + \int_0^t \eta q b(u) \mathrm{e}^{-\int_0^u \eta(p-q)\cdot b(\tau)\mathrm{d}\tau} \mathrm{d}u \right] . \tag{27.4}$$

This is the generalized form of the NHPP software reliability model. When $p = 1$, $\eta = 1$ and $q = 0$, then for any given function $a(t)$ and $b(t)$, all the functions listed in Table 27.1 can easily be obtained.

27.2 Generalized Random Field Environment (RFE) Model

The testing environment is often a controlled environment with much less variation compared to the field environments, which may be quite different for the field application software. Once a software program is released, it may be used in many different locations and various applications in industries. The operating environments for the software are quite different. Therefore, the randomness of the field environment will affect the cumulative software failure data in an unpredictable way.

Figure 27.1 shows the last two phases of the software life cycle: in-house testing and field operation [27.18]. If T is the time to stop testing and release the software for field operations, then the time period $0 \le t \le T$ refers to the time period of *software testing*, while the time period $T \le t$ refers to the post-release period—*field operation*.

The environmental factor η is used to capture the uncertainty about the environment and its effects on the software failure rate. In general, software testing is carried out in a controlled environment with very small variations, which can be used as a reference environment where η is constant and equal to 1. For the field operating environment, the environmental factor η is assumed to be a nonnegative random variable (RV) with probability density function (PDF) $f(\eta)$, i. e.

$$\eta = \begin{cases} 1 & t \le T \\ \text{RV with PDF } f(\eta) & t \ge T \end{cases} . \qquad (27.5)$$

If the value of η is less than 1, this indicates that the conditions are less favorable to fault detection than that of testing environment. Likewise, if the value of η is greater than 1, it indicates that the conditions are more favorable to fault detection than that of the testing environment.

From (27.3) and (27.5), the mean-value function and the function $a_1(t)$ during testing can be obtained as

$$m_1(t) = a \int_0^t b(u) \mathrm{e}^{-\int_0^u (p-q)b(\tau)\mathrm{d}\tau} \mathrm{d}u \quad t \le T ,$$

$$a_1(t) = a\left[1 + \int_0^t qb(u) \times \mathrm{e}^{-\int_0^u (p-q)\cdot b(\tau)\mathrm{d}\tau} \mathrm{d}u\right] \quad t \le T . \qquad (27.6)$$

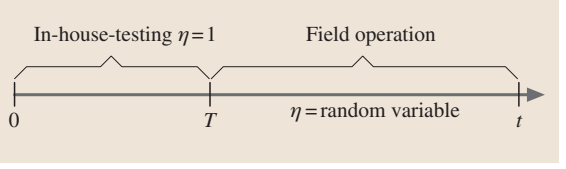

Fig. 27.1 Testing versus field environment where T is the time to stop testing and release the software

For the field operation where $t \ge T$ the mean-value function can be represented as

$$\begin{aligned} m_2(t) &= m_1(T) + \int_0^\infty m_\eta(t) f(\eta)\mathrm{d}\eta \\ &= m_1(T) + \int_0^\infty \left[a_\mathrm{F} \int_T^t \eta b(u) \times \mathrm{e}^{-\int_T^u \eta(p-q)b(\tau)\mathrm{d}\tau} \mathrm{d}u \right] f(\eta)\mathrm{d}\eta \quad t \ge T \\ &= m_1(T) + \int_T^t a_\mathrm{F} b(u) \left[\int_0^\infty \eta \times \mathrm{e}^{-\eta\int_T^u (p-q)b(\tau)\mathrm{d}\tau} f(\eta)\mathrm{d}\eta \right] \mathrm{d}u , \end{aligned} \qquad (27.7)$$

where a_F is the number of faults in the software at time T. Using the Laplace transform formula, the mean-value function can be rewritten as

$$\begin{aligned} m_2(t) &= m_1(T) + \int_T^t a_\mathrm{F} b(u) \times \left(-\frac{\mathrm{d}F^*(s)}{\mathrm{d}s}\bigg|_{s=\int_0^u (p-q)b(\tau)\mathrm{d}\tau} \right) \mathrm{d}u , \\ &\quad t \ge T \\ &= m_1(T) + \frac{a_\mathrm{F}}{(p-q)} \times \int_T^t \left\{ -\mathrm{d}F^* \left[(p-q) \int_T^u b(\tau)\mathrm{d}\tau \right] \right\} , \end{aligned}$$

where $F^*(s)$ is the Laplace transform of the PDF $f(x)$ and

$$\int_0^\infty x\,\mathrm{e}^{-x\cdot s} f(x)\,\mathrm{d}x = -\frac{\mathrm{d}F^*(s)}{\mathrm{d}s}$$

or, equivalently,

$$\begin{aligned} m_2(t) &= m_1(T) - \frac{a_\mathrm{F}}{(p-q)} \\ &\quad \times F^*\left[(p-q)\int_T^u b(\tau)\,\mathrm{d}\tau\right]\Bigg|_T^t, \quad t \ge T \\ &= m_1(T) + \frac{a_\mathrm{F}}{(p-q)} \\ &\quad \times \left\{F^*(0) - F^*\left[(p-q)\int_T^t b(\tau)\,\mathrm{d}\tau\right]\right\}. \end{aligned}$$

Notice that $F^*(0) = \int_0^\infty \mathrm{e}^{-0x} f(x)\,\mathrm{d}x = 1$, so

$$\begin{aligned} m_2(t) &= m_1(T) + \frac{a_\mathrm{F}}{(p-q)} \\ &\quad \times \left\{1 - F^*\left[(p-q)\int_T^t b(\tau)\,\mathrm{d}\tau\right]\right\} \quad t \ge T. \end{aligned}$$

The expected number of faults in the software at time T is given by

$$\begin{aligned} a_\mathrm{F} &= a_1(T) - p m_1(T) \\ &= a\left[1 - \int_0^t (p-q) b(u)\,\mathrm{e}^{-\int_0^u (p-q)\cdot b(\tau)\,\mathrm{d}\tau}\,\mathrm{d}u\right] \\ &= a\,\mathrm{e}^{-\int_0^t (p-q) b(\tau)\,\mathrm{d}\tau}. \end{aligned}$$

The generalized RFE model can be obtained as

$$m(t) = \begin{cases} \frac{a}{(p-q)}\left(1 - \mathrm{e}^{-(p-q)\int_0^u b(\tau)\,\mathrm{d}\tau}\right) & t \le T \\ \frac{a}{(p-q)}\left\{1 - \mathrm{e}^{-(p-q)\int_0^T b(\tau)\,\mathrm{d}\tau}\right. \\ \left.\times F^*\left[(p-q)\int_T^t b(\tau)\,\mathrm{d}\tau\right]\right\} & t \ge T. \end{cases} \tag{27.8}$$

The model in (27.8) is a generalized software reliability model subject to random field environments. The next section presents specific RFE models for the gamma and beta distributions of the random field environmental factor η.

27.3 RFE Software Reliability Models

Obviously, the environmental factor η must be nonnegative. Any suitable nonnegative distribution may be used to describe the uncertainty about η. In this section we present two RFE models. The first model is a γ-RFE model, based on the gamma distribution, which can be used to evaluate and predict software reliability in field environments where the software failure-detection rate can be either greater or less than the failure detection rate in the testing environment. The second model is a β-RFE model, based on the beta distribution, which can be used to predict software reliability in field environments where the software failure detection rate can only be less than the failure detection rate in the testing environment.

27.3.1 γ-RFE Model

In this model, we use the gamma distribution to describe the random environmental factor η. This model is called the γ-RFE model.

Assume that η follows a gamma distribution with a probability density function as follows

$$f_\gamma(\eta) = \frac{\theta^\gamma \eta^{\gamma-1}\,\mathrm{e}^{-\theta\cdot\eta}}{\Gamma(\gamma)}, \gamma, \theta > 0; \eta \ge 0. \tag{27.9}$$

The gamma distribution has sufficient flexibility and has desirable qualities with respect to computations [27.18]. Figure 27.2 shows an example of the gamma density

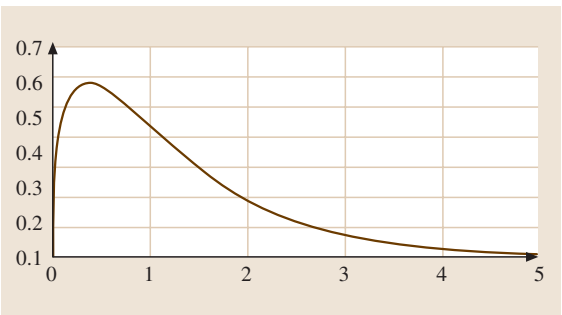

Fig. 27.2 A gamma density function

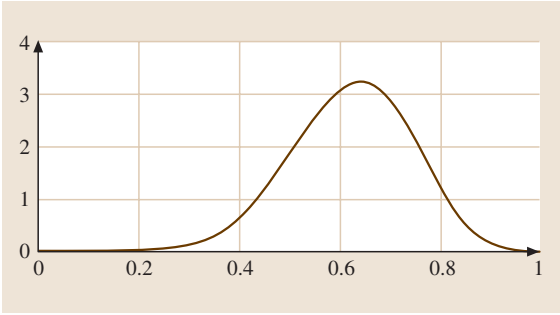

Fig. 27.3 A PDF curve of the beta distribution

probability function. The gamma function seems to be reasonable to describe a software failure process in those field environments where the software failure-detection rate can be either greater (i. e., $\eta > 1$) or less than (i. e., $\eta < 1$) the failure-detection rate in the testing environment.

The Laplace transform of the probability density function in (27.9) is

$$F^*(s) = \left(\frac{\theta}{\theta + s}\right)^{\gamma} . \tag{27.10}$$

Assume that the error-detection rate function $b(t)$ is given by

$$b(t) = \frac{b}{1 + c\,\mathrm{e}^{-b \cdot t}} , \tag{27.11}$$

where b is the asymptotic unit software-failure detection rate and c is the parameter defining the shape of the learning curve, then from (27.8) the mean-value function of the γ-RFE model can be obtained as follows

$$m_{\gamma}(t) = \begin{cases} \frac{a}{(p-q)}\left[1 - \left(\frac{1+c}{\mathrm{e}^{bt}+c}\right)^{(p-q)}\right] & t \le T , \\ \frac{a}{(p-q)}\left[1 - \left(\frac{1+c}{\mathrm{e}^{bT}+c}\right)^{(p-q)}\right. & \\ \left. \times \left(\frac{\theta}{\theta + (p-q)\ln\left(\frac{c+\mathrm{e}^{bt}}{c+\mathrm{e}^{bT}}\right)}\right)^{\gamma}\right] & t \ge T . \end{cases} \tag{27.12}$$

27.3.2 β-RFE Model

This section presents a model using the beta distribution that describes the random environmental factor η, called the β-RFE model.

The beta PDF is

$$f_{\beta}(\eta) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)}\eta^{\alpha-1}(1-\eta)^{\beta-1} , \quad 0 \le \eta \le 1, \alpha > 0, \beta > 0 . \tag{27.13}$$

Figure 27.3 shows an example of the beta density function. It seems that the β-RFE model is a reasonable function to describe a software failure process in those field environments where the software failure-detection rate can only be less than the failure-detection rate in the testing environment. This is not uncommon in the software industry because, during software testing, the engineers generally test the software intensely and conduct an *accelerated* test on the software in order to detect most of the software faults as early as possible.

The Laplace transform of the PDF in (27.13) is

$$F^*_{\beta}(s) = \mathrm{e}^{-s} \cdot HG([\beta], [\alpha+\beta], s) , \tag{27.14}$$

where $HG([\beta], [\alpha+\beta], s)$ is a generalized hypergeometric function such that

$$HG([a_1, a_2, \ldots, a_m], [b_1, b_2, \ldots, b_n], s) = \sum_{k=0}^{\infty}\left(\frac{s^k \prod_{i=1}^{m}\frac{\Gamma(a_i+k)}{\Gamma(a_i)}}{\prod_{i=1}^{n}\frac{\Gamma(b_i+k)}{\Gamma(b_i)}k!}\right) ,$$

Therefore

$$\begin{aligned} F^*_{\beta}(s) &= \mathrm{e}^{-s}\sum_{k=0}^{\infty}\left(\frac{\Gamma(\alpha+\beta)\Gamma(\beta+k)s^k}{\Gamma(\beta)\Gamma(\alpha+\beta+k)k!}\right) \\ &= \sum_{k=0}^{\infty}\left(\frac{\Gamma(\alpha+\beta)\Gamma(\beta+k)}{\Gamma(\beta)\Gamma(\alpha+\beta+k)}\frac{s^k\,\mathrm{e}^{-s}}{k!}\right) \\ &= \sum_{k=0}^{\infty}\left(\frac{\Gamma(\alpha+\beta)\Gamma(\beta+k)}{\Gamma(\beta)\Gamma(\alpha+\beta+k)}\mathrm{Poisson}(k,s)\right) . \end{aligned}$$

where the Poisson probability density function is given by

$$\mathrm{Poisson}(k, s) = \frac{s^k\,\mathrm{e}^{-s}}{k!} .$$

Using the same error-detection rate function in (27.11) and replacing $F^*(s)$ by $F^*_{\beta}(s)$, the mean-value function of the β-RFE model is

$$m_{\beta}(t) = \begin{cases} \frac{a}{(p-q)}\left[1 - \left(\frac{1+c}{\mathrm{e}^{bt}+c}\right)^{(p-q)}\right] & t \le T , \\ \frac{a}{(p-q)}\left[1 - \left(\frac{1+c}{\mathrm{e}^{bT}+c}\right)^{(p-q)}\right. & \\ \left. \times \sum_{k=0}^{\infty}\left(\frac{\Gamma(\alpha+\beta)\Gamma(\beta+k)\mathrm{Poisson}(k,s)}{\Gamma(\beta)\Gamma(\alpha+\beta+k)}\right)\right] & t \ge T . \end{cases} \tag{27.15}$$

where

$$s = (p-q)\left[\ln\left(\frac{c+\mathrm{e}^{bt}}{c+\mathrm{e}^{bT}}\right)\right] .$$

27.4 Parameter Estimation

27.4.1 Maximum Likelihood Estimation (MLE)

We use the MLE method to estimate the parameters in these two RFE models. Let y_i be the cumulative number of software faults detected up to time t_i, $i = 1, 2, \ldots, n$. Based on the NHPP, the likelihood function is given by

$$L = \prod_{i=1}^{n} \frac{\left[m(t_i) - m(t_{i-1})\right]^{y_i - y_{i-1}}}{(y_i - y_{i-1})!} \mathrm{e}^{-\left[m(t_i) - m(t_{i-1})\right]} . \tag{27.16}$$

The logarithmic form of the above likelihood function is

$$\ln L = \sum_{i=1}^{n} \left\{ (y_i - y_{i-1}) \ln \left[m(t_i) - m(t_{i-1})\right] - \left[m(t_i) - m(t_{i-1})\right] - \ln \left[(y_i - y_{i-1})!\right] \right\} . \tag{27.17}$$

In this analysis, the error-removal efficiency p is given. Each model has five unknown parameters. For example, in the γ-RFE model, we need to estimate the following five unknown parameters: a, b, q, γ and θ. For the β-RFE model, we need to estimate: a, b, q, α and β. By taking derivatives of (27.18) with respect to each parameter and setting the results equal to zero, we can obtain five equations for each RFE model. After solving all those equations, we obtain the maximum likelihood estimates (MLEs) of all parameters for each RFE model.

Table 27.2 Normalized cumulative failures and times during software testing

Table 27.2 shows a set of failure data from a telecommunication software application during software testing [27.16]. The column "Time" shows the normalized cumulative time spent in software testing for this telecommunication application, and the column "Failures" shows the normalized cumulative number of failures occurring in the testing period up to the given time.

The time to stop testing is $T = 0.0184$. After the time T, the software is released for field operations. Table 27.3 shows the field data for this software release. Similarly, the column "Time" shows the normalized cumulative time spent in the field for this software application, and the time in Table 27.3 is continued from the time to stop testing T. The column "Failures" shows the normalized cumulative number of failures found after releasing the software for field operations up to the given time. The cumulative number of failures is the total number of software failures since the beginning of software testing.

To obtain a better understanding of the software development process, we show the actual results of the MLE solutions instead of the normalized results. In this study, let us assume that testing engineers have a number of years of experience of this particular product and software development skills and therefore conducted perfect debugging during the test. In other word, $p = 1$. The maximum likelihood estimates of all the parameters in the γ-RFE model are obtained as shown in Table 27.4.

236.07	0.001449	0	0	0.1862	8.6922

Similarly, set $p = 1$, the MLE of all the parameters in the β-RFE model are obtained as shown in Table 27.5.

For both RFE models, the MLE results can be used to obtain more insightful information about the software development process. In this example, at the time to stop testing the software $T = 0.0184$, the estimated number of remaining faults in the system is $a_F = a - (p-q)m(T) = 55$.

27.4.2 Mean-Value Function Fits

After we obtain the MLEs for all the parameters, we can plot the mean-value function curve fits for both the γ-RFE and β-RFE models based on the MLE parameters against the actual software application failures.

Table 27.6 shows the mean-value function curve fits for both the models where the column $m_\gamma(t)$ and $m_\beta(t)$ show the mean-value function for the γ-RFE model and the β-RFE model, respectively.

The γ-RFE and β-RFE models yield very close fits and predictions on software failures. Figure 27.4 shows the mean-value function curve fits for both the γ-RFE model and β-RFE model. Both models appear to be a good fit for the given data set. Since we are particularly interested in the fits and the predictions for software failure data during field operation, we also plot the detailed mean-value curve fits for both the γ-RFE model and the β-RFE model in Fig. 27.5.

For the overall fitting of the mean-value function against the actual software failures, the mean squared error (MSE) is 23.63 for the γ-RFE model fit, and is 23.69 for the β-RFE model. We can also obtain the fits and predictions for software failures by applying some existing NHPP software reliability models to the same set of failure data. Since all these existing models assumes a constant failure-detection rate throughout both the software testing and operation periods, we only apply the software testing data to the software models and then predict the software failures in the field environments.

Figure 27.6 shows the comparisons of the mean-value function curve fits between the two RFE models and some existing NHPP software reliability models. It appears that the two models that

include consideration of the field environment on the software failure-detection rate perform better in terms of the predictions for software failures in the field.

27.4.3 Software Reliability

Once the MLEs of all the parameters in (27.12) and (27.14) are obtained, the software reliability within

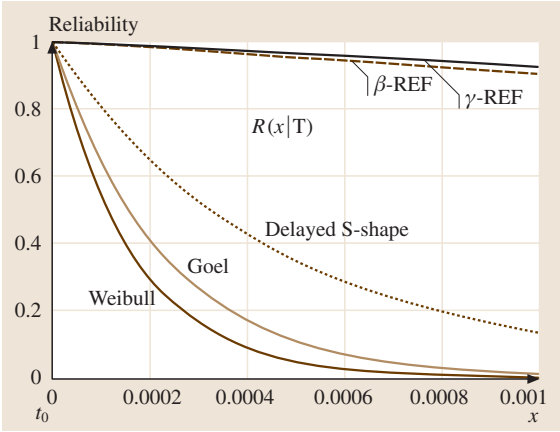

Fig. 27.7 Reliability prediction comparisons

$(t, t+x)$ can be determined as

$$R(x|t) = \mathrm{e}^{-[m(t+x)-m(t)]} \,. \tag{27.18}$$

Let $T = 0.0184$, and change x from 0 to 0.004, then we can compare the reliability predictions between the two RFE models and some other NHPP models that assume a constant failure-detection rate for both software testing and operation. The reliability prediction curves are shown in Fig. 27.7. From Fig. 27.7, we can see that the NHPP models without consideration of the environmental factor yield much lower predictions for software reliability in the field than the two proposed RFE software reliability models.

27.4.4 Confidence Interval

γ-RFE Model

To see how good the reliability predictions given by the two RFE models are, in this section we describe how to construct confidence intervals for the prediction of software reliability in the random field environments. From Tables 27.4 and 27.5, the MLEs of c and q are equal to zero and, if p is set to 1, then the model in (27.12) becomes

$$m(t) = \begin{cases} a\left(1 - \mathrm{e}^{-b\cdot t}\right) & t \le T \,, \\ a\left[1 - \mathrm{e}^{-b\cdot T}\left(\frac{\theta}{\theta + b(t-T)}\right)^{\gamma}\right] & t \ge T \,. \end{cases} \tag{27.19}$$

This model leads to the same MLE results for the parameters a, b, γ and θ, and also yields exactly the same mean-value function fits and predictions as the model in (27.12). To obtain the confidence interval for the reliability predictions for the γ-RFE model, we derive the variance–covariance matrix for all the maximum likelihood estimates as follows.

If we use x_i, $i = 1, 2, 3$, and 4, to denote all the parameters in the model, or

$$x_1 \to a \quad x_2 \to b \quad x_3 \to \theta \quad x_4 \to \gamma \,.$$

The Fisher information matrix H can be obtained as

$$H = \begin{pmatrix} h_{11} & h_{12} & h_{13} & h_{14} \\ h_{21} & h_{22} & h_{23} & h_{24} \\ h_{31} & h_{32} & h_{33} & h_{34} \\ h_{41} & h_{42} & h_{43} & h_{44} \end{pmatrix} \,, \tag{27.20}$$

where

$$h_{ij} = E\left(-\frac{\partial^2 L}{\partial x_i \partial x_j}\right) i, j = 1, \cdots, 6 \,, \tag{27.21}$$

where L is the log-likelihood function in (27.18).

If we denote $z(t_k) = m(t_k) - m(t_{k-1})$ and $\Delta y_k = y_k - y_{k-1}$, $k = 1, 2, \ldots, n$, then we have

$$\frac{\partial^2 L}{\partial x_i \partial x_j} = \sum_{k=1}^{n}\left[-\frac{\Delta y_k}{z(t_k)^2}\frac{\partial z(t_k)}{\partial x_i}\cdot\frac{\partial z(t_k)}{\partial x_j} + \left(\frac{\Delta y_k - z(t_k)}{z(t_k)}\cdot\frac{\partial^2 z(t_k)}{\partial x_i \partial x_j}\right)\right] \,. \tag{27.22}$$

Then we can obtain each element in the Fisher information matrix H. For example,

$$\begin{aligned} h_{11} &= E\left(-\frac{\partial^2 L}{\partial x_1^2}\right) \\ &= \sum_{k=1}^{n}\left\{\sum_{\Delta y_k=0}^{\infty}\left[\frac{\Delta y_k}{z(t_k)^2}\left(\frac{\partial z(t_k)}{\partial a}\right)^2\right] \times \frac{[z(t_k)]^{\Delta y_k}\,\mathrm{e}^{-z(t_k)}}{(\Delta y_k)!}\right\} \\ &= \sum_{k=1}^{n}\left\{\sum_{\Delta y_k=0}^{\infty}\left[\frac{\Delta y_k}{z(t_k)^2}\left(\frac{z(t_k)}{a}\right)^2\right] \times \frac{[z(t_k)]^{\Delta y_k}\,\mathrm{e}^{-z(t_k)}}{(\Delta y_k)!}\right\} \\ &= \sum_{k=1}^{n}\left(\frac{1}{a^2}\sum_{\Delta y_k=0}^{\infty}\Delta y_k \frac{[z(t_k)]^{\Delta y_k}\,\mathrm{e}^{-z(t_k)}}{(\Delta y_k)!}\right) \\ &= \sum_{k=1}^{n}\left[\frac{1}{a^2}\cdot z(t_k)\right] \\ &= \frac{1}{a^2}m(t_n) \,. \end{aligned} \tag{27.23}$$

The variance matrix, V, can also be obtained

$$V = (H)^{-1} = \begin{pmatrix} v_{11} & v_{12} & v_{13} & v_{14} \\ v_{21} & v_{22} & v_{23} & v_{24} \\ v_{31} & v_{32} & v_{33} & v_{34} \\ v_{41} & v_{42} & v_{43} & v_{44} \end{pmatrix} . \tag{27.24}$$

The variances of all the estimate parameters are given by

$$\begin{aligned} \mathrm{Var}(\hat{a}) &= \mathrm{Var}(x_1) = v_{11} , \\ \mathrm{Var}(\hat{b}) &= \mathrm{Var}(x_2) = v_{22} , \\ \mathrm{Var}(\hat{\gamma}) &= \mathrm{Var}(x_3) = v_{33} , \\ \mathrm{Var}(\hat{\theta}) &= \mathrm{Var}(x_4) = v_{44} . \end{aligned} \tag{27.25}$$

The actual numerical results for the γ-RFE model variance matrix are

$$V_\gamma = \begin{pmatrix} 703.8472 & -0.005387 & -88.6906 & -2.6861 \\ -0.005387 & 7.3655\times10^{-8} & 1.11\times10^{-3} & 3.097\times10^{-5} \\ -88.6906 & 1.11\times10^{-3} & 92.4287 & 1.1843 \\ -2.6861 & 3.097\times10^{-5} & 1.1843 & 0.0238 \end{pmatrix} . \tag{27.26}$$

β-RFE Model

The model in (27.14) can also be simplified given that the estimates of both q and c are equal to zero and p is set to 1. The mean-value function becomes

$$m_\beta(t) = \begin{cases} a(1-\mathrm{e}^{-bt}) & t \le T , \\ a\left[1-\mathrm{e}^{-bT} \right. & \\ \left. \times \sum_{k=0}^{\infty} \left(\frac{\Gamma(\alpha+\beta)\Gamma(\beta+k)\mathrm{Poisson}[k,b(t-T)]}{\Gamma(\beta)\Gamma(\alpha+\beta+k)} \right) \right] & \\ & t \ge T . \end{cases} \tag{27.27}$$

This model leads to the same MLE results for the parameters a, b, α and β, and also yields exactly the same mean-value function fits and predictions. To obtain the confidence interval for the reliability predictions for the β-RFE model, we need to obtain the variance–covariance matrix for all the maximum likelihood estimates.

If we use x_i, $i = 1, 2, 3$, and 4, to denote all the parameters in the model, or

$$x_1 \to a \quad x_2 \to b \quad x_3 \to \alpha \quad x_4 \to \beta ,$$

and go through similar steps as for the γ-RFE model, the actual numerical results for the β-RFE model variance matrix can be obtained as

$$V_\beta = \begin{pmatrix} 691.2 & -0.00536 & -2.728 & -66.2172 \\ -0.00536 & 7.4485\times10^{-8} & 2.671\times10^{-5} & 0.00085 \\ -2.7652 & 2.671\times10^{-5} & 0.01820 & 0.8295 \\ -66.2172 & 0.00085 & 0.8295 & 60.5985 \end{pmatrix} . \tag{27.28}$$

Confidence Interval of the Reliability Predictions

If we define a partial derivative vector for the reliability $R(x|t)$ in (27.18) as

$$vR(x|t) = \left(\frac{\partial R(x|t)}{\partial x_1}, \frac{\partial R(x|t)}{\partial x_2}, \frac{\partial Rb(x|t)}{\partial x_3}, \frac{\partial R(x|t)}{\partial x_4} \right) \tag{27.29}$$

then the variance of $R(x|t)$ in (27.18) can be obtained as

$$\mathrm{Var}\left[R(x|t)\right] = vR(x|t)V\left[vR(x|t)\right]^T . \tag{27.30}$$

Assume that the reliability estimation follows a normal distribution, then the 95% confidence interval for the reliability prediction $R(x|t)$ is

$$\begin{aligned} &\left[R(x|t) - 1.96\times\sqrt{\mathrm{Var}\left[R(x|t)\right]} \right. , \\ &\left. R(x|t) + 1.96\times\sqrt{\mathrm{Var}\left[R(x|t)\right]} \right] . \end{aligned} \tag{27.31}$$

Figures 27.8 and 27.9 show the 95% confidence interval of the reliability predicted by the γ-RFE and β-RFE models, respectively.

We plot the reliability predictions and their 95% confidence interval for both the γ-RFE model and the

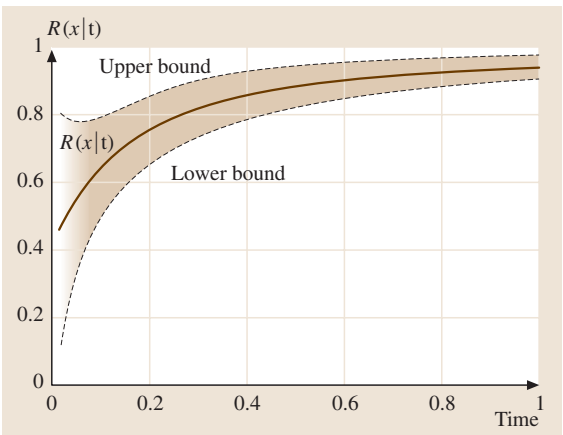

Fig. 27.8 γ-RFE model reliability growth curve and its 95% confidence interval

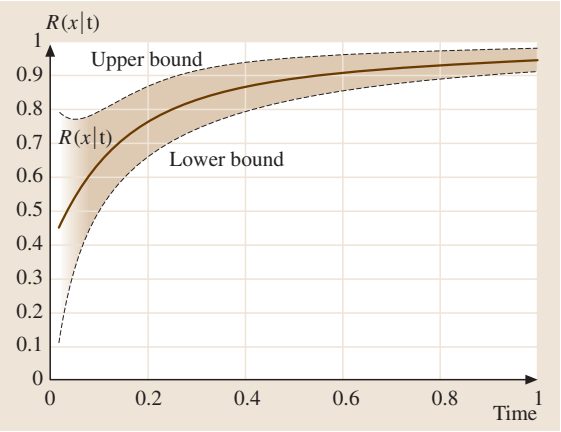

Fig. 27.9 β-RFE model reliability growth prediction and its 95% confidence interval

β-RFE model in Fig. 27.10. For this given application data set, the reliability predictions for the γ-RFE model and the β-RFE model are very close to each other, as are their confidence intervals. Therefore, it would not matter too much which one of the two RFE models were used to evaluate the software reliability for this application. However, will these two RFE models always yield similar reliability predictions for all software applications? or, which model should one choose for applications if they are not always that close to each other? We will try to answer these two questions in the next section. Figure 27.11 shows the 95% confidence interval for the mean-value function fits and predictions from the γ-RFE model.

27.4.5 Concluding and Remarks

Table 27.7 shows all the maximum likelihood estimates of all the parameters and other fitness measures. The maximum likelihood estimates (MLEs) on common parameters, such as a—the initial number of faults in the software, and b—the unit software failure-detection rate during testing, are consistent for both models. Both models provide very close predictions for software reliability and also give similar results for the mean and variance of the random environment factor η.

The underlying rationale for this phenomenon is the similarity between the gamma and beta distributions when the random variable η is close to zero. In this application, the field environments are much less liable to software failure than the testing environment. The random field environmental factor, η, is mostly much less than 1 with mean $(\eta) \approx 0.02$.

Figure 27.12 shows the probability density function curves of the environmental factor η based on the MLEs of all the parameters for both the γ-RFE model and

Table 27.7 MLEs and fitness comparisons

Parameter	γ-RFE	β-RFE
$\hat{a}$	236.5793016	236.0745369
$\hat{b}$	0.001443362	0.001448854
$\hat{\theta}$	10.7160153	
$\hat{\gamma}$	0.213762945	
$\hat{\alpha}$		0.186224489
$\hat{\beta}$		8.692191792
Mean	0.019948	0.020975
Variance	0.0018615	0.002079
MSE	23.63	23.69
Likelihood	**−136.1039497**	**−129.7811199**

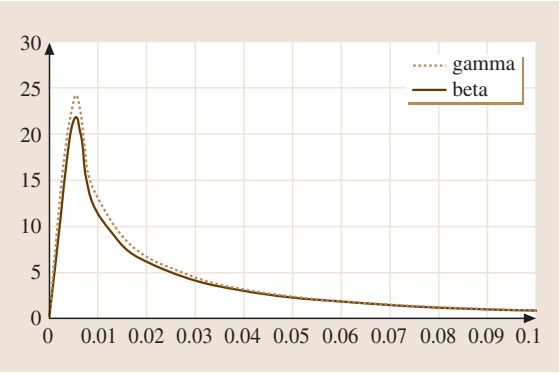

Fig. 27.12 Probability density function curves comparison for the environmental factor η

the β-RFE model. We observe that the PDF curves for the beta and gamma distributions are also very close to each other. The two RFEs models give similar results because this software application is much less likely to fail in the field environment, with mean $(\eta) = 0.02$. If the mean (η) is not so close to 0, then we would expect to have different prediction results from the γ-RFE model and the β-RFE model.

We suggest the following criteria as ways to select between the two models discussed in this chapter for predicting the software reliability in the random field environments:

1. Software less liable to failure in the field than in testing, i. e., $\eta \leq 1$

   In the γ-RFE model, the random field environmental factor, η following a gamma distribution, ranges from 0 to $+\infty$. For the β-RFE model, the random field environmental factor, η following a beta distribution, ranging from 0 to 1. Therefore, the β-RFE model will be more appropriate for describing field environments in which the software application is likely to fail than in the controlled testing environment.

   For this given application, we notice that, when the field environmental factor η is much less than 1 [mean$(\eta) = 0.02$], the γ-RFE model yields similar results to the β-RFE model. However, we also observe that the γ-RFE model does not always yield similar results to the β-RFE model when η is not close to 0. In this case, if we keep using the γ-RFE model instead of the β-RFE model, we would expect to see a large variance in the maximum likelihood estimates for all the unknown parameters, and hence a wider confidence interval for the reliability prediction.
2. Smaller variance of the RFE factor η

   A smaller variance of the random environmental factor η will generally lead to a smaller confidence interval for the software reliability prediction. It therefore represents a better prediction in the random field environments.
3. Smaller variances for the common parameters a and b

   The software parameter a and the process parameter b are directly related to the accuracy of reliability prediction. They can also be used to investigate the software development process. Smaller variances of a and b would lead, in general, to smaller confidence intervals for the mean-value function predictions and reliability predictions.
4. Smaller mean squared error (MSE) of the mean-value function fits

   A smaller MSE for the mean-value function fits means a better fit of the model to the real system failures. This smaller MSE will usually lead to a better prediction of software failures in random field environments.

The above criteria can be used with care to determine which RFE model should be chosen in practice. They may sometime provide contradictory results. In the case of contradictions, practitioners can often consider selecting the model with the smaller confidence interval for the reliability prediction.
